Adding (1) and (2), $2\langle T\mathbf{u}, \mathbf{w}\rangle = 0$, so $\langle T\mathbf{u}, \mathbf{w}\rangle = 0$ for all $\mathbf{u}, \mathbf{w}$. Taking $\mathbf{w} = T\mathbf{u}$ gives $\|T\mathbf{u}\|^2 = 0$, hence $T = 0$.

■

This statement appeared once already, as Exercise (C2: Linearity is a hypothesis, not a consequence) (b), where it was an exercise in the arithmetic of complex inner products. It is restated and proved here because Section 3 needs to cite it as a theorem: the four characterizations of a

normal operator all come from applying it to $T^*T - TT^*$. The proof is the same one; what is new is the company it now keeps.

Warning. **Over $\mathbb{R}$, the quadratic form does not determine the operator.** Let T be the quarter turn of $\mathbb{R}^2$, $T(x_1, x_2) = (-x_2, x_1)$. Then

$$\langle T\mathbf{x}, \mathbf{x}\rangle = -x_2x_1 + x_1x_2 = 0 \qquad \text{for every } \mathbf{x} \in \mathbb{R}^2,$$

and yet $T \neq 0$. So Theorem 11.2.6 genuinely fails over $\mathbb{R}$, and Theorem 11.2.5 genuinely needs its hypothesis: this T is not self-adjoint, since $T^* = -T$. The general real statement is that $\langle T\mathbf{v}, \mathbf{v}\rangle = 0$ for all $\mathbf{v}$ forces $T^* = -T$ and no more — Exercise (C3: What the real quadratic form does determine).

Quick check. Over $\mathbb{C}$, suppose $\langle T\mathbf{v}, \mathbf{v}\rangle$ is **real** for every $\mathbf{v} \in V$. Must T be self-adjoint?

Solution. Yes. Put $S = T - T^*$. For every $\mathbf{v}$, $\langle T^*\mathbf{v}, \mathbf{v}\rangle = \langle \mathbf{v}, T\mathbf{v}\rangle = \overline{\langle T\mathbf{v}, \mathbf{v}\rangle} = \langle T\mathbf{v}, \mathbf{v}\rangle$, the last step because the number is real. Hence $\langle S\mathbf{v}, \mathbf{v}\rangle = 0$ for all $\mathbf{v}$, and Theorem 11.2.6 gives $S = 0$, that is $T^* = T$. Combined with Proposition 10.6.7 (a), this says that over $\mathbb{C}$ "self-adjoint" and "$\langle T\mathbf{v}, \mathbf{v}\rangle$ always real" are the same condition. Over $\mathbb{R}$ the criterion is useless, since $\langle T\mathbf{v}, \mathbf{v}\rangle$ is automatically real for every operator.

11.2.7 Exercises

11.2.7.1 A. Check your understanding

Exercise A1.

(a) State what it means for $T \in \mathcal{L}(V)$ to be self-adjoint, in terms of T^* and in terms of inner products, and say what the matrix condition is and in which bases it may be used.

(b) True or false: a symmetric matrix in $M_2(\mathbb{C})$ has real eigenvalues. Justify your answer.

(c) Which field does Theorem 11.2.2 concern, and which earlier theorem supplies the eigenvalue it borrows?

(d) True or false: if T is self-adjoint and U is any subspace, then $U^\perp$ is T-invariant. Justify your answer.

(e) State the difference between Theorem 11.2.5 and Theorem 11.2.6, and give the standard example showing the second has no real analogue.

(f) Give a normal operator on $\mathbb{R}^2$ that is not self-adjoint.

Solution.

(a) $T^* = T$; equivalently $\langle T\mathbf{u}, \mathbf{v}\rangle = \langle \mathbf{u}, T\mathbf{v}\rangle$ for **all** $\mathbf{u}, \mathbf{v} \in V$ (Definition 10.6.2). The matrix condition is $\mathbf{A}^* = \mathbf{A}$, and by Theorem 10.6.3 it may be used only in an **orthonormal** basis.

(b) False. $\mathbf{B} = \begin{pmatrix} 1 & i \\ i & 1 \end{pmatrix}$ is symmetric with eigenvalues $1 \pm i$ (Example (Four Tests) (b) and the warning after it). Over $\mathbb{C}$ the relevant condition is $\mathbf{A}^* = \mathbf{A}$, not $\mathbf{A}^\top = \mathbf{A}$.

(c) The real field: it says a self-adjoint operator on a non-zero **real** inner product space has an eigenvalue. The eigenvalue is borrowed from Theorem 8.2.4, applied to the matrix read as a complex matrix on the complexification $\mathbb{C}^n$ of $\mathbb{R}^n$, and is then shown to be real by Theorem 11.2.1.

(d) False as stated: U must be **T-invariant** (Theorem 11.2.4). For example, $T = T_{\mathbf{A}}$ on $\mathbb{R}^2$ with $\mathbf{A} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$ is self-adjoint, and $U = \operatorname{span}(\mathbf{e}_1)$ has $U^\perp = \operatorname{span}(\mathbf{e}_2)$ with $T\mathbf{e}_2 = \mathbf{e}_1 \notin U^\perp$. Here U was not invariant either, since $T\mathbf{e}_1 = \mathbf{e}_2$.

(e) Theorem 11.2.5 holds over $\mathbb{R}$ and $\mathbb{C}$ but assumes T self-adjoint; Theorem 11.2.6 drops that assumption but holds only over $\mathbb{C}$. The quarter turn $T(x_1, x_2) = (-x_2, x_1)$ of $\mathbb{R}^2$ satisfies $\langle T\mathbf{x}, \mathbf{x}\rangle = 0$ for every $\mathbf{x}$ and is not zero.

(f) The same quarter turn: $T^* = -T$, so $T^*T = TT^* = \mathrm{id}$ and T is normal, while $T^* \neq T$.

11.2.7.2 B. Practice

Exercise B1: Determine which are self-adjoint.

Determine which of the following operators are self-adjoint. Justify your answer; for those that are not, exhibit a pair $\mathbf{u}, \mathbf{v}$ with $\langle T\mathbf{u}, \mathbf{v}\rangle \neq \langle \mathbf{u}, T\mathbf{v}\rangle$, or compute T^*.

(a) $T_{\mathbf{A}}$ on $\mathbb{C}^2$, $\mathbf{A} = \begin{pmatrix} 1 & 2+i \\ 2-i & -5 \end{pmatrix}$, standard inner product.

(b) $T_{\mathbf{B}}$ on $\mathbb{C}^2$, $\mathbf{B} = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}$, standard inner product.

(c) $T_{\mathbf{C}}$ on $\mathbb{R}^3$, $\mathbf{C} = \begin{pmatrix} 1 & 2 & 0 \\ 2 & 1 & 3 \\ 0 & 3 & 1 \end{pmatrix}$, standard inner product.

(d) S^*S, for an arbitrary $S \in \mathcal{L}(V, W)$ between finite-dimensional inner product spaces.

(e) $P_U - P_{U^\perp}$, for a subspace U of a finite-dimensional V.

(f) $T(x_1, x_2) = (x_2, x_1)$ on $\mathbb{R}^2$ with the standard inner product, whose matrix in the basis $\mathcal{C} = ((1,0),(1,2))$ is $\begin{pmatrix} -\frac{1}{2} & \frac{3}{2} \\ \frac{1}{2} & \frac{1}{2} \end{pmatrix}$, which is not symmetric.

Solution.

(a) Self-adjoint. The diagonal entries 1 and -5 are real and the off-diagonal pair $2+i$, $2-i$ are conjugates, so $\mathbf{A}^* = \mathbf{A}$; the standard basis is orthonormal, so Theorem 10.6.3 applies.

(b) Not self-adjoint. $\mathbf{B}^* = \mathbf{B}^\top = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} = -\mathbf{B}$, so $T_{\mathbf{B}}$ is skew-adjoint. Concretely $\langle \mathbf{B}\mathbf{e}_1, \mathbf{e}_2\rangle = -1$ while $\langle \mathbf{e}_1, \mathbf{B}\mathbf{e}_2\rangle = 1$.

(c) Self-adjoint. $\mathbf{C}$ is real and $\mathbf{C}^\top = \mathbf{C}$, and the standard basis of $\mathbb{R}^3$ is orthonormal.

(d) Self-adjoint, for every S. By Theorem 10.6.2 (c) and (d), $(S^*S)^* = S^*S^{**} = S^*S$.

(e) Self-adjoint. Each of P_U and $P_{U^\perp}$ is self-adjoint (Example (Four Tests) (d)), and by Theorem 10.6.2 (a) and (b) the difference of self-adjoint operators is self-adjoint: $(P_U - P_{U^\perp})^* = P_U^* - P_{U^\perp}^* = P_U - P_{U^\perp}$.

(f) Self-adjoint, in spite of the non-symmetric matrix. The basis $\mathcal{C}$ is **not** orthonormal — $\langle (1,0),(1,2)\rangle = 1 \neq 0$ — so Theorem 10.6.3 does not apply to it, and the shape of $[T]_{\mathcal{C}}^{\mathcal{C}}$ says nothing either way. Test the definition instead: for $\mathbf{x},\mathbf{y} \in \mathbb{R}^2$,

$$\langle T\mathbf{x},\mathbf{y}\rangle = x_2y_1 + x_1y_2 = \langle \mathbf{x}, T\mathbf{y}\rangle,$$

so $T^* = T$. In the standard basis, which *is* orthonormal, the matrix is $\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$, symmetric as it must be. The moral is the one Chapter 10, Section 6 closes with: self-adjointness is a property of the operator and the inner product, never of a matrix taken on its own.

Exercise B2: Eigenvalues and orthogonality.

(a) For $\mathbf{A} = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix} \in M_2(\mathbb{C})$, check that $\mathbf{A}$ is Hermitian, find its eigenvalues and an eigenvector for each, and verify that the eigenvectors are orthogonal.

(b) For $\mathbf{S} = \begin{pmatrix} 3 & 1 & 1 \\ 1 & 3 & 1 \\ 1 & 1 & 3 \end{pmatrix} \in M_3(\mathbb{R})$, find the eigenvalues with their multiplicities and bases of the eigenspaces, and verify that the two eigenspaces are orthogonal.

(c) Hence write down an orthonormal basis of $\mathbb{R}^3$ consisting of eigenvectors of $\mathbf{S}$.

Solution.

(a) $\mathbf{A}^* = \overline{\mathbf{A}}^{\top} = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix} = \mathbf{A}$, so $\mathbf{A}$ is Hermitian. Then $\operatorname{tr}\mathbf{A} = 0$ and $\det\mathbf{A} = 0 - (-i)(i) = -1$, so $p_{\mathbf{A}} = x^2 - 1$ and the eigenvalues are 1 and -1, both real. $\mathbf{A}(1,i) = (-i\cdot i,\ i\cdot 1) = (1,i)$, so $\mathbf{u} = (1,i)$ works for $\lambda = 1$. $\mathbf{A}(1,-i) = (-1,\ i) = -(1,-i)$, so $\mathbf{v} = (1,-i)$ works for $\lambda = -1$. Finally

$$\langle \mathbf{u},\mathbf{v}\rangle = 1\cdot\overline{1} + i\,\overline{(-i)} = 1 + i\cdot i = 0.$$

(b) Expanding the determinant gives $p_{\mathbf{S}} = (x-5)(x-2)^2$, so $\operatorname{spec}(\mathbf{S}) = \{5,2\}$ with algebraic multiplicities 1 and 2. The eigenspaces are read off from $\mathbf{S} = 2\mathbf{I} + \mathbf{J}$, where $\mathbf{J}$ is the all-ones matrix: since $\mathbf{J}(1,1,1) = (3,3,3)$ and $\mathbf{Jx} = \mathbf{0}$ exactly when $x_1 + x_2 + x_3 = 0$,

$$E_5(\mathbf{S}) = \operatorname{span}\big((1,1,1)\big), \quad E_2(\mathbf{S}) = \operatorname{span}\big((1,-1,0),(1,0,-1)\big),$$

of dimensions 1 and 2. Orthogonality: $(1,1,1)\cdot(1,-1,0) = 0$ and $(1,1,1)\cdot(1,0,-1) = 0$, so $E_5(\mathbf{S}) \perp E_2(\mathbf{S})$, as Theorem 11.2.3 requires.

(c) The two vectors spanning $E_2(\mathbf{S})$ are not orthogonal to each other, so run Gram–Schmidt inside that eigenspace (Theorem 10.2.2). With $\mathbf{w}_1 = (1,-1,0)$,

$$(1,0,-1) - \tfrac{1}{2}(1,-1,0) = \tfrac{1}{2}(1,1,-2).$$

Normalizing all three vectors gives the orthonormal eigenbasis

$$\tfrac{1}{\sqrt{3}}(1,1,1), \quad \tfrac{1}{\sqrt{2}}(1,-1,0), \quad \tfrac{1}{\sqrt{6}}(1,1,-2).$$

The eigenvalues are $5, 2, 2$ in that order.

Exercise B3: A self-adjoint square root of zero.

Let $T \in \mathcal{L}(V)$ be self-adjoint with $T^2 = 0$. Prove that $T = 0$. Deduce that a self-adjoint T with $T^k = 0$ for some $k \geq 1$ is zero.

Solution. For every $\mathbf{v} \in V$, by Definition 10.6.2,

$$\|T\mathbf{v}\|^2 = \langle T\mathbf{v}, T\mathbf{v}\rangle = \langle T^2\mathbf{v}, \mathbf{v}\rangle = \langle \mathbf{0}, \mathbf{v}\rangle = 0,$$

so $T\mathbf{v} = \mathbf{0}$. As $\mathbf{v}$ was arbitrary, $T = 0$.

For the deduction, use strong induction on k (Theorem 0.2.10). If $k = 1$ there is nothing to prove. Let $k \geq 2$ with $T^k = 0$, and put $m = \lceil k/2 \rceil$, so that $1 \leq m < k$ and $2m \geq k$. Then $(T^m)^2 = T^{2m} = T^{2m-k}T^k = 0$, and T^m is self-adjoint, since $(T^m)^* = (T^*)^m = T^m$ by Theorem 10.6.2 (c). By the first part, $T^m = 0$, and the inductive hypothesis applied to the exponent m gives $T = 0$.

11.2.7.3 C. Going deeper

Exercise C1: The operator S^*S.

Let $S \in \mathcal{L}(V, W)$ between finite-dimensional inner product spaces over F, and set $T = S^*S \in \mathcal{L}(V)$.

(a) Prove that T is self-adjoint and that $\langle T\mathbf{v}, \mathbf{v}\rangle \geq 0$ for every $\mathbf{v} \in V$, with equality if and only if $S\mathbf{v} = \mathbf{0}$.

(b) Deduce that every eigenvalue of T is a non-negative real number.

(c) Prove that T is invertible if and only if S is injective.

Hint for (a): the quantity $\langle T\mathbf{v}, \mathbf{v}\rangle$ is a norm squared in disguise.

Solution.

(a) $T^* = (S^*S)^* = S^*S^{**} = S^*S = T$, by Theorem 10.6.2 (c) and (d). For the second claim, use conjugate symmetry and then Definition 10.6.1:

$$\langle T\mathbf{v}, \mathbf{v}\rangle = \overline{\langle \mathbf{v}, S^*S\mathbf{v}\rangle} = \overline{\langle S\mathbf{v}, S\mathbf{v}\rangle} = \|S\mathbf{v}\|^2,$$

the last step because a norm squared is a non-negative real number and is its own conjugate. So $\langle T\mathbf{v}, \mathbf{v}\rangle \geq 0$, with equality exactly when $\|S\mathbf{v}\| = 0$, that is $S\mathbf{v} = \mathbf{0}$ (Definition 10.1.1).

(b) Let $T\mathbf{v} = \lambda\mathbf{v}$ with $\mathbf{v} \neq \mathbf{0}$. By Theorem 11.2.1, $\lambda \in \mathbb{R}$. By (a), $0 \leq \langle T\mathbf{v}, \mathbf{v}\rangle = \lambda\|\mathbf{v}\|^2$, and $\|\mathbf{v}\|^2 > 0$, so $\lambda \geq 0$.

(c) ($\Rightarrow$) If $S\mathbf{v} = \mathbf{0}$ then $T\mathbf{v} = \mathbf{0}$, so injectivity of T forces $\mathbf{v} = \mathbf{0}$; and an invertible operator is injective. ($\Leftarrow$) If S is injective and $T\mathbf{v} = \mathbf{0}$, then by (a) $\|S\mathbf{v}\|^2 = \langle T\mathbf{v}, \mathbf{v}\rangle = 0$, so $S\mathbf{v} = \mathbf{0}$ and $\mathbf{v} = \mathbf{0}$. Thus $\ker T = \{\mathbf{0}\}$, so T is injective, hence bijective by Corollary 3.3.2 (e). This is Corollary 10.6.6 (b) again, seen from the quadratic form.

Operators with the property in (a) are called **positive**, and they are the subject of Chapter 12; part (b) is the first half of the characterization proved there.

Exercise C2: Sums and products.

Let $S, T \in \mathcal{L}(V)$ be self-adjoint.

(a) Prove that $S+T$ and cT are self-adjoint for every **real** scalar c, and show by example that cT need not be self-adjoint for $c \in \mathbb{C}$.

(b) Prove that ST is self-adjoint if and only if $ST = TS$.

(c) Give self-adjoint $S, T \in \mathcal{L}(\mathbb{C}^2)$ with ST not self-adjoint.

Solution.

(a) By Theorem 10.6.2 (a), $(S+T)^* = S^* + T^* = S+T$. By (b) of the same theorem, $(cT)^* = \overline{c}\,T^* = \overline{c}\,T$, which equals cT exactly when $\overline{c} = c$ or $T = 0$. For a complex counterexample take $T = \mathrm{id}$ on $\mathbb{C}^2$ and $c = i$: then $(i\,\mathrm{id})^* = -i\,\mathrm{id} \neq i\,\mathrm{id}$.

(b) By Theorem 10.6.2 (c), $(ST)^* = T^*S^* = TS$. So $(ST)^* = ST$ if and only if $TS = ST$.

(c) Take $S = T_{\mathbf{A}}$ and $T = T_{\mathbf{B}}$ on $\mathbb{C}^2$ with

$$\mathbf{A} = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}, \qquad \mathbf{B} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}.$$

Both are Hermitian. But $\mathbf{AB} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$ and $\mathbf{BA} = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix}$, which differ, so by (b) the product is not self-adjoint. Indeed $(\mathbf{AB})^* = \mathbf{BA} \neq \mathbf{AB}$.

Exercise C3: What the real quadratic form does determine.

Let V be a finite-dimensional inner product space over $\mathbb{R}$ and $T \in \mathcal{L}(V)$. Call T **skew-adjoint** if $T^* = -T$.

(a) Prove that $\langle T\mathbf{v}, \mathbf{v}\rangle = 0$ for every $\mathbf{v} \in V$ if and only if T is skew-adjoint.

(b) Deduce that every $T \in \mathcal{L}(V)$ can be written uniquely as $T = A + B$ with A self-adjoint and B skew-adjoint, and that $\langle T\mathbf{v}, \mathbf{v}\rangle = \langle A\mathbf{v}, \mathbf{v}\rangle$ for every $\mathbf{v}$.

(c) Conclude that over $\mathbb{R}$ the function $\mathbf{v} \mapsto \langle T\mathbf{v}, \mathbf{v}\rangle$ determines A and nothing about B. Contrast this with the complex case.

Solution.

(a) ($\Leftarrow$) If $T^* = -T$, then for every $\mathbf{v}$, $\langle T\mathbf{v}, \mathbf{v}\rangle = \langle \mathbf{v}, T^*\mathbf{v}\rangle = -\langle \mathbf{v}, T\mathbf{v}\rangle = -\langle T\mathbf{v}, \mathbf{v}\rangle$, the last step by symmetry of a real inner product. A real number equal to its own negative is 0.
($\Rightarrow$) Suppose $\langle T\mathbf{v}, \mathbf{v}\rangle = 0$ for all $\mathbf{v}$. Expanding $\langle T(\mathbf{u}+\mathbf{w}), \mathbf{u}+\mathbf{w}\rangle = 0$ and canceling the two diagonal terms,

$$\langle T\mathbf{u}, \mathbf{w}\rangle + \langle T\mathbf{w}, \mathbf{u}\rangle = 0.$$

Over $\mathbb{R}$, $\langle T\mathbf{w}, \mathbf{u}\rangle = \langle \mathbf{u}, T\mathbf{w}\rangle$, so $\langle T\mathbf{u}, \mathbf{w}\rangle = \langle \mathbf{u}, -T\mathbf{w}\rangle$ for all $\mathbf{u}, \mathbf{w}$. By the unique-

ness in Theorem 10.6.1, $T^* = -T$.

(b) Put $A = \frac{1}{2}(T + T^*)$ and $B = \frac{1}{2}(T - T^*)$. Then $A + B = T$, and by Theorem 10.6.2 (a), (b) and (d), $A^* = A$ and $B^* = -B$. For uniqueness, if $T = A' + B'$ is another such splitting, then $T^* = A' - B'$, so $A' = \frac{1}{2}(T + T^*) = A$ and $B' = B$. Finally $\langle B\mathbf{v}, \mathbf{v}\rangle = 0$ for every $\mathbf{v}$ by (a), so $\langle T\mathbf{v}, \mathbf{v}\rangle = \langle A\mathbf{v}, \mathbf{v}\rangle + \langle B\mathbf{v}, \mathbf{v}\rangle = \langle A\mathbf{v}, \mathbf{v}\rangle$.

(c) By (b), two operators T and T' with the same self-adjoint part have the same quadratic form; and conversely, if $\langle T\mathbf{v}, \mathbf{v}\rangle = \langle T'\mathbf{v}, \mathbf{v}\rangle$ for all $\mathbf{v}$, then $A - A'$ is self-adjoint with vanishing quadratic form, so $A = A'$ by Theorem 11.2.5. So the quadratic form sees exactly A. The skew part is invisible: the quarter turn of $\mathbb{R}^2$ is skew-adjoint, and adding it to any T changes nothing. Over $\mathbb{C}$, by contrast, Theorem 11.2.6 says the quadratic form determines T completely — there is no invisible part at all, which is why the complex theory is the easier one.

11.3 Normal Operators

Section 2 collected everything a self-adjoint operator gives us: real eigenvalues, orthogonal eigenspaces, an invariant orthogonal complement. That is exactly the equipment an orthonormal basis of eigenvectors needs. But over $\mathbb{C}$ the hypothesis is too heavy, and this section finds the lighter one that still carries the load. It is a condition already met in Chapter 10, and the rest of the chapter runs on it.

As throughout, F is $\mathbb{R}$ or $\mathbb{C}$, inner products are linear in the first slot, and every inner product space is finite-dimensional unless we say otherwise.

11.3.1 The hypothesis that self-adjointness overshoots

Take the operator on $\mathbb{C}^2$ whose matrix in the standard basis is $\mathbf{D} = \operatorname{diag}(1, i)$. The standard basis is orthonormal and consists of eigenvectors of $\mathbf{D}$, so this operator has everything the spectral theorem promises. Yet it is not self-adjoint: one of its eigenvalues is i, and a self-adjoint operator has only real eigenvalues (Theorem 11.2.1). So over $\mathbb{C}$ self-adjointness cannot be the condition we are looking for. It is sufficient and not necessary, and we are throwing away every operator with a non-real eigenvalue — including every unitary operator other than the trivial ones.

What survives? Compare the two computations. For a self-adjoint T we have $T^*T = TT = TT^*$. For $\mathbf{D} = \operatorname{diag}(1, i)$ we have $\mathbf{D}^* = \operatorname{diag}(1, -i)$, which is a different matrix, but

$$\mathbf{D}^*\mathbf{D} = \operatorname{diag}(1, 1) = \mathbf{D}\mathbf{D}^*.$$

Neither operator equals its adjoint; both **commute** with their adjoints. That is the common feature, and Chapter 10 already gave it a name.

A normal operator is one that never gets in its adjoint's way: the two may be applied in either order.

Recall Definition 10.6.3: an operator $T \in \mathcal{L}(V)$ is **normal** when $T^*T = TT^*$. That is a single equation between two operators, with no vectors and no quantifiers in it, and it is strictly weaker than $T^* = T$. Section 6 of Chapter 10 checked the definition on self-adjoint operators, on unitary

ones, on $i\mathbf{I}$ and on diagonal matrices, and found the 2×2 Jordan block $\mathbf{J}_2(0)$ failing it. We take those for granted and go one step further: normality is best understood as a statement about **lengths**, and that is the content of the first theorem below.

Before it, a wider catalog, since the class is larger than Chapter 10's four examples suggest.

Example. (Which of these are normal?)

Decide which of the following matrices are normal, with the standard inner product on $\mathbb{C}^n$ or $\mathbb{R}^n$. For those that are, say which familiar family they belong to.

(a) $\mathbf{A} = \begin{pmatrix} 2 & 1+i \\ 1-i & 3 \end{pmatrix}$ over $\mathbb{C}$.

(b) $\mathbf{B} = \begin{pmatrix} 0 & 2 \\ -2 & 0 \end{pmatrix}$ over $\mathbb{R}$.

(c) $\mathbf{U} = \frac{1}{\sqrt{2}}\begin{pmatrix} 1 & i \\ i & 1 \end{pmatrix}$ over $\mathbb{C}$.

(d) $\mathbf{C} = \begin{pmatrix} 1 & 2 & 3 \\ 3 & 1 & 2 \\ 2 & 3 & 1 \end{pmatrix}$ over $\mathbb{C}$.

(e) $\mathbf{M} = \begin{pmatrix} 2 & 1 \\ -1 & 2 \end{pmatrix}$ over $\mathbb{R}$.

(f) $\mathbf{N} = \begin{pmatrix} 1 & 1 \\ 0 & 2 \end{pmatrix}$ over $\mathbb{R}$.

Solution.

(a) Normal. $\mathbf{A}^* = \mathbf{A}$, since transposing swaps the off-diagonal entries and conjugating swaps them back, so $\mathbf{A}$ is Hermitian and both products equal $\mathbf{A}^2$. Every **self-adjoint** operator is normal.

(b) Normal. $\mathbf{B}^\top = -\mathbf{B}$, so $\mathbf{B}^\top\mathbf{B} = -\mathbf{B}^2 = \mathbf{B}\mathbf{B}^\top$. An operator with $T^* = -T$ is called **skew-adjoint**, and the same one-line computation makes every such operator normal.

(c) Normal. $\mathbf{U}^*\mathbf{U} = \frac{1}{2}\begin{pmatrix} 1 & -i \\ -i & 1 \end{pmatrix}\begin{pmatrix} 1 & i \\ i & 1 \end{pmatrix} = \frac{1}{2}\begin{pmatrix} 2 & 0 \\ 0 & 2 \end{pmatrix} = \mathbf{I}$, so $\mathbf{U}$ is **unitary** (Definition 10.7.2), and then $\mathbf{U}^*\mathbf{U} = \mathbf{I} = \mathbf{U}\mathbf{U}^*$.

(d) Normal. Each row of $\mathbf{C}$ is the previous one shifted cyclically to the right; such a matrix is called a **circulant**. Writing out the products,

$$\mathbf{C}^\top\mathbf{C} = \mathbf{C}\mathbf{C}^\top = \begin{pmatrix} 14 & 11 & 11 \\ 11 & 14 & 11 \\ 11 & 11 & 14 \end{pmatrix}.$$

Both entries in position (i,j) are the dot product of two rows of $\mathbf{C}$, or of two columns, and cyclic shifting makes those two lists of dot products agree. Section 9 explains circulants properly and diagonalizes all of them at once.

(e) Normal, and in none of the families above: $\mathbf{M}^\top \neq \pm\mathbf{M}$ and $\mathbf{M}^\top\mathbf{M} = 5\mathbf{I} \neq \mathbf{I}$. Still,

$$\mathbf{M}^\top\mathbf{M} = \mathbf{M}\mathbf{M}^\top = \begin{pmatrix} 5 & 0 \\ 0 & 5 \end{pmatrix}.$$

This is $\sqrt{5}$ times a rotation of the plane, which is the rotation-scaling block $\mathbf{\Lambda}(2+i)$ transposed (Definition 9.4.1). Normality is genuinely wider than "self-adjoint or unitary".

(f) **Not** normal:

$$\mathbf{N}^{\top}\mathbf{N} = \begin{pmatrix} 1 & 1 \\ 1 & 5 \end{pmatrix}, \qquad \mathbf{N}\mathbf{N}^{\top} = \begin{pmatrix} 2 & 2 \\ 2 & 4 \end{pmatrix}.$$

The $(1,1)$ entries already disagree, $1 \neq 2$. This matrix is diagonalizable, with eigenvalues 1 and 2; Section 4 shows what it costs to be diagonalizable and not normal.

11.3.2 Normality is a statement about lengths

The definition compares two operators. The next theorem turns it into a comparison of two numbers, one vector at a time, and that is the form every later proof uses. The engine is the zero test of Section 2: a self-adjoint operator S with $\langle S\mathbf{v}, \mathbf{v}\rangle = 0$ for all $\mathbf{v}$ is zero.

Theorem 11.3.1 — Characterizations of Normality

Let V be a finite-dimensional inner product space over F and let $T \in \mathcal{L}(V)$. The following are equivalent.

(a) T is normal.
(b) $\|T\mathbf{v}\| = \|T^*\mathbf{v}\|$ for every $\mathbf{v} \in V$.
(c) $\langle T\mathbf{u}, T\mathbf{v}\rangle = \langle T^*\mathbf{u}, T^*\mathbf{v}\rangle$ for all $\mathbf{u}, \mathbf{v} \in V$.

Suppose in addition that $F = \mathbb{C}$, and set

$$A = \tfrac{1}{2}(T + T^*), \qquad B = \tfrac{1}{2i}(T - T^*),$$

so that A and B are self-adjoint and $T = A + iB$. Then (a)–(c) are further equivalent to

(d) $AB = BA$.

Idea. Condition (a) says that the operator $S = T^*T - TT^*$ is zero. That operator is self-adjoint, so by the zero test of Theorem 11.2.5 it is enough to know $\langle S\mathbf{v}, \mathbf{v}\rangle = 0$ for every $\mathbf{v}$ — and $\langle S\mathbf{v}, \mathbf{v}\rangle$ is exactly $\|T\mathbf{v}\|^2 - \|T^*\mathbf{v}\|^2$. So (a) and (b) are the same statement read at two different levels of resolution. Condition (c) is (b) with the two slots unglued, and it costs nothing in one direction and a specialization in the other. Condition (d) is the operator version of writing a complex number as $a+bi$; that decomposition appeared in Exercise (C2: Skew-adjoint operators) (c), and multiplying out $TT^* - T^*T$ in terms of A and B leaves only the commutator.

Proof.

(a) $\Rightarrow$ (c). For all $\mathbf{u}, \mathbf{v} \in V$, by Definition 10.6.1 and $T^{**} = T$ (Theorem 10.6.2 (d)),

$$\langle T\mathbf{u}, T\mathbf{v}\rangle = \langle T^*T\mathbf{u}, \mathbf{v}\rangle, \qquad \langle T^*\mathbf{u}, T^*\mathbf{v}\rangle = \langle TT^*\mathbf{u}, \mathbf{v}\rangle.$$

Since $T^*T = TT^*$, the two right-hand sides agree.

(b) $\Rightarrow$ (b). Take $\mathbf{u} = \mathbf{v}$. Then $\|T\mathbf{v}\|^2 = \|T^*\mathbf{v}\|^2$, and both norms are non-negative reals, so they are equal.

(c) $\Rightarrow$ (a). Put $S = T^*T - TT^*$. Then S is self-adjoint: by Theorem 10.6.2 (a), (c) and (d),

$$S^* = (T^*T)^* - (TT^*)^* = T^*T^{**} - T^{**}T^* = T^*T - TT^* = S.$$

For any $\mathbf{v} \in V$, using Definition 10.6.1 twice,

$$\begin{aligned} \langle S\mathbf{v}, \mathbf{v}\rangle &= \langle T^*T\mathbf{v}, \mathbf{v}\rangle - \langle TT^*\mathbf{v}, \mathbf{v}\rangle \\ &= \langle T\mathbf{v}, T\mathbf{v}\rangle - \langle T^*\mathbf{v}, T^*\mathbf{v}\rangle \\ &= \|T\mathbf{v}\|^2 - \|T^*\mathbf{v}\|^2 = 0 \end{aligned}$$

by (b). Since S is self-adjoint, Theorem 11.2.5 gives $S = 0$, that is $T^*T = TT^*$.

Now let $F = \mathbb{C}$. By Theorem 10.6.2 (a), (b) and (d),

$$\begin{aligned} A^* &= \tfrac{1}{2}(T^* + T) = A, \\ B^* &= \overline{\left(\tfrac{1}{2i}\right)}(T^* - T) = \tfrac{1}{2i}(T - T^*) = B, \end{aligned}$$

so both are self-adjoint, and $A + iB = \frac{1}{2}(T + T^*) + \frac{1}{2}(T - T^*) = T$; this is the decomposition of Exercise (C2: Skew-adjoint operators) (c). Expanding $T = A + iB$ and $T^* = A - iB$,

$$\begin{aligned} TT^* &= (A + iB)(A - iB) = A^2 + B^2 + i(BA - AB), \\ T^*T &= (A - iB)(A + iB) = A^2 + B^2 + i(AB - BA). \end{aligned}$$

Subtracting, $TT^* - T^*T = 2i(BA - AB)$. So T is normal exactly when $AB = BA$, which is (a) $\Leftrightarrow$ (d). This proves the theorem.

■

Condition (b) is the one to remember. It says that T and T^* stretch every single vector by the same amount, even though they need not move it in the same direction. Everything in the next three sections is squeezed out of that sentence. Condition (d) records that normality over $\mathbb{C}$ is the operator analogue of the fact that any two real numbers commute: split T into a "real part" and an "imaginary part", and normality is precisely the failure of those two parts to interfere.

Quick check. The symmetric matrix $\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$ and the skew-symmetric matrix $\begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}$ are both normal, the first being self-adjoint and the second skew-adjoint. Is their sum normal?

Solution. No. The sum is $\begin{pmatrix} 0 & 2 \\ 0 & 0 \end{pmatrix} = 2\mathbf{J}_2(0)$, which is twice the standard non-normal example: it kills $\mathbf{e}_1$ and sends $\mathbf{e}_2$ to a vector of length 2, while its transpose does the opposite, so condition (b) fails at $\mathbf{v} = \mathbf{e}_1$. The normal operators do not form a subspace of $\mathcal{L}(V)$, and they are not closed under composition either.

11.3.3 What normality buys

Four consequences, all short, all obtained by turning some statement about T into the same statement about T^*.

Corollary 11.3.2 — Kernel, Image and an Orthogonal Splitting

Let $T \in \mathcal{L}(V)$ be normal on a finite-dimensional inner product space V. Then:

(a) $\ker T = \ker T^*$;
(b) $\operatorname{im} T = \operatorname{im} T^*$;
(c) $V = \ker T \oplus \operatorname{im} T$, and the two summands are orthogonal to each other.

Proof.

(a) For $\mathbf{v} \in V$, Theorem 11.3.1 (b) gives $\|T\mathbf{v}\| = \|T^*\mathbf{v}\|$. So $T\mathbf{v} = \mathbf{0}$ if and only if $\|T\mathbf{v}\| = 0$, if and only if $\|T^*\mathbf{v}\| = 0$, if and only if $T^*\mathbf{v} = \mathbf{0}$.

(b) By Theorem 10.6.5 (b) applied to T^* in place of T, and using $T^{**} = T$ (Theorem 10.6.2 (d)),

$$\operatorname{im} T = \operatorname{im} T^{**} = (\ker T^*)^{\perp} = (\ker T)^{\perp} = \operatorname{im} T^*,$$

where the third equality is (a) and the fourth is Theorem 10.6.5 (b) for T.

(c) By (b), $\operatorname{im} T = (\ker T)^{\perp}$, and $V = \ker T \oplus (\ker T)^{\perp}$ by Theorem 10.3.2 (a). Orthogonality of the summands is the definition of the orthogonal complement.

■

Part (c) fails badly without normality, and the failure is not subtle: for a general operator $\ker T$ and $\operatorname{im} T$ can be **equal**. Take T with matrix $\mathbf{J}_2(0) = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$ on $\mathbb{C}^2$. Then $T\mathbf{e}_1 = \mathbf{0}$ and $T\mathbf{e}_2 = \mathbf{e}_1$, so

$$\ker T = \operatorname{span}(\mathbf{e}_1) = \operatorname{im} T.$$

The sum $\ker T + \operatorname{im} T$ is one-dimensional, so it is neither direct nor all of $\mathbb{C}^2$. Normality is exactly what rules this out.

Theorem 11.3.3 — An Eigenvector of a Normal Operator Is an Eigenvector of Its Adjoint

Let $T \in \mathcal{L}(V)$ be normal, let $\lambda \in F$ and let $\mathbf{v} \in V$. Then

$$T\mathbf{v} = \lambda\mathbf{v} \quad \text{if and only if} \quad T^*\mathbf{v} = \overline{\lambda}\,\mathbf{v}.$$

In particular $E_\lambda(T) = E_{\overline{\lambda}}(T^*)$, and $\lambda \in \operatorname{spec}(T)$ if and only if $\overline{\lambda} \in \operatorname{spec}(T^*)$.

Idea. Both sides say that $\mathbf{v}$ lies in a kernel: the left in $\ker(T - \lambda\,\mathrm{id}_V)$, the right in $\ker(T^* - \overline{\lambda}\,\mathrm{id}_V)$. Those two operators are adjoint to each other, so Corollary 11.3.2 (a) closes the gap — provided $T - \lambda\,\mathrm{id}_V$ is itself normal, which is the only thing to check.

Proof. Write $S = T - \lambda\,\mathrm{id}_V$. By Theorem 10.6.2 (a), (b) and (d), $S^* = T^* - \overline{\lambda}\,\mathrm{id}_V$. Since $T^*T = TT^*$ and id_V commutes with everything,

$$\begin{aligned} S^*S &= T^*T - \overline{\lambda}T - \lambda T^* + |\lambda|^2\,\mathrm{id}_V \\ &= TT^* - \lambda T^* - \overline{\lambda}T + |\lambda|^2\,\mathrm{id}_V = SS^*, \end{aligned}$$

so S is normal. By Corollary 11.3.2 (a), $\ker S = \ker S^*$. Now $T\mathbf{v} = \lambda\mathbf{v}$ says $\mathbf{v} \in \ker S$, and $T^*\mathbf{v} = \overline{\lambda}\mathbf{v}$ says $\mathbf{v} \in \ker S^*$, so the two conditions agree. The statement about eigenspaces is the equality $\ker S = \ker S^*$ rewritten, and the statement about spectra follows because an eigenspace is non-zero exactly when the scalar is an eigenvalue (Theorem 8.2.1).

■

The theorem is the reason normal operators are so easy to handle: T and T^* have the *same* eigenvectors, with conjugate eigenvalues. The proof of the next corollary is the classical self-adjoint argument (Theorem 11.2.3) with one conjugate bar inserted, and that bar is exactly what Theorem 11.3.3 supplies.

Corollary 11.3.4 — Eigenvectors for Distinct Eigenvalues Are Orthogonal

Let $T \in \mathcal{L}(V)$ be normal, let $\lambda \neq \mu$ be eigenvalues of T, and let $T\mathbf{u} = \lambda\mathbf{u}$ and $T\mathbf{v} = \mu\mathbf{v}$. Then $\langle \mathbf{u}, \mathbf{v}\rangle = 0$. Hence $E_\lambda(T) \perp E_\mu(T)$ whenever $\lambda \neq \mu$.

Proof. Compute $\langle T\mathbf{u}, \mathbf{v}\rangle$ in two ways. First, $\langle T\mathbf{u}, \mathbf{v}\rangle = \langle \lambda\mathbf{u}, \mathbf{v}\rangle = \lambda\langle \mathbf{u}, \mathbf{v}\rangle$. Second, by Definition 10.6.1 and then Theorem 11.3.3 applied to $\mathbf{v}$,

$$\langle T\mathbf{u}, \mathbf{v}\rangle = \langle \mathbf{u}, T^*\mathbf{v}\rangle = \langle \mathbf{u}, \overline{\mu}\,\mathbf{v}\rangle = \mu\langle \mathbf{u}, \mathbf{v}\rangle,$$

the last step because a scalar leaves the second slot conjugated. Subtracting, $(\lambda - \mu)\langle \mathbf{u}, \mathbf{v}\rangle = 0$, and $\lambda - \mu \neq 0$, so $\langle \mathbf{u}, \mathbf{v}\rangle = 0$. Every vector of $E_\lambda(T)$ is orthogonal to every vector of $E_\mu(T)$ by the same computation.

■

Theorem 11.3.5 — A Normal Operator Has No Hidden Kernel

Let $T \in \mathcal{L}(V)$ be normal. Then $\ker T^k = \ker T$ for every integer $k \geq 1$. In particular, a normal nilpotent operator is the zero operator.

Idea. The inclusion $\ker T \subseteq \ker T^2$ is free, and the whole content is the reverse one. If $T^2\mathbf{v} = \mathbf{0}$, then the vector $\mathbf{w} = T\mathbf{v}$ lies in $\ker T$, hence also in $\ker T^*$ by Corollary 11.3.2; and a vector that is killed by T^* and is itself in the image of T must be $\mathbf{0}$, because pairing it with itself moves T across the inner product and hits the T^*.

Proof. First take $k = 2$. The inclusion $\ker T \subseteq \ker T^2$ holds for every operator. Conversely, suppose $T^2\mathbf{v} = \mathbf{0}$ and put $\mathbf{w} = T\mathbf{v}$. Then $T\mathbf{w} = \mathbf{0}$, so $T^*\mathbf{w} = \mathbf{0}$ by Corol-

lary 11.3.2 (a). Therefore, by Definition 10.6.1,

$$\begin{aligned}\|\mathbf{w}\|^2 &= \langle \mathbf{w}, \mathbf{w}\rangle = \langle T\mathbf{v}, \mathbf{w}\rangle \\ &= \langle \mathbf{v}, T^*\mathbf{w}\rangle = \langle \mathbf{v}, \mathbf{0}\rangle = 0,\end{aligned}$$

so $\mathbf{w} = T\mathbf{v} = \mathbf{0}$ and $\mathbf{v} \in \ker T$. Hence $\ker T^2 = \ker T$.

Now induct on k. The cases $k = 1, 2$ are done. Let $k \geq 2$ and assume $\ker T^k = \ker T$. If $T^{k+1}\mathbf{v} = \mathbf{0}$, then $T^2\big(T^{k-1}\mathbf{v}\big) = \mathbf{0}$, so $T^k\mathbf{v} = T\big(T^{k-1}\mathbf{v}\big) = \mathbf{0}$ by the case $k = 2$, and then $T\mathbf{v} = \mathbf{0}$ by the inductive hypothesis. So $\ker T^{k+1} \subseteq \ker T$, and the reverse inclusion is again free.

Finally, if T is nilpotent (Definition 9.2.1), say $T^k = 0$, then $\ker T = \ker T^k = V$, so $T = 0$.

■

This is the sentence that explains why normal operators never produce Jordan blocks. Over $\mathbb{C}$, a Jordan block of size $m \geq 2$ for the eigenvalue λ contributes a vector killed by $(T - \lambda \operatorname{id}_V)^m$ but not by $T - \lambda \operatorname{id}_V$ (Definition 9.2.2). For a normal T the operator $T - \lambda \operatorname{id}_V$ is normal, as the proof of Theorem 11.3.3 showed, so Theorem 11.3.5 forbids such a vector. Every block in the Jordan form of a normal operator therefore has size 1, and a normal operator on a complex space is diagonalizable (Theorem 9.3.1, Definition 8.4.1).

Remark. That is diagonalizable, not yet **orthogonally** diagonalizable. The eigenspaces of distinct eigenvalues are already mutually orthogonal by Corollary 11.3.4, so all that is missing is an orthonormal basis inside each eigenspace, which Gram–Schmidt supplies (Theorem 10.2.2). Section 4 proves the whole statement in one stroke instead, from Schur's theorem, because that proof also delivers the converse and works without Chapter 9.

Two converses are worth flagging now, so that you know they are coming and do not try to prove them here. A normal operator whose eigenvalues are all real is self-adjoint, and a normal operator whose eigenvalues all have modulus 1 is unitary. Both are false without normality, and neither can be reached with the tools of this section: they need an orthonormal basis of eigenvectors, which is the business of Section 4.

Before the warning, one structural fact deserves to be stated where later sections can lean on it. It is the reason a normal operator can be taken apart orthogonally at all.

Proposition 11.3.6 — An Invariant Subspace of a Normal Operator Is Reducing

Let $T \in \mathcal{L}(V)$ be normal on a finite-dimensional inner product space, and let $U \subseteq V$ be T-invariant. Then U is T^*-invariant, $U^\perp$ is T-invariant, and $T|_U$ is a normal operator on U.

Idea. Write the matrix in an orthonormal basis adapted to U. Invariance kills the block below the diagonal, and normality, read on the top-left block alone, kills the block above it. The trace is what converts "these two blocks agree" into "that block is zero".

Proof. Choose an orthonormal basis $(\mathbf{e}_1, \dots, \mathbf{e}_r)$ of U and extend it to an orthonormal basis $\mathcal{B}$ of V (Corollary 10.2.3). Since $T\mathbf{e}_j \in U$ for $j \le r$, the first r columns of $\mathbf{A} = [T]_{\mathcal{B}}^{\mathcal{B}}$ have zeros below row r, so

$$\mathbf{A} = \begin{pmatrix} \mathbf{B} & \mathbf{C} \\ \mathbf{0} & \mathbf{D} \end{pmatrix},$$

with $\mathbf{B}$ of size $r \times r$. Because $\mathcal{B}$ is orthonormal, $[T^*]_{\mathcal{B}}^{\mathcal{B}} = \mathbf{A}^*$ (Theorem 10.6.3), and T normal means $\mathbf{A}^*\mathbf{A} = \mathbf{A}\mathbf{A}^*$. Comparing the $(1,1)$ blocks (Theorem 7.1.1),

$$(\mathbf{A}^*\mathbf{A})_{11} = \mathbf{B}^*\mathbf{B}, \qquad (\mathbf{A}\mathbf{A}^*)_{11} = \mathbf{B}\mathbf{B}^* + \mathbf{C}\mathbf{C}^*.$$

Taking traces and using $\operatorname{tr}(\mathbf{B}^*\mathbf{B}) = \operatorname{tr}(\mathbf{B}\mathbf{B}^*)$ (Theorem 0.9.6 (3)) gives $\operatorname{tr}(\mathbf{C}\mathbf{C}^*) = 0$. But $\operatorname{tr}(\mathbf{C}\mathbf{C}^*) = \sum_{i,j} |c_{ij}|^2$, a sum of non-negative reals, so $\mathbf{C} = \mathbf{0}$.

Hence $\mathbf{A} = \mathbf{B} \oplus \mathbf{D}$. Reading the last $n - r$ columns, $T\mathbf{e}_j \in U^\perp$ for $j > r$, so $U^\perp$ is T-invariant; reading the first r columns of $\mathbf{A}^*$, U is T^*-invariant. Finally $[T|_U] = \mathbf{B}$ and the $(1,1)$ blocks above now read $\mathbf{B}^*\mathbf{B} = \mathbf{B}\mathbf{B}^*$, so $T|_U$ is normal. This shows all three claims.

■

Warning. **Normality cannot be read off a corner.** A principal submatrix of a normal matrix need not be normal. The 3×3 cyclic shift

$$\mathbf{S} = \begin{pmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix}$$

is a permutation matrix, hence orthogonal (Exercise (B3: Permutations are orthogonal)), hence normal; but deleting its last row and column leaves $\begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix}$, the transpose of $\mathbf{J}_2(0)$, which is not normal. Equivalently: the operator that $\mathbf{S}$ compresses to $\operatorname{span}(\mathbf{e}_1, \mathbf{e}_2)$ is not normal, because that subspace is not $\mathbf{S}$-invariant. What **is** true is that an invariant subspace of a normal operator is automatically invariant under the adjoint too, and the restriction there is normal; that is Proposition 11.3.6, proved just above.

11.3.4 Exercises

11.3.4.1 A. Check your understanding

Exercise A1.

(a) State the definition of a normal operator, and state one equivalent condition phrased in terms of norms.

(b) True or false: every self-adjoint operator is normal, and every normal operator is self-adjoint. Justify both halves.

(c) Let T be normal with $T\mathbf{v} = 3\mathbf{v}$. What is $T^*\mathbf{v}$? What if $T\mathbf{v} = 3i\mathbf{v}$?

(d) Give a normal operator on $\mathbb{R}^2$ that is neither self-adjoint nor unitary.

(e) True or false: if S and T are normal then $S + T$ is normal. Justify your answer.

(f) Explain in one sentence why a normal operator cannot be nilpotent unless it is zero.

Solution.

(a) T is normal when $T^*T = TT^*$ (Definition 10.6.3). Equivalently, $\|T\mathbf{v}\| = \|T^*\mathbf{v}\|$ for every $\mathbf{v} \in V$ (Theorem 11.3.1 (b)).

(b) The first half is true: if $T^* = T$ then both products are T^2. The second half is false: $\operatorname{diag}(1, i)$ on $\mathbb{C}^2$ is normal and has a non-real eigenvalue, so it is not self-adjoint (Theorem 11.2.1).

(c) $T^*\mathbf{v} = 3\mathbf{v}$ in the first case and $T^*\mathbf{v} = -3i\mathbf{v}$ in the second, by Theorem 11.3.3: the adjoint has the conjugate eigenvalue on the same eigenvector.

(d) $\begin{pmatrix} 2 & 1 \\ -1 & 2 \end{pmatrix}$ works (Example (Which of these are normal?) (e)): it is not symmetric, and $\mathbf{M}^\top\mathbf{M} = 5\mathbf{I} \neq \mathbf{I}$. Any $\mathbf{\Lambda}(\lambda)$ with $|\lambda| \neq 1$ and $\operatorname{Im}\lambda \neq 0$ does.

(e) False. $\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} + \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} = \begin{pmatrix} 0 & 2 \\ 0 & 0 \end{pmatrix}$ is a sum of two normal matrices and is not normal.

(f) If $T^k = 0$ then $\ker T = \ker T^k = V$ by Theorem 11.3.5, so $T = 0$.

11.3.4.2 B. Practice

Exercise B1: Determine which are normal.

Determine which of the following matrices are normal, with the standard inner product. Justify your answer; for those that are not, exhibit a vector $\mathbf{v}$ with $\|\mathbf{A}\mathbf{v}\| \neq \|\mathbf{A}^*\mathbf{v}\|$.

(a) $\begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix}$ over $\mathbb{R}$.

(b) $\begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$ over $\mathbb{R}$.

(c) $\begin{pmatrix} 0 & i \\ i & 0 \end{pmatrix}$ over $\mathbb{C}$.

(d) $\begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & -1 \\ 0 & 1 & 0 \end{pmatrix}$ over $\mathbb{R}$.

(e) $\begin{pmatrix} i & 1 \\ 0 & i \end{pmatrix}$ over $\mathbb{C}$.

Solution.

(a) Normal: the matrix is symmetric, so it is self-adjoint over $\mathbb{R}$, and self-adjoint implies normal.

(b) Not normal. $\mathbf{A}^\top\mathbf{A} = \begin{pmatrix} 1 & 1 \\ 1 & 2 \end{pmatrix}$ and $\mathbf{A}\mathbf{A}^\top = \begin{pmatrix} 2 & 1 \\ 1 & 1 \end{pmatrix}$. With $\mathbf{v} = \mathbf{e}_1$, $\|\mathbf{A}\mathbf{e}_1\| = \|(1, 0)\| = 1$ while $\|\mathbf{A}^\top\mathbf{e}_1\| = \|(1, 1)\| = \sqrt{2}$.

(c) Normal. $\mathbf{A}^* = \begin{pmatrix} 0 & -i \\ -i & 0 \end{pmatrix} = -\mathbf{A}$, so $\mathbf{A}$ is skew-adjoint and $\mathbf{A}^*\mathbf{A} = -\mathbf{A}^2 = \mathbf{A}\mathbf{A}^*$.

(Concretely both products are $\mathbf{I}$.)

(d) Normal: the matrix is $(1) \oplus \mathbf{\Lambda}(i)$, a direct sum of a 1×1 block and a rotation by a quarter turn, and its columns are orthonormal, so it is orthogonal (Theorem 10.7.3 (f)).

(e) Not normal. $\mathbf{A}^*\mathbf{A} = \begin{pmatrix} 1 & -i \\ i & 2 \end{pmatrix}$ and $\mathbf{A}\mathbf{A}^* = \begin{pmatrix} 2 & -i \\ i & 1 \end{pmatrix}$; with $\mathbf{v} = \mathbf{e}_1$ we get $\|\mathbf{A}\mathbf{e}_1\| = |i| = 1$ and $\|\mathbf{A}^*\mathbf{e}_1\| = \|(-i, 1)\| = \sqrt{2}$. Adding $i\mathbf{I}$ to a non-normal matrix does not repair it: $\mathbf{A} = i\mathbf{I} + \mathbf{J}_2(0)$ and $i\mathbf{I}$ is normal, but sums of normal matrices need not be normal.

Exercise B2: The splitting of a singular normal operator.

Let $\mathbf{C} = \begin{pmatrix} 1 & -1 & 0 \\ 0 & 1 & -1 \\ -1 & 0 & 1 \end{pmatrix} \in M_3(\mathbb{R})$, and let $T = T_{\mathbf{C}}$ be the operator it defines on $\mathbb{R}^3$.

(a) Verify that T is normal.

(b) Compute $\ker T$ and $\ker T^*$ and check that they agree.

(c) Compute $\operatorname{im} T$, and verify directly that $\mathbb{R}^3 = \ker T \oplus \operatorname{im} T$ with the two summands orthogonal, as Corollary 11.3.2 (c) predicts.

Solution.

(a) Each row of $\mathbf{C}$ is the previous one shifted cyclically, so $\mathbf{C}$ is a circulant. Explicitly,

$$\mathbf{C}^\top\mathbf{C} = \mathbf{C}\mathbf{C}^\top = \begin{pmatrix} 2 & -1 & -1 \\ -1 & 2 & -1 \\ -1 & -1 & 2 \end{pmatrix},$$

so T is normal.

(b) $\mathbf{C}\mathbf{x} = \mathbf{0}$ reads $x_1 = x_2 = x_3$, because the first two rows give $x_1 = x_2$ and $x_2 = x_3$. So $\ker T = \operatorname{span}\big((1,1,1)\big)$. The transpose $\mathbf{C}^\top$ has rows $(1,0,-1)$, $(-1,1,0)$, $(0,-1,1)$, and $\mathbf{C}^\top\mathbf{x} = \mathbf{0}$ again reads $x_1 = x_3$ and $x_1 = x_2$. The two kernels agree, as Corollary 11.3.2 (a) requires.

(c) The rank is $3 - 1 = 2$ by Theorem 3.3.1, and the first two columns $(1,0,-1)$ and $(-1,1,0)$ are independent, so

$$\operatorname{im} T = \operatorname{span}\big((1,0,-1),\ (-1,1,0)\big).$$

Both spanning vectors have coordinate sum 0, hence are orthogonal to $(1,1,1)$, so $\operatorname{im} T \perp \ker T$. Since $\dim \ker T + \dim \operatorname{im} T = 1 + 2 = 3$ and the two subspaces meet only in $\mathbf{0}$ (being orthogonal), $\mathbb{R}^3 = \ker T \oplus \operatorname{im} T$. Indeed $\operatorname{im} T = \{\mathbf{x} : x_1 + x_2 + x_3 = 0\} = (\ker T)^\perp$.

Exercise B3: Triangular and normal, by hand.

Let $\mathbf{A} = \begin{pmatrix} a & b \\ 0 & d \end{pmatrix} \in M_2(\mathbb{C})$.

(a) Compute the $(1,1)$ entries of $\mathbf{A}^*\mathbf{A}$ and of $\mathbf{A}\mathbf{A}^*$.

(b) Hence prove that $\mathbf{A}$ is normal if and only if $b = 0$, that is, if and only if $\mathbf{A}$ is diagonal.

(c) Which upper triangular matrices in $M_2(\mathbb{C})$ are unitary?

Hint: for (a), you only need one entry of each product.

Solution.

(a) The $(1,1)$ entry of $\mathbf{A}^*\mathbf{A}$ is the squared norm of the first **column** of $\mathbf{A}$, namely $|a|^2$. The $(1,1)$ entry of $\mathbf{A}\mathbf{A}^*$ is the squared norm of the first **row**, namely $|a|^2 + |b|^2$. In full,

$$\mathbf{A}^*\mathbf{A} = \begin{pmatrix} |a|^2 & \overline{a}b \\ a\overline{b} & |b|^2 + |d|^2 \end{pmatrix},$$

$$\mathbf{A}\mathbf{A}^* = \begin{pmatrix} |a|^2 + |b|^2 & b\overline{d} \\ \overline{b}d & |d|^2 \end{pmatrix}.$$

(b) ($\Rightarrow$) If $\mathbf{A}$ is normal, comparing the $(1,1)$ entries gives $|a|^2 = |a|^2 + |b|^2$, so $|b|^2 = 0$ and $b = 0$. ($\Leftarrow$) A diagonal matrix is normal, since $\mathbf{D}^*\mathbf{D} = \mathbf{D}\mathbf{D}^* = \operatorname{diag}(|a|^2, |d|^2)$.

(c) A unitary matrix is normal, so by (b) it must be diagonal, $\operatorname{diag}(a,d)$, and then $\mathbf{A}^*\mathbf{A} = \operatorname{diag}(|a|^2, |d|^2) = \mathbf{I}$ forces $|a| = |d| = 1$. Conversely every such matrix is unitary. So the upper triangular unitary matrices are exactly $\operatorname{diag}(a,d)$ with $|a| = |d| = 1$.

11.3.4.3 C. Going deeper

Exercise C1: A normal operator with no proper invariant subspace.

Let V be a finite-dimensional complex inner product space with $V \neq \{\mathbf{0}\}$, and let $T \in \mathcal{L}(V)$ be normal. Suppose the only T-invariant subspaces of V are $\{\mathbf{0}\}$ and V.

(a) Show that $\dim V = 1$.

(b) Show that the conclusion fails over $\mathbb{R}$, by exhibiting a normal operator on $\mathbb{R}^2$ whose only invariant subspaces are $\{\mathbf{0}\}$ and $\mathbb{R}^2$.

(c) Where exactly does the argument of (a) use that the field is $\mathbb{C}$?

Hint: an eigenvector spans an invariant subspace.

Solution.

(a) Since $V \neq \{\mathbf{0}\}$ and the field is $\mathbb{C}$, T has an eigenvector $\mathbf{v} \neq \mathbf{0}$ (Theorem 8.2.4). Then $\operatorname{span}(\mathbf{v})$ is T-invariant and non-zero, so by hypothesis $\operatorname{span}(\mathbf{v}) = V$ and $\dim V = 1$. Normality is not needed for this direction.

(b) The quarter turn $\mathbf{R}_{\pi/2} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$ is orthogonal, hence normal. A 1-dimensional invariant subspace would be spanned by a real eigenvector, and $\mathbf{R}_{\pi/2}$ has none: its characteristic polynomial is $x^2 + 1$, with no real root. So its only invariant subspaces are $\{\mathbf{0}\}$ and $\mathbb{R}^2$, while $\dim \mathbb{R}^2 = 2$.

(c) Only in the existence of an eigenvector. Over $\mathbb{C}$ that is the Fundamental The-

orem of Algebra (Theorem 5.5.1) reaching the characteristic polynomial; over $\mathbb{R}$ the polynomial may have no root, which is exactly what (b) exploits. Note that Proposition 11.3.6 still holds over $\mathbb{R}$ — it says nothing about invariant subspaces *existing*.

Exercise C2: Arithmetic of normal operators.

Let $S, T \in \mathcal{L}(V)$ be normal.

(a) Prove that T^* is normal and that cT is normal for every $c \in F$.

(b) Prove that $p(T)$ is normal for every polynomial $p \in F[x]$.

(c) Give a concrete S and T, both normal, with ST not normal. (Part (b) shows that this cannot happen when S is a polynomial in T.)

Solution.

(a) $(T^*)^*T^* = TT^* = T^*T = T^*(T^*)^*$, using $T^{**} = T$ (Theorem 10.6.2 (d)). For cT, by Theorem 10.6.2 (b) we have $(cT)^* = \overline{c}T^*$, so

$$(cT)^*(cT) = \overline{c}c\,T^*T = |c|^2\,TT^* = (cT)(cT)^*.$$

(b) Write $p(x) = \sum_k a_k x^k$. Then $p(T)^* = \sum_k \overline{a_k}(T^*)^k$ by Theorem 10.6.2 (a), (b) and (c). Every power of T commutes with every power of T^*: from $TT^* = T^*T$ one moves a T^* past one T at a time. Hence $p(T)$ and $p(T)^*$, being sums of products of such powers, commute, and $p(T)$ is normal.

(c) Take $S = \begin{pmatrix} 1 & 0 \\ 0 & 2 \end{pmatrix}$ and $T = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$, both symmetric and hence normal. Then

$$ST = \begin{pmatrix} 0 & 1 \\ 2 & 0 \end{pmatrix},$$

$$(ST)^\top(ST) = \begin{pmatrix} 4 & 0 \\ 0 & 1 \end{pmatrix}, \qquad (ST)(ST)^\top = \begin{pmatrix} 1 & 0 \\ 0 & 4 \end{pmatrix},$$

so ST is not normal.

Exercise C3: Normality depends on the inner product.

Normality is a property of T **together with** an inner product, not of T alone. Work on $V = \mathbb{R}^2$ with the operator T whose standard matrix is $\mathbf{A} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$.

(a) Verify that T is normal for the standard inner product.

(b) Now use $\langle \mathbf{x}, \mathbf{y} \rangle_{\mathbf{G}} = \mathbf{y}^\top \mathbf{G}\mathbf{x}$ with $\mathbf{G} = \operatorname{diag}(1, 2)$, which is an inner product on $\mathbb{R}^2$. Using the rule $[T^*]_{\mathcal{E}}^{\mathcal{E}} = \mathbf{G}^{-1}\mathbf{A}^\top\mathbf{G}$ in the standard basis $\mathcal{E}$ (Exercise (C3: The adjoint in an arbitrary basis)), compute the matrix of the adjoint of T for this inner product.

(c) Show that T is **not** normal for $\langle \cdot, \cdot \rangle_{\mathbf{G}}$, and reconcile this with (a).

Solution.

(a) $\mathbf{A}^{\top}\mathbf{A} = \mathbf{A}\mathbf{A}^{\top} = \mathbf{I}$, so T is even orthogonal, hence normal.

(b) $\mathbf{G}^{-1} = \operatorname{diag}(1, \tfrac{1}{2})$, so

$$\mathbf{G}^{-1}\mathbf{A}^{\top}\mathbf{G} = \begin{pmatrix} 1 & 0 \\ 0 & \frac{1}{2} \end{pmatrix} \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ 0 & 2 \end{pmatrix} = \begin{pmatrix} 0 & 2 \\ -\frac{1}{2} & 0 \end{pmatrix}.$$

Call this matrix $\mathbf{A}^{\star}$.

(c) Computing both products,

$$\mathbf{A}\mathbf{A}^{\star} = \begin{pmatrix} \frac{1}{2} & 0 \\ 0 & 2 \end{pmatrix}, \qquad \mathbf{A}^{\star}\mathbf{A} = \begin{pmatrix} 2 & 0 \\ 0 & \frac{1}{2} \end{pmatrix},$$

which differ, so T is not normal for $\langle \cdot, \cdot \rangle_{\mathbf{G}}$. There is no contradiction: the adjoint is built from the inner product (Definition 10.6.1), so changing the inner product changes T^{*}, and with it the equation $T^{*}T = TT^{*}$. The standard basis is orthonormal for the first inner product and not for the second, which is exactly the hypothesis Theorem 10.6.3 needs.

11.4 The Complex Spectral Theorem

Two things are now on the table. Section 1 put every complex operator into upper triangular form in an **orthonormal** basis, and Section 3 identified the operators that commute with their adjoints. Put them together and the chapter's main theorem falls out in a few lines: a triangular matrix that is normal has nothing above the diagonal. This section proves that, reads off the consequences, and says exactly how much of the resulting picture is unique.

The field is $\mathbb{C}$ throughout this section, and every inner product space is finite-dimensional. The reason for insisting on $\mathbb{C}$ is Schur's theorem, and behind it the Fundamental Theorem of Algebra (Theorem 5.5.1): over $\mathbb{R}$ an operator can fail to have a single eigenvector, and Section 5 shows what has to change.

11.4.1 Triangular plus normal forces diagonal

Start with the smallest case, where the mechanism is visible at a glance. Let

$$\mathbf{A} = \begin{pmatrix} a & b \\ 0 & d \end{pmatrix} \in M_2(\mathbb{C})$$

be upper triangular. The $(1,1)$ entry of $\mathbf{A}^{*}\mathbf{A}$ is the squared length of the first **column** of $\mathbf{A}$, and the $(1,1)$ entry of $\mathbf{A}\mathbf{A}^{*}$ is the squared length of the first **row**:

$$(\mathbf{A}^{*}\mathbf{A})_{11} = |a|^2, \qquad (\mathbf{A}\mathbf{A}^{*})_{11} = |a|^2 + |b|^2.$$

If $\mathbf{A}$ is normal these are equal, so $|b|^2 = 0$ and $b = 0$. One entry of one product did all the work. (This is Exercise (B3: Triangular and normal, by hand), which you may already have done.)

The general case is the same comparison run down the diagonal, one row at a time. Nothing is clever; the only care needed is to use, at step j, the zeros that steps $1, \dots, j-1$ have already produced.

Lemma 11.4.1 — A Normal Triangular Matrix Is Diagonal

Let $\mathbf{T} = (t_{ij}) \in M_n(\mathbb{C})$ be upper triangular and normal. Then $\mathbf{T}$ is diagonal.

Idea. For any square matrix, the j-th diagonal entry of $\mathbf{T}^*\mathbf{T}$ is the squared length of column j, and the j-th diagonal entry of $\mathbf{T}\mathbf{T}^*$ is the squared length of row j. Normality says those two lengths agree for every j. For an upper triangular matrix, column j reaches only down to the diagonal and row j only rightwards from it, so the equation compares "what sits above t_{jj}" with "what sits to the right of t_{jj}". Row 1 has nothing above it, so the right side must be empty too; that clears row 1, which empties the column sums one step further down, and the argument walks down the diagonal.

Proof. For each j, computing the (j,j) entries of the two products entry by entry,

$$(\mathbf{T}^*\mathbf{T})_{jj} = \sum_{i=1}^{n} \overline{t_{ij}}\, t_{ij} = \sum_{i=1}^{n} |t_{ij}|^2, \qquad (\mathbf{T}\mathbf{T}^*)_{jj} = \sum_{k=1}^{n} |t_{jk}|^2.$$

Since $\mathbf{T}$ is upper triangular, $t_{ij} = 0$ whenever $i > j$, and $t_{jk} = 0$ whenever $k < j$. So normality of $\mathbf{T}$ says

$$\sum_{i \le j} |t_{ij}|^2 = \sum_{k \ge j} |t_{jk}|^2 \qquad (j = 1, \dots, n). \tag{11.4.1}$$

We prove by induction on j that $t_{jk} = 0$ for every $k > j$.

Base case $j = 1$. The left-hand side of Eq. 11.4.1 has the single term $|t_{11}|^2$, so

$$|t_{11}|^2 = |t_{11}|^2 + \sum_{k>1} |t_{1k}|^2.$$

Hence $\sum_{k>1} |t_{1k}|^2 = 0$, a sum of non-negative reals, so $t_{1k} = 0$ for every $k > 1$.

Inductive step. Let $1 < j \le n$ and suppose $t_{mk} = 0$ whenever $m < j$ and $k > m$. In the left-hand side of Eq. 11.4.1, every term with $i < j$ is $|t_{ij}|^2$ with $i < j$, hence with $j > i$; by the inductive hypothesis, taking $m = i$ and $k = j$, each such t_{ij} is 0. So the left-hand side reduces to $|t_{jj}|^2$ and Eq. 11.4.1 becomes

$$|t_{jj}|^2 = |t_{jj}|^2 + \sum_{k>j} |t_{jk}|^2,$$

whence $t_{jk} = 0$ for every $k > j$, again because a sum of non-negative reals vanishes only when every term does.

By induction, every entry strictly above the diagonal is zero. Every entry strictly below it is zero because $\mathbf{T}$ is upper triangular. So $\mathbf{T}$ is diagonal, as claimed.

■

Note what the proof did **not** need: no eigenvector was chosen, no dimension was inducted on, no subspace was split off. The whole argument is an identity between two lists of non-negative numbers. That is why it also survives, unchanged in spirit, into the block version used in Section 5 and the quantitative version in Section 11.

11.4.2 The theorem

Theorem 11.4.2 — Complex Spectral Theorem

Let V be a finite-dimensional inner product space over $\mathbb{C}$ and let $T \in \mathcal{L}(V)$. The following are equivalent.

(a) T is normal.

(b) V has an orthonormal basis consisting of eigenvectors of T.

Idea. ($\Leftarrow$) is a one-line check: in such a basis the matrix of T is diagonal, the matrix of T^* is its conjugate transpose, and two diagonal matrices commute. ($\Rightarrow$) is Schur plus the lemma: take an orthonormal basis making the matrix triangular, observe that normality of T is normality of that matrix because the basis is orthonormal, and apply Lemma 11.4.1. A diagonal matrix in the basis $\mathcal{B}$ says precisely that each vector of $\mathcal{B}$ is an eigenvector.

Proof. ($\Leftarrow$) Suppose $\mathcal{B} = (\mathbf{e}_1, \dots, \mathbf{e}_n)$ is an orthonormal basis with $T\mathbf{e}_j = \lambda_j \mathbf{e}_j$ for each j. Then $\mathbf{D} := [T]_{\mathcal{B}}^{\mathcal{B}} = \operatorname{diag}(\lambda_1, \dots, \lambda_n)$, and since $\mathcal{B}$ is orthonormal, $[T^*]_{\mathcal{B}}^{\mathcal{B}} = \mathbf{D}^* = \operatorname{diag}(\overline{\lambda_1}, \dots, \overline{\lambda_n})$ by Theorem 10.6.3. Both products are the same diagonal matrix:

$$\mathbf{D}^*\mathbf{D} = \mathbf{D}\mathbf{D}^* = \operatorname{diag}\big(|\lambda_1|^2, \dots, |\lambda_n|^2\big).$$

Taking the matrix of an operator in a fixed basis turns composition into matrix multiplication and is injective (Theorem 3.6.2, Theorem 3.6.4), so $T^*T = TT^*$.

($\Rightarrow$) Suppose T is normal. By Schur's theorem (Theorem 11.1.2) there is an orthonormal basis $\mathcal{B} = (\mathbf{e}_1, \dots, \mathbf{e}_n)$ of V in which $\mathbf{T} := [T]_{\mathcal{B}}^{\mathcal{B}}$ is upper triangular. Because $\mathcal{B}$ is orthonormal, Theorem 10.6.3 gives $[T^*]_{\mathcal{B}}^{\mathcal{B}} = \mathbf{T}^*$, so the equation $T^*T = TT^*$ reads $\mathbf{T}^*\mathbf{T} = \mathbf{T}\mathbf{T}^*$: the matrix $\mathbf{T}$ is normal. By Lemma 11.4.1, $\mathbf{T}$ is diagonal, say $\mathbf{T} = \operatorname{diag}(\lambda_1, \dots, \lambda_n)$. Reading off the j-th column (Definition 3.6.1), $T\mathbf{e}_j = \lambda_j \mathbf{e}_j$, and $\mathbf{e}_j \neq \mathbf{0}$ because $\|\mathbf{e}_j\| = 1$. So $\mathcal{B}$ is an orthonormal basis of eigenvectors of T. This proves the theorem.

■

Corollary 11.4.3 — Unitary Diagonalization

Let $\mathbf{A} \in M_n(\mathbb{C})$. Then $\mathbf{A}$ is normal if and only if there exist a unitary $\mathbf{U} \in \mathrm{U}(n)$ and a diagonal $\mathbf{D} \in M_n(\mathbb{C})$ with

$$\mathbf{A} = \mathbf{U}\mathbf{D}\mathbf{U}^*.$$

A matrix admitting such a factorization is called **unitarily diagonalizable**. The diagonal of $\mathbf{D}$ is the list of eigenvalues of $\mathbf{A}$ with multiplicity, in an order that may be

prescribed in advance, and the columns of $\mathbf{U}$ are a corresponding orthonormal basis of eigenvectors.

Proof. Apply Theorem 11.4.2 to the operator $T_{\mathbf{A}}$ on $\mathbb{C}^n$ with its standard inner product, for which the standard basis is orthonormal.

($\Rightarrow$) Let $(\mathbf{u}_1, \dots, \mathbf{u}_n)$ be an orthonormal basis of eigenvectors, $\mathbf{A}\mathbf{u}_j = \lambda_j \mathbf{u}_j$, and let $\mathbf{U}$ be the matrix with these columns; it is unitary because its columns are orthonormal (Theorem 10.7.3 (f)). Then $\mathbf{AU}$ has j-th column $\lambda_j \mathbf{u}_j$, which is the j-th column of $\mathbf{UD}$ for $\mathbf{D} = \operatorname{diag}(\lambda_1, \dots, \lambda_n)$. So $\mathbf{AU} = \mathbf{UD}$ and $\mathbf{A} = \mathbf{UDU}^{-1} = \mathbf{UDU}^*$.

($\Leftarrow$) If $\mathbf{A} = \mathbf{UDU}^*$ then $\mathbf{A}^* = \mathbf{UD}^*\mathbf{U}^*$, and

$$\mathbf{A}^*\mathbf{A} = \mathbf{UD}^*\mathbf{DU}^* = \mathbf{UDD}^*\mathbf{U}^* = \mathbf{AA}^*,$$

using $\mathbf{U}^*\mathbf{U} = \mathbf{I}$ twice and the fact that diagonal matrices commute.

Finally, $\mathbf{A}$ is similar to $\mathbf{D}$, so they have the same characteristic polynomial (Theorem 6.10.3), and the roots of $\det(x\mathbf{I} - \mathbf{D}) = \prod_j (x - \lambda_j)$ are the diagonal entries with multiplicity. Reordering the eigenvectors reorders the columns of $\mathbf{U}$ and the diagonal of $\mathbf{D}$ in the same way, so any order may be prescribed.

■

Example. (Unitarily diagonalizing a Hermitian matrix)

Find a unitary $\mathbf{U}$ and a diagonal $\mathbf{D}$ with $\mathbf{U}^*\mathbf{AU} = \mathbf{D}$, for

$$\mathbf{A} = \begin{pmatrix} 2 & 1-i \\ 1+i & 3 \end{pmatrix}.$$

Solution. $\mathbf{A}^* = \mathbf{A}$, so $\mathbf{A}$ is Hermitian, hence normal, and Corollary 11.4.3 applies. Its characteristic polynomial is

$$\begin{aligned} x^2 - (\operatorname{tr}\mathbf{A})x + \det\mathbf{A} &= x^2 - 5x + \big(6 - (1-i)(1+i)\big) \\ &= x^2 - 5x + 4, \end{aligned}$$

since $(1-i)(1+i) = 1 - i^2 = 2$. So the eigenvalues are 4 and 1, both real as Theorem 11.2.1 promises.

For $\lambda = 4$, the first row of $\mathbf{A} - 4\mathbf{I} = \begin{pmatrix} -2 & 1-i \\ 1+i & -1 \end{pmatrix}$ gives $-2z_1 + (1-i)z_2 = 0$; taking $z_2 = 2$ gives $\mathbf{u} = (1-i,\, 2)$, with $\|\mathbf{u}\|^2 = 2 + 4 = 6$.

For $\lambda = 1$, the first row of $\mathbf{A} - \mathbf{I} = \begin{pmatrix} 1 & 1-i \\ 1+i & 2 \end{pmatrix}$ gives $z_1 = -(1-i)z_2$; taking $z_2 = 1$ gives $\mathbf{w} = (-1+i,\, 1)$, with $\|\mathbf{w}\|^2 = 2 + 1 = 3$.

The two are orthogonal, as Corollary 11.3.4 predicts:

$$\begin{aligned} \langle \mathbf{u}, \mathbf{w} \rangle &= (1-i)\overline{(-1+i)} + 2 \cdot \overline{1} \\ &= (1-i)(-1-i) + 2 = -2 + 2 = 0. \end{aligned}$$

Normalizing and using them as columns,

$$\mathbf{U} = \begin{pmatrix} \frac{1-i}{\sqrt{6}} & \frac{-1+i}{\sqrt{3}} \\ \frac{2}{\sqrt{6}} & \frac{1}{\sqrt{3}} \end{pmatrix}, \qquad \mathbf{D} = \begin{pmatrix} 4 & 0 \\ 0 & 1 \end{pmatrix},$$

and $\mathbf{U}^*\mathbf{U} = \mathbf{I}$, $\mathbf{U}^*\mathbf{A}\mathbf{U} = \mathbf{D}$. As a check on the arithmetic, $\operatorname{tr}\mathbf{D} = 5 = \operatorname{tr}\mathbf{A}$ and $\det\mathbf{D} = 4 = \det\mathbf{A}$.

11.4.3 Reading the class off the spectrum

Once the eigenvalues sit on a diagonal, every question about T that is invariant under a unitary change of basis becomes a question about a list of complex numbers. Here are three answers.

Corollary 11.4.4 — The Spectrum Decides

Let $T \in \mathcal{L}(V)$ be normal on a finite-dimensional complex inner product space.

(a) T is self-adjoint if and only if every eigenvalue of T is real.

(b) T is unitary if and only if every eigenvalue of T has modulus 1.

(c) $\langle T\mathbf{v}, \mathbf{v}\rangle$ is a non-negative real number for every $\mathbf{v} \in V$ if and only if every eigenvalue of T is a non-negative real.

Idea. By Theorem 11.4.2 there is an orthonormal basis $(\mathbf{e}_1, \dots, \mathbf{e}_n)$ with $T\mathbf{e}_j = \lambda_j \mathbf{e}_j$, and then $T^*\mathbf{e}_j = \overline{\lambda_j}\mathbf{e}_j$ by Theorem 11.3.3. Two operators that agree on a basis are equal, so each of the three conditions can be tested one basis vector at a time, where it becomes a statement about the single number λ_j.

Proof. Fix an orthonormal basis $(\mathbf{e}_1, \dots, \mathbf{e}_n)$ of eigenvectors, $T\mathbf{e}_j = \lambda_j \mathbf{e}_j$ (Theorem 11.4.2), and recall $T^*\mathbf{e}_j = \overline{\lambda_j}\mathbf{e}_j$ (Theorem 11.3.3). Every eigenvalue of T occurs among $\lambda_1, \dots, \lambda_n$, because $\operatorname{diag}(\lambda_1, \dots, \lambda_n)$ is the matrix of T and its characteristic polynomial is $\prod_j (x - \lambda_j)$.

(a) $T = T^*$ holds if and only if $T\mathbf{e}_j = T^*\mathbf{e}_j$ for every j (Theorem 3.1.5), that is $\lambda_j \mathbf{e}_j = \overline{\lambda_j}\mathbf{e}_j$, that is $\lambda_j = \overline{\lambda_j}$ since $\mathbf{e}_j \neq \mathbf{0}$. A complex number equals its conjugate exactly when it is real.

(b) $T^*T\mathbf{e}_j = T^*(\lambda_j \mathbf{e}_j) = \lambda_j \overline{\lambda_j}\mathbf{e}_j = |\lambda_j|^2 \mathbf{e}_j$, so $T^*T = \mathrm{id}_V$ if and only if $|\lambda_j|^2 = 1$ for every j. That is what it means for T to be unitary (Definition 10.7.2): the equation $T^*T = \mathrm{id}_V$ makes T injective, hence invertible on a finite-dimensional space (Theorem 3.5.7), with $T^{-1} = T^*$ and therefore $TT^* = \mathrm{id}_V$ as well.

(c) Write $\mathbf{v} = \sum_j c_j \mathbf{e}_j$. Expanding both slots and using $\langle \mathbf{e}_j, \mathbf{e}_i\rangle = \delta_{ij}$,

$$\langle T\mathbf{v}, \mathbf{v}\rangle = \Big\langle \sum_j c_j \lambda_j \mathbf{e}_j, \sum_i c_i \mathbf{e}_i \Big\rangle = \sum_j \lambda_j |c_j|^2.$$

($\Leftarrow$) If every λ_j is a non-negative real, this is a sum of non-negative reals. ($\Rightarrow$) Taking $\mathbf{v} = \mathbf{e}_j$ gives $\langle T\mathbf{e}_j, \mathbf{e}_j\rangle = \lambda_j$, which is then a non-negative real by hypothesis.

■

Part (c) names a class that Chapter 12 takes as its subject: the **positive** operators. Over $\mathbb{C}$ the hypothesis of normality is not really needed in (c), because $\langle T\mathbf{v}, \mathbf{v}\rangle$ real for every $\mathbf{v}$ already forces $T = T^*$: apply Theorem 11.2.6 to the operator $T - T^*$, for which $\langle (T - T^*)\mathbf{v}, \mathbf{v}\rangle = \langle T\mathbf{v}, \mathbf{v}\rangle - \overline{\langle T\mathbf{v}, \mathbf{v}\rangle} = 0$. Over $\mathbb{R}$ that shortcut is unavailable, and Section 5 shows the quarter turn defeating it.

The next corollary is a small shock. The adjoint is defined through the inner product and has nothing to do with polynomials. For a normal operator it is one anyway.

Corollary 11.4.5 — The Adjoint of a Normal Operator Is a Polynomial in It

Let $T \in \mathcal{L}(V)$ be normal on a finite-dimensional complex inner product space, with distinct eigenvalues $\lambda_1, \dots, \lambda_k$. Then there is a polynomial $p \in \mathbb{C}[x]$ of degree less than k with $T^* = p(T)$.

Proof. The scalars $\lambda_1, \dots, \lambda_k$ are distinct, so by Lagrange interpolation (Theorem 5.6.1) there is a polynomial $p \in \mathbb{C}[x]$ of degree less than k with

$$p(\lambda_i) = \overline{\lambda_i} \qquad (i = 1, \dots, k).$$

Let $(\mathbf{e}_1, \dots, \mathbf{e}_n)$ be an orthonormal basis of eigenvectors (Theorem 11.4.2), with $T\mathbf{e}_j = \mu_j \mathbf{e}_j$ where each μ_j is one of the λ_i. Then $p(T)\mathbf{e}_j = p(\mu_j)\mathbf{e}_j = \overline{\mu_j}\mathbf{e}_j = T^*\mathbf{e}_j$, the first equality because $T^i\mathbf{e}_j = \mu_j^i \mathbf{e}_j$ for every $i \geq 0$, by induction from $T\mathbf{e}_j = \mu_j \mathbf{e}_j$, and the last by Theorem 11.3.3. The operators $p(T)$ and T^* agree on a basis, hence are equal (Theorem 3.1.5).

■

One consequence is worth stating on its own. Any operator S that commutes with T also commutes with every polynomial in T, hence with T^*. So for normal operators the apparently stronger requirement "commutes with T and with T^*" is no requirement at all, and Section 7 will use this to diagonalize whole commuting families at once. The polynomial depends on T and not only on its size: for $T = \mathrm{id}_V$ one may take the constant $p = 1$, while for the matrix $\mathrm{diag}(1, i)$ the conditions $p(1) = 1$ and $p(i) = -i$ are met by

$$p(x) = ix + (1 - i),$$

as one checks by substituting $x = 1$ and $x = i$.

11.4.4 Exactly what is unique

The factorization $\mathbf{A} = \mathbf{U}\mathbf{D}\mathbf{U}^*$ is not unique, and it is worth being precise about which parts of it are.

Unique: the **set** of eigenvalues $\mathrm{spec}(T)$, and for each $\lambda \in \mathrm{spec}(T)$ the eigenspace $E_\lambda(T)$ with its dimension. These are defined from T alone, without any choice. Consequently the diagonal of $\mathbf{D}$ is unique **as a list with multiplicities up to reordering**: each λ appears exactly $\dim E_\lambda(T)$ times.

Not unique: the order of the diagonal, and the matrix $\mathbf{U}$. Two freedoms create all the others. First, permuting the eigenvectors permutes the columns of $\mathbf{U}$ and the diagonal of $\mathbf{D}$ in

step. Second, within a single eigenspace $E_\lambda(T)$ of dimension m, **any** orthonormal basis of that eigenspace will do, and there are many when $m \geq 2$: the choices are related by the unitary maps of $E_\lambda(T)$. For $\mathbf{A} = \mathbf{I}_n$, for instance, every unitary $\mathbf{U}$ satisfies $\mathbf{U}^*\mathbf{A}\mathbf{U} = \mathbf{I}_n$. What no freedom can change is that eigenvectors for distinct eigenvalues stay orthogonal (Corollary 11.3.4), so the decomposition

$$V = E_{\lambda_1}(T) \oplus \cdots \oplus E_{\lambda_k}(T)$$

into mutually orthogonal eigenspaces is itself unique. Section 8 turns that decomposition into the spectral resolution and shows it determines T completely.

> *Quick check.* The matrix $\mathbf{A} = \operatorname{diag}(1, 1, 2)$ is normal. Write down two different unitary matrices $\mathbf{U}$ with $\mathbf{U}^*\mathbf{A}\mathbf{U} = \mathbf{A}$, and explain why, for $\operatorname{diag}(1, 2, 3)$ with the order of the diagonal fixed, the freedom shrinks to a single unit-modulus scalar on each column.

> *Solution.* Take $\mathbf{U}_1 = \mathbf{I}_3$ and $\mathbf{U}_2 = \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix}$; more generally $\mathbf{R} \oplus (1)$ works for **any** $\mathbf{R} \in \mathrm{U}(2)$, because $\mathbf{A} = \mathbf{I}_2 \oplus (2)$ and $\mathbf{R}^*\mathbf{I}_2\mathbf{R} = \mathbf{I}_2$. The freedom comes from the two-dimensional eigenspace $E_1(\mathbf{A}) = \operatorname{span}(\mathbf{e}_1, \mathbf{e}_2)$, inside which every orthonormal basis is as good as any other. For $\operatorname{diag}(1, 2, 3)$ each eigenspace is a line, and a line has exactly two unit vectors over $\mathbb{R}$ and a circle of them over $\mathbb{C}$; the residual freedom is only the scalar factor of modulus 1 in each column, which changes $\mathbf{U}$ but not the decomposition into eigenspaces.

> *Warning.* **"Diagonalizable" and "unitarily diagonalizable" are different conditions.** Every unitarily diagonalizable matrix is diagonalizable, because $\mathbf{U}$ is in particular invertible. The converse fails, and it fails for matrices as small and as ordinary as $\begin{pmatrix} 1 & 1 \\ 0 & 2 \end{pmatrix}$. Having n distinct eigenvalues guarantees diagonalizability (Corollary 8.4.2) and guarantees nothing about orthogonality.

Example. (Diagonalizable, and no orthonormal eigenbasis)

For $\mathbf{A} = \begin{pmatrix} 1 & 1 \\ 0 & 2 \end{pmatrix} \in M_2(\mathbb{R})$, find an invertible $\mathbf{P}$ with $\mathbf{P}^{-1}\mathbf{A}\mathbf{P}$ diagonal, and show that no **orthogonal** $\mathbf{Q}$ makes $\mathbf{Q}^\top\mathbf{A}\mathbf{Q}$ diagonal.

> *Solution.* The matrix is upper triangular, so its eigenvalues are the diagonal entries 1 and 2 (Theorem 6.4.6). For $\lambda = 1$, $\mathbf{A} - \mathbf{I} = \begin{pmatrix} 0 & 1 \\ 0 & 1 \end{pmatrix}$ has kernel spanned by $(1, 0)$. For $\lambda = 2$, $\mathbf{A} - 2\mathbf{I} = \begin{pmatrix} -1 & 1 \\ 0 & 0 \end{pmatrix}$ has kernel spanned by $(1, 1)$. Two distinct eigenvalues in dimension 2 give a basis of eigenvectors (Corollary 8.4.2), so with
>
> $$\mathbf{P} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix} \quad \text{we get} \quad \mathbf{P}^{-1}\mathbf{A}\mathbf{P} = \begin{pmatrix} 1 & 0 \\ 0 & 2 \end{pmatrix}.$$
>
> Now suppose $\mathbf{Q}^\top\mathbf{A}\mathbf{Q} = \mathbf{D}$ were diagonal with $\mathbf{Q}$ orthogonal. Then $\mathbf{A} = \mathbf{Q}\mathbf{D}\mathbf{Q}^\top$ would be normal by Corollary 11.4.3. But
>
> $$\mathbf{A}^\top\mathbf{A} = \begin{pmatrix} 1 & 1 \\ 1 & 5 \end{pmatrix} \neq \begin{pmatrix} 2 & 2 \\ 2 & 4 \end{pmatrix} = \mathbf{A}\mathbf{A}^\top,$$

so $\mathbf{A}$ is not normal and no such $\mathbf{Q}$ exists. The obstruction is visible without any theory: the eigenvectors are $(1,0)$ and $(1,1)$, the eigenspaces are lines and therefore the *only* candidates for eigenvector directions, and $(1,0)\cdot(1,1) = 1 \neq 0$. There simply is no orthogonal pair of eigenvectors to build $\mathbf{Q}$ from.

11.4.5 Exercises

11.4.5.1 A. Check your understanding

Exercise A1.

(a) State the complex spectral theorem, including every hypothesis, and state its matrix form.

(b) What goes wrong with the proof if the field is $\mathbb{R}$? Name the exact step.

(c) True or false: a matrix in $M_n(\mathbb{C})$ with n distinct eigenvalues is unitarily diagonalizable. Justify your answer.

(d) Let $\mathbf{A} \in M_3(\mathbb{C})$ be normal with $\operatorname{spec}(\mathbf{A}) = \{2, 2, -1\}$ as a list with multiplicity. Is the unitary $\mathbf{U}$ in $\mathbf{A} = \mathbf{U}\mathbf{D}\mathbf{U}^*$ determined by $\mathbf{A}$ and the order of $\mathbf{D}$? What is determined?

(e) A normal operator T satisfies $T^* = T^3$. What can you say about its eigenvalues?

(f) Explain why Lemma 11.4.1 cannot be weakened to "a normal matrix with some of its below-diagonal entries zero is diagonal".

Solution.

(a) For a finite-dimensional inner product space V over $\mathbb{C}$ and $T \in \mathcal{L}(V)$: T is normal if and only if V has an orthonormal basis of eigenvectors of T (Theorem 11.4.2). Matrix form: $\mathbf{A} \in M_n(\mathbb{C})$ is normal if and only if $\mathbf{A} = \mathbf{U}\mathbf{D}\mathbf{U}^*$ with $\mathbf{U}$ unitary and $\mathbf{D}$ diagonal (Corollary 11.4.3).

(b) Schur's theorem. It needs an eigenvalue at every stage of its induction, which over $\mathbb{C}$ comes from Theorem 5.5.1; over $\mathbb{R}$ an operator may have none at all, and then there is no triangular form to start from.

(c) False. $\begin{pmatrix} 1 & 1 \\ 0 & 2 \end{pmatrix}$ has the distinct eigenvalues 1 and 2 and is not normal, hence is not unitarily diagonalizable (Example (Diagonalizable, and no orthonormal eigenbasis)).

(d) No. The eigenspace $E_2(\mathbf{A})$ is two-dimensional, and replacing its orthonormal basis by any other one changes $\mathbf{U}$ while leaving $\mathbf{D}$ alone. What is determined: $\operatorname{spec}(\mathbf{A}) = \{2, -1\}$, the eigenspaces $E_2(\mathbf{A})$ and $E_{-1}(\mathbf{A})$, their dimensions 2 and 1, and their mutual orthogonality.

(e) By Theorem 11.3.3, $T\mathbf{v} = \lambda\mathbf{v}$ gives $T^*\mathbf{v} = \overline{\lambda}\mathbf{v}$, while $T^* = T^3$ gives $T^*\mathbf{v} = \lambda^3\mathbf{v}$. Hence $\overline{\lambda} = \lambda^3$. Taking moduli, $|\lambda| = |\lambda|^3$, so $|\lambda|$ is 0 or 1. If $\lambda \neq 0$, multiplying $\overline{\lambda} = \lambda^3$ by λ gives $|\lambda|^2 = \lambda^4$, that is $\lambda^4 = 1$. So every eigenvalue lies in $\{0, 1, -1, i, -i\}$.

(f) The lemma uses triangularity at **every** index, not at a few places: the comparison of row and column lengths at step j is informative only because the whole of column j below the diagonal is already known to vanish. Zeros in some of those positions

buy nothing. The circulant $\begin{pmatrix} 1 & 1 & 0 \\ 0 & 1 & 1 \\ 1 & 0 & 1 \end{pmatrix}$ is normal and has zeros in positions $(2,1)$ and $(3,2)$, two of the three places below its diagonal, and it is not diagonal.

11.4.5.2 B. Practice

Exercise B1: Unitarily diagonalize.

For each matrix, find a unitary $\mathbf{U}$ and a diagonal $\mathbf{D}$ with $\mathbf{U}^*\mathbf{A}\mathbf{U} = \mathbf{D}$.

(a) $\mathbf{A} = \begin{pmatrix} 3 & -i \\ i & 3 \end{pmatrix}$.

(b) $\mathbf{A} = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & i \\ i & 1 \end{pmatrix}$.

Solution.

(a) $\mathbf{A}^* = \mathbf{A}$, so $\mathbf{A}$ is Hermitian and normal. Its characteristic polynomial is $x^2 - 6x + (9 - (-i)(i)) = x^2 - 6x + 8$, with roots 4 and 2.
For $\lambda = 4$: $\mathbf{A} - 4\mathbf{I} = \begin{pmatrix} -1 & -i \\ i & -1 \end{pmatrix}$, and the first row gives $z_1 = -iz_2$; take $\mathbf{u} = (-i, 1)$, $\|\mathbf{u}\|^2 = 2$. For $\lambda = 2$: $\mathbf{A} - 2\mathbf{I} = \begin{pmatrix} 1 & -i \\ i & 1 \end{pmatrix}$, and the first row gives $z_1 = iz_2$; take $\mathbf{w} = (i, 1)$, $\|\mathbf{w}\|^2 = 2$. They are orthogonal: $\langle \mathbf{u}, \mathbf{w} \rangle = (-i)\bar{i} + 1 = (-i)(-i) + 1 = -1 + 1 = 0$. Hence

$$\mathbf{U} = \frac{1}{\sqrt{2}} \begin{pmatrix} -i & i \\ 1 & 1 \end{pmatrix}, \qquad \mathbf{D} = \begin{pmatrix} 4 & 0 \\ 0 & 2 \end{pmatrix}.$$

(b) $\mathbf{A}$ is unitary (Example (Which of these are normal?) (c)), hence normal. Here $\operatorname{tr} \mathbf{A} = \sqrt{2}$ and $\det \mathbf{A} = \frac{1}{2}(1 - i^2) = 1$, so the characteristic polynomial is $x^2 - \sqrt{2}x + 1$, with roots

$$x = \frac{\sqrt{2} \pm \sqrt{2 - 4}}{2} = \frac{1 \pm i}{\sqrt{2}},$$

both of modulus 1, as Corollary 11.4.4 (b) requires. For $\lambda = (1 + i)/\sqrt{2}$, the equation $\mathbf{A}\mathbf{z} = \lambda \mathbf{z}$ reads $\frac{1}{\sqrt{2}}(z_1 + iz_2) = \frac{1+i}{\sqrt{2}} z_1$, that is $iz_2 = iz_1$, so $\mathbf{u} = (1, 1)$. For $\lambda = (1 - i)/\sqrt{2}$ the same line gives $iz_2 = -iz_1$, so $\mathbf{w} = (1, -1)$. These are orthogonal, so

$$\mathbf{U} = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}, \qquad \mathbf{D} = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 + i & 0 \\ 0 & 1 - i \end{pmatrix}.$$

Here $\mathbf{U}$ is real orthogonal even though $\mathbf{A}$ is not real.

Exercise B2: A circulant, diagonalized.

Let $\omega = e^{2\pi i/3}$, so $\omega^3 = 1$ and $1 + \omega + \omega^2 = 0$, and let

$$\mathbf{C} = \begin{pmatrix} 1 & 1 & 0 \\ 0 & 1 & 1 \\ 1 & 0 & 1 \end{pmatrix} \in M_3(\mathbb{C}).$$

(a) Verify that $\mathbf{C}$ is normal.

(b) Show that $\mathbf{f}_j = \frac{1}{\sqrt{3}}(1, \omega^j, \omega^{2j})$ is an eigenvector of $\mathbf{C}$ for $j = 0, 1, 2$, and find the eigenvalue.

(c) Deduce a unitary $\mathbf{F}$ with $\mathbf{F}^*\mathbf{C}\mathbf{F}$ diagonal, and write down the diagonal explicitly.

Solution.

(a) Both products are the same matrix:

$$\mathbf{C}^*\mathbf{C} = \mathbf{C}\mathbf{C}^* = \begin{pmatrix} 2 & 1 & 1 \\ 1 & 2 & 1 \\ 1 & 1 & 2 \end{pmatrix}.$$

(The entries are dot products of pairs of rows, respectively columns, of $\mathbf{C}$; cyclic shifting makes the two lists agree.)

(b) Write $\mathbf{f} = (1, \omega^j, \omega^{2j})$ before normalizing. Then

$$\mathbf{C}\mathbf{f} = \big(1 + \omega^j,\ \omega^j + \omega^{2j},\ 1 + \omega^{2j}\big).$$

Using $\omega^{3j} = 1$, the second entry is $\omega^j(1 + \omega^j)$ and the third is $\omega^{2j}(\omega^{-2j} + 1) = \omega^{2j}(\omega^j + 1)$, since $\omega^{-2j} = \omega^j$. So $\mathbf{C}\mathbf{f} = (1 + \omega^j)\mathbf{f}$, and the eigenvalue is $1 + \omega^j$.

(c) The three vectors $\mathbf{f}_0, \mathbf{f}_1, \mathbf{f}_2$ are orthonormal: each has norm $\frac{1}{\sqrt{3}}\sqrt{3} = 1$, and for $j \neq l$,

$$\langle \mathbf{f}_j, \mathbf{f}_l \rangle = \tfrac{1}{3} \sum_{m=0}^{2} \omega^{mj}\overline{\omega^{ml}} = \tfrac{1}{3} \sum_{m=0}^{2} \big(\omega^{j-l}\big)^m = 0,$$

because $\omega^{j-l} \neq 1$ is a cube root of unity and $1 + z + z^2 = 0$ for such z. Taking $\mathbf{F}$ with columns $\mathbf{f}_0, \mathbf{f}_1, \mathbf{f}_2$,

$$\begin{aligned} \mathbf{F}^*\mathbf{C}\mathbf{F} &= \operatorname{diag}\big(2,\ 1 + \omega,\ 1 + \omega^2\big) \\ &= \operatorname{diag}\Big(2,\ \tfrac{1}{2} + \tfrac{\sqrt{3}}{2}i,\ \tfrac{1}{2} - \tfrac{\sqrt{3}}{2}i\Big), \end{aligned}$$

using $\omega = -\frac{1}{2} + \frac{\sqrt{3}}{2}i$. Section 9 shows that this one matrix $\mathbf{F}$ diagonalizes **every** 3×3 circulant.

Exercise B3: Decide unitary diagonalizability.

Determine which of the following matrices are unitarily diagonalizable over $\mathbb{C}$, and which are merely diagonalizable. Justify your answer.

(a) $\begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}$.

(b) $\begin{pmatrix} 2 & 3 \\ 0 & 2 \end{pmatrix}$.

(c) $\begin{pmatrix} 1 & 2 \\ 0 & 3 \end{pmatrix}$.

(d) $\begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 0 & 0 \end{pmatrix}$.

Solution.

(a) Unitarily diagonalizable: the matrix is skew-symmetric, hence skew-adjoint over $\mathbb{C}$ and normal, so Corollary 11.4.3 applies. (Its eigenvalues are $\pm i$.)

(b) Neither. Comparing $(1,1)$ entries, $(\mathbf{A}^*\mathbf{A})_{11} = 4$ and $(\mathbf{A}\mathbf{A}^*)_{11} = 4 + 9 = 13$, so $\mathbf{A}$ is not normal. It is not even diagonalizable: the only eigenvalue is 2 and $\mathbf{A} - 2\mathbf{I} = 3\mathbf{J}_2(0) \neq \mathbf{0}$ has rank 1, so $\dim E_2(\mathbf{A}) = 1 < 2$ (Theorem 8.4.1).

(c) Diagonalizable but not unitarily: the eigenvalues 1 and 3 are distinct (Corollary 8.4.2), while $(\mathbf{A}^*\mathbf{A})_{11} = 1 \neq 5 = (\mathbf{A}\mathbf{A}^*)_{11}$, so $\mathbf{A}$ is not normal.

(d) Unitarily diagonalizable: the matrix is a permutation matrix, so its columns are orthonormal and it is unitary, hence normal. (Its eigenvalues are the cube roots of unity.)

11.4.5.3 C. Going deeper

Exercise C1: Operators of finite order.

Let $T \in \mathcal{L}(V)$ be normal on a finite-dimensional complex inner product space, and suppose $T^k = \mathrm{id}_V$ for some integer $k \geq 1$.

(a) Prove that every eigenvalue of T is a k-th root of unity.

(b) Deduce that T is unitary and unitarily diagonalizable.

(c) Show that the hypothesis "normal" cannot be dropped from (b) by exhibiting a T with $T^2 = \mathrm{id}_V$ that is not unitary.

Solution.

(a) If $T\mathbf{v} = \lambda\mathbf{v}$ with $\mathbf{v} \neq \mathbf{0}$, then $T^k\mathbf{v} = \lambda^k\mathbf{v}$ (Exercise (B3: Eigenvalues of powers and inverses) (a)) and $T^k\mathbf{v} = \mathbf{v}$, so $(\lambda^k - 1)\mathbf{v} = \mathbf{0}$ and $\lambda^k = 1$.

(b) Every k-th root of unity has modulus 1, so T is unitary by Corollary 11.4.4 (b), and it is unitarily diagonalizable by Theorem 11.4.2 because it is normal.

(c) On $\mathbb{C}^2$ take $\mathbf{A} = \begin{pmatrix} 1 & 1 \\ 0 & -1 \end{pmatrix}$. Then $\mathbf{A}^2 = \mathbf{I}$, so $T_{\mathbf{A}}$ has order 2; but its second column $(1, -1)$ has norm $\sqrt{2} \neq 1$, so $\mathbf{A}$ is not unitary (Theorem 10.7.3 (f)). It is still diagonalizable, with eigenvalues 1 and -1; what fails is only the orthogonality of the eigenvectors.

Exercise C2: Same spectrum, same multiplicities.

Let $\mathbf{A}, \mathbf{B} \in M_n(\mathbb{C})$ be normal, and suppose they have the same eigenvalues with the same multiplicities, that is, the same characteristic polynomial.

(a) Prove that there is a unitary $\mathbf{W}$ with $\mathbf{B} = \mathbf{WAW}^*$ (one says $\mathbf{A}$ and $\mathbf{B}$ are **unitarily similar**).

(b) Give two matrices in $M_2(\mathbb{C})$ with the same characteristic polynomial that are not unitarily similar, and say which hypothesis of (a) they violate.

(c) Deduce that two normal matrices are unitarily similar if and only if they are similar.

Solution.

(a) By Corollary 11.4.3 write $\mathbf{A} = \mathbf{UDU}^*$ and $\mathbf{B} = \mathbf{VD'V}^*$ with $\mathbf{U}, \mathbf{V}$ unitary and $\mathbf{D}, \mathbf{D'}$ diagonal. The diagonals of $\mathbf{D}$ and $\mathbf{D'}$ are the eigenvalue lists of $\mathbf{A}$ and $\mathbf{B}$ with multiplicity, which agree as multisets; and the order on the diagonal may be prescribed, so we may choose the eigenvector orderings to make $\mathbf{D'} = \mathbf{D}$. Then

$$\mathbf{B} = \mathbf{VDV}^* = \mathbf{VU}^*\mathbf{AUV}^* = \mathbf{WAW}^* \quad \text{with} \quad \mathbf{W} = \mathbf{VU}^*,$$

and $\mathbf{W}$ is unitary because $\mathrm{U}(n)$ is closed under products and inverses (Proposition 10.7.4).

(b) $\mathbf{A} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$ and $\mathbf{B} = \mathbf{0}$ both have characteristic polynomial x^2; they are not even similar, since similar matrices have equal rank. A pair that is similar but not unitarily similar: $\begin{pmatrix} 1 & 1 \\ 0 & 2 \end{pmatrix}$ and $\mathrm{diag}(1, 2)$. In both cases the violated hypothesis is normality of one of the two matrices.

(c) ($\Rightarrow$) A unitary similarity is a similarity. ($\Leftarrow$) Similar matrices have the same characteristic polynomial (Theorem 6.10.3), so if both are normal, (a) upgrades the similarity to a unitary one.

Exercise C3: Normality cannot be dropped.

Corollary 11.4.4 reads the class of a **normal** operator off its spectrum. This exercise shows that each part fails without that hypothesis.

(a) Give $\mathbf{A} \in M_2(\mathbb{C})$ with both eigenvalues real that is not Hermitian.

(b) Give $\mathbf{A} \in M_2(\mathbb{C})$ with both eigenvalues of modulus 1 that is not unitary.

(c) Over $\mathbb{R}$, give $\mathbf{A} \in M_2(\mathbb{R})$ with $\langle \mathbf{Ax}, \mathbf{x} \rangle \geq 0$ for every $\mathbf{x} \in \mathbb{R}^2$ whose eigenvalues are not non-negative reals. Why does no such example exist over $\mathbb{C}$?

Solution.

(a) $\mathbf{A} = \begin{pmatrix} 1 & 1 \\ 0 & 2 \end{pmatrix}$ has eigenvalues 1 and 2 and is not Hermitian, since $\mathbf{A}^* = \begin{pmatrix} 1 & 0 \\ 1 & 2 \end{pmatrix} \neq \mathbf{A}$. It is not normal (Example (Diagonalizable, and no orthonormal eigenbasis)).

(b) $\mathbf{A} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$ has 1 as its only eigenvalue, of modulus 1, and is not unitary: its second column has norm $\sqrt{2}$. Again it is not normal, the $(1,1)$ entries of $\mathbf{A}^*\mathbf{A}$ and $\mathbf{AA}^*$ being 1 and 2.

(c) Take the quarter turn $\mathbf{A} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$. For every $\mathbf{x} = (x_1, x_2) \in \mathbb{R}^2$,

$$\langle \mathbf{A}\mathbf{x}, \mathbf{x} \rangle = -x_2 x_1 + x_1 x_2 = 0 \geq 0,$$

yet $\mathbf{A}$ has no real eigenvalue at all; over $\mathbb{C}$ its eigenvalues are $\pm i$, which are not non-negative reals. Over $\mathbb{C}$ no such example exists: if $\langle T\mathbf{v}, \mathbf{v} \rangle = 0$ for every $\mathbf{v}$ then $T = 0$ by Theorem 11.2.6, and more generally $\langle T\mathbf{v}, \mathbf{v} \rangle$ real for every $\mathbf{v}$ forces T to be self-adjoint, hence normal, by applying Theorem 11.2.6 to $T - T^*$. Real scalars are not enough to detect an operator over $\mathbb{R}$, and they are over $\mathbb{C}$.

11.5 The Real Spectral Theorem

Over $\mathbb{C}$ the answer was clean: an orthonormal basis of eigenvectors exists exactly for the normal operators. Over $\mathbb{R}$ the same question has a different answer, and a smaller one. The class shrinks from normal to self-adjoint, and the reason is a single example that we have met since Chapter 8 and can finally name as the obstruction: a rotation of the plane is as normal as an operator can be and has no eigenvector at all. This section proves the real theorem, examines that obstruction, and then rescues what can be rescued for real normal operators. It ends with the application that made the theorem famous outside linear algebra: the axes of a conic.

Throughout, V is a finite-dimensional inner product space over $\mathbb{R}$ unless stated otherwise, and "symmetric" means $\mathbf{A}^\top = \mathbf{A}$.

11.5.1 One eigenvector, then its orthogonal complement

The proof is the signature move of the chapter, run as an induction. Section 2 did all the work: it produced an eigenvector, and it showed that the orthogonal complement of an invariant subspace is again invariant with a self-adjoint restriction. Those two facts fit together into an induction on dimension with nothing left over.

Theorem 11.5.1 — Real Spectral Theorem

Let V be a finite-dimensional inner product space over $\mathbb{R}$ and let $T \in \mathcal{L}(V)$. The following are equivalent.

(a) T is self-adjoint.

(b) V has an orthonormal basis consisting of eigenvectors of T.

Idea. ($\Leftarrow$) In such a basis the matrix is diagonal, and a real diagonal matrix is its own transpose. ($\Rightarrow$) Induct on $\dim V$. Peel off one unit eigenvector $\mathbf{e}_1$, which exists by Theorem 11.2.2; the line $U = \operatorname{span}(\mathbf{e}_1)$ is invariant, so Theorem 11.2.4 makes $U^\perp$ invariant with a self-adjoint restriction. That restriction lives on a space of dimension $\dim V - 1$, so the inductive hypothesis applies to it, and the basis it returns is already orthogonal to $\mathbf{e}_1$.

Proof. ($\Leftarrow$) Let $\mathcal{B}$ be an orthonormal basis of eigenvectors, so $\mathbf{D} := [T]_{\mathcal{B}}^{\mathcal{B}}$ is diagonal with real entries. Since $\mathcal{B}$ is orthonormal, $[T^*]_{\mathcal{B}}^{\mathcal{B}} = \mathbf{D}^* = \mathbf{D}^\top = \mathbf{D}$ by Theorem 10.6.3, the last equality because a diagonal matrix equals its transpose. Two operators with the same matrix in one basis are equal (Theorem 3.6.4), so $T^* = T$.

($\Rightarrow$) Induct on $n = \dim V$. If $n = 0$ the empty list is an orthonormal basis and there is nothing to prove. Let $n \geq 1$ and suppose the statement holds for every real inner product space of dimension $n - 1$.

Since $V \neq \{\mathbf{0}\}$ and T is self-adjoint, T has an eigenvalue $\lambda \in \mathbb{R}$ by Theorem 11.2.2, say $T\mathbf{v} = \lambda\mathbf{v}$ with $\mathbf{v} \neq \mathbf{0}$. Put $\mathbf{e}_1 = \mathbf{v}/\|\mathbf{v}\|$, a unit eigenvector, and $U = \operatorname{span}(\mathbf{e}_1)$. Then U is T-invariant, because $T(c\mathbf{e}_1) = c\lambda\mathbf{e}_1 \in U$.

By Theorem 11.2.4, $U^\perp$ is T-invariant and the restriction $T|_{U^\perp}$ is a self-adjoint operator on $U^\perp$, which is an inner product space in its own right under the restricted inner product. Its dimension is $n-1$ by Theorem 10.3.2 (c). By the inductive hypothesis, $U^\perp$ has an orthonormal basis $(\mathbf{e}_2, \dots, \mathbf{e}_n)$ of eigenvectors of $T|_{U^\perp}$; each $\mathbf{e}_j$ satisfies $T\mathbf{e}_j = \mu_j\mathbf{e}_j$ in V as well, since the restriction is the same map.

Finally $(\mathbf{e}_1, \dots, \mathbf{e}_n)$ is orthonormal: the last $n-1$ vectors are orthonormal among themselves and each lies in $U^\perp$, hence is orthogonal to $\mathbf{e}_1$, which has norm 1. An orthonormal list is linearly independent (Theorem 10.1.4), and it has $n = \dim V$ members, so it is a basis (Theorem 1.6.4). Every member is an eigenvector of T. This proves the theorem. ∎

Remark. No complexification appears anywhere in that induction, which is worth noticing: the argument is entirely real. The one place where complex numbers were needed is inside Theorem 11.2.2, whose proof complexifies once to borrow an eigenvalue from the Fundamental Theorem of Algebra (Theorem 5.5.1) and then observes that the eigenvalue is real. So $\mathbb{C}$ is used exactly once, to start the machine, and never again.

Corollary 11.5.2 — Orthogonal Diagonalization

Let $\mathbf{A} \in M_n(\mathbb{R})$. Then $\mathbf{A}$ is symmetric if and only if there are an orthogonal $\mathbf{Q} \in \mathrm{O}(n)$ and a **real** diagonal $\mathbf{D}$ with

$$\mathbf{A} = \mathbf{Q}\mathbf{D}\mathbf{Q}^\top.$$

The diagonal of $\mathbf{D}$ is the eigenvalue list of $\mathbf{A}$ with multiplicity, in any prescribed order, and the columns of $\mathbf{Q}$ are a corresponding orthonormal basis of eigenvectors.

Proof. Apply Theorem 11.5.1 to $T_{\mathbf{A}}$ on $\mathbb{R}^n$ with the standard inner product, for which the standard basis is orthonormal, so that $\mathbf{A}^\top = \mathbf{A}$ is exactly self-adjointness (Theorem 10.6.3).

($\Rightarrow$) Let $(\mathbf{q}_1, \dots, \mathbf{q}_n)$ be an orthonormal basis with $\mathbf{A}\mathbf{q}_j = \lambda_j\mathbf{q}_j$, and let $\mathbf{Q}$ have these columns; it is orthogonal by Theorem 10.7.3 (f). Column j of $\mathbf{A}\mathbf{Q}$ is $\lambda_j\mathbf{q}_j$, which is column j of $\mathbf{Q}\mathbf{D}$ for $\mathbf{D} = \operatorname{diag}(\lambda_1, \dots, \lambda_n)$. So $\mathbf{A}\mathbf{Q} = \mathbf{Q}\mathbf{D}$ and $\mathbf{A} = \mathbf{Q}\mathbf{D}\mathbf{Q}^{-1} = \mathbf{Q}\mathbf{D}\mathbf{Q}^\top$. The eigenvalues are real because $\mathbf{A}$ is self-adjoint (Theorem 11.2.1), so $\mathbf{D}$ is a real matrix.

($\Leftarrow$) If $\mathbf{A} = \mathbf{Q}\mathbf{D}\mathbf{Q}^\top$ with $\mathbf{D}$ real diagonal, then

$$\mathbf{A}^\top = (\mathbf{Q}\mathbf{D}\mathbf{Q}^\top)^\top = \mathbf{Q}\mathbf{D}^\top\mathbf{Q}^\top = \mathbf{Q}\mathbf{D}\mathbf{Q}^\top = \mathbf{A}.$$

The claims about the order and the columns are as in Corollary 11.4.3.

■

11.5.2 The negative result: normal is not enough over the reals

Over $\mathbb{C}$ the class with an orthonormal eigenbasis was the normal operators. Over $\mathbb{R}$ Theorem 11.5.1 says it is the self-adjoint ones, which is a strictly smaller class: every self-adjoint operator is normal, and the converse now fails. It is worth seeing exactly how it fails, because the failure is not a technicality about multiplicities or about a badly chosen basis. It is the complete absence of an eigenvector.

Example. (A normal real operator with no eigenvector)

Let $T \in \mathcal{L}(\mathbb{R}^2)$ be the quarter turn, with matrix

$$\mathbf{R} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$$

in the standard basis. Show that T is normal, and that T has no eigenvalue and no eigenvector in $\mathbb{R}^2$.

Solution. Normality: $\mathbf{R}^\top \mathbf{R} = \mathbf{R}\mathbf{R}^\top = \mathbf{I}$, so T is even orthogonal, hence normal. (One may also read it off the shape: $\mathbf{R} = \mathbf{\Lambda}(i)$ is the rotation-scaling block of Definition 9.4.1.)

No eigenvalue: $p_{\mathbf{R}}(x) = x^2 + 1$, which has no root in $\mathbb{R}$. So $\mathbf{R} - \lambda \mathbf{I}$ is invertible for every real λ, and $\ker(T - \lambda\ \mathrm{id}) = \{\mathbf{0}\}$ (Theorem 8.2.1). Geometrically, T turns every non-zero vector by a right angle, so $T\mathbf{v}$ is never a real multiple of $\mathbf{v}$; the operator maps no line to itself.

That example rules out every possible improvement of Theorem 11.5.1 to normal operators over $\mathbb{R}$, and not by a narrow margin. An orthonormal basis of eigenvectors needs n eigenvectors; the quarter turn supplies none. So the two spectral theorems are not two versions of one statement with a technical difference: the real one has a genuinely smaller hypothesis, and the only reason it is not smaller still is Theorem 11.2.2, which manufactures the eigenvector that the rotation lacks.

Two further remarks keep the picture honest. First, the quarter turn is not exceptional. Over $\mathbb{R}$, *every* normal operator that is not self-adjoint fails to have an orthonormal eigenbasis, because Theorem 11.5.1 is an equivalence: having such a basis and being self-adjoint are the same condition. Second, nothing is wrong with the operator; what is missing is the field. Regard $\mathbf{R}$ as a complex matrix and it is unitarily diagonalizable, with eigenvalues $\pm i$ and eigenvectors $(1, \mp i)$ in $\mathbb{C}^2$ (the sign of the eigenvalue and of the entry being opposite). The complex spectral theorem never fails; it simply answers a question about $\mathbb{C}^n$.

Quick check. Is $\mathbf{R} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$ orthogonally diagonalizable over $\mathbb{R}$? Is it unitarily diagonalizable over $\mathbb{C}$? Are the two answers consistent?

Solution. Not over $\mathbb{R}$: an orthogonal diagonalization $\mathbf{R} = \mathbf{Q}\mathbf{D}\mathbf{Q}^\top$ would make $\mathbf{R}$ symmetric by Corollary 11.5.2, and $\mathbf{R}^\top = -\mathbf{R} \neq \mathbf{R}$. Over $\mathbb{C}$ it is unitarily diagonalizable, because it is normal (Corollary 11.4.3); explicitly $\mathbf{U}^*\mathbf{R}\mathbf{U} = \operatorname{diag}(i, -i)$ for $\mathbf{U} = \frac{1}{\sqrt{2}}\begin{pmatrix} 1 & 1 \\ -i & i \end{pmatrix}$. There is no conflict: the two statements concern different spaces, $\mathbb{R}^2$ and $\mathbb{C}^2$, and the diagonalizing basis of the second one is not real.

11.5.3 What a real normal operator does look like

The rotation is not a defect to be apologized for; it is a building block. Chapter 9 already promoted it to one when it built the real Jordan form, and the same 2×2 block returns here as the only thing that can obstruct a real diagonalization of a normal operator.

Theorem 11.5.3 — Real Normal Form of a Normal Operator

Let V be a finite-dimensional inner product space over $\mathbb{R}$ and let $T \in \mathcal{L}(V)$ be normal. Then V has an orthonormal basis in which the matrix of T is block diagonal,

$$(c_1) \oplus \cdots \oplus (c_p) \oplus \mathbf{\Lambda}(\lambda_1) \oplus \cdots \oplus \mathbf{\Lambda}(\lambda_q),$$

with $c_1, \ldots, c_p \in \mathbb{R}$ and, for each j, $\lambda_j = a_j + b_j i$ with $b_j > 0$ and

$$\mathbf{\Lambda}(\lambda_j) = \begin{pmatrix} a_j & -b_j \\ b_j & a_j \end{pmatrix}$$

the rotation-scaling block of Definition 9.4.1. In matrix form: $\mathbf{A} \in M_n(\mathbb{R})$ is normal if and only if $\mathbf{A} = \mathbf{Q}\mathbf{B}\mathbf{Q}^\top$ with $\mathbf{Q} \in \mathrm{O}(n)$ and $\mathbf{B}$ of the displayed shape.

Idea. The real Schur form of Section 1 gets us to a **block** triangular matrix with 1×1 and 2×2 diagonal blocks, and the corner blocks above the diagonal are the only obstruction left. The argument that killed them in the complex case, comparing a diagonal entry of $\mathbf{T}^\top\mathbf{T}$ with the same entry of $\mathbf{T}\mathbf{T}^\top$, works verbatim on blocks once "entry" is replaced by "trace of a block": the identity $\operatorname{tr}(\mathbf{X}\mathbf{X}^\top) = \sum_{i,j} x_{ij}^2$ turns the comparison into a sum of squares that has to vanish. What remains is to see what a 2×2 real normal matrix can be, and there are exactly two answers: symmetric, which splits further, or a rotation-scaling block.

Proof. Fix an orthonormal basis of V and let $\mathbf{A} \in M_n(\mathbb{R})$ be the matrix of T in it; then $\mathbf{A}^\top$ is the matrix of T^* (Theorem 10.6.3), and T normal means $\mathbf{A}^\top\mathbf{A} = \mathbf{A}\mathbf{A}^\top$. Every orthogonal change of orthonormal basis replaces $\mathbf{A}$ by $\mathbf{Q}^\top\mathbf{A}\mathbf{Q}$, which is again normal:

$$(\mathbf{Q}^\top\mathbf{A}\mathbf{Q})^\top(\mathbf{Q}^\top\mathbf{A}\mathbf{Q}) = \mathbf{Q}^\top\mathbf{A}^\top\mathbf{A}\mathbf{Q} = \mathbf{Q}^\top\mathbf{A}\mathbf{A}^\top\mathbf{Q},$$

and the same computation in the other order gives $(\mathbf{Q}^\top\mathbf{A}\mathbf{Q})(\mathbf{Q}^\top\mathbf{A}\mathbf{Q})^\top$. So we may replace $\mathbf{A}$ by any orthogonally similar matrix at will.

Step 1: a block triangular form. By the real Schur form (Theorem 11.1.7) there is $\mathbf{Q}_1 \in \mathrm{O}(n)$ with $\mathbf{T} = \mathbf{Q}_1^\top\mathbf{A}\mathbf{Q}_1$ block upper triangular, its diagonal blocks of size 1×1 and 2×2. Write the block partition as $\mathbf{T} = (\mathbf{T}_{kl})_{1 \le k,l \le m}$ with $\mathbf{T}_{kl} = \mathbf{0}$ for $k > l$. By the previous paragraph $\mathbf{T}$ is normal.

Step 2: the corners vanish.

Claim. A normal, block upper triangular real matrix is block diagonal.

Proof. Induct on the number m of diagonal blocks; $m = 1$ is trivial. Comparing the $(1,1)$ blocks of the two products (Theorem 7.1.1) and using $\mathbf{T}_{k1} = \mathbf{0}$ for $k > 1$,

$$(\mathbf{T}^\top \mathbf{T})_{11} = \mathbf{T}_{11}^\top \mathbf{T}_{11},$$
$$(\mathbf{T}\mathbf{T}^\top)_{11} = \mathbf{T}_{11}\mathbf{T}_{11}^\top + \sum_{l>1} \mathbf{T}_{1l}\mathbf{T}_{1l}^\top.$$

Take traces. Since $\operatorname{tr}(\mathbf{X}\mathbf{Y}) = \operatorname{tr}(\mathbf{Y}\mathbf{X})$ (Theorem 0.9.6), the two terms $\operatorname{tr}(\mathbf{T}_{11}^\top \mathbf{T}_{11})$ and $\operatorname{tr}(\mathbf{T}_{11}\mathbf{T}_{11}^\top)$ are equal and cancel, leaving

$$\sum_{l>1} \operatorname{tr}\big(\mathbf{T}_{1l}\mathbf{T}_{1l}^\top\big) = 0.$$

For a real matrix $\mathbf{X}$, $\operatorname{tr}(\mathbf{X}\mathbf{X}^\top) = \sum_{i,j} x_{ij}^2 \geq 0$, with equality only for $\mathbf{X} = \mathbf{0}$. So $\mathbf{T}_{1l} = \mathbf{0}$ for every $l > 1$: the first block row is clear, and $\mathbf{T} = \mathbf{T}_{11} \oplus \mathbf{T}'$ where $\mathbf{T}'$ is the trailing block upper triangular matrix with $m - 1$ diagonal blocks. Then

$$\mathbf{T}^\top \mathbf{T} = \mathbf{T}_{11}^\top \mathbf{T}_{11} \oplus \mathbf{T}'^\top \mathbf{T}', \qquad \mathbf{T}\mathbf{T}^\top = \mathbf{T}_{11}\mathbf{T}_{11}^\top \oplus \mathbf{T}'\mathbf{T}'^\top,$$

so normality of $\mathbf{T}$ gives normality of $\mathbf{T}'$, and the inductive hypothesis applies.

■

So after Step 2 the matrix is $\mathbf{D}_1 \oplus \cdots \oplus \mathbf{D}_m$ with each $\mathbf{D}_k$ of size 1 or 2. Both products are now computed blockwise, so normality of the whole reads $\mathbf{D}_k^\top \mathbf{D}_k = \mathbf{D}_k \mathbf{D}_k^\top$ for each k: every diagonal block is normal.

Step 3: the shape of a 2×2 real normal block. Let $\mathbf{D} = \begin{pmatrix} p & q \\ r & s \end{pmatrix}$ be real and normal. Expanding both products,

$$\mathbf{D}\mathbf{D}^\top - \mathbf{D}^\top \mathbf{D} = \begin{pmatrix} q^2 - r^2 & (r-q)(p-s) \\ (r-q)(p-s) & r^2 - q^2 \end{pmatrix},$$

so normality says $q^2 = r^2$ and $(r - q)(p - s) = 0$. The first equation gives $q = r$ or $q = -r$, and when $q = -r = 0$ both hold, so the following two cases are exhaustive.

Case 1: $q = r$. Then $\mathbf{D}$ is symmetric, and Corollary 11.5.2 supplies an orthogonal 2×2 matrix turning it into a real diagonal matrix, which is two 1×1 blocks.

Case 2: $q = -r$ *and* $q \neq 0$. Then $r - q = -2q \neq 0$, so $p = s$ and

$$\mathbf{D} = \begin{pmatrix} p & q \\ -q & p \end{pmatrix}.$$

If $q < 0$, this is $\mathbf{\Lambda}(p - qi)$ with $-q > 0$, as required. If $q > 0$, conjugate by the orthogonal matrix $\operatorname{diag}(1, -1)$:

$$\begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \begin{pmatrix} p & q \\ -q & p \end{pmatrix} \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} = \begin{pmatrix} p & -q \\ q & p \end{pmatrix},$$

which is $\mathbf{\Lambda}(p+qi)$ with $q>0$.

Step 4: assembling. Apply Step 3 inside each diagonal block, using the direct sum $\mathbf{Q}_2$ of the resulting 1×1 and 2×2 orthogonal matrices, which is orthogonal because its columns are orthonormal. Then $\mathbf{Q}=\mathbf{Q}_1\mathbf{Q}_2$ is orthogonal and $\mathbf{Q}^\top\mathbf{A}\mathbf{Q}$ has the stated shape; reordering the blocks by a permutation matrix, itself orthogonal, puts the 1×1 blocks first. The columns of $\mathbf{Q}$ are the required orthonormal basis.

For the converse, a block diagonal matrix $\mathbf{B}$ of the displayed shape is normal, since $\mathbf{B}^\top\mathbf{B}$ and $\mathbf{B}\mathbf{B}^\top$ are computed blockwise and every block is normal: $(c)^\top(c)=(c^2)=(c)(c)^\top$, and $\mathbf{\Lambda}(\lambda)^\top\mathbf{\Lambda}(\lambda)=|\lambda|^2\mathbf{I}_2=\mathbf{\Lambda}(\lambda)\mathbf{\Lambda}(\lambda)^\top$. Then $\mathbf{A}=\mathbf{Q}\mathbf{B}\mathbf{Q}^\top$ is normal by the first paragraph. This proves the theorem.

■

The two theorems now fit together. A real normal operator is self-adjoint exactly when no $\mathbf{\Lambda}$ block occurs, and then Theorem 11.5.3 is Theorem 11.5.1. The eigenvalues of $\mathbf{A}$ are the numbers c_i together with the conjugate pairs $\lambda_j,\overline{\lambda_j}$, so the $\mathbf{\Lambda}$ blocks are precisely the non-real part of the spectrum, packaged two real dimensions at a time. Section 6 specializes this to orthogonal operators, where $|\lambda|=1$ forces every 2×2 block to be a plane rotation.

11.5.4 A symmetric matrix as a sum of projections

Writing $\mathbf{A}=\mathbf{Q}\mathbf{D}\mathbf{Q}^\top$ and expanding the product column by column turns the diagonalization into a sum of very simple matrices.

Corollary 11.5.4 — Spectral Decomposition of a Symmetric Matrix

Let $\mathbf{A}\in M_n(\mathbb{R})$ be symmetric, and let $(\mathbf{q}_1,\dots,\mathbf{q}_n)$ be an orthonormal basis of $\mathbb{R}^n$ with $\mathbf{A}\mathbf{q}_i=\lambda_i\mathbf{q}_i$. Then

$$\mathbf{A}=\sum_{i=1}^{n}\lambda_i\,\mathbf{q}_i\mathbf{q}_i^\top,$$

and each $\mathbf{q}_i\mathbf{q}_i^\top$ is the matrix of the orthogonal projection of $\mathbb{R}^n$ onto the line $\operatorname{span}(\mathbf{q}_i)$.

Proof. Let $\mathbf{Q}$ have columns $\mathbf{q}_1,\dots,\mathbf{q}_n$ and $\mathbf{D}=\operatorname{diag}(\lambda_1,\dots,\lambda_n)$, so $\mathbf{A}=\mathbf{Q}\mathbf{D}\mathbf{Q}^\top$ by Corollary 11.5.2. The columns of $\mathbf{Q}\mathbf{D}$ are $\lambda_i\mathbf{q}_i$, and the rows of $\mathbf{Q}^\top$ are $\mathbf{q}_i^\top$, so the column-times-row expansion of the product (Corollary 7.1.3) gives $\mathbf{A}=\sum_i(\lambda_i\mathbf{q}_i)\mathbf{q}_i^\top$, which is the stated sum.

For the second claim, $\mathbf{q}_i$ is a unit vector, so the orthogonal projection onto $\operatorname{span}(\mathbf{q}_i)$ is $\mathbf{x}\mapsto\langle\mathbf{x},\mathbf{q}_i\rangle\mathbf{q}_i$ by Theorem 10.3.3. Since $\langle\mathbf{x},\mathbf{q}_i\rangle=\mathbf{q}_i^\top\mathbf{x}$ is a scalar, $\langle\mathbf{x},\mathbf{q}_i\rangle\mathbf{q}_i=\mathbf{q}_i(\mathbf{q}_i^\top\mathbf{x})=(\mathbf{q}_i\mathbf{q}_i^\top)\mathbf{x}$.

■

Example. (Orthogonally diagonalizing a 3 by 3 matrix)

Orthogonally diagonalize

$$\mathbf{A} = \begin{pmatrix} 3 & 1 & 1 \\ 1 & 3 & 1 \\ 1 & 1 & 3 \end{pmatrix},$$

and write it as a sum of rank-one orthogonal projections.

Solution. The rows all sum to 5, so $\mathbf{A}(1,1,1) = 5(1,1,1)$ and 5 is an eigenvalue. Also $\mathbf{A} = 2\mathbf{I} + \mathbf{J}$ where $\mathbf{J}$ is the all-ones matrix, and $\mathbf{J}\mathbf{x} = \mathbf{0}$ exactly when $x_1 + x_2 + x_3 = 0$; on that plane $\mathbf{A}\mathbf{x} = 2\mathbf{x}$. So

$$E_5(\mathbf{A}) = \operatorname{span}\big((1,1,1)\big), \qquad E_2(\mathbf{A}) = \{\mathbf{x} : x_1 + x_2 + x_3 = 0\},$$

of dimensions 1 and 2, which already account for all of $\mathbb{R}^3$. The two eigenspaces are orthogonal, as Theorem 11.2.3 requires.

Inside $E_2(\mathbf{A})$ any orthonormal basis will do. Start from the independent pair $(1,-1,0)$ and $(1,0,-1)$, both in the plane, and run one step of Gram–Schmidt (Theorem 10.2.2): the second vector minus its component along the first is $(1,0,-1) - \tfrac{1}{2}(1,-1,0) = \tfrac{1}{2}(1,1,-2)$, a multiple of $(1,1,-2)$. Normalizing all three,

$$\mathbf{q}_1 = \tfrac{1}{\sqrt{3}}(1,1,1), \quad \mathbf{q}_2 = \tfrac{1}{\sqrt{2}}(1,-1,0), \quad \mathbf{q}_3 = \tfrac{1}{\sqrt{6}}(1,1,-2).$$

With $\mathbf{Q} = (\mathbf{q}_1 \mid \mathbf{q}_2 \mid \mathbf{q}_3)$ we get $\mathbf{Q}^{\top}\mathbf{Q} = \mathbf{I}$ and $\mathbf{Q}^{\top}\mathbf{A}\mathbf{Q} = \operatorname{diag}(5,2,2)$. By Corollary 11.5.4,

$$\mathbf{A} = 5\,\mathbf{q}_1\mathbf{q}_1^{\top} + 2\,\mathbf{q}_2\mathbf{q}_2^{\top} + 2\,\mathbf{q}_3\mathbf{q}_3^{\top}.$$

As a check, $\mathbf{q}_2\mathbf{q}_2^{\top} + \mathbf{q}_3\mathbf{q}_3^{\top} = \mathbf{I} - \mathbf{q}_1\mathbf{q}_1^{\top}$ because the three projections sum to the identity, so the right-hand side is $2\mathbf{I} + 3\,\mathbf{q}_1\mathbf{q}_1^{\top} = 2\mathbf{I} + \mathbf{J}$, which is $\mathbf{A}$. Notice that $\mathbf{q}_2$ and $\mathbf{q}_3$ were not forced on us, while the two projections $\mathbf{q}_1\mathbf{q}_1^{\top}$ and $\mathbf{q}_2\mathbf{q}_2^{\top} + \mathbf{q}_3\mathbf{q}_3^{\top}$ were: they are the projections onto the two eigenspaces. Section 8 makes that observation into a theorem.

11.5.5 The principal axis theorem

Here is the application. A **quadratic form** on $\mathbb{R}^n$ is a function

$$q(\mathbf{x}) = \mathbf{x}^{\top}\mathbf{A}\mathbf{x} = \sum_{i,j} a_{ij} x_i x_j$$

for some $\mathbf{A} \in M_n(\mathbb{R})$. Only the symmetric part of $\mathbf{A}$ matters, since $\mathbf{x}^{\top}\mathbf{A}\mathbf{x} = \mathbf{x}^{\top}\mathbf{A}^{\top}\mathbf{x}$ for a 1×1 matrix, so we always take $\mathbf{A}$ symmetric; then $\mathbf{A}$ is determined by q, with a_{ii} the coefficient of x_i^2 and a_{ij} **half** the coefficient of $x_i x_j$ for $i \neq j$. Chapter 13 studies such forms in their own right.

Theorem 11.5.5 — Principal Axis Theorem

Let $\mathbf{A} \in M_n(\mathbb{R})$ be symmetric, let $q(\mathbf{x}) = \mathbf{x}^{\top}\mathbf{A}\mathbf{x}$, and let $\mathbf{Q} \in \mathrm{O}(n)$ with $\mathbf{Q}^{\top}\mathbf{A}\mathbf{Q} = \mathbf{D} = \operatorname{diag}(\lambda_1, \dots, \lambda_n)$, the columns $\mathbf{q}_1, \dots, \mathbf{q}_n$ of $\mathbf{Q}$ being an orthonormal basis of eigenvectors. Substituting $\mathbf{x} = \mathbf{Q}\mathbf{y}$, that is, taking $y_i = \langle \mathbf{x}, \mathbf{q}_i \rangle$ to be the coordinates of $\mathbf{x}$ in that basis,

$$q(\mathbf{x}) = \sum_{i=1}^{n} \lambda_i y_i^2.$$

In particular, for $n = 2$ with $\lambda_1, \lambda_2 > 0$, the level set $\{q = 1\}$ is an ellipse whose axes lie along $\mathbf{q}_1$ and $\mathbf{q}_2$, with half-lengths $1/\sqrt{\lambda_1}$ and $1/\sqrt{\lambda_2}$.

Proof. Since $\mathbf{Q}$ is invertible, $\mathbf{x} = \mathbf{Q}\mathbf{y}$ sets up a bijection between $\mathbf{x}$ and $\mathbf{y} = \mathbf{Q}^{-1}\mathbf{x} = \mathbf{Q}^{\top}\mathbf{x}$, whose i-th entry is $\mathbf{q}_i^{\top}\mathbf{x} = \langle \mathbf{x}, \mathbf{q}_i \rangle$. Substituting,

$$q(\mathbf{Q}\mathbf{y}) = (\mathbf{Q}\mathbf{y})^{\top}\mathbf{A}(\mathbf{Q}\mathbf{y}) = \mathbf{y}^{\top}(\mathbf{Q}^{\top}\mathbf{A}\mathbf{Q})\mathbf{y} = \mathbf{y}^{\top}\mathbf{D}\mathbf{y} = \sum_i \lambda_i y_i^2,$$

using $(\mathbf{Q}\mathbf{y})^{\top} = \mathbf{y}^{\top}\mathbf{Q}^{\top}$ (Theorem 0.9.5).

For $n = 2$ with both $\lambda_i > 0$, the condition $q(\mathbf{x}) = 1$ becomes $\lambda_1 y_1^2 + \lambda_2 y_2^2 = 1$, the standard equation of an ellipse in the $\mathbf{y}$ coordinates, meeting the y_1-axis where $y_1 = \pm 1/\sqrt{\lambda_1}$ and the y_2-axis where $y_2 = \pm 1/\sqrt{\lambda_2}$. Those axes are the lines $\operatorname{span}(\mathbf{q}_1)$ and $\operatorname{span}(\mathbf{q}_2)$ of the original picture, because $\mathbf{y} = \mathbf{e}_1$ corresponds to $\mathbf{x} = \mathbf{Q}\mathbf{e}_1 = \mathbf{q}_1$. Since $\mathbf{Q}$ is orthogonal, it preserves lengths (Theorem 10.7.3), so the half-lengths are unchanged by the substitution.

■

Example. (Finding the axes of a conic)

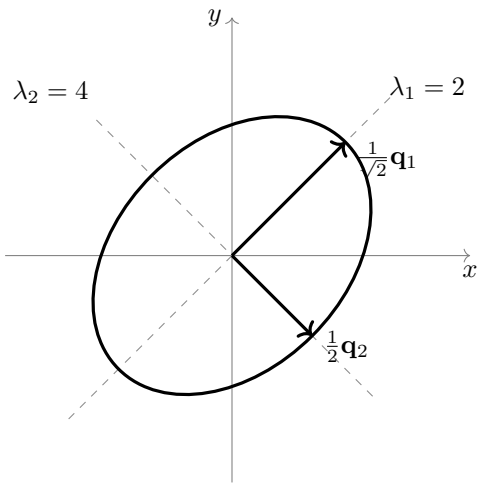
Identify the curve $3x^2 - 2xy + 3y^2 = 1$ in $\mathbb{R}^2$, and find its axes and their half-lengths.

Solution. The symmetric matrix of the form is

$$\mathbf{A} = \begin{pmatrix} 3 & -1 \\ -1 & 3 \end{pmatrix},$$

the off-diagonal entries being half of -2. Its characteristic polynomial is $x^2 - 6x + 8$, so the eigenvalues are 2 and 4. For $\lambda = 2$, $\mathbf{A} - 2\mathbf{I} = \begin{pmatrix} 1 & -1 \\ -1 & 1 \end{pmatrix}$ gives $x = y$ and the unit eigenvector $\mathbf{q}_1 = \frac{1}{\sqrt{2}}(1, 1)$. For $\lambda = 4$, $\mathbf{A} - 4\mathbf{I} = \begin{pmatrix} -1 & -1 \\ -1 & -1 \end{pmatrix}$ gives $x = -y$ and $\mathbf{q}_2 = \frac{1}{\sqrt{2}}(1, -1)$.

In the coordinates $y_1 = \langle \mathbf{x}, \mathbf{q}_1 \rangle$, $y_2 = \langle \mathbf{x}, \mathbf{q}_2 \rangle$, the equation is $2y_1^2 + 4y_2^2 = 1$. Both eigenvalues are positive, so the curve is an **ellipse**. Its major axis lies along $\mathbf{q}_1$, the line $y = x$, with half-length $1/\sqrt{2}$; its minor axis lies along $\mathbf{q}_2$, the line $y = -x$, with half-length $1/2$. The check is that $\frac{1}{\sqrt{2}}(1, 1)$ scaled to length $1/\sqrt{2}$ is the point $(\frac{1}{2}, \frac{1}{2})$, and $3 \cdot \frac{1}{4} - 2 \cdot \frac{1}{4} + 3 \cdot \frac{1}{4} = 1$.



$3x^2 - 2xy + 3y^2 = 1$: the axes lie along the eigenvectors, with half-lengths $1/\sqrt{\lambda_i}$

Two features of the picture are worth naming. The axes are **orthogonal** because the eigenvectors are, and that is the whole content of the theorem; a non-symmetric matrix in the same role would produce a pair of distinguished directions that need not be perpendicular. And the bigger eigenvalue gives the **shorter** axis, since the half-length is $1/\sqrt{\lambda}$: a large λ makes q reach the value 1 sooner.

Remark. Chapter 13 will diagonalize quadratic forms again, but by **congruence**: replacing $\mathbf{A}$ by $\mathbf{P}^\top\mathbf{AP}$ for an arbitrary invertible $\mathbf{P}$, not necessarily orthogonal. That is a weaker relation, and it destroys the eigenvalues while preserving only their signs, which is Sylvester's law of inertia. What makes the present theorem special is that $\mathbf{Q}^\top = \mathbf{Q}^{-1}$, so $\mathbf{Q}^\top\mathbf{AQ} = \mathbf{Q}^{-1}\mathbf{AQ}$ and the two relations coincide: an orthogonal change of variables is a similarity *and* a congruence, so it keeps the eigenvalues and the geometry at once.

Warning. **The theorem needs $\mathbb{R}$, and symmetry is not the same as having real eigenvalues.** The matrix $\begin{pmatrix} 1 & 1 \\ 1 & 0 \end{pmatrix}$ is symmetric with rational entries, but its eigenvalues are $(1\pm\sqrt{5})/2$, which are irrational; over $\mathbb{Q}$ there is no eigenvector at all, and no version of Theorem 11.5.1 survives. Conversely $\begin{pmatrix} 1 & 1 \\ 0 & 2 \end{pmatrix}$ has the real eigenvalues 1 and 2 and is not symmetric; real eigenvalues alone buy nothing, since they do not make the eigenvectors orthogonal.

11.5.6 Exercises

11.5.6.1 A. Check your understanding

Exercise A1.

(a) State the real spectral theorem and its matrix form, with every hypothesis.

(b) Which two results from Section 2 does the induction use, and what does each one supply?

(c) True or false: a normal operator on a real inner product space has an orthonormal

basis of eigenvectors. Justify your answer.

(d) What are the possible diagonal blocks in the real normal form of a normal operator, and what does the condition $b > 0$ rule out?

(e) Given a symmetric $\mathbf{A}$ with orthonormal eigenvectors $\mathbf{q}_1, \mathbf{q}_2$ and eigenvalues 9 and 1, describe the curve $\mathbf{x}^\top \mathbf{A}\mathbf{x} = 1$.

(f) True or false: a real matrix with real eigenvalues is symmetric. Justify your answer.

Solution.

(a) For a finite-dimensional real inner product space V and $T \in \mathcal{L}(V)$: T is self-adjoint if and only if V has an orthonormal basis of eigenvectors (Theorem 11.5.1). Matrix form: $\mathbf{A} \in M_n(\mathbb{R})$ is symmetric if and only if $\mathbf{A} = \mathbf{Q}\mathbf{D}\mathbf{Q}^\top$ with $\mathbf{Q}$ orthogonal and $\mathbf{D}$ real diagonal (Corollary 11.5.2).

(b) Theorem 11.2.2 supplies one eigenvector to peel off, and Theorem 11.2.4 supplies the smaller object to induct on, namely the self-adjoint restriction to the orthogonal complement.

(c) False. The quarter turn of $\mathbb{R}^2$ is normal and has no eigenvector at all (Example (A normal real operator with no eigenvector)).

(d) Blocks (c) with $c \in \mathbb{R}$, and 2×2 blocks $\mathbf{\Lambda}(\lambda) = \begin{pmatrix} a & -b \\ b & a \end{pmatrix}$ with $b > 0$ (Theorem 11.5.3). The condition $b > 0$ rules out the transposed block $\mathbf{\Lambda}(\overline{\lambda})$, which is orthogonally similar to it via $\mathrm{diag}(1, -1)$; fixing the sign is what makes the list of blocks well defined.

(e) An ellipse with axes along $\mathbf{q}_1$ and $\mathbf{q}_2$, of half-lengths $1/3$ and 1 (Theorem 11.5.5). The longer axis is along $\mathbf{q}_2$, the eigenvector for the **smaller** eigenvalue.

(f) False. $\begin{pmatrix} 1 & 1 \\ 0 & 2 \end{pmatrix}$ has eigenvalues $1, 2$ and is not symmetric. The correct statement is the converse: a symmetric real matrix has real eigenvalues.

11.5.6.2 B. Practice

Exercise B1: Orthogonally diagonalize.

For each symmetric matrix, find an orthogonal $\mathbf{Q}$ and a diagonal $\mathbf{D}$ with $\mathbf{Q}^\top \mathbf{A}\mathbf{Q} = \mathbf{D}$.

(a) $\mathbf{A} = \begin{pmatrix} 1 & 2 \\ 2 & 1 \end{pmatrix}$.

(b) $\mathbf{A} = \begin{pmatrix} 4 & 0 & 1 \\ 0 & 2 & 0 \\ 1 & 0 & 4 \end{pmatrix}$.

Solution.

(a) $p_{\mathbf{A}}(x) = x^2 - 2x - 3 = (x-3)(x+1)$, so the eigenvalues are 3 and -1. For $\lambda = 3$, $\mathbf{A} - 3\mathbf{I} = \begin{pmatrix} -2 & 2 \\ 2 & -2 \end{pmatrix}$ gives $x_1 = x_2$ and $\mathbf{q}_1 = \frac{1}{\sqrt{2}}(1, 1)$; for $\lambda = -1$, $\mathbf{q}_2 = \frac{1}{\sqrt{2}}(1, -1)$.

Hence

$$\mathbf{Q} = \tfrac{1}{\sqrt{2}}\begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}, \qquad \mathbf{D} = \begin{pmatrix} 3 & 0 \\ 0 & -1 \end{pmatrix}.$$

(b) The second coordinate is untouched: $\mathbf{A}\mathbf{e}_2 = 2\mathbf{e}_2$. On $\operatorname{span}(\mathbf{e}_1, \mathbf{e}_3)$ the matrix acts as $\begin{pmatrix} 4 & 1 \\ 1 & 4 \end{pmatrix}$, with eigenvalues 5 and 3 and eigenvectors $(1,1)$ and $(1,-1)$ there. Lifting back,

$$\mathbf{q}_1 = \tfrac{1}{\sqrt{2}}(1,0,1), \quad \mathbf{q}_2 = \tfrac{1}{\sqrt{2}}(-1,0,1), \quad \mathbf{q}_3 = (0,1,0),$$

with eigenvalues $5, 3, 2$. These are orthonormal, so $\mathbf{Q} = (\mathbf{q}_1 \mid \mathbf{q}_2 \mid \mathbf{q}_3)$ is orthogonal and $\mathbf{Q}^\top \mathbf{A}\mathbf{Q} = \operatorname{diag}(5,3,2)$. As a check, $5 + 3 + 2 = 10 = \operatorname{tr}\mathbf{A}$.

Exercise B2: Identify the conic.

Identify the curve $5x^2 + 4xy + 5y^2 = 1$: say what kind of conic it is, find its axes, and find their half-lengths.

Solution. The symmetric matrix of the form is $\mathbf{A} = \begin{pmatrix} 5 & 2 \\ 2 & 5 \end{pmatrix}$, the off-diagonal entries being half of 4. Its characteristic polynomial is $x^2 - 10x + 21 = (x-7)(x-3)$, so the eigenvalues are 7 and 3. For $\lambda = 7$, $\mathbf{A} - 7\mathbf{I} = \begin{pmatrix} -2 & 2 \\ 2 & -2 \end{pmatrix}$ gives $\mathbf{q}_1 = \frac{1}{\sqrt{2}}(1,1)$; for $\lambda = 3$, $\mathbf{q}_2 = \frac{1}{\sqrt{2}}(1,-1)$.

By Theorem 11.5.5 the equation becomes $7y_1^2 + 3y_2^2 = 1$. Both eigenvalues are positive, so the curve is an ellipse. Its axes are the lines $y = x$ and $y = -x$, with half-lengths $1/\sqrt{7}$ along $\mathbf{q}_1$ and $1/\sqrt{3}$ along $\mathbf{q}_2$; the major axis is the second one. Check: the point $\frac{1}{\sqrt{3}}\mathbf{q}_2 = \frac{1}{\sqrt{6}}(1,-1)$ gives $\frac{5}{6} - \frac{4}{6} + \frac{5}{6} = 1$.

Exercise B3: A sum of rank-one projections.

Using your answer to Exercise (B1: Orthogonally diagonalize) (b), write

$$\mathbf{A} = \begin{pmatrix} 4 & 0 & 1 \\ 0 & 2 & 0 \\ 1 & 0 & 4 \end{pmatrix}$$

as $\sum_i \lambda_i \mathbf{q}_i \mathbf{q}_i^\top$, with the three matrices $\mathbf{q}_i \mathbf{q}_i^\top$ written out, and verify the identity by adding them.

Solution. With $\mathbf{q}_1 = \frac{1}{\sqrt{2}}(1,0,1)$, $\mathbf{q}_2 = \frac{1}{\sqrt{2}}(-1,0,1)$, $\mathbf{q}_3 = (0,1,0)$ and $\lambda = 5, 3, 2$,

$$\mathbf{q}_1\mathbf{q}_1^\top = \tfrac{1}{2}\begin{pmatrix} 1 & 0 & 1 \\ 0 & 0 & 0 \\ 1 & 0 & 1 \end{pmatrix}, \qquad \mathbf{q}_2\mathbf{q}_2^\top = \tfrac{1}{2}\begin{pmatrix} 1 & 0 & -1 \\ 0 & 0 & 0 \\ -1 & 0 & 1 \end{pmatrix},$$

and $\mathbf{q}_3\mathbf{q}_3^\top$ is the matrix with a single 1 in position $(2,2)$. Then

$$5\,\mathbf{q}_1\mathbf{q}_1^\top + 3\,\mathbf{q}_2\mathbf{q}_2^\top = \begin{pmatrix} 4 & 0 & 1 \\ 0 & 0 & 0 \\ 1 & 0 & 4 \end{pmatrix},$$

since $\frac{1}{2}(5+3) = 4$ on the diagonal and $\frac{1}{2}(5-3) = 1$ off it. Adding $2\,\mathbf{q}_3\mathbf{q}_3^\top$ inserts the 2 in position $(2,2)$ and gives $\mathbf{A}$, as Corollary 11.5.4 requires.

11.5.6.3 C. Going deeper

Exercise C1: One eigenvalue only.

(a) Let $\mathbf{A} \in M_n(\mathbb{R})$ be symmetric with every eigenvalue equal to λ. Prove that $\mathbf{A} = \lambda\mathbf{I}$.

(b) Show that (a) fails without symmetry, by exhibiting a matrix in $M_2(\mathbb{R})$ whose only eigenvalue is 0 and which is not $\mathbf{0}$.

(c) Deduce that a symmetric $\mathbf{A}$ with $\mathbf{A}^2 = \mathbf{A}$ is the matrix of an orthogonal projection.

Solution.

(a) By Corollary 11.5.2, $\mathbf{A} = \mathbf{Q}\mathbf{D}\mathbf{Q}^\top$ with $\mathbf{D}$ diagonal carrying the eigenvalues, so $\mathbf{D} = \lambda\mathbf{I}$. Hence $\mathbf{A} = \mathbf{Q}(\lambda\mathbf{I})\mathbf{Q}^\top = \lambda\mathbf{Q}\mathbf{Q}^\top = \lambda\mathbf{I}$.

(b) $\mathbf{J}_2(0) = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$ has characteristic polynomial x^2, so 0 is its only eigenvalue, and it is not the zero matrix. It is of course not symmetric.

(c) If $\mathbf{A}^2 = \mathbf{A}$ and $\mathbf{A}\mathbf{x} = \lambda\mathbf{x}$ with $\mathbf{x} \neq \mathbf{0}$, then $\lambda^2\mathbf{x} = \mathbf{A}^2\mathbf{x} = \mathbf{A}\mathbf{x} = \lambda\mathbf{x}$, so $\lambda^2 = \lambda$ and $\lambda \in \{0, 1\}$. By Corollary 11.5.2, $\mathbf{A} = \mathbf{Q}\mathbf{D}\mathbf{Q}^\top$ with $\mathbf{D}$ diagonal of zeros and ones, so $\mathbf{A} = \sum_{i \in S} \mathbf{q}_i\mathbf{q}_i^\top$ where S indexes the eigenvalue 1 (Corollary 11.5.4). That is the sum of the projections onto an orthonormal basis of $U = E_1(\mathbf{A})$, which is the orthogonal projection P_U by Theorem 10.3.3.

Exercise C2: Diagonalizing two matrices at once.

Let $\mathbf{A}, \mathbf{B} \in M_n(\mathbb{R})$ be symmetric with $\mathbf{A}\mathbf{B} = \mathbf{B}\mathbf{A}$.

(a) Prove that each eigenspace $E_\lambda(\mathbf{A})$ is $\mathbf{B}$-invariant, and that the restriction of $T_\mathbf{B}$ to it is self-adjoint.

(b) Prove that there is a single $\mathbf{Q} \in \mathrm{O}(n)$ with $\mathbf{Q}^\top\mathbf{A}\mathbf{Q}$ and $\mathbf{Q}^\top\mathbf{B}\mathbf{Q}$ both diagonal.

(c) Show that the conclusion fails without commutativity, using $\begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}$ and $\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$.

Hint for (b): apply Theorem 11.5.1 inside each eigenspace of $\mathbf{A}$.

Solution.

(a) Invariance is Theorem 8.9.1: if $\mathbf{A}\mathbf{x} = \lambda\mathbf{x}$ then $\mathbf{A}(\mathbf{B}\mathbf{x}) = \mathbf{B}(\mathbf{A}\mathbf{x}) = \lambda\mathbf{B}\mathbf{x}$. For self-adjointness of the restriction, take $\mathbf{u}, \mathbf{v} \in E_\lambda(\mathbf{A})$; then $\langle \mathbf{B}\mathbf{u}, \mathbf{v}\rangle = \langle \mathbf{u}, \mathbf{B}\mathbf{v}\rangle$ because $\mathbf{B}$ is symmetric on all of $\mathbb{R}^n$, and both $\mathbf{B}\mathbf{u}$ and $\mathbf{B}\mathbf{v}$ lie in $E_\lambda(\mathbf{A})$ by the first part,

so the identity holds inside the subspace with its restricted inner product.

(b) Let $\lambda_1, \dots, \lambda_k$ be the distinct eigenvalues of $\mathbf{A}$. By Theorem 11.5.1, $\mathbb{R}^n$ is the direct sum of the eigenspaces $E_{\lambda_i}(\mathbf{A})$, and these are mutually orthogonal (Theorem 11.2.3). By (a) and Theorem 11.5.1 applied to the self-adjoint operator $T_{\mathbf{B}}|_{E_{\lambda_i}(\mathbf{A})}$, each $E_{\lambda_i}(\mathbf{A})$ has an orthonormal basis of eigenvectors of $\mathbf{B}$. Every vector of $E_{\lambda_i}(\mathbf{A})$ is an eigenvector of $\mathbf{A}$, so these basis vectors are common eigenvectors. Stringing the k bases together gives an orthonormal basis of $\mathbb{R}^n$, orthonormal across the blocks because distinct eigenspaces of $\mathbf{A}$ are orthogonal. Let $\mathbf{Q}$ have those vectors as columns; then $\mathbf{Q} \in \mathrm{O}(n)$ and both $\mathbf{Q}^\top\mathbf{A}\mathbf{Q}$ and $\mathbf{Q}^\top\mathbf{B}\mathbf{Q}$ are diagonal.

(c) These two do not commute: $\mathbf{A}\mathbf{B} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$ while $\mathbf{B}\mathbf{A} = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix}$. And no common eigenbasis exists: the eigenvectors of $\mathbf{A}$ are the multiples of $\mathbf{e}_1$ and of $\mathbf{e}_2$, while $\mathbf{B}\mathbf{e}_1 = \mathbf{e}_2$ is not a multiple of $\mathbf{e}_1$. Commutativity is necessary as well as sufficient, since two simultaneously diagonalized matrices commute.

Exercise C3: A rotation-scaling in normal form.

Let $\mathbf{A} = \begin{pmatrix} 3 & 4 \\ -4 & 3 \end{pmatrix} \in M_2(\mathbb{R})$.

(a) Verify that $\mathbf{A}$ is normal and not symmetric, and find its complex eigenvalues.

(b) Find an orthogonal $\mathbf{Q}$ with $\mathbf{Q}^\top\mathbf{A}\mathbf{Q} = \mathbf{\Lambda}(\lambda)$ for the eigenvalue λ with positive imaginary part.

(c) Explain why no orthogonal $\mathbf{Q}$ makes $\mathbf{Q}^\top\mathbf{A}\mathbf{Q}$ diagonal, and why this does not contradict Theorem 11.4.2.

Solution.

(a) $\mathbf{A}^\top\mathbf{A} = \mathbf{A}\mathbf{A}^\top = 25\mathbf{I}$, so $\mathbf{A}$ is normal; $\mathbf{A}^\top \neq \mathbf{A}$ since $4 \neq -4$. Its characteristic polynomial is $x^2 - 6x + 25 = (x-3)^2 + 16$, with roots $3 \pm 4i$.

(b) The eigenvalue with positive imaginary part is $\lambda = 3 + 4i$, so $\mathbf{\Lambda}(\lambda) = \begin{pmatrix} 3 & -4 \\ 4 & 3 \end{pmatrix}$. Take $\mathbf{Q} = \mathrm{diag}(1, -1)$, which is orthogonal. Then

$$\mathbf{Q}^\top\mathbf{A}\mathbf{Q} = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}\begin{pmatrix} 3 & 4 \\ -4 & 3 \end{pmatrix}\begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} = \begin{pmatrix} 3 & -4 \\ 4 & 3 \end{pmatrix},$$

which is $\mathbf{\Lambda}(3+4i)$. This is Case 2 of the proof of Theorem 11.5.3 with $p = 3$ and $q = 4$.

(c) If $\mathbf{Q}^\top\mathbf{A}\mathbf{Q}$ were diagonal for some $\mathbf{Q} \in \mathrm{O}(2)$, then $\mathbf{A} = \mathbf{Q}\mathbf{D}\mathbf{Q}^\top$ would be symmetric by Corollary 11.5.2, and it is not. There is no contradiction with Theorem 11.4.2, which concerns a **complex** inner product space: over $\mathbb{C}^2$ the matrix $\mathbf{A}$ is indeed unitarily diagonalizable, to $\mathrm{diag}(3+4i, 3-4i)$, but the diagonalizing basis $\frac{1}{\sqrt{2}}(1, \pm i)$ is not real, so it is unavailable inside $\mathbb{R}^2$.

11.6 The Shape of an Orthogonal Matrix

An orthogonal matrix is normal, so the real normal form of the previous section applies to it — and the extra information that an orthogonal matrix carries, that every eigenvalue has modulus 1, collapses that form into something very small. What comes out is a complete description of the rigid motions of $\mathbb{R}^n$ fixing the origin: a few axes reversed, and the rest of the space turned in independent two-dimensional planes. In dimension 3 this is the statement that every rotation has an axis, and we push it as far as an explicit formula for the rotation matrix in terms of its axis and angle.

Throughout, $\mathbb{R}^n$ carries the standard inner product, and $\mathbf{Q}$ is a real matrix.

11.6.1 From the real normal form to the canonical form

Two pieces of notation, both recalled. For $\theta \in \mathbb{R}$, Chapter 10 wrote

$$\mathbf{R}_\theta = \begin{pmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{pmatrix}$$

for the matrix that rotates the plane by θ (Theorem 10.7.5). It is exactly the rotation-scaling block of Chapter 9 for a complex number on the unit circle: $\mathbf{R}_\theta = \mathbf{\Lambda}(e^{i\theta})$ in the notation of Definition 9.4.1, since $e^{i\theta} = \cos\theta + i\sin\theta$. And $\mathbf{A} \oplus \mathbf{B}$ is the block diagonal matrix with diagonal blocks $\mathbf{A}$ and $\mathbf{B}$.

Now the observation that starts everything. If $\mathbf{Q} \in \mathrm{O}(n)$ then $\mathbf{Q}^\top\mathbf{Q} = \mathbf{I}_n = \mathbf{Q}\mathbf{Q}^\top$, so $\mathbf{Q}$ commutes with its own adjoint: **every orthogonal matrix is normal**. So Theorem 11.5.3 applies. All that remains is to say what the blocks can be, and for that we use the one thing an orthogonal matrix has that a general normal matrix does not.

Theorem 11.6.1 — Canonical Form of an Orthogonal Matrix

Let $\mathbf{Q} \in \mathrm{O}(n)$. Then there are integers $p, q, m \geq 0$ with $p + q + 2m = n$, and angles $\theta_1, \ldots, \theta_m$ with $0 < \theta_j < \pi$, and a matrix $\mathbf{P} \in \mathrm{O}(n)$, such that

$$\mathbf{P}^\top\mathbf{Q}\mathbf{P} = \mathbf{I}_p \oplus (-\mathbf{I}_q) \oplus \mathbf{R}_{\theta_1} \oplus \cdots \oplus \mathbf{R}_{\theta_m}.$$

Moreover $\det\mathbf{Q} = (-1)^q$, and p, q and the multiset $\{\theta_1, \ldots, \theta_m\}$ are determined by $\mathbf{Q}$.

Idea. $\mathbf{Q}$ is normal, so Theorem 11.5.3 already hands us a block diagonal matrix with 1×1 blocks $[a]$ and 2×2 blocks $\mathbf{\Lambda}(\lambda)$. The blocks are unconstrained for a general normal matrix; here they are not, because the eigenvalues of an isometry lie on the unit circle. A real eigenvalue on the unit circle is ±1, and a conjugate pair on the unit circle is $e^{\pm i\theta}$, which turns the scaling block into a pure rotation. Then sort the ±1s to the front.

Proof. The operator $T_\mathbf{Q}$ on $\mathbb{R}^n$ satisfies $T_\mathbf{Q}^* = T_{\mathbf{Q}^\top}$ by Theorem 10.6.3, since the standard basis is orthonormal, so $T_\mathbf{Q}^* T_\mathbf{Q} = T_{\mathbf{Q}^\top\mathbf{Q}} = \mathrm{id}$ and likewise in the other order. Hence $T_\mathbf{Q}$ is normal (Definition 10.6.3), and by Theorem 11.5.3 there is an orthonormal basis $\mathcal{B}$ of

$\mathbb{R}^n$ in which

$$[T_{\mathbf{Q}}]_{\mathcal{B}} = [a_1] \oplus \cdots \oplus [a_r] \oplus \mathbf{\Lambda}(\lambda_1) \oplus \cdots \oplus \mathbf{\Lambda}(\lambda_m),$$

where $a_i \in \mathbb{R}$ and $\lambda_j = c_j + d_j i$ with $d_j > 0$. Let $\mathbf{P}$ be the matrix whose columns are the vectors of $\mathcal{B}$. Its columns are orthonormal, so $\mathbf{P} \in \mathrm{O}(n)$ by Theorem 10.7.3 (f), and $\mathbf{P}^{\top}\mathbf{Q}\mathbf{P} = \mathbf{P}^{-1}\mathbf{Q}\mathbf{P} = [T_{\mathbf{Q}}]_{\mathcal{B}}$ by Theorem 3.7.3.

The blocks. A block diagonal matrix is triangular by blocks, so the eigenvalues of $[T_{\mathbf{Q}}]_{\mathcal{B}}$ over $\mathbb{C}$ are the a_i together with the roots of each $\det(x\mathbf{I}_2 - \mathbf{\Lambda}(\lambda_j)) = (x - c_j)^2 + d_j^2$, namely λ_j and $\overline{\lambda_j}$. Now $\mathrm{O}(n) = \mathrm{U}(n) \cap M_n(\mathbb{R})$ by Proposition 10.7.4 (a), so $\mathbf{Q}$ is unitary, and every complex eigenvalue λ of $\mathbf{Q}$ satisfies $|\lambda| = 1$ by Proposition 10.7.1 applied to $T_{\mathbf{Q}}$ on $\mathbb{C}^n$. Therefore $a_i = \pm 1$ for each i, and $c_j^2 + d_j^2 = 1$ for each j. Since $c_j^2 + d_j^2 = 1$ and $d_j > 0$, there is a unique $\theta_j \in (0, \pi)$ with $c_j = \cos\theta_j$ and $d_j = \sin\theta_j$, and then $\mathbf{\Lambda}(\lambda_j) = \mathbf{R}_{\theta_j}$.

Sorting. Let p be the number of i with $a_i = 1$ and q the number with $a_i = -1$, so $p + q + 2m = n$. Reordering the vectors of $\mathcal{B}$ so that the $+1$ blocks come first, then the -1 blocks, then the rotation blocks in pairs, leaves the basis orthonormal and permutes the diagonal blocks; the new $\mathbf{P}$ is the old one with its columns permuted, still orthogonal. This gives the displayed form.

The determinant and uniqueness. By Theorem 6.5.4 and Corollary 6.5.7, $\det\mathbf{Q} = \det(\mathbf{P}^{\top}\mathbf{Q}\mathbf{P})$, and the determinant of a block diagonal matrix is the product of the determinants of its blocks (Theorem 6.8.4), which are 1, -1 and $\det\mathbf{R}_{\theta_j} = \cos^2\theta_j + \sin^2\theta_j = 1$. Hence $\det\mathbf{Q} = (-1)^q$. Finally, similar matrices have the same eigenvalues with the same multiplicities, and reading the eigenvalues off the displayed form gives 1 with multiplicity p, -1 with multiplicity q, and the pairs $e^{\pm i\theta_j}$; so p, q and the θ_j are recovered from $\mathbf{Q}$ alone. This proves the theorem.

■

So an orthogonal matrix is, up to an orthogonal change of coordinates, nothing but a list of angles together with a count of reversed axes. The number q of reversed axes is not itself an invariant of the *geometry* — a -1 block and a -1 block together make $-\mathbf{I}_2 = \mathbf{R}_{\pi}$, a rotation by π — which is why the theorem demands $\theta_j \neq \pi$ and keeps the -1s separate. What the determinant sees is only the parity of q.

Quick check. What is the canonical form of a $\mathbf{Q} \in \mathrm{O}(2)$ with $\det\mathbf{Q} = -1$? Compare with Theorem 10.7.5.

Solution. Here $p + q + 2m = 2$ and $(-1)^q = -1$, so q is odd, forcing $q = 1$, $p = 1$, $m = 0$. The canonical form is $\mathbf{I}_1 \oplus (-\mathbf{I}_1) = \mathrm{diag}(1, -1)$. Chapter 10 found that such a $\mathbf{Q}$ is the reflection $\mathbf{M}_{\theta}$ in a line L, fixing L and negating $L^{\perp}$; in the orthonormal basis of eigenvectors of Theorem 10.7.5 (b) its matrix is exactly $\mathrm{diag}(1, -1)$. Note what the canonical form drops: the angle of the mirror. All reflections of the plane are orthogonally similar to one another, and Exercise (C1: The plane, re-derived) makes this comparison precise.

11.6.2 Rotations of space

In dimension 3 the arithmetic $p+q+2m=3$ leaves very few possibilities, and they all look the same.

Corollary 11.6.2 — Orthogonal Matrices in Dimension Three

Let $\mathbf{Q} \in \mathrm{O}(3)$. Then there are an orthonormal basis $(\mathbf{u}, \mathbf{w}_1, \mathbf{w}_2)$ of $\mathbb{R}^3$ and an angle $\theta \in [0, \pi]$ such that, in that basis, the matrix of $T_{\mathbf{Q}}$ is

$$[1] \oplus \mathbf{R}_\theta \quad \text{if } \det \mathbf{Q} = 1, \qquad [-1] \oplus \mathbf{R}_\theta \quad \text{if } \det \mathbf{Q} = -1.$$

In particular every $\mathbf{Q} \in \mathrm{SO}(3)$ fixes the line $\mathrm{span}(\mathbf{u})$ pointwise and rotates the plane $\mathrm{span}(\mathbf{u})^\perp$ by θ.

Proof. Write the canonical form of Theorem 11.6.1, with $p+q+2m=3$ and $\det \mathbf{Q} = (-1)^q$.

Case $\det \mathbf{Q} = 1$. Then q is even, so $q \in \{0, 2\}$. If $q = 0$ then $p + 2m = 3$, giving $(p, m) = (3, 0)$ or $(1, 1)$; if $q = 2$ then $p = 1$ and $m = 0$. The three forms are

$$\mathbf{I}_3 = [1] \oplus \mathbf{R}_0, \qquad [1] \oplus \mathbf{R}_{\theta_1}, \qquad [1] \oplus (-\mathbf{I}_2) = [1] \oplus \mathbf{R}_\pi,$$

and in every case $p \geq 1$, so the form is $[1] \oplus \mathbf{R}_\theta$ with $\theta \in [0, \pi]$.

Case $\det \mathbf{Q} = -1$. Then q is odd, so $q \in \{1, 3\}$. If $q = 1$ then $p+2m = 2$, giving $(p, m) = (2, 0)$ or $(0, 1)$; if $q = 3$ then $p = m = 0$. The three forms are $[-1] \oplus \mathbf{I}_2 = [-1] \oplus \mathbf{R}_0$, then $[-1] \oplus \mathbf{R}_{\theta_1}$, and $-\mathbf{I}_3 = [-1] \oplus \mathbf{R}_\pi$.

In both cases the first basis vector $\mathbf{u}$ spans the ± 1 eigenline and $(\mathbf{w}_1, \mathbf{w}_2)$ is an orthonormal basis of $\mathrm{span}(\mathbf{u})^\perp$, which is what the last sentence asserts when $\det \mathbf{Q} = 1$.

■

Chapter 10 proved the SO(3) statement directly, as Theorem 10.7.6, by producing a real eigenvalue from the odd degree of the characteristic polynomial and then invoking the classification of O(2). We do not repeat that argument: the point here is that the same conclusion falls out of the canonical form with no work at all, and that the same three lines also settle $\det \mathbf{Q} = -1$. An orthogonal matrix of determinant -1 in dimension 3 is a **rotatory reflection**: a rotation about an axis followed by the reflection in the plane perpendicular to it. Its two extreme cases are the plane reflection ($\theta = 0$) and the antipodal map $-\mathbf{I}_3$ ($\theta = \pi$).

Remark. The angle θ is determined by $\mathbf{Q}$ only up to sign, because exchanging $\mathbf{w}_1$ and $\mathbf{w}_2$ replaces $\mathbf{R}_\theta$ by $\mathbf{R}_{-\theta}$. Restricting to $\theta \in [0, \pi]$, as above, makes it unique; to speak of a *signed* angle one must also fix which of the two unit vectors on the axis is called $\mathbf{u}$.

11.6.3 The cross-product matrix

The canonical form tells us that a rotation of $\mathbb{R}^3$ exists in a suitable basis. For computation we want it in the standard basis, written directly in terms of the axis. The bookkeeping is done by

one matrix.

Recall from Chapter 6 that the cross product of $\mathbf{a}, \mathbf{b} \in \mathbb{R}^3$ is

$$\mathbf{a} \times \mathbf{b} = (a_2b_3 - a_3b_2,\ a_3b_1 - a_1b_3,\ a_1b_2 - a_2b_1).$$

For fixed $\mathbf{a}$ this is linear in $\mathbf{b}$, so it is given by a matrix.

Definition 11.6.1 — Cross-product Matrix

For $\mathbf{n} = (n_1, n_2, n_3) \in \mathbb{R}^3$, the **cross-product matrix** of $\mathbf{n}$ is

$$\mathbf{K_n} \coloneqq \begin{pmatrix} 0 & -n_3 & n_2 \\ n_3 & 0 & -n_1 \\ -n_2 & n_1 & 0 \end{pmatrix} \in M_3(\mathbb{R}),$$

so that $\mathbf{K_n v} = \mathbf{n} \times \mathbf{v}$ for every $\mathbf{v} \in \mathbb{R}^3$.

The last clause is a check of the three entries against the formula above, with $\mathbf{a} = \mathbf{n}$ and $\mathbf{b} = \mathbf{v}$. The map $\mathbf{n} \mapsto \mathbf{K_n}$ is linear and injective, and its image is exactly the set of skew-symmetric 3×3 matrices: a skew matrix has zero diagonal and three free entries below it, and those three entries are $n_3, -n_2, n_1$. We record the facts we need, all of them for a **unit** vector.

Lemma 11.6.3 — Properties of the Cross-product Matrix

Let $\mathbf{n} \in \mathbb{R}^3$ with $\|\mathbf{n}\| = 1$, and write $\mathbf{K} = \mathbf{K_n}$. Then

(a) $\mathbf{K}^\top = -\mathbf{K}$ and $\mathbf{Kn} = \mathbf{0}$;
(b) $\mathbf{K}^2 = \mathbf{nn}^\top - \mathbf{I}_3$, so $\mathbf{K}^2$ is symmetric and $\mathbf{K}^2\mathbf{v} = -\mathbf{v}$ for every $\mathbf{v} \perp \mathbf{n}$;
(c) $\mathbf{K}^3 = -\mathbf{K}$;
(d) for every $\mathbf{v} \perp \mathbf{n}$: $\|\mathbf{Kv}\| = \|\mathbf{v}\|$, $\mathbf{Kv} \perp \mathbf{v}$ and $\mathbf{Kv} \perp \mathbf{n}$.

Idea. Everything follows from (b), and (b) is one entry of a matrix product together with $n_1^2+n_2^2+n_3^2 = 1$. Part (c) is (b) multiplied by $\mathbf{K}$, where the term $\mathbf{Knn}^\top$ dies by (a). For (d), a norm is computed through its square, and $\|\mathbf{Kv}\|^2 = \mathbf{v}^\top\mathbf{K}^\top\mathbf{Kv} = -\mathbf{v}^\top\mathbf{K}^2\mathbf{v}$ turns (d) into (b) as well.

Proof.

(a) Transposing $\mathbf{K_n}$ changes the sign of each of the three off-diagonal pairs, and the diagonal is zero. For the second claim, $\mathbf{Kn} = \mathbf{n} \times \mathbf{n} = \mathbf{0}$ directly from the formula, each coordinate being of the form $n_in_j - n_jn_i$.

(b) The $(1,1)$ entry of $\mathbf{K}^2$ is $0 \cdot 0 + (-n_3)n_3 + n_2(-n_2) = -n_2^2 - n_3^2 = n_1^2 - 1$, using $\|\mathbf{n}\|^2 = 1$; and $(\mathbf{nn}^\top - \mathbf{I}_3)_{11} = n_1^2 - 1$. The $(1,2)$ entry of $\mathbf{K}^2$ is $0(-n_3) + (-n_3)0 + n_2n_1 = n_1n_2 = (\mathbf{nn}^\top)_{12}$, and the $(1,3)$ entry is $0n_2 + (-n_3)(-n_1) + n_20 = n_1n_3$. The remaining six entries are obtained by cycling the indices $1 \to 2 \to 3 \to 1$, under which both $\mathbf{K}$ and $\mathbf{nn}^\top - \mathbf{I}_3$ are unchanged in form. Hence $\mathbf{K}^2 = \mathbf{nn}^\top - \mathbf{I}_3$, which is symmetric since $(\mathbf{nn}^\top)^\top = \mathbf{nn}^\top$. If $\mathbf{v} \perp \mathbf{n}$ then $\mathbf{n}^\top\mathbf{v} = 0$, so $\mathbf{K}^2\mathbf{v} = \mathbf{n}(\mathbf{n}^\top\mathbf{v}) - \mathbf{v} = -\mathbf{v}$.

(c) By (b) and (a), $\mathbf{K}^3 = \mathbf{K}(\mathbf{nn}^\top - \mathbf{I}_3) = (\mathbf{Kn})\mathbf{n}^\top - \mathbf{K} = -\mathbf{K}$.

(d) Let $\mathbf{v} \perp \mathbf{n}$. Using (a) and then (b),

$$\|\mathbf{K}\mathbf{v}\|^2 = (\mathbf{K}\mathbf{v})^\top(\mathbf{K}\mathbf{v}) = \mathbf{v}^\top\mathbf{K}^\top\mathbf{K}\mathbf{v} = -\mathbf{v}^\top\mathbf{K}^2\mathbf{v} = \mathbf{v}^\top\mathbf{v} = \|\mathbf{v}\|^2.$$

Next, $\langle \mathbf{K}\mathbf{v}, \mathbf{v}\rangle = \mathbf{v}^\top\mathbf{K}\mathbf{v}$ is a 1×1 matrix, hence equal to its own transpose $\mathbf{v}^\top\mathbf{K}^\top\mathbf{v} = -\mathbf{v}^\top\mathbf{K}\mathbf{v}$; a number equal to its own negative is 0, so $\mathbf{K}\mathbf{v} \perp \mathbf{v}$. Finally $\langle \mathbf{K}\mathbf{v}, \mathbf{n}\rangle = \mathbf{n}^\top\mathbf{K}\mathbf{v} = (\mathbf{K}^\top\mathbf{n})^\top\mathbf{v} = -(\mathbf{K}\mathbf{n})^\top\mathbf{v} = 0$ by (a). This proves the lemma.

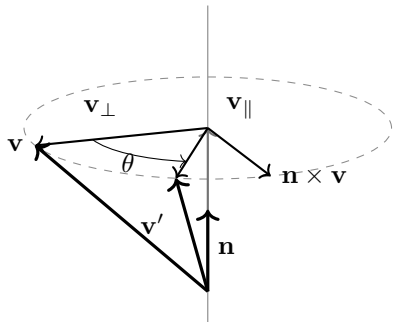
■

Part (c) is the identity that makes every power of $\mathbf{K}$ reduce to $\mathbf{K}$ or $\mathbf{K}^2$, and it is the reason Rodrigues' formula has only three terms and no more.

11.6.4 Rodrigues' formula

Fix a unit vector $\mathbf{n}$ and an angle θ. We want a formula for "turn space by θ about the axis $\operatorname{span}(\mathbf{n})$". The construction is forced by the picture: split a vector into the part along the axis, which does not move, and the part perpendicular to the axis, which turns inside a single plane.

Write $\mathbf{v}_\parallel = \langle \mathbf{v}, \mathbf{n}\rangle\mathbf{n} = \mathbf{n}\mathbf{n}^\top\mathbf{v}$ for the component of $\mathbf{v}$ along the axis and $\mathbf{v}_\perp = \mathbf{v} - \mathbf{v}_\parallel$ for the component perpendicular to it; this is the splitting of Theorem 10.3.2 for $U = \operatorname{span}(\mathbf{n})$, and $\mathbf{v}_\parallel = P_U\mathbf{v}$ by Theorem 10.3.3 (a) with the orthonormal basis $(\mathbf{n})$ of U. Write $\mathbf{v}'$ for the vector we want, the image of $\mathbf{v}$ under the turn.



the axis part stays, the perpendicular part turns

By Lemma 11.6.3 (d), the vector $\mathbf{K}_\mathbf{n}\mathbf{v}_\perp$ has the same length as $\mathbf{v}_\perp$ and is perpendicular to both $\mathbf{v}_\perp$ and $\mathbf{n}$: it is $\mathbf{v}_\perp$ turned by a quarter turn inside the plane $\mathbf{n}^\perp$. So turning $\mathbf{v}_\perp$ by θ means taking $\cos\theta\,\mathbf{v}_\perp + \sin\theta\,\mathbf{K}_\mathbf{n}\mathbf{v}_\perp$, and $\mathbf{v}' = \mathbf{v}_\parallel + \cos\theta\,\mathbf{v}_\perp + \sin\theta\,\mathbf{K}_\mathbf{n}\mathbf{v}_\perp$. Finally $\mathbf{K}_\mathbf{n}\mathbf{v}_\perp = \mathbf{K}_\mathbf{n}\mathbf{v}$, since $\mathbf{K}_\mathbf{n}\mathbf{v}_\parallel$ is a multiple of $\mathbf{K}_\mathbf{n}\mathbf{n} = \mathbf{0}$. That is the definition we take, and the theorem says it is the right one.

Theorem 11.6.4 — Rodrigues' Rotation Formula

Let $\mathbf{n} \in \mathbb{R}^3$ be a unit vector, let $\theta \in \mathbb{R}$, and write $\mathbf{K} = \mathbf{K}_\mathbf{n}$. Define

$$\mathbf{R}_{\mathbf{n},\theta} \coloneqq \mathbf{I}_3 + \sin\theta\,\mathbf{K} + (1 - \cos\theta)\,\mathbf{K}^2.$$

(a) For every $\mathbf{v} \in \mathbb{R}^3$,

$$\mathbf{R}_{\mathbf{n},\theta}\mathbf{v} = \langle \mathbf{v}, \mathbf{n}\rangle \mathbf{n} + \cos\theta \left(\mathbf{v} - \langle \mathbf{v}, \mathbf{n}\rangle \mathbf{n}\right) + \sin\theta \, (\mathbf{n} \times \mathbf{v}).$$

(b) $\mathbf{R}_{\mathbf{n},\theta}\mathbf{n} = \mathbf{n}$, and for every unit $\mathbf{w} \perp \mathbf{n}$ the list $\mathcal{B} = (\mathbf{n}, \mathbf{w}, \mathbf{n} \times \mathbf{w})$ is an orthonormal basis of $\mathbb{R}^3$ with $[T_{\mathbf{R}_{\mathbf{n},\theta}}]_{\mathcal{B}} = [1] \oplus \mathbf{R}_\theta$. In particular $\mathbf{R}_{\mathbf{n},\theta} \in \mathrm{SO}(3)$.

(c) Conversely, every $\mathbf{Q} \in \mathrm{SO}(3)$ equals $\mathbf{R}_{\mathbf{n},\theta}$ for some unit vector $\mathbf{n}$ and some $\theta \in [0, \pi]$.

Idea. Part (a) is the paragraph above, read backwards: substitute $\mathbf{n}\mathbf{n}^\top = \mathbf{K}^2 + \mathbf{I}_3$ from Lemma 11.6.3 (b) into the geometric expression and collect terms. Part (b) then needs only the images of three basis vectors, and every one of them is a two-line computation with (a) and the lemma; the matrix that comes out is the canonical form of Corollary 11.6.2, which also gives orthogonality and the determinant for free. Part (c) runs Corollary 11.6.2 in reverse: it hands us a basis $(\mathbf{u}, \mathbf{w}_1, \mathbf{w}_2)$, and the only question is whether $\mathbf{w}_2$ is $\mathbf{u} \times \mathbf{w}_1$ or its negative — and if it is the negative, we change the sign of the angle.

Proof.

(a) By Lemma 11.6.3 (b), $\mathbf{n}\mathbf{n}^\top = \mathbf{K}^2 + \mathbf{I}_3$. Hence, writing $\langle \mathbf{v}, \mathbf{n}\rangle \mathbf{n} = \mathbf{n}\mathbf{n}^\top \mathbf{v}$ and $\mathbf{n} \times \mathbf{v} = \mathbf{K}\mathbf{v}$,

$$\begin{aligned} &\mathbf{n}\mathbf{n}^\top \mathbf{v} + \cos\theta \, (\mathbf{v} - \mathbf{n}\mathbf{n}^\top \mathbf{v}) + \sin\theta \, \mathbf{K}\mathbf{v} \\ &\quad = \cos\theta \, \mathbf{v} + (1 - \cos\theta)\mathbf{n}\mathbf{n}^\top \mathbf{v} + \sin\theta \, \mathbf{K}\mathbf{v} \\ &\quad = \cos\theta \, \mathbf{v} + (1 - \cos\theta)(\mathbf{K}^2 + \mathbf{I}_3)\mathbf{v} + \sin\theta \, \mathbf{K}\mathbf{v} \\ &\quad = \left(\mathbf{I}_3 + \sin\theta \, \mathbf{K} + (1 - \cos\theta)\mathbf{K}^2\right)\mathbf{v}, \end{aligned}$$

since $\cos\theta + (1 - \cos\theta) = 1$. The right-hand side is $\mathbf{R}_{\mathbf{n},\theta}\mathbf{v}$.

(b) First $\mathbf{K}\mathbf{n} = \mathbf{0}$ and $\mathbf{K}^2\mathbf{n} = \mathbf{K}(\mathbf{K}\mathbf{n}) = \mathbf{0}$ by Lemma 11.6.3 (a), so $\mathbf{R}_{\mathbf{n},\theta}\mathbf{n} = \mathbf{n}$. Let $\mathbf{w}$ be a unit vector with $\mathbf{w} \perp \mathbf{n}$, and put $\mathbf{z} = \mathbf{K}\mathbf{w} = \mathbf{n} \times \mathbf{w}$. By Lemma 11.6.3 (d), $\|\mathbf{z}\| = 1$, $\mathbf{z} \perp \mathbf{w}$ and $\mathbf{z} \perp \mathbf{n}$, so $\mathcal{B} = (\mathbf{n}, \mathbf{w}, \mathbf{z})$ is an orthonormal list of three vectors in $\mathbb{R}^3$, hence an orthonormal basis (Theorem 10.1.4 and Theorem 1.6.4). Now compute the three images. We have $\mathbf{R}_{\mathbf{n},\theta}\mathbf{n} = \mathbf{n}$. Next, $\mathbf{K}^2\mathbf{w} = -\mathbf{w}$ by Lemma 11.6.3 (b), since $\mathbf{w} \perp \mathbf{n}$, so

$$\mathbf{R}_{\mathbf{n},\theta}\mathbf{w} = \mathbf{w} + \sin\theta \, \mathbf{z} - (1 - \cos\theta)\mathbf{w} = \cos\theta \, \mathbf{w} + \sin\theta \, \mathbf{z}.$$

Finally $\mathbf{z} \perp \mathbf{n}$, so $\mathbf{K}^2\mathbf{z} = -\mathbf{z}$, and $\mathbf{K}\mathbf{z} = \mathbf{K}^2\mathbf{w} = -\mathbf{w}$; hence

$$\mathbf{R}_{\mathbf{n},\theta}\mathbf{z} = \mathbf{z} - \sin\theta \, \mathbf{w} - (1 - \cos\theta)\mathbf{z} = -\sin\theta \, \mathbf{w} + \cos\theta \, \mathbf{z}.$$

Reading off the columns (Definition 3.6.1), $[T_{\mathbf{R}_{\mathbf{n},\theta}}]_{\mathcal{B}} = [1] \oplus \mathbf{R}_\theta$. This matrix is orthogonal, and it is the matrix of $T_{\mathbf{R}_{\mathbf{n},\theta}}$ in an orthonormal basis, so $T_{\mathbf{R}_{\mathbf{n},\theta}}$ is an isometry and $\mathbf{R}_{\mathbf{n},\theta} \in \mathrm{O}(3)$ by Theorem 10.7.3 (f) and Definition 10.7.2. The two matrices are matrices of the same operator, hence similar (Theorem 3.7.4 (a)), so they have the same determinant (Corollary 6.5.7), namely 1; so $\mathbf{R}_{\mathbf{n},\theta} \in \mathrm{SO}(3)$.

(c) Let $\mathbf{Q} \in \mathrm{SO}(3)$. By Corollary 11.6.2 there are an orthonormal basis $(\mathbf{u}, \mathbf{w}_1, \mathbf{w}_2)$ of $\mathbb{R}^3$ and $\theta \in [0, \pi]$ with $[T_{\mathbf{Q}}]_{(\mathbf{u},\mathbf{w}_1,\mathbf{w}_2)} = [1] \oplus \mathbf{R}_\theta$. The vector $\mathbf{u} \times \mathbf{w}_1$ is a unit vector orthogonal to $\mathbf{u}$ and $\mathbf{w}_1$ by Lemma 11.6.3 (d), and so is $\mathbf{w}_2$; since $\mathrm{span}(\mathbf{u}, \mathbf{w}_1)^\perp$ is

a line (Theorem 10.3.2 (c)), its unit vectors are $\pm\mathbf{u}\times\mathbf{w}_1$, so $\mathbf{w}_2=\varepsilon\,\mathbf{u}\times\mathbf{w}_1$ with $\varepsilon=\pm1$.

Case $\varepsilon=1$. Then (b), applied with $\mathbf{n}=\mathbf{u}$ and $\mathbf{w}=\mathbf{w}_1$, gives $[T_{\mathbf{R}_{\mathbf{u},\theta}}]_{(\mathbf{u},\mathbf{w}_1,\mathbf{w}_2)}=[1]\oplus\mathbf{R}_\theta=[T_{\mathbf{Q}}]_{(\mathbf{u},\mathbf{w}_1,\mathbf{w}_2)}$. Operators with the same matrix in one basis are equal, so $\mathbf{Q}=\mathbf{R}_{\mathbf{u},\theta}$.

Case $\varepsilon=-1$. Then $\mathbf{u}\times\mathbf{w}_1=-\mathbf{w}_2$, and the matrix of $T_{\mathbf{Q}}$ in the basis $(\mathbf{u},\mathbf{w}_1,-\mathbf{w}_2)$ is obtained from $[1]\oplus\mathbf{R}_\theta$ by changing the sign of the third basis vector, which changes the sign of the two off-diagonal entries of the $\mathbf{R}_\theta$ block: it is $[1]\oplus\mathbf{R}_{-\theta}$. By the previous case, $\mathbf{Q}=\mathbf{R}_{\mathbf{u},-\theta}$. Finally $\mathbf{K}_{-\mathbf{u}}=-\mathbf{K}_{\mathbf{u}}$, so

$$\mathbf{R}_{-\mathbf{u},\theta}=\mathbf{I}_3-\sin\theta\,\mathbf{K}_{\mathbf{u}}+(1-\cos\theta)\mathbf{K}_{\mathbf{u}}^2=\mathbf{R}_{\mathbf{u},-\theta},$$

and $\mathbf{Q}=\mathbf{R}_{-\mathbf{u},\theta}$ with $-\mathbf{u}$ a unit vector and $\theta\in[0,\pi]$. This proves the theorem.

■

Part (c) is worth restating on its own: **a rotation of $\mathbb{R}^3$ is nothing but a unit vector and an angle**. That is three numbers of data, one of them redundant, for an object that started life as nine matrix entries subject to six equations.

Quick check. Compute $\mathbf{R}_{\mathbf{n},\pi}$ from Rodrigues' formula and identify the map geometrically.

Solution. With $\sin\pi=0$ and $1-\cos\pi=2$, the formula gives $\mathbf{R}_{\mathbf{n},\pi}=\mathbf{I}_3+2\mathbf{K}^2=\mathbf{I}_3+2(\mathbf{n}\mathbf{n}^{\top}-\mathbf{I}_3)=2\mathbf{n}\mathbf{n}^{\top}-\mathbf{I}_3$, using Lemma 11.6.3 (b). It fixes $\mathbf{n}$ and negates every vector perpendicular to $\mathbf{n}$: the half-turn about the axis. Equivalently $\mathbf{R}_{\mathbf{n},\pi}=-(\mathbf{I}_3-2\mathbf{n}\mathbf{n}^{\top})=-\mathbf{H}_{\mathbf{n}}$, minus the Householder reflection of Definition 10.8.1 in the plane $\mathbf{n}^{\perp}$.

11.6.5 Reading off the axis and the angle

Rodrigues' formula runs one way: from $(\mathbf{n},\theta)$ to $\mathbf{Q}$. The inverse direction is just as cheap, because the formula splits $\mathbf{Q}$ into a symmetric part and a skew part that carry the two pieces of data separately.

Theorem 11.6.5 — Axis and Angle from the Matrix

Let $\mathbf{Q}=\mathbf{R}_{\mathbf{n},\theta}\in\mathrm{SO}(3)$ with $\mathbf{n}$ a unit vector and $\theta\in[0,\pi]$. Then

(a) $\operatorname{tr}\mathbf{Q}=1+2\cos\theta$, so $\cos\theta=\frac{1}{2}(\operatorname{tr}\mathbf{Q}-1)$ and θ is determined by $\mathbf{Q}$;

(b) $\mathbf{Q}-\mathbf{Q}^{\top}=2\sin\theta\,\mathbf{K}_{\mathbf{n}}$;

(c) if $0<\theta<\pi$, then $\sin\theta>0$ and

$$\mathbf{n}=\frac{1}{2\sin\theta}\,(q_{32}-q_{23},\ q_{13}-q_{31},\ q_{21}-q_{12});$$

if $\theta=0$ then $\mathbf{Q}=\mathbf{I}_3$ and the axis is arbitrary; and if $\theta=\pi$ then $\mathbf{Q}+\mathbf{I}_3=2\mathbf{n}\mathbf{n}^{\top}$, whose non-zero columns are the multiples $2n_i\mathbf{n}$ of $\mathbf{n}$.

Proof. Write $\mathbf{K} = \mathbf{K_n}$. By Lemma 11.6.3 (b), $\mathbf{K}^2 = \mathbf{n}\mathbf{n}^\top - \mathbf{I}_3$, so $\operatorname{tr}\mathbf{K}^2 = \operatorname{tr}(\mathbf{n}\mathbf{n}^\top) - 3 = \|\mathbf{n}\|^2 - 3 = -2$; and $\operatorname{tr}\mathbf{K} = 0$, the diagonal of $\mathbf{K}$ being zero.

(a) Taking traces in Rodrigues' formula, which is legitimate because the trace is linear (Theorem 0.9.6 (1)),

$$\operatorname{tr}\mathbf{Q} = 3 + \sin\theta \cdot 0 + (1 - \cos\theta)(-2) = 1 + 2\cos\theta.$$

Since cos is injective on $[0, \pi]$, this determines θ.

(b) By Lemma 11.6.3 (a) and (b), $\mathbf{K}^\top = -\mathbf{K}$ and $(\mathbf{K}^2)^\top = \mathbf{K}^2$. Transposing Rodrigues' formula therefore gives $\mathbf{Q}^\top = \mathbf{I}_3 - \sin\theta\,\mathbf{K} + (1-\cos\theta)\mathbf{K}^2$, and subtracting, $\mathbf{Q} - \mathbf{Q}^\top = 2\sin\theta\,\mathbf{K}$.

(c) For $\theta \in (0, \pi)$ we have $\sin\theta > 0$, so (b) may be divided by $2\sin\theta$, and the three independent entries of $\mathbf{K_n}$ are $(\mathbf{K_n})_{32} = n_1$, $(\mathbf{K_n})_{13} = n_2$ and $(\mathbf{K_n})_{21} = n_3$ by Definition 11.6.1; the displayed formula reads these off $\mathbf{Q} - \mathbf{Q}^\top$. If $\theta = 0$ then Rodrigues' formula gives $\mathbf{Q} = \mathbf{I}_3$. If $\theta = \pi$ then $\mathbf{Q} = 2\mathbf{n}\mathbf{n}^\top - \mathbf{I}_3$, as computed in the Quick check above, so $\mathbf{Q} + \mathbf{I}_3 = 2\mathbf{n}\mathbf{n}^\top$, whose i-th column is $2n_i\mathbf{n}$; at least one $n_i \neq 0$, so at least one column is a non-zero multiple of $\mathbf{n}$. This proves the theorem.

■

The two degenerate angles are exactly the two at which the skew part $\mathbf{Q} - \mathbf{Q}^\top$ vanishes, and they are exactly the two at which the axis is not determined by a *signed* angle: at $\theta = 0$ there is no rotation to speak of, and at $\theta = \pi$ turning by $+\pi$ and $-\pi$ about the same axis give the same map. Everywhere else, part (c) is a two-subtraction recipe.

Example. (Axis and Angle of a Space Rotation)

Let

$$\mathbf{Q} = \tfrac{1}{9}\begin{pmatrix} 1 & -4 & 8 \\ 8 & 4 & 1 \\ -4 & 7 & 4 \end{pmatrix}.$$

Verify that $\mathbf{Q} \in \mathrm{SO}(3)$, find its axis and angle, and confirm the answer with Rodrigues' formula.

Solution. Orthogonality. The columns are $\frac{1}{9}(1, 8, -4)$, $\frac{1}{9}(-4, 4, 7)$ and $\frac{1}{9}(8, 1, 4)$. Each has squared norm $\frac{1}{81}(1 + 64 + 16) = \frac{1}{81}(16 + 16 + 49) = \frac{1}{81}(64 + 1 + 16) = 1$, and the three pairwise inner products are

$$\tfrac{1}{81}(-4 + 32 - 28) = \tfrac{1}{81}(8 + 8 - 16) = \tfrac{1}{81}(-32 + 4 + 28) = 0.$$

So $\mathbf{Q} \in \mathrm{O}(3)$ by Theorem 10.7.3 (f).

Determinant. Expanding along the first row, $729\det\mathbf{Q} = 1(16 - 7) - (-4)(32 + 4) + 8(56 + 16) = 9 + 144 + 576 = 729$, so $\det\mathbf{Q} = 1$ and $\mathbf{Q} \in \mathrm{SO}(3)$.

Angle. $\operatorname{tr}\mathbf{Q} = \frac{1}{9}(1 + 4 + 4) = 1$, so $\cos\theta = \frac{1}{2}(1 - 1) = 0$ and $\theta = \pi/2$ by Theorem 11.6.5 (a).

Axis. Here $2\sin\theta = 2$. The three entries needed by Theorem 11.6.5 (c) are

$$q_{32} - q_{23} = \tfrac{7-1}{9} = \tfrac{6}{9},$$
$$q_{13} - q_{31} = q_{21} - q_{12} = \tfrac{8+4}{9} = \tfrac{12}{9},$$

so $\mathbf{n} = \tfrac{1}{2}\big(\tfrac{6}{9}, \tfrac{12}{9}, \tfrac{12}{9}\big) = \tfrac{1}{3}(1,2,2)$, which is a unit vector since $1+4+4=9$.

Check. $\mathbf{Q}(1,2,2) = \tfrac{1}{9}(1-8+16,\ 8+8+2,\ -4+14+8) = \tfrac{1}{9}(9,18,18) = (1,2,2)$, so the axis is fixed. And Rodrigues' formula with $\theta = \pi/2$ reads $\mathbf{R}_{\mathbf{n},\pi/2} = \mathbf{I}_3 + \mathbf{K} + \mathbf{K}^2$, where

$$\mathbf{K} = \tfrac{1}{3}\begin{pmatrix} 0 & -2 & 2 \\ 2 & 0 & -1 \\ -2 & 1 & 0 \end{pmatrix}, \qquad \mathbf{K}^2 = \mathbf{n}\mathbf{n}^{\top} - \mathbf{I}_3 = \tfrac{1}{9}\begin{pmatrix} -8 & 2 & 2 \\ 2 & -5 & 4 \\ 2 & 4 & -5 \end{pmatrix}.$$

Adding $\mathbf{I}_3 + \mathbf{K} + \mathbf{K}^2$ entry by entry, for instance $1 + 0 - \tfrac{8}{9} = \tfrac{1}{9}$ in position $(1,1)$ and $0 - \tfrac{2}{3} + \tfrac{2}{9} = -\tfrac{4}{9}$ in position $(1,2)$, returns $\mathbf{Q}$.

11.6.6 Reflections generate

The canonical form is one way to say that an orthogonal matrix is built from simple pieces. Here is another, and the pieces are even simpler: mirrors. Recall from Chapter 10 the Householder reflection $\mathbf{H}_{\mathbf{w}} = \mathbf{I}_n - 2\mathbf{w}\mathbf{w}^{\top}/\|\mathbf{w}\|^2$ determined by a non-zero $\mathbf{w}$ (Definition 10.8.1); it is orthogonal, equal to its own inverse, and has determinant -1 (Proposition 10.8.2).

Lemma 11.6.6 — A Mirror Between Two Vectors of Equal Length

Let $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$ with $\|\mathbf{x}\| = \|\mathbf{y}\|$ and $\mathbf{x} \neq \mathbf{y}$. Then $\mathbf{w} \coloneqq \mathbf{x} - \mathbf{y}$ is non-zero and $\mathbf{H}_{\mathbf{w}}\mathbf{x} = \mathbf{y}$.

Proof. $\mathbf{w} \neq \mathbf{0}$ because $\mathbf{x} \neq \mathbf{y}$. Expanding the two inner products and using $\|\mathbf{y}\|^2 = \|\mathbf{x}\|^2$,

$$\|\mathbf{w}\|^2 = \|\mathbf{x}\|^2 - 2\langle \mathbf{x}, \mathbf{y}\rangle + \|\mathbf{y}\|^2 = 2\big(\|\mathbf{x}\|^2 - \langle \mathbf{x}, \mathbf{y}\rangle\big),$$
$$\langle \mathbf{x}, \mathbf{w}\rangle = \|\mathbf{x}\|^2 - \langle \mathbf{x}, \mathbf{y}\rangle,$$

so $2\langle \mathbf{x}, \mathbf{w}\rangle = \|\mathbf{w}\|^2$. Hence, by the formula $\mathbf{H}_{\mathbf{w}}\mathbf{v} = \mathbf{v} - 2\big(\langle \mathbf{v}, \mathbf{w}\rangle/\|\mathbf{w}\|^2\big)\mathbf{w}$ of Definition 10.8.1,

$$\mathbf{H}_{\mathbf{w}}\mathbf{x} = \mathbf{x} - \mathbf{w} = \mathbf{x} - (\mathbf{x} - \mathbf{y}) = \mathbf{y},$$

as claimed. ∎

This is Theorem 10.8.3 with the target chosen for geometry rather than for arithmetic: there, $\mathbf{y}$ was a prescribed multiple of $\mathbf{e}_1$ and the sign was picked to avoid cancellation; here $\mathbf{y}$ is whatever we need, and the mirror is the perpendicular bisector of the segment from $\mathbf{x}$ to $\mathbf{y}$.

Theorem 11.6.7 — Reflections Generate the Orthogonal Group

Let $n \geq 1$ and $\mathbf{Q} \in \mathrm{O}(n)$. Then $\mathbf{Q}$ is a product of at most n Householder reflections. (The identity is the empty product, of zero reflections.)

Idea. Induct on n, and make the induction bite by fixing one coordinate at a time. If $\mathbf{Q}$ already fixes $\mathbf{e}_1$, then it maps $\mathbf{e}_1^\perp$ into itself, and the inductive hypothesis applied inside that $(n-1)$-dimensional space produces at most $n-1$ reflections, each of which extends to a reflection of $\mathbb{R}^n$ by taking the same $\mathbf{w}$. If $\mathbf{Q}$ does not fix $\mathbf{e}_1$, spend one reflection making it do so: $\mathbf{Q}\mathbf{e}_1$ and $\mathbf{e}_1$ are two distinct vectors of the same length, and Lemma 11.6.6 is exactly the tool that swaps them.

Proof. Induction on n. For $n = 1$, a matrix $[a] \in \mathrm{O}(1)$ satisfies $a^2 = [a]^\top[a] = 1$, so $(a-1)(a+1) = 0$ and $a = \pm 1$; thus $\mathrm{O}(1) = \{[1], [-1]\}$, where $[1]$ is the empty product and $[-1] = \mathbf{H}_{\mathbf{e}_1}$, one reflection.

Let $n \geq 2$ and assume the statement in dimension $n-1$. Let $\mathbf{Q} \in \mathrm{O}(n)$ and set $\mathbf{x} = \mathbf{Q}\mathbf{e}_1$, a unit vector since $T_{\mathbf{Q}}$ is an isometry (Theorem 10.7.3).

Case 1: $\mathbf{x} = \mathbf{e}_1$. Put $U = \mathrm{span}(\mathbf{e}_1)^\perp$, of dimension $n-1$ by Theorem 10.3.2 (c). For $\mathbf{v} \in U$ we have $\langle \mathbf{Q}\mathbf{v}, \mathbf{e}_1 \rangle = \langle \mathbf{Q}\mathbf{v}, \mathbf{Q}\mathbf{e}_1 \rangle = \langle \mathbf{v}, \mathbf{e}_1 \rangle = 0$, the middle equality by Theorem 10.7.3 (b); so U is $T_{\mathbf{Q}}$-invariant. Identify U with $\mathbb{R}^{n-1}$ through the orthonormal basis $(\mathbf{e}_2, \dots, \mathbf{e}_n)$. The restriction $T_{\mathbf{Q}}|_U$ is an isometry of U, so its matrix $\mathbf{Q}'$ in that basis lies in $\mathrm{O}(n-1)$ (Theorem 10.7.3 (f)), and by the inductive hypothesis $\mathbf{Q}' = \mathbf{H}_{\mathbf{w}'_1} \cdots \mathbf{H}_{\mathbf{w}'_k}$ with $k \leq n-1$ and $\mathbf{w}'_i \in \mathbb{R}^{n-1}$. Let $\mathbf{w}_i \in U \subseteq \mathbb{R}^n$ be the vector with coordinates $\mathbf{w}'_i$ in the basis $(\mathbf{e}_2, \dots, \mathbf{e}_n)$. Then $\mathbf{H}_{\mathbf{w}_i}$ fixes $\mathbf{e}_1$, because $\mathbf{e}_1 \perp \mathbf{w}_i$ (Proposition 10.8.2 (d)), and on U it acts as $\mathbf{H}_{\mathbf{w}'_i}$, because the defining formula only involves inner products, which agree. Hence $\mathbf{Q}$ and $\mathbf{H}_{\mathbf{w}_1} \cdots \mathbf{H}_{\mathbf{w}_k}$ agree on $\mathbf{e}_1$ and on U, so they agree on $\mathbb{R}^n = \mathrm{span}(\mathbf{e}_1) \oplus U$, and $\mathbf{Q}$ is a product of $k \leq n-1 \leq n$ reflections.

Case 2: $\mathbf{x} \neq \mathbf{e}_1$. Then $\|\mathbf{x}\| = 1 = \|\mathbf{e}_1\|$, so $\mathbf{w} \coloneqq \mathbf{x} - \mathbf{e}_1$ is non-zero and $\mathbf{H}_{\mathbf{w}}\mathbf{x} = \mathbf{e}_1$ by Lemma 11.6.6. The matrix $\mathbf{H}_{\mathbf{w}}\mathbf{Q}$ is orthogonal, being a product of orthogonal matrices (Proposition 10.7.4 (a)), and $\mathbf{H}_{\mathbf{w}}\mathbf{Q}\mathbf{e}_1 = \mathbf{H}_{\mathbf{w}}\mathbf{x} = \mathbf{e}_1$. By Case 1, $\mathbf{H}_{\mathbf{w}}\mathbf{Q}$ is a product of at most $n-1$ reflections. Multiplying on the left by $\mathbf{H}_{\mathbf{w}}$ and using $\mathbf{H}_{\mathbf{w}}^2 = \mathbf{I}_n$ (Proposition 10.8.2 (b)),

$$\mathbf{Q} = \mathbf{H}_{\mathbf{w}}(\mathbf{H}_{\mathbf{w}}\mathbf{Q}),$$

a product of at most n reflections. This completes the induction. ∎

Counting reflections recovers the determinant: each factor contributes -1 (Proposition 10.8.2 (e)), so a product of k reflections has determinant $(-1)^k$, and an element of $\mathrm{SO}(n)$ needs an even number of them. The bound n is sharp — $-\mathbf{I}_n$ is a product of n reflections and no fewer, since a product of k reflections fixes the intersection of k hyperplanes, a subspace of dimension at least $n-k$, while $-\mathbf{I}_n$ fixes only $\mathbf{0}$.

Remark. The general theorem behind this one, due to Cartan and Dieudonné, says the same for the orthogonal group of any non-degenerate symmetric bilinear form over any field of characteristic $\neq 2$. Only the Euclidean case is proved here, and only the Euclidean case is used.

11.6.7 Composing rotations

Two rotations of the plane about the origin compose into a rotation, and the angles add: $\mathbf{R}_\alpha \mathbf{R}_\beta = \mathbf{R}_{\alpha+\beta}$, so SO(2) is abelian (Chapter 10). The reason is visible in the canonical form: in dimension 2 there is only one rotation block, so a rotation is a single number, and numbers commute.

In dimension 3 the picture changes completely, because there is an axis to move as well as an angle to add.

Example. (Two Quarter Turns in Two Orders)

Let $\mathbf{A} = \mathbf{R}_{\mathbf{e}_1,\pi/2}$ and $\mathbf{B} = \mathbf{R}_{\mathbf{e}_3,\pi/2}$, the quarter turns about the first and third coordinate axes. Compute $\mathbf{AB}$ and $\mathbf{BA}$, and find the axis and angle of each.

Solution. From Theorem 11.6.4 (b), $\mathbf{A}$ fixes $\mathbf{e}_1$ and turns the $(\mathbf{e}_2, \mathbf{e}_3)$-plane by $\pi/2$, and $\mathbf{B}$ fixes $\mathbf{e}_3$ and turns the $(\mathbf{e}_1, \mathbf{e}_2)$-plane by $\pi/2$:

$$\mathbf{A} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & -1 \\ 0 & 1 & 0 \end{pmatrix}, \qquad \mathbf{B} = \begin{pmatrix} 0 & -1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix}.$$

Multiplying,

$$\mathbf{AB} = \begin{pmatrix} 0 & -1 & 0 \\ 0 & 0 & -1 \\ 1 & 0 & 0 \end{pmatrix}, \qquad \mathbf{BA} = \begin{pmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix}.$$

These are different matrices, so SO(3) is not abelian. Both have trace 0, so both are rotations by the angle θ with $\cos\theta = \frac{1}{2}(0-1) = -\frac{1}{2}$, that is $\theta = 2\pi/3$. Their axes differ. Solving $\mathbf{ABv} = \mathbf{v}$ gives $-v_2 = v_1$, $-v_3 = v_2$, $v_1 = v_3$, so the axis of $\mathbf{AB}$ is $\operatorname{span}((1,-1,1))$; solving $\mathbf{BAv} = \mathbf{v}$ gives $v_3 = v_1$, $v_1 = v_2$, $v_2 = v_3$, so the axis of $\mathbf{BA}$ is $\operatorname{span}((1,1,1))$. Same angle, different axes: the order of two quarter turns changes where the resulting axis points.

That the product is *again* a rotation is not an accident of this example: SO(3) is a group (Proposition 10.7.4), so any product of rotations is orthogonal with determinant 1, and Corollary 11.6.2 makes it a rotation. What no formula makes obvious is which one; Exercise (C2: Products of rotations) pursues this.

Warning. **In dimension 4 and above, $\det \mathbf{Q} = 1$ does not mean "rotation about an axis".** Take

$$\mathbf{Q} = \mathbf{R}_{\pi/2} \oplus \mathbf{R}_{\pi/3} \in \mathrm{O}(4), \qquad \det \mathbf{Q} = 1 \cdot 1 = 1.$$

Its canonical form is itself, with $p = q = 0$ and $m = 2$, so 1 is not an eigenvalue and $\mathbf{Q}$ fixes no non-zero vector at all: there is no axis. Worse, the two angles are different, so $\mathbf{Q}$ is not a rotation "in a plane" either — it turns two orthogonal planes at two different speeds, and no single angle describes it. Chapter 10 made the same point with $-\mathbf{I}_4 \in \mathrm{SO}(4)$; the canonical form explains it, since for even n the counts $p = q = 0$ are allowed. The clean statement "determinant 1 means a rotation about an axis" is a feature of dimension 3, where $p + q + 2m = 3$ is odd and forces $p \geq 1$ when q is even.

11.6.8 Exercises

11.6.8.1 A. Check your understanding

Exercise A1.

(a) State the canonical form of an element of $\mathrm{O}(n)$, saying what the blocks are and which angles are allowed.

(b) Which hypothesis on $\mathbf{Q}$ turns the rotation-scaling blocks of the real normal form into rotation blocks, and why?

(c) Write down the cross-product matrix $\mathbf{K_n}$ and state the identity $\mathbf{K_n^3} =?$ for a unit $\mathbf{n}$.

(d) Given $\mathbf{Q} \in \mathrm{SO}(3)$, how do you find its angle, and how do you find its axis? Name the two degenerate cases.

(e) True or false: if $\mathbf{Q} \in \mathrm{O}(n)$ and $\det \mathbf{Q} = 1$, then $\mathbf{Q}$ fixes a non-zero vector. Justify your answer.

(f) How many Householder reflections can be needed to write an element of $\mathrm{O}(n)$, and what does the parity of that number say?

Solution.

(a) By Theorem 11.6.1, $\mathbf{P}^\top \mathbf{Q} \mathbf{P} = \mathbf{I}_p \oplus (-\mathbf{I}_q) \oplus \mathbf{R}_{\theta_1} \oplus \cdots \oplus \mathbf{R}_{\theta_m}$ for some $\mathbf{P} \in \mathrm{O}(n)$, with $p + q + 2m = n$ and $0 < \theta_j < \pi$. The angles 0 and π are excluded because $\mathbf{R}_0 = \mathbf{I}_2$ and $\mathbf{R}_\pi = -\mathbf{I}_2$ are already accounted for by the ± 1 blocks.

(b) Orthogonality. An orthogonal matrix is unitary as a complex matrix (Proposition 10.7.4 (a)), so each of its eigenvalues has modulus 1 (Proposition 10.7.1). A block $\mathbf{\Lambda}(\lambda)$ has eigenvalues $\lambda, \overline{\lambda}$, so $|\lambda| = 1$ and the scaling factor is 1.

(c) $\mathbf{K_n}$ has rows $(0, -n_3, n_2)$, $(n_3, 0, -n_1)$, $(-n_2, n_1, 0)$ (Definition 11.6.1), and $\mathbf{K_n^3} = -\mathbf{K_n}$ when $\|\mathbf{n}\| = 1$ (Lemma 11.6.3 (c)).

(d) The angle from the trace, $\cos\theta = \frac{1}{2}(\operatorname{tr}\mathbf{Q} - 1)$ with $\theta \in [0, \pi]$; the axis from the skew part, $\mathbf{Q} - \mathbf{Q}^\top = 2\sin\theta\, \mathbf{K_n}$ (Theorem 11.6.5). The degenerate cases are $\theta = 0$, where $\mathbf{Q} = \mathbf{I}_3$ and there is no axis to find, and $\theta = \pi$, where the skew part vanishes and one reads $\mathbf{n}$ off $\mathbf{Q} + \mathbf{I}_3 = 2\mathbf{n}\mathbf{n}^\top$ instead.

(e) False for even n. The matrix $\mathbf{R}_{\pi/2} \oplus \mathbf{R}_{\pi/3} \in \mathrm{SO}(4)$ has no eigenvalue 1. It is true for odd n: then $p + q + 2m = n$ is odd and q is even, so $p = n - q - 2m$ is odd, hence $p \geq 1$, and the $\mathbf{I}_p$ block supplies a fixed vector.

(f) At most n (Theorem 11.6.7). Each reflection has determinant -1, so the number used has the same parity in every such factorization as the sign of $\det \mathbf{Q}$ dictates: even for $\det \mathbf{Q} = 1$, odd for $\det \mathbf{Q} = -1$.

11.6.8.2 B. Practice

Exercise B1: Axis and angle.

For each of the following, decide whether it lies in $\mathrm{SO}(3)$, $\mathrm{O}(3) \setminus \mathrm{SO}(3)$, or neither. For those in $\mathrm{SO}(3)$, find the axis and the angle; for those in $\mathrm{O}(3)$ with determinant -1, give the canonical form $[-1] \oplus \mathbf{R}_\theta$ and say what the map is geometrically.

(a) $\frac{1}{9}\begin{pmatrix} 4 & -8 & 1 \\ 4 & 1 & -8 \\ 7 & 4 & 4 \end{pmatrix}$.

(b) $\frac{1}{9}\begin{pmatrix} -7 & 4 & 4 \\ 4 & -1 & 8 \\ 4 & 8 & -1 \end{pmatrix}$.

(c) $\frac{1}{9}\begin{pmatrix} 7 & -4 & -4 \\ -4 & 1 & -8 \\ -4 & -8 & 1 \end{pmatrix}$.

(d) $\frac{1}{9}\begin{pmatrix} 4 & -8 & 1 \\ 4 & 1 & -8 \\ 7 & 4 & 5 \end{pmatrix}$.

Solution.

(a) The columns $\frac{1}{9}(4,4,7)$, $\frac{1}{9}(-8,1,4)$, $\frac{1}{9}(1,-8,4)$ have squared norms $\frac{1}{81}(16+16+49) = \frac{1}{81}(64+1+16) = \frac{1}{81}(1+64+16) = 1$ and pairwise inner products $\frac{1}{81}(-32+4+28) = \frac{1}{81}(4-32+28) = \frac{1}{81}(-8-8+16) = 0$, so the matrix is orthogonal. Expanding along the first row, $729\det = 4(4+32)+8(16+56)+1(16-7) = 144+576+9 = 729$, so it lies in $\mathrm{SO}(3)$. Its trace is $\frac{1}{9}(4+1+4) = 1$, so $\cos\theta = 0$ and $\theta = \pi/2$. For the axis, $q_{32}-q_{23} = \frac{1}{9}(4+8) = \frac{12}{9}$, $q_{13}-q_{31} = \frac{1}{9}(1-7) = -\frac{6}{9}$ and $q_{21}-q_{12} = \frac{1}{9}(4+8) = \frac{12}{9}$; dividing by $2\sin\theta = 2$ gives $\mathbf{n} = \frac{1}{3}(2,-1,2)$. Check: $\mathbf{Q}(2,-1,2) = \frac{1}{9}(8+8+2,\ 8-1-16,\ 14-4+8) = (2,-1,2)$.

(b) The matrix is symmetric. Each column has entries $\pm 7, \pm 4, \pm 4$ in some order, so each has squared norm $\frac{1}{81}(49+16+16) = 1$, and the pairwise inner products are $\frac{1}{81}(-28-4+32) = \frac{1}{81}(-28+32-4) = \frac{1}{81}(16-8-8) = 0$; so it is orthogonal. Expanding along the first row, $729\det = -7(1-64)-4(-4-32)+4(32+4) = 441+144+144 = 729$, so it lies in $\mathrm{SO}(3)$. Its trace is $\frac{1}{9}(-7-1-1) = -1$, so $\cos\theta = -1$ and $\theta = \pi$: a half-turn. The skew part is $\mathbf{0}$, so use $\mathbf{Q}+\mathbf{I}_3 = \frac{1}{9}\begin{pmatrix} 2 & 4 & 4 \\ 4 & 8 & 8 \\ 4 & 8 & 8 \end{pmatrix} = 2\mathbf{n}\mathbf{n}^\top$ with $\mathbf{n} = \frac{1}{3}(1,2,2)$. Check: $\mathbf{Q}(1,2,2) = \frac{1}{9}(-7+8+8,\ 4-2+16,\ 4+16-2) = (1,2,2)$.

(c) This is the negative of (b), so it is orthogonal with $\det = (-1)^3 \cdot 1 = -1$. Its trace is 1, and for the form $[-1]\oplus\mathbf{R}_\theta$ the trace is $-1+2\cos\theta$, so $\cos\theta = 1$ and $\theta = 0$: the canonical form is $[-1]\oplus\mathbf{I}_2 = \mathrm{diag}(-1,1,1)$, a reflection. Indeed it equals $\mathbf{I}_3 - 2\mathbf{n}\mathbf{n}^\top = \mathbf{H}_\mathbf{n}$ with $\mathbf{n} = \frac{1}{3}(1,2,2)$, the reflection in the plane $x_1+2x_2+2x_3 = 0$.

(d) Neither. This is (a) with the $(3,3)$ entry changed from 4 to 5. The third column $\frac{1}{9}(1,-8,5)$ has squared norm $\frac{1}{81}(1+64+25) = \frac{90}{81} = \frac{10}{9} \neq 1$, so the columns are not orthonormal and the matrix is not orthogonal (Theorem 10.7.3 (f)). Its determinant is $\frac{85}{81}$, neither 1 nor -1, which settles it a second way (Proposition 10.7.4). Note that checking the determinant alone is never enough: $\det = 1$ does not make a matrix orthogonal.

Exercise B2: Mirrors.

(a) Write the matrix $\mathbf{M} = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 1 & 0 \\ 1 & 0 & 0 \end{pmatrix}$ as a Householder reflection $\mathbf{H}_\mathbf{w}$, and say which plane is its mirror.

(b) Following the proof of Theorem 11.6.7, write $\mathbf{Q} = \begin{pmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix}$ as a product of Householder reflections, and check the count against $\det \mathbf{Q}$.

Solution.

(a) $\mathbf{M}$ exchanges $\mathbf{e}_1$ and $\mathbf{e}_3$ and fixes $\mathbf{e}_2$. By Lemma 11.6.6 with $\mathbf{x} = \mathbf{e}_1$ and $\mathbf{y} = \mathbf{e}_3$, take $\mathbf{w} = \mathbf{e}_1 - \mathbf{e}_3 = (1, 0, -1)$; then $\|\mathbf{w}\|^2 = 2$ and

$$\mathbf{H}_{\mathbf{w}} = \mathbf{I}_3 - \mathbf{w}\mathbf{w}^\top = \mathbf{I}_3 - \begin{pmatrix} 1 & 0 & -1 \\ 0 & 0 & 0 \\ -1 & 0 & 1 \end{pmatrix} = \mathbf{M}.$$

The mirror is $\operatorname{span}(\mathbf{w})^\perp$, the plane $x_1 = x_3$.

(b) $\mathbf{Q}\mathbf{e}_1 = \mathbf{e}_2 \neq \mathbf{e}_1$, so we are in Case 2 with $\mathbf{w}_1 = \mathbf{Q}\mathbf{e}_1 - \mathbf{e}_1 = (-1, 1, 0)$ and $\|\mathbf{w}_1\|^2 = 2$:

$$\mathbf{H}_{\mathbf{w}_1} = \mathbf{I}_3 - \mathbf{w}_1\mathbf{w}_1^\top = \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix}.$$

Then $\mathbf{H}_{\mathbf{w}_1}\mathbf{Q} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix}$, which fixes $\mathbf{e}_1$ and exchanges $\mathbf{e}_2$ and $\mathbf{e}_3$; the computation of (a), with the indices shifted, shows that it is $\mathbf{H}_{\mathbf{w}_2}$ for $\mathbf{w}_2 = \mathbf{e}_2 - \mathbf{e}_3 = (0, 1, -1)$. Hence $\mathbf{Q} = \mathbf{H}_{\mathbf{w}_1}\mathbf{H}_{\mathbf{w}_2}$, a product of two reflections. The count is even, matching $\det \mathbf{Q} = (-1)^2 = 1$; and indeed $\mathbf{Q}$ is the rotation by $2\pi/3$ about $(1, 1, 1)$ found in Example (Two Quarter Turns in Two Orders).

Exercise B3: Rodrigues in an example.

(a) Compute $\mathbf{R}_{\mathbf{e}_3,\theta}$ from Rodrigues' formula and check that it is $\mathbf{R}_\theta \oplus [1]$.

(b) Compute $\mathbf{R}_{\mathbf{n},2\pi/3}$ for $\mathbf{n} = \frac{1}{\sqrt{3}}(1, 1, 1)$, and identify the resulting matrix.

Solution.

(a) With $\mathbf{n} = \mathbf{e}_3$ we have $\mathbf{K} = \begin{pmatrix} 0 & -1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}$ and $\mathbf{K}^2 = \mathbf{e}_3\mathbf{e}_3^\top - \mathbf{I}_3 = \operatorname{diag}(-1, -1, 0)$. Hence

$$\mathbf{R}_{\mathbf{e}_3,\theta} = \mathbf{I}_3 + \sin\theta\,\mathbf{K} + (1 - \cos\theta)\mathbf{K}^2 = \begin{pmatrix} \cos\theta & -\sin\theta & 0 \\ \sin\theta & \cos\theta & 0 \\ 0 & 0 & 1 \end{pmatrix},$$

the diagonal entries being $1 - (1 - \cos\theta) = \cos\theta$ twice and 1 once. This is $\mathbf{R}_\theta \oplus [1]$, the rotation of the $(\mathbf{e}_1, \mathbf{e}_2)$-plane, as it must be.

(b) Here $\cos\theta = -\frac{1}{2}$ and $\sin\theta = \frac{\sqrt{3}}{2}$. Writing $\mathbf{1} = (1, 1, 1)$, so that $\mathbf{n} = \mathbf{1}/\sqrt{3}$ and

$\mathbf{n}\mathbf{n}^\top = \frac{1}{3}\mathbf{1}\mathbf{1}^\top$,

$$\sin\theta\,\mathbf{K} = \tfrac{\sqrt{3}}{2}\cdot\tfrac{1}{\sqrt{3}}\,\mathbf{K_1} = \tfrac{1}{2}\begin{pmatrix} 0 & -1 & 1 \\ 1 & 0 & -1 \\ -1 & 1 & 0 \end{pmatrix},$$
$$(1-\cos\theta)\mathbf{K}^2 = \tfrac{3}{2}\left(\tfrac{1}{3}\mathbf{1}\mathbf{1}^\top - \mathbf{I}_3\right) = \tfrac{1}{2}\mathbf{1}\mathbf{1}^\top - \tfrac{3}{2}\mathbf{I}_3.$$

Adding $\mathbf{I}_3$ to these two gives $\frac{1}{2}\mathbf{1}\mathbf{1}^\top - \frac{1}{2}\mathbf{I}_3$ plus the skew part. The first piece has 0 on the diagonal and $\frac{1}{2}$ elsewhere, and adding the skew part turns each off-diagonal pair $\frac{1}{2}, \frac{1}{2}$ into $0, 1$:

$$\mathbf{R}_{\mathbf{n},2\pi/3} = \begin{pmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix}.$$

This is the cyclic shift $\mathbf{e}_1 \mapsto \mathbf{e}_2 \mapsto \mathbf{e}_3 \mapsto \mathbf{e}_1$, which is the matrix $\mathbf{BA}$ of Example (Two Quarter Turns in Two Orders): same axis $(1,1,1)$, same angle $2\pi/3$.

11.6.8.3 C. Going deeper

Exercise C1: The plane, re-derived.

(a) Use Theorem 11.6.1 to prove that every $\mathbf{Q} \in \mathrm{O}(2)$ is either orthogonally similar to $\mathbf{R}_\theta$ for a unique $\theta \in [0, \pi]$, or orthogonally similar to $\mathrm{diag}(1, -1)$.

(b) Chapter 10 proved more: $\mathbf{Q}$ **equals** $\mathbf{R}_\theta$ or $\mathbf{M}_\theta$ (Theorem 10.7.5). Explain exactly what information (a) loses, and why the canonical form must lose it.

(c) Deduce that any two reflections of $\mathbb{R}^2$ are orthogonally similar, and that $\mathbf{R}_\alpha$ and $\mathbf{R}_\beta$ are orthogonally similar if and only if $\beta = \pm\alpha$.

Solution.

(a) With $n = 2$, $p + q + 2m = 2$. If $m = 1$ then $p = q = 0$ and the form is $\mathbf{R}_{\theta_1}$ with $\theta_1 \in (0, \pi)$. If $m = 0$ then $(p, q) \in \{(2, 0), (1, 1), (0, 2)\}$, giving $\mathbf{I}_2 = \mathbf{R}_0$, $\mathrm{diag}(1, -1)$ and $-\mathbf{I}_2 = \mathbf{R}_\pi$. So the possibilities are $\mathbf{R}_\theta$ with $\theta \in [0, \pi]$ and $\mathrm{diag}(1, -1)$, and they are distinguished by the determinant. Uniqueness of θ follows from Theorem 11.6.1, or directly from $\mathrm{tr}\,\mathbf{R}_\theta = 2\cos\theta$ and the injectivity of cos on $[0, \pi]$.

(b) Part (a) determines $\mathbf{Q}$ only up to orthogonal similarity, that is, up to a change of orthonormal coordinates. It therefore cannot see *which* line is the mirror of a reflection, nor the sign of the angle of a rotation. It must lose the mirror, because the mirror moves: if $\mathbf{P}$ is the rotation by φ then $\mathbf{P}\mathbf{M}_\theta\mathbf{P}^\top = \mathbf{M}_{\theta+2\varphi}$, so all the $\mathbf{M}_\theta$ are conjugate. It must lose the sign of the angle, because conjugating by $\mathrm{diag}(1, -1)$ sends $\mathbf{R}_\theta$ to $\mathbf{R}_{-\theta}$.

(c) Every reflection has determinant -1, so by (a) each is orthogonally similar to $\mathrm{diag}(1, -1)$, and orthogonal similarity is an equivalence relation, so any two of them are similar to each other. For rotations: if $\beta = \pm\alpha$ then $\mathbf{R}_\beta = \mathbf{R}_\alpha$ or $\mathbf{R}_\beta = \mathrm{diag}(1, -1)\mathbf{R}_\alpha\,\mathrm{diag}(1, -1)$, so they are orthogonally similar. Conversely, similar matrices have equal traces (Theorem 3.7.5), so $\cos\alpha = \cos\beta$, which for real angles means $\beta \equiv \pm\alpha$ modulo 2π.

Exercise C2: Products of rotations.

(a) Prove that the product of two rotations of $\mathbb{R}^3$ is a rotation of $\mathbb{R}^3$, and explain which theorem supplies the axis.

(b) Let $\mathbf{A}$ and $\mathbf{B}$ be the half-turns about two **perpendicular** axes $\mathrm{span}(\mathbf{a})$ and $\mathrm{span}(\mathbf{b})$, with $\mathbf{a} \perp \mathbf{b}$ unit vectors. Prove that $\mathbf{AB}$ is the half-turn about the axis $\mathrm{span}(\mathbf{a} \times \mathbf{b})$.

(c) Deduce that every rotation of $\mathbb{R}^3$ is a product of two half-turns.

Hint for (c): use Theorem 11.6.7, or the description of a half-turn in the Quick check after Theorem 11.6.4.

Solution.

(a) $\mathrm{SO}(3)$ is a group (Proposition 10.7.4 (c)), so if $\mathbf{A}, \mathbf{B} \in \mathrm{SO}(3)$ then $\mathbf{AB} \in \mathrm{SO}(3)$. By Corollary 11.6.2, $\mathbf{AB}$ fixes a line pointwise and rotates the perpendicular plane; that corollary is what supplies the axis, and it does so through the count $p \geq 1$ in the canonical form.

(b) Extend $(\mathbf{a}, \mathbf{b})$ to an orthonormal basis $(\mathbf{a}, \mathbf{b}, \mathbf{c})$ of $\mathbb{R}^3$, where we may take $\mathbf{c} = \mathbf{a} \times \mathbf{b}$: it is a unit vector orthogonal to $\mathbf{a}$ and $\mathbf{b}$ by Lemma 11.6.3 (d). By the Quick check after Theorem 11.6.4, $\mathbf{A} = 2\mathbf{a}\mathbf{a}^{\top} - \mathbf{I}_3$ fixes $\mathbf{a}$ and negates $\mathbf{a}^{\perp}$, so in the basis $(\mathbf{a}, \mathbf{b}, \mathbf{c})$, $\mathbf{A}$ is $\mathrm{diag}(1, -1, -1)$ and $\mathbf{B}$ is $\mathrm{diag}(-1, 1, -1)$. Their product is $\mathrm{diag}(-1, -1, 1)$, which fixes $\mathbf{c}$ and negates $\mathbf{c}^{\perp}$: the half-turn about $\mathrm{span}(\mathbf{c}) = \mathrm{span}(\mathbf{a} \times \mathbf{b})$. (Its trace is -1, confirming $\theta = \pi$ through Theorem 11.6.5 (a).)

(c) Let $\mathbf{Q} = \mathbf{R}_{\mathbf{n},\theta} \in \mathrm{SO}(3)$, with $\mathbf{n}$ a unit vector and $\theta \in [0, \pi]$ (Theorem 11.6.4 (c)). Choose a unit $\mathbf{w} \perp \mathbf{n}$, and work throughout in the orthonormal basis $\mathcal{B} = (\mathbf{n}, \mathbf{w}, \mathbf{K}_{\mathbf{n}}\mathbf{w})$ of Theorem 11.6.4 (b), in which $\mathbf{Q}$ has matrix $[1] \oplus \mathbf{R}_{\theta}$. Put $\mathbf{w}' = \mathbf{R}_{\mathbf{n},\theta/2}\mathbf{w}$, again a unit vector perpendicular to $\mathbf{n}$, since $\mathbf{R}_{\mathbf{n},\theta/2}$ fixes $\mathbf{n}$ and is an isometry; by Theorem 11.6.4 (b) its coordinate vector in $\mathcal{B}$ is $\mathbf{d} = (0, \cos\frac{\theta}{2}, \sin\frac{\theta}{2})$. Let $\mathbf{A}$ and $\mathbf{B}$ be the half-turns about $\mathrm{span}(\mathbf{w}')$ and $\mathrm{span}(\mathbf{w})$, so that in $\mathcal{B}$ their matrices are $2\mathbf{d}\mathbf{d}^{\top} - \mathbf{I}_3$ and $\mathrm{diag}(-1, 1, -1)$ respectively, by the Quick check after Theorem 11.6.4. Using $2\cos^2\frac{\theta}{2} - 1 = \cos\theta$, $2\sin^2\frac{\theta}{2} - 1 = -\cos\theta$ and $2\cos\frac{\theta}{2}\sin\frac{\theta}{2} = \sin\theta$,

$$2\mathbf{d}\mathbf{d}^{\top} - \mathbf{I}_3 = [-1] \oplus \begin{pmatrix} \cos\theta & \sin\theta \\ \sin\theta & -\cos\theta \end{pmatrix}.$$

Multiplying the two matrices blockwise, $\mathbf{AB}$ has matrix

$$[1] \oplus \begin{pmatrix} \cos\theta & \sin\theta \\ \sin\theta & -\cos\theta \end{pmatrix} \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} = [1] \oplus \mathbf{R}_{\theta},$$

which is the matrix of $\mathbf{Q}$ in the same basis. Hence $\mathbf{Q} = \mathbf{AB}$.

Exercise C3: Moving one point of the sphere to another.

Let $S = \{\mathbf{x} \in \mathbb{R}^3 : \|\mathbf{x}\| = 1\}$.

(a) Prove that for all $\mathbf{u}, \mathbf{v} \in S$ there is $\mathbf{Q} \in \mathrm{SO}(3)$ with $\mathbf{Q}\mathbf{u} = \mathbf{v}$. (One says that $\mathrm{SO}(3)$ **acts transitively** on S.)

(b) Prove that $\{\mathbf{Q} \in \mathrm{SO}(3) : \mathbf{Q}\mathbf{u} = \mathbf{u}\} = \{\mathbf{R}_{\mathbf{u},\theta} : \theta \in \mathbb{R}\}$, and that this set is an

abelian subgroup of SO(3).

(c) Is the analogue of (a) true for SO(2) acting on the unit circle of $\mathbb{R}^2$? And for SO(4) acting on the unit sphere of $\mathbb{R}^4$? Justify your answers.

Solution.

(a) Extend $\mathbf{u}$ to an orthonormal basis $(\mathbf{u}, \mathbf{a}_2, \mathbf{a}_3)$ of $\mathbb{R}^3$ (Corollary 10.2.3), and likewise extend $\mathbf{v}$ to $(\mathbf{v}, \mathbf{b}_2, \mathbf{b}_3)$. Let $\mathbf{A} = (\mathbf{u} \mid \mathbf{a}_2 \mid \mathbf{a}_3)$ and $\mathbf{B} = (\mathbf{v} \mid \mathbf{b}_2 \mid \mathbf{b}_3)$; both are orthogonal, since their columns are orthonormal (Theorem 10.7.3 (f)). Replacing $\mathbf{a}_3$ by $-\mathbf{a}_3$ changes the sign of $\det \mathbf{A}$ and keeps the basis orthonormal, so we may assume $\det \mathbf{A} = 1$, and likewise $\det \mathbf{B} = 1$. Put $\mathbf{Q} = \mathbf{B}\mathbf{A}^\top$. Then $\mathbf{Q} \in \mathrm{O}(3)$ and $\det \mathbf{Q} = \det \mathbf{B} \det \mathbf{A}^\top = 1$ by Theorem 6.5.4 and Theorem 6.4.5, so $\mathbf{Q} \in \mathrm{SO}(3)$; and $\mathbf{A}^\top \mathbf{u} = \mathbf{e}_1$, because the entries of $\mathbf{A}^\top \mathbf{u}$ are the inner products of $\mathbf{u}$ with the columns of $\mathbf{A}$, so $\mathbf{Q}\mathbf{u} = \mathbf{B}\mathbf{e}_1 = \mathbf{v}$.

(b) ($\supseteq$) Each $\mathbf{R}_{\mathbf{u},\theta}$ lies in SO(3) and fixes $\mathbf{u}$, by Theorem 11.6.4 (b). ($\subseteq$) If $\mathbf{Q} \in \mathrm{SO}(3)$ fixes $\mathbf{u}$, write $\mathbf{Q} = \mathbf{R}_{\mathbf{n},\theta}$ with $\theta \in [0, \pi]$ (Theorem 11.6.4 (c)). If $\theta = 0$ then $\mathbf{Q} = \mathbf{I}_3 = \mathbf{R}_{\mathbf{u},0}$. Otherwise the fixed space of $\mathbf{Q}$ is exactly the line $\mathrm{span}(\mathbf{n})$, since in the basis of Theorem 11.6.4 (b) the matrix is $[1] \oplus \mathbf{R}_\theta$ and $\mathbf{R}_\theta$ fixes no non-zero vector for $\theta \in (0, \pi]$; so $\mathbf{u} = \pm\mathbf{n}$, and $\mathbf{R}_{-\mathbf{n},\theta} = \mathbf{R}_{\mathbf{n},-\theta}$ gives $\mathbf{Q} = \mathbf{R}_{\mathbf{u},\pm\theta}$. For the group claim: all these matrices are simultaneously $[1] \oplus \mathbf{R}_\theta$ in the *same* orthonormal basis $(\mathbf{u}, \mathbf{w}, \mathbf{K}_\mathbf{u}\mathbf{w})$, and $\mathbf{R}_\alpha \mathbf{R}_\beta = \mathbf{R}_{\alpha+\beta} = \mathbf{R}_\beta \mathbf{R}_\alpha$, so the set is closed under products and inverses and is abelian.

(c) Yes for SO(2): given unit $\mathbf{u}, \mathbf{v} \in \mathbb{R}^2$, write $\mathbf{u} = (\cos\alpha, \sin\alpha)$ and $\mathbf{v} = (\cos\beta, \sin\beta)$ and take $\mathbf{Q} = \mathbf{R}_{\beta-\alpha}$, which is in SO(2) and sends $\mathbf{u}$ to $\mathbf{v}$. Yes for SO(4) as well, by the same argument as (a): extend $\mathbf{u}$ and $\mathbf{v}$ to orthonormal bases of $\mathbb{R}^4$, fix the determinants to 1 by flipping the sign of the last vector if necessary, and take $\mathbf{Q} = \mathbf{B}\mathbf{A}^\top$. Nothing in that argument used the dimension 3 — transitivity holds for $\mathrm{SO}(n)$ with $n \geq 2$. What is special to $n = 3$ is the classification of the maps themselves, not their ability to move one unit vector to another.

11.7 Commuting Families

Chapter 8 asked when several operators can be diagonalized in one basis and answered: exactly when they commute, provided each of them is diagonalizable on its own. With an inner product in hand the question sharpens in the same way the spectral theorem sharpened diagonalization. Can one **orthonormal** basis diagonalize all of them at once? For normal operators over $\mathbb{C}$ the answer is yes, and the proof is the chapter's signature move applied family-wide: cut the space into the eigenspaces of one member and recurse.

Throughout, V is a finite-dimensional inner product space over $F = \mathbb{R}$ or $\mathbb{C}$, and a family $\mathcal{F} \subseteq \mathcal{L}(V)$ is called **commuting** if $ST = TS$ for all $S, T \in \mathcal{F}$, as in Chapter 8.

11.7.1 What Chapter 8 already gives, and what is missing

Three results from Chapter 8 do the bookkeeping, and it is worth being exact about what each one delivers.

- Theorem 8.9.1: if $ST = TS$ then every eigenspace $E_\lambda(T)$ is S-invariant. No hypothesis at all beyond commuting — not even finite dimension. This is what lets us look for common eigenvectors *inside* an eigenspace.
- Theorem 8.9.3: a commuting family whose characteristic polynomials all split has a common eigenvector. Over $\mathbb{C}$ the splitting is automatic.
- Theorem 8.9.5 and Theorem 8.9.6: a commuting family of **diagonalizable** operators is simultaneously diagonalizable (Definition 8.9.1), and conversely.

Two things are missing from that list. First, diagonalizability is a hypothesis there, and it has to be checked separately for each member. Second, and more to the point here, the common basis produced is just a basis: nothing says its vectors are orthogonal, and in general they are not.

Normality repairs both at once, over $\mathbb{C}$. It repairs the first because a normal operator is automatically diagonalizable, by Theorem 11.4.2. It repairs the second because that same theorem produces an *orthonormal* eigenbasis, so the pieces we cut the space into are mutually orthogonal.

One more ingredient is needed before the recursion can run: after cutting V into the eigenspaces of one member, the other members must still be normal on each piece. Section 3 supplies exactly this. An invariant subspace of a normal operator is automatically invariant under the adjoint as well, and the restriction to it is again normal: that is Proposition 11.3.6, proved there by a trace computation on the block form. Over $\mathbb{R}$ the self-adjoint version is Theorem 11.2.4. (What fails, as the warning of Section 3 records, is the analogous statement for a subspace that is **not** invariant: a principal submatrix of a normal matrix need not be normal.) With that recalled, nothing stands in the way.

11.7.2 One orthonormal basis for the whole family

Theorem 11.7.1 — One Orthonormal Eigenbasis for a Commuting Family

Let $V \neq \{\mathbf{0}\}$ be a finite-dimensional **complex** inner product space and let $\mathcal{F} \subseteq \mathcal{L}(V)$ be a non-empty commuting family of **normal** operators. Then V has an orthonormal basis $\mathcal{B}$ each of whose vectors is an eigenvector of every $T \in \mathcal{F}$; equivalently, $[T]_{\mathcal{B}}$ is diagonal for every $T \in \mathcal{F}$.

Conversely, if some orthonormal basis $\mathcal{B}$ makes every $[T]_{\mathcal{B}}$ diagonal, then $\mathcal{F}$ is commuting and every member of $\mathcal{F}$ is normal.

Idea. Induction on $\dim V$, with the two cases that every such induction has. If every member of the family is a scalar multiple of the identity, any orthonormal basis will do and there is nothing to arrange. Otherwise some $T_0 \in \mathcal{F}$ has at least two distinct eigenvalues, and Theorem 11.4.2 splits V into the eigenspaces of T_0 — **orthogonally**,

and into pieces strictly smaller than V. Each piece is invariant under the whole family because the operators commute, and the restriction of a normal operator to an invariant subspace is normal, so each restricted family is again a commuting family of normal operators on a smaller space. Run the induction on each piece and glue.

Proof. Induction on $n = \dim V \geq 1$.

If $n = 1$, any unit vector $\mathbf{v}$ of V is a basis, and $T\mathbf{v} \in V = \operatorname{span}(\mathbf{v})$ makes $\mathbf{v}$ an eigenvector of every $T \in \mathcal{L}(V)$.

Let $n \geq 2$ and assume the theorem for all complex inner product spaces of dimension less than n.

Case 1: every $T \in \mathcal{F}$ is a scalar multiple of id_V. Then every non-zero vector is an eigenvector of every $T \in \mathcal{F}$, and V has an orthonormal basis by Theorem 10.2.2.

Case 2: some $T_0 \in \mathcal{F}$ is not a scalar multiple of id_V. Since T_0 is normal, Theorem 11.4.2 gives an orthonormal basis $\mathcal{C} = (\mathbf{c}_1, \dots, \mathbf{c}_n)$ of V with $T_0\mathbf{c}_j = \mu_j \mathbf{c}_j$. Let $\lambda_1, \dots, \lambda_k$ be the distinct values among $\mu_1, \dots, \mu_n$, and put

$$V_i = \operatorname{span}\{\mathbf{c}_j : \mu_j = \lambda_i\}, \qquad i = 1, \dots, k.$$

The V_i are spanned by disjoint sub-lists of an orthonormal basis, so they are pairwise orthogonal, $V = V_1 \oplus \cdots \oplus V_k$, and $\dim V_1 + \cdots + \dim V_k = n$.

Claim. $V_i = E_{\lambda_i}(T_0)$ for each i.

Proof. The inclusion $V_i \subseteq E_{\lambda_i}(T_0)$ holds because every spanning vector $\mathbf{c}_j$ of V_i satisfies $T_0\mathbf{c}_j = \lambda_i \mathbf{c}_j$. Conversely let $\mathbf{v} \in E_{\lambda_i}(T_0)$ and write $\mathbf{v} = \mathbf{v}_1 + \cdots + \mathbf{v}_k$ with $\mathbf{v}_j \in V_j$. Applying T_0, which acts as λ_j on V_j, gives $\sum_j \lambda_j \mathbf{v}_j = T_0\mathbf{v} = \lambda_i \mathbf{v} = \sum_j \lambda_i \mathbf{v}_j$, so $\sum_j (\lambda_j - \lambda_i)\mathbf{v}_j = \mathbf{0}$. The sum being direct, each term vanishes, and $\lambda_j \neq \lambda_i$ for $j \neq i$ forces $\mathbf{v}_j = \mathbf{0}$. Hence $\mathbf{v} = \mathbf{v}_i \in V_i$. ∎

Because T_0 is not a scalar multiple of id_V, we have $k \geq 2$: if $k = 1$ then $V = V_1 = E_{\lambda_1}(T_0)$ and $T_0 = \lambda_1 \mathrm{id}_V$. Hence $\dim V_i < n$ for every i.

Fix i and let $S \in \mathcal{F}$. By Theorem 8.9.1, $V_i = E_{\lambda_i}(T_0)$ is S-invariant, and therefore $S|_{V_i}$ is a normal operator on V_i by Proposition 11.3.6. Moreover the family

$$\mathcal{F}_i = \{\, S|_{V_i} : S \in \mathcal{F} \,\}$$

is commuting, since $(S|_{V_i})(T|_{V_i}) = (ST)|_{V_i} = (TS)|_{V_i} = (T|_{V_i})(S|_{V_i})$ for $S, T \in \mathcal{F}$, all four restrictions being defined because V_i is invariant.

By the inductive hypothesis applied to $V_i \neq \{\mathbf{0}\}$ and $\mathcal{F}_i$, there is an orthonormal basis $\mathcal{B}_i$ of V_i whose vectors are eigenvectors of every $S|_{V_i}$; such a vector $\mathbf{v} \in V_i$ satisfies $S\mathbf{v} = (S|_{V_i})\mathbf{v} = \mu\mathbf{v}$, so it is an eigenvector of S itself. Let $\mathcal{B}$ be the concatenation $\mathcal{B}_1, \dots, \mathcal{B}_k$. It is orthonormal, because each $\mathcal{B}_i$ is and because $V_i \perp V_j$ for $i \neq j$, and it has $\sum_i \dim V_i = n$ vectors, so it is an orthonormal basis of V (Theorem 10.1.4 and Theorem 1.6.4). Every vector of $\mathcal{B}$ is an eigenvector of every $T \in \mathcal{F}$. This completes the induction.

For the converse, suppose every $[T]_{\mathcal{B}}$ is diagonal with $\mathcal{B}$ orthonormal. Diagonal matrices commute, so $[ST]_{\mathcal{B}} = [TS]_{\mathcal{B}}$ and hence $ST = TS$ (Theorem 3.6.4). And $[T^*]_{\mathcal{B}} = ([T]_{\mathcal{B}})^*$ by Theorem 10.6.3 is diagonal as well, so $[T^*T]_{\mathcal{B}}$ and $[TT^*]_{\mathcal{B}}$ are products of diagonal matrices in the two orders, hence equal; so T is normal. This proves the theorem.

■

Notice which hypothesis did which job. *Commuting* made the eigenspaces of T_0 invariant under the rest of the family; *normal* made those eigenspaces orthogonal and made the restrictions normal again; and *complex* is what makes T_0 have any eigenvalues at all. Drop any one of the three and the argument stops.

In matrix language:

Corollary 11.7.2 — Commuting Normal Matrices

Let $\mathbf{A}_1, \dots, \mathbf{A}_r \in M_n(\mathbb{C})$ be normal and pairwise commuting. Then there is a unitary $\mathbf{U} \in \mathrm{U}(n)$ such that $\mathbf{U}^*\mathbf{A}_i\mathbf{U}$ is diagonal for every i. The same holds for an arbitrary commuting family of normal matrices in $M_n(\mathbb{C})$.

Proof. Apply Theorem 11.7.1 to the family $\{T_{\mathbf{A}_1}, \dots, T_{\mathbf{A}_r}\}$ on $\mathbb{C}^n$. Each $T_{\mathbf{A}_i}$ is normal because $T_{\mathbf{A}_i}^* = T_{\mathbf{A}_i^*}$ (Theorem 10.6.3, the standard basis being orthonormal) and $\mathbf{A}_i^*\mathbf{A}_i = \mathbf{A}_i\mathbf{A}_i^*$; and the operators commute because the matrices do. Let $\mathbf{U}$ have the resulting orthonormal basis $\mathcal{B}$ as its columns; then $\mathbf{U} \in \mathrm{U}(n)$ by Theorem 10.7.3 (f), and $\mathbf{U}^*\mathbf{A}_i\mathbf{U} = \mathbf{U}^{-1}\mathbf{A}_i\mathbf{U} = [T_{\mathbf{A}_i}]_{\mathcal{B}}$ is diagonal by Theorem 3.7.3. Nothing in the argument used that the family is finite.

■

Corollary 11.7.3 — Commuting Symmetric Matrices

Let V be a finite-dimensional **real** inner product space and let $\mathcal{F} \subseteq \mathcal{L}(V)$ be a nonempty commuting family of self-adjoint operators. Then V has an orthonormal basis of common eigenvectors. Equivalently, if $\mathbf{A}_1, \dots, \mathbf{A}_r \in M_n(\mathbb{R})$ are symmetric and pairwise commuting, there is $\mathbf{Q} \in \mathrm{O}(n)$ with every $\mathbf{Q}^{\top}\mathbf{A}_i\mathbf{Q}$ diagonal.

Proof. Repeat the proof of Theorem 11.7.1 word for word, with two substitutions: use Theorem 11.5.1 in place of Theorem 11.4.2 to split V into the eigenspaces of a member T_0 that is not a scalar multiple of id_V, and use Theorem 11.2.4 (b) in place of Proposition 11.3.6 to see that each restriction $S|_{V_i}$ is again self-adjoint. Every other step is unchanged, and the only property of $\mathbb{C}$ used in the original was the existence of an eigenvalue, which Theorem 11.5.1 supplies over $\mathbb{R}$ from self-adjointness. The matrix statement follows as in Corollary 11.7.2, using Corollary 11.5.2 and $\mathbf{Q}^{\top} = \mathbf{Q}^{-1}$.

■

Example. (Two Commuting Symmetric Matrices, Diagonalized Together)

Let
$$\mathbf{A} = \begin{pmatrix} 0 & 1 & 1 \\ 1 & 0 & 1 \\ 1 & 1 & 0 \end{pmatrix}, \qquad \mathbf{B} = \begin{pmatrix} 2 & 0 & 0 \\ 0 & 1 & 1 \\ 0 & 1 & 1 \end{pmatrix} \in M_3(\mathbb{R}).$$
Check that $\mathbf{AB} = \mathbf{BA}$ and find $\mathbf{Q} \in \mathrm{O}(3)$ with $\mathbf{Q}^{\top}\mathbf{AQ}$ and $\mathbf{Q}^{\top}\mathbf{BQ}$ both diagonal.

Solution. They commute. Multiplying out,
$$\mathbf{AB} = \begin{pmatrix} 0 & 2 & 2 \\ 2 & 1 & 1 \\ 2 & 1 & 1 \end{pmatrix} = \mathbf{BA}.$$

Both matrices are symmetric, so Corollary 11.7.3 applies.

Diagonalize $\mathbf{A}$. Each row of $\mathbf{A}$ sums to 2, so $\mathbf{A}(1,1,1) = (2,2,2)$ and 2 is an eigenvalue with eigenvector $(1,1,1)$. Also $\mathbf{A} = \mathbf{1}\mathbf{1}^{\top} - \mathbf{I}_3$, where $\mathbf{1} = (1,1,1)$; any $\mathbf{v}$ with $\mathbf{1}^{\top}\mathbf{v} = 0$, that is with $v_1 + v_2 + v_3 = 0$, satisfies $\mathbf{Av} = -\mathbf{v}$. So $E_2(\mathbf{A}) = \operatorname{span}((1,1,1))$ and $E_{-1}(\mathbf{A})$ is the plane $v_1 + v_2 + v_3 = 0$, and these account for all of $\mathbb{R}^3$.

The one-dimensional eigenspace. By Theorem 8.9.1 the line $E_2(\mathbf{A})$ is $\mathbf{B}$-invariant, so its spanning vector must already be an eigenvector of $\mathbf{B}$. Indeed $\mathbf{B}(1,1,1) = (2,2,2)$.

The plane. Inside $E_{-1}(\mathbf{A})$ we must search. The matrix $\mathbf{B}$ has $\mathbf{B}(0,1,-1) = (0,0,0)$ and $\mathbf{B}(-2,1,1) = (-4,2,2) = 2(-2,1,1)$, and both $(0,1,-1)$ and $(-2,1,1)$ have coordinate sum 0, so they lie in $E_{-1}(\mathbf{A})$. They are orthogonal, and independent, so they are a basis of the plane.

The common basis. Normalizing the three vectors,
$$\mathbf{Q} = \begin{pmatrix} 1/\sqrt{3} & -2/\sqrt{6} & 0 \\ 1/\sqrt{3} & 1/\sqrt{6} & 1/\sqrt{2} \\ 1/\sqrt{3} & 1/\sqrt{6} & -1/\sqrt{2} \end{pmatrix},$$
whose columns are orthonormal, so $\mathbf{Q} \in \mathrm{O}(3)$ by Theorem 10.7.3 (f). Then
$$\mathbf{Q}^{\top}\mathbf{AQ} = \operatorname{diag}(2,-1,-1), \qquad \mathbf{Q}^{\top}\mathbf{BQ} = \operatorname{diag}(2,2,0),$$
the diagonal entries being the eigenvalues found above, column by column. Neither matrix alone forces the choice: $\mathbf{A}$ cannot tell the second column from the third, and $\mathbf{B}$ cannot tell the first from the second. Together they pin down all three lines.

Warning. **Neither hypothesis can be dropped.**

Commuting is not enough. The matrices $\mathbf{A} = \begin{pmatrix} 1 & 1 \\ 0 & 2 \end{pmatrix}$ and $\mathbf{B} = \begin{pmatrix} 1 & 3 \\ 0 & 4 \end{pmatrix}$ satisfy $\mathbf{AB} = \begin{pmatrix} 1 & 7 \\ 0 & 8 \end{pmatrix} = \mathbf{BA}$, and each is diagonalizable, having two distinct eigenvalues. They even share the eigenbasis $\mathbf{e}_1, (1,1)$: $\mathbf{A}(1,1) = 2(1,1)$ and $\mathbf{B}(1,1) = 4(1,1)$. But that basis is not orthogonal, and no orthonormal one exists, because an orthonormal eigenbasis would make $\mathbf{A}$ normal (Corollary 11.4.3), whereas
$$\mathbf{A}^{*}\mathbf{A} = \begin{pmatrix} 1 & 1 \\ 1 & 5 \end{pmatrix} \neq \begin{pmatrix} 2 & 2 \\ 2 & 4 \end{pmatrix} = \mathbf{AA}^{*}.$$

Normal is not enough. The matrices $\mathbf{X} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$ and $\mathbf{Z} = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$ are real symmetric, hence normal, and each is orthogonally diagonalizable on its own. They do not commute:

$$\mathbf{XZ} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} \neq \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} = \mathbf{ZX}.$$

In fact they share no eigenvector at all: the eigenvectors of $\mathbf{Z}$ are the multiples of $\mathbf{e}_1$ and of $\mathbf{e}_2$, and $\mathbf{Xe}_1 = \mathbf{e}_2$ is a multiple of neither.

11.7.3 Sums and products stay normal

Normality is not preserved by addition or multiplication. It is preserved by both as soon as the two operators commute, and the common eigenbasis makes this a one-line matter.

Theorem 11.7.4 — Sums and Products of Commuting Normal Operators

Let V be a finite-dimensional complex inner product space and let $S, T \in \mathcal{L}(V)$ be normal with $ST = TS$. Then $S + T$ and ST are normal.

Proof. If $V = \{\mathbf{0}\}$ there is nothing to prove. Otherwise apply Theorem 11.7.1 to the family $\{S, T\}$: there is an orthonormal basis $\mathcal{B}$ with $[S]_{\mathcal{B}} = \mathbf{D}$ and $[T]_{\mathcal{B}} = \mathbf{D}'$ both diagonal. Then $[S+T]_{\mathcal{B}} = \mathbf{D} + \mathbf{D}'$ and $[ST]_{\mathcal{B}} = \mathbf{DD}'$ are diagonal, so every vector of $\mathcal{B}$ is an eigenvector of both operators, and both are normal by Theorem 11.4.2. ∎

Remark. Commutativity is essential, not a convenience. Take $\mathbf{M} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$, which is symmetric, and $\mathbf{N} = \operatorname{diag}(1, 2i)$, which is diagonal; both are normal and they do not commute. Then

$$\mathbf{M} + \mathbf{N} = \begin{pmatrix} 1 & 1 \\ 1 & 2i \end{pmatrix}, \qquad \mathbf{MN} = \begin{pmatrix} 0 & 2i \\ 1 & 0 \end{pmatrix},$$

and neither is normal: for the sum, $(\mathbf{M}+\mathbf{N})(\mathbf{M}+\mathbf{N})^*$ has $(1,2)$ entry $1 - 2i$ while $(\mathbf{M}+\mathbf{N})^*(\mathbf{M}+\mathbf{N})$ has $1 + 2i$ there; for the product, $(\mathbf{MN})(\mathbf{MN})^* = \operatorname{diag}(4, 1)$ while $(\mathbf{MN})^*(\mathbf{MN}) = \operatorname{diag}(1, 4)$.

Quick check. Let $\mathbf{A} \in M_n(\mathbb{C})$ be normal and let $p \in \mathbb{C}[x]$. Explain, without using Theorem 11.7.1, why $\mathbf{A}$ and $p(\mathbf{A})$ are simultaneously unitarily diagonalizable.

Solution. By Corollary 11.4.3, $\mathbf{A} = \mathbf{UDU}^*$ with $\mathbf{U}$ unitary and $\mathbf{D}$ diagonal. Then $\mathbf{A}^m = \mathbf{UD}^m\mathbf{U}^*$ for every $m \geq 0$, since the inner factors $\mathbf{U}^*\mathbf{U}$ cancel, so $p(\mathbf{A}) = \mathbf{U}p(\mathbf{D})\mathbf{U}^*$, and $p(\mathbf{D}) = \operatorname{diag}(p(d_1), \dots, p(d_n))$ is diagonal. The *same* $\mathbf{U}$ diagonalizes both. This is consistent with the theorem, since $\mathbf{A}$ and $p(\mathbf{A})$ commute and $p(\mathbf{A})$ is normal, being unitarily diagonalizable.

11.7.4 Without normality: simultaneous triangularization

If we ask only for triangular matrices, normality may be dropped entirely. Chapter 8 proved this with ordinary bases (Theorem 8.9.4); over $\mathbb{C}$ an inner product upgrades the basis to an orthonormal one, exactly as Theorem 11.1.2 upgraded Theorem 8.7.2.

Theorem 11.7.5 — Simultaneous Unitary Triangularization

Let $V \neq \{\mathbf{0}\}$ be a finite-dimensional complex inner product space and let $\mathcal{F} \subseteq \mathcal{L}(V)$ be a non-empty commuting family. Then there is an orthonormal basis $\mathcal{B}$ of V such that $[T]_{\mathcal{B}}$ is upper triangular for **every** $T \in \mathcal{F}$. In particular, if $\mathbf{A}_1, \dots, \mathbf{A}_r \in M_n(\mathbb{C})$ commute pairwise, there is $\mathbf{U} \in \mathrm{U}(n)$ with every $\mathbf{U}^*\mathbf{A}_i\mathbf{U}$ upper triangular.

Idea. The same swap that proves Schur's theorem (Theorem 11.1.2). A common eigenvector $\mathbf{v}$ of $\mathcal{F}$ gives an invariant line, but $\operatorname{span}(\mathbf{v})^{\perp}$ need not be invariant, so the recursion has nowhere to go. Take instead a common eigenvector $\mathbf{u}$ of the **adjoints** T^*: they commute too, and $\operatorname{span}(\mathbf{u})^{\perp}$ *is* invariant under every $T \in \mathcal{F}$. Recurse there, and put $\mathbf{u}$ at the **end** of the basis, where an upper triangular matrix allows an arbitrary column.

Proof. Induction on $n = \dim V \geq 1$. For $n = 1$ every 1×1 matrix is upper triangular, and a unit vector is an orthonormal basis.

Let $n \geq 2$ and assume the theorem in dimension $n - 1$. The family $\mathcal{F}^* = \{T^* : T \in \mathcal{F}\}$ is commuting: for $S, T \in \mathcal{F}$, $S^*T^* = (TS)^* = (ST)^* = T^*S^*$ by Theorem 10.6.2. Since V is a complex space, Theorem 8.9.3 provides $\mathbf{u} \neq \mathbf{0}$ with $T^*\mathbf{u} = \nu_T\mathbf{u}$ for every $T \in \mathcal{F}$; dividing by $\|\mathbf{u}\|$, take $\|\mathbf{u}\| = 1$.

Put $W = \operatorname{span}(\mathbf{u})$ and $U = W^{\perp}$, of dimension $n - 1$ by Theorem 10.3.2 (c). For each $T \in \mathcal{F}$ the line W is T^*-invariant, since $T^*\mathbf{u} = \nu_T\mathbf{u}$, so U is T-invariant by Lemma 11.1.1. The family $\{T|_U : T \in \mathcal{F}\}$ is commuting, by the same computation on restrictions as in the proof of Theorem 11.7.1. By the inductive hypothesis there is an orthonormal basis $(\mathbf{v}_1, \dots, \mathbf{v}_{n-1})$ of U in which every $[T|_U]$ is upper triangular.

Let $\mathcal{B} = (\mathbf{v}_1, \dots, \mathbf{v}_{n-1}, \mathbf{u})$. It is orthonormal, since $\mathbf{u}$ is a unit vector orthogonal to U, and it has n vectors, so it is an orthonormal basis of V. Fix $T \in \mathcal{F}$. For $j \leq n - 1$, $T\mathbf{v}_j = T|_U\mathbf{v}_j \in \operatorname{span}(\mathbf{v}_1, \dots, \mathbf{v}_j)$, because the matrix of $T|_U$ is upper triangular; so the j-th column of $[T]_{\mathcal{B}}$ has zeros below row j. The last column is unconstrained, and an upper triangular matrix permits any entries there. Hence $[T]_{\mathcal{B}}$ is upper triangular, which completes the induction.

For the matrix statement, apply this to the operators $T_{\mathbf{A}_i}$ on $\mathbb{C}^n$ and let $\mathbf{U}$ have the vectors of $\mathcal{B}$ as columns, as in Corollary 11.7.2.

■

The order matters: the common eigenvector of the adjoints goes last, and the triangular shape is built from the bottom right corner upward. Running the same recursion with a common eigenvector of $\mathcal{F}$ itself and putting it first would work only if $\operatorname{span}(\mathbf{v})^{\perp}$ were invariant, which is the extra fact that normality supplies and a bare commuting family does not.

11.7.5 Exercises

11.7.5.1 A. Check your understanding

Exercise A1.

(a) State Theorem 11.7.1, naming every hypothesis.

(b) Which result of Chapter 8 makes the eigenspaces of one member invariant under the others, and which hypothesis does it use?

(c) Why is the restriction of a normal operator to an invariant subspace again normal, and which earlier result says so? Why does the same fail for a subspace that is not invariant?

(d) True or false: two commuting diagonalizable matrices are simultaneously **unitarily** diagonalizable. Justify your answer.

(e) True or false: if S and T are normal then $S+T$ is normal. Justify your answer.

(f) Which hypothesis of Theorem 11.7.1 is dropped in Theorem 11.7.5, and what is lost in the conclusion?

Solution.

(a) Let $V \neq \{\mathbf{0}\}$ be a finite-dimensional **complex** inner product space and $\mathcal{F} \subseteq \mathcal{L}(V)$ a **non-empty** family of **normal** operators that **commute pairwise**. Then V has an orthonormal basis of common eigenvectors.

(b) Theorem 8.9.1: if $ST = TS$, then $E_\lambda(T)$ is S-invariant. The only hypothesis is that the two operators commute.

(c) Proposition 11.3.6: in an orthonormal basis adapted to U the matrix of a normal T is $\mathbf{A} = \begin{pmatrix} \mathbf{B} & \mathbf{C} \\ \mathbf{0} & \mathbf{D} \end{pmatrix}$, and comparing the traces of the $(1,1)$ blocks of $\mathbf{A}^*\mathbf{A}$ and $\mathbf{A}\mathbf{A}^*$ forces $\mathbf{C} = \mathbf{0}$; the matrix is then block diagonal and its first block is normal. For a subspace that is not invariant the zero block below is absent and the argument collapses: the Section 3 warning compresses the 3×3 cyclic shift to $\operatorname{span}(\mathbf{e}_1, \mathbf{e}_2)$ and gets a non-normal 2×2 matrix.

(d) False. $\begin{pmatrix} 1 & 1 \\ 0 & 2 \end{pmatrix}$ and $\begin{pmatrix} 1 & 3 \\ 0 & 4 \end{pmatrix}$ commute and are diagonalizable, but the first is not normal, so it has no orthonormal eigenbasis at all (Corollary 11.4.3). Simultaneous diagonalization by an invertible matrix is all that Chapter 8 promises (Theorem 8.9.5).

(e) False in general, true when they commute (Theorem 11.7.4). For a counterexample take $\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$ and $\operatorname{diag}(1, 2i)$, as in the Remark after that theorem.

(f) Normality. What is lost is that the common matrices are only upper triangular, not diagonal.

11.7.5.2 B. Practice

Exercise B1: Diagonalize two at once.

Let
$$\mathbf{A} = \begin{pmatrix} 2 & 1 & 1 \\ 1 & 2 & 1 \\ 1 & 1 & 2 \end{pmatrix}, \qquad \mathbf{B} = \begin{pmatrix} 2 & 0 & -2 \\ 0 & 2 & -2 \\ -2 & -2 & 4 \end{pmatrix} \in M_3(\mathbb{R}).$$

(a) Verify that $\mathbf{AB} = \mathbf{BA}$ and that both are symmetric.

(b) Find $\mathbf{Q} \in \mathrm{O}(3)$ with $\mathbf{Q}^{\top}\mathbf{AQ}$ and $\mathbf{Q}^{\top}\mathbf{BQ}$ both diagonal, and write down the two diagonal matrices.

(c) Explain why $\mathbf{A}$ on its own does not determine $\mathbf{Q}$ up to permuting and rescaling columns, but the pair does.

Solution.

(a) Both are equal to their transposes by inspection. Each row of $\mathbf{B}$ sums to 0 and each column too, so $\mathbf{1}\mathbf{1}^{\top}\mathbf{B} = \mathbf{0} = \mathbf{B}\mathbf{1}\mathbf{1}^{\top}$ where $\mathbf{1} = (1,1,1)$. Since $\mathbf{A} = \mathbf{1}\mathbf{1}^{\top} + \mathbf{I}_3$, we get $\mathbf{AB} = \mathbf{B} = \mathbf{BA}$. (Direct multiplication confirms $\mathbf{AB} = \mathbf{B}$.)

(b) The eigenvectors of $\mathbf{A} = \mathbf{1}\mathbf{1}^{\top} + \mathbf{I}_3$ are $\mathbf{1}$, with $\mathbf{A}\mathbf{1} = 3\mathbf{1} + \mathbf{1} = 4\mathbf{1}$, and every $\mathbf{v}$ with $v_1 + v_2 + v_3 = 0$, with $\mathbf{Av} = \mathbf{v}$. Inside that plane we search with $\mathbf{B}$:
$$\mathbf{B}(1,-1,0) = (2,-2,0) = 2(1,-1,0),$$
$$\mathbf{B}(1,1,-2) = (6,6,-12) = 6(1,1,-2),$$
and both vectors have coordinate sum 0. Also $\mathbf{B}\mathbf{1} = \mathbf{0}$. The three vectors $\mathbf{1}$, $(1,-1,0)$, $(1,1,-2)$ are pairwise orthogonal, as one checks from $1-1+0=0$, $1+1-2=0$ and $1-1+0=0$. Normalizing,
$$\mathbf{Q} = \begin{pmatrix} 1/\sqrt{3} & 1/\sqrt{2} & 1/\sqrt{6} \\ 1/\sqrt{3} & -1/\sqrt{2} & 1/\sqrt{6} \\ 1/\sqrt{3} & 0 & -2/\sqrt{6} \end{pmatrix},$$
and $\mathbf{Q}^{\top}\mathbf{AQ} = \mathrm{diag}(4,1,1)$, $\mathbf{Q}^{\top}\mathbf{BQ} = \mathrm{diag}(0,2,6)$.

(c) The eigenvalue 1 of $\mathbf{A}$ has a two-dimensional eigenspace, so *every* orthonormal basis of that plane serves $\mathbf{A}$ equally well, and there are infinitely many, not obtained from one another by permuting and rescaling columns. The matrix $\mathbf{B}$ has three distinct eigenvalues, so its eigenlines are determined, and the pair therefore determines the three lines of $\mathbf{Q}$ up to order and sign.

Exercise B2: Check the two warnings.

(a) For $\mathbf{A} = \begin{pmatrix} 1 & 1 \\ 0 & 2 \end{pmatrix}$ and $\mathbf{B} = \begin{pmatrix} 1 & 3 \\ 0 & 4 \end{pmatrix}$, find an invertible $\mathbf{P}$ with $\mathbf{P}^{-1}\mathbf{AP}$ and $\mathbf{P}^{-1}\mathbf{BP}$ diagonal, and show that no **unitary** $\mathbf{P}$ does this.

(b) For $\mathbf{X} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$ and $\mathbf{Z} = \mathrm{diag}(1,-1)$, write down an orthogonal $\mathbf{Q}_1$ diagonalizing $\mathbf{X}$ and an orthogonal $\mathbf{Q}_2$ diagonalizing $\mathbf{Z}$, and prove that no single invertible matrix diagonalizes both.

Solution.

(a) The common eigenvectors are $\mathbf{e}_1$ (eigenvalues 1 and 1) and $(1,1)$ (eigenvalues

2 and 4): $\mathbf{A}(1,1) = (2,2)$ and $\mathbf{B}(1,1) = (4,4)$. So $\mathbf{P} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$ works, with $\mathbf{P}^{-1}\mathbf{A}\mathbf{P} = \operatorname{diag}(1,2)$ and $\mathbf{P}^{-1}\mathbf{B}\mathbf{P} = \operatorname{diag}(1,4)$. If a unitary $\mathbf{P}$ did the same, then $\mathbf{A} = \mathbf{P}\mathbf{D}\mathbf{P}^*$ with $\mathbf{D}$ diagonal would be normal by Corollary 11.4.3; but $\mathbf{A}^*\mathbf{A} = \begin{pmatrix} 1 & 1 \\ 1 & 5 \end{pmatrix}$ and $\mathbf{A}\mathbf{A}^* = \begin{pmatrix} 2 & 2 \\ 2 & 4 \end{pmatrix}$ differ in every entry.

(b) $\mathbf{X}$ has eigenvectors $(1,1)$ and $(1,-1)$ for the eigenvalues 1 and -1, so $\mathbf{Q}_1 = \frac{1}{\sqrt{2}}\begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}$ gives $\mathbf{Q}_1^{\top}\mathbf{X}\mathbf{Q}_1 = \operatorname{diag}(1,-1)$. $\mathbf{Z}$ is already diagonal, so $\mathbf{Q}_2 = \mathbf{I}_2$. No single invertible $\mathbf{P}$ diagonalizes both: if it did, then $\mathbf{P}^{-1}\mathbf{X}\mathbf{P}$ and $\mathbf{P}^{-1}\mathbf{Z}\mathbf{P}$ would be diagonal, hence commuting, and multiplying by $\mathbf{P}$ and $\mathbf{P}^{-1}$ would give $\mathbf{X}\mathbf{Z} = \mathbf{Z}\mathbf{X}$. But $\mathbf{X}\mathbf{Z} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$ and $\mathbf{Z}\mathbf{X} = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}$.

Exercise B3: Triangularize two at once.

Let $\mathbf{A} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$ and $\mathbf{B} = \begin{pmatrix} 2 & 3 \\ 0 & 2 \end{pmatrix}$ in $M_2(\mathbb{C})$.

(a) Verify that $\mathbf{A}\mathbf{B} = \mathbf{B}\mathbf{A}$.

(b) Determine whether $\mathbf{A}$ and $\mathbf{B}$ are simultaneously diagonalizable, and justify your answer.

(c) Exhibit a unitary $\mathbf{U}$ with $\mathbf{U}^*\mathbf{A}\mathbf{U}$ and $\mathbf{U}^*\mathbf{B}\mathbf{U}$ both upper triangular, as Theorem 11.7.5 promises.

Solution.

(a) $\mathbf{A}\mathbf{B} = \begin{pmatrix} 2 & 5 \\ 0 & 2 \end{pmatrix} = \mathbf{B}\mathbf{A}$.

(b) No. If one basis made both diagonal, then $\mathbf{A}$ alone would be diagonalizable; but $p_{\mathbf{A}} = (x-1)^2$ and $\mathbf{A} - \mathbf{I}_2 = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} \neq \mathbf{0}$, so $\mathbf{A}$ has the single eigenvalue 1 with a one-dimensional eigenspace, and is not diagonalizable. This is the hypothesis that Theorem 8.9.5 needs and that commuting does not supply.

(c) $\mathbf{U} = \mathbf{I}_2$: both matrices are already upper triangular in the standard basis, which is orthonormal. The content of the theorem is that such a basis always exists, not that it is hard to find in this example.

11.7.5.3 C. Going deeper

Exercise C1: A special case of a theorem of Fuglede.

Let V be a finite-dimensional complex inner product space and let $S, T \in \mathcal{L}(V)$ be **both normal**, with $ST = TS$.

(a) Prove that $ST^* = T^*S$ and $S^*T = TS^*$.

(b) Deduce that $S + T^*$ and ST^* are normal.

(c) Give an example of two commuting operators, **not** both normal, for which the conclusion of (a) fails as stated for the pair — that is, exhibit commuting S, T

with $ST^* \neq T^*S$.

Note on the hypotheses: a theorem of Fuglede says that in (a) the operator S need not be assumed normal — it is enough that T be normal and that S commute with T. That stronger statement is true and is not proved in this book; (a) is only the case in which both are normal, and its proof uses the normality of S in an essential way.

Solution.

(a) By Theorem 11.7.1 applied to the commuting family $\{S, T\}$ of normal operators, there is an orthonormal basis $\mathcal{B}$ with $[S]_{\mathcal{B}} = \mathbf{D}$ and $[T]_{\mathcal{B}} = \mathbf{D}'$ diagonal. By Theorem 10.6.3, $[T^*]_{\mathcal{B}} = (\mathbf{D}')^*$, which is the diagonal matrix with the conjugated entries. Diagonal matrices commute, so

$$[ST^*]_{\mathcal{B}} = \mathbf{D}(\mathbf{D}')^* = (\mathbf{D}')^*\mathbf{D} = [T^*S]_{\mathcal{B}},$$

and $ST^* = T^*S$ because a map is determined by its matrix (Theorem 3.6.4). Exchanging the roles of S and T gives $TS^* = S^*T$.

(b) T^* is normal, since $(T^*)^*T^* = TT^* = T^*T = T^*(T^*)^*$. By (a), S and T^* commute, and both are normal, so Theorem 11.7.4 applies to the pair (S, T^*) and gives that $S + T^*$ and ST^* are normal.

(c) Take $S = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$ and $T = \mathbf{I}_2$. They commute, T is normal, and S is not. Here $ST^* = S = T^*S$, so this pair does not refute anything — as the theorem of Fuglede predicts, since T is normal. Take instead $T = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$ and $S = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$, which commute, since both are polynomials in T. Then

$$ST^* = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}\begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ 1 & 0 \end{pmatrix}, \qquad T^*S = \begin{pmatrix} 0 & 0 \\ 1 & 1 \end{pmatrix},$$

which differ. Here it is T, not S, that fails to be normal, and that is exactly the hypothesis the theorem of Fuglede keeps.

Exercise C2: A commuting family of orthogonal projections.

Let $V \neq \{\mathbf{0}\}$ be a finite-dimensional inner product space over $F = \mathbb{R}$ or $\mathbb{C}$, and let $P_1, \dots, P_r \in \mathcal{L}(V)$ be the orthogonal projections onto subspaces $U_1, \dots, U_r$, pairwise commuting.

(a) Prove that there is an orthonormal basis $\mathcal{B}$ of V such that every vector of $\mathcal{B}$ lies in U_i or in $U_i^{\perp}$, for every i.

(b) Deduce that P_iP_j is the orthogonal projection onto $U_i \cap U_j$.

(c) Prove that $P_i + P_j$ is an orthogonal projection if and only if $U_i \perp U_j$, and identify the subspace in that case.

Hint for (a): the eigenvalues of an idempotent operator.

Solution.

(a) Each P_i is self-adjoint, by Example (Four Adjoints) (d). Over $\mathbb{R}$, Corollary 11.7.3

applies directly to the commuting family $\{P_1, \dots, P_r\}$; over $\mathbb{C}$ a self-adjoint operator is normal, since $P^*P = P^2 = PP^*$, so Theorem 11.7.1 applies. Either way there is an orthonormal basis $\mathcal{B}$ of common eigenvectors. Let $\mathbf{v} \in \mathcal{B}$ and fix i. If $P_i\mathbf{v} = \mu\mathbf{v}$, then $\mu^2\mathbf{v} = P_i^2\mathbf{v} = P_i\mathbf{v} = \mu\mathbf{v}$, so $\mu \in \{0, 1\}$, since $\mathbf{v} \neq \mathbf{0}$. If $\mu = 1$ then $\mathbf{v} = P_i\mathbf{v} \in \operatorname{im} P_i = U_i$; if $\mu = 0$ then $\mathbf{v} \in \ker P_i = U_i^\perp$ (Definition 10.3.2).

(b) Write $\mathcal{B} = (\mathbf{v}_1, \dots, \mathbf{v}_n)$ and let $W = U_i \cap U_j$. By (a) each $\mathbf{v}_t$ satisfies $P_i\mathbf{v}_t = a_t\mathbf{v}_t$ and $P_j\mathbf{v}_t = b_t\mathbf{v}_t$ with $a_t, b_t \in \{0, 1\}$, so $P_iP_j\mathbf{v}_t = a_tb_t\mathbf{v}_t$, which is $\mathbf{v}_t$ when $\mathbf{v}_t \in U_i \cap U_j$ and $\mathbf{0}$ otherwise. Let $L = \operatorname{span}\{\mathbf{v}_t : a_tb_t = 1\}$; then $L \subseteq W$. Conversely, if $\mathbf{w} \in W$, expand $\mathbf{w} = \sum_t c_t\mathbf{v}_t$; applying P_i gives $\mathbf{w} = \sum_t a_tc_t\mathbf{v}_t$, so $c_t = a_tc_t$ and hence $c_t = 0$ whenever $a_t = 0$, and likewise for b_t. So $\mathbf{w} \in L$ and $W = L$. Now P_iP_j fixes each $\mathbf{v}_t \in L$ and kills the rest, and by Theorem 10.3.3 (a) with the orthonormal basis $\{\mathbf{v}_t : a_tb_t = 1\}$ of W, so does P_W; two operators agreeing on a basis are equal, so $P_iP_j = P_W$.

(c) Write $Q = P_i + P_j$.

($\Rightarrow$) Suppose Q is the orthogonal projection onto some subspace W. Then $Q^2 = Q$ (Definition 10.3.2), and expanding,

$$P_i + P_j = Q^2 = P_i^2 + P_iP_j + P_jP_i + P_j^2 = P_i + P_j + 2P_iP_j,$$

using $P_i^2 = P_i$, $P_j^2 = P_j$ and $P_jP_i = P_iP_j$. Hence $2P_iP_j = 0$, so $P_iP_j = 0$. Now let $\mathbf{v} \in U_j$; then $P_i\mathbf{v} = P_i(P_j\mathbf{v}) = \mathbf{0}$, so $\mathbf{v} \in \ker P_i = U_i^\perp$. Therefore $U_j \subseteq U_i^\perp$, which says $U_i \perp U_j$.

($\Leftarrow$) Suppose $U_i \perp U_j$, so $U_j \subseteq U_i^\perp = \ker P_i$ and $U_i \subseteq \ker P_j$. For $\mathbf{v} \in U_i$ we get $Q\mathbf{v} = \mathbf{v} + \mathbf{0} = \mathbf{v}$, and symmetrically $Q\mathbf{v} = \mathbf{v}$ for $\mathbf{v} \in U_j$, so Q is the identity on $U_i \oplus U_j$. For $\mathbf{v} \in (U_i \oplus U_j)^\perp = U_i^\perp \cap U_j^\perp$ we get $Q\mathbf{v} = \mathbf{0} + \mathbf{0} = \mathbf{0}$. Since $V = (U_i \oplus U_j) \oplus (U_i \oplus U_j)^\perp$ by Theorem 10.3.2 (a), Q agrees with $P_{U_i \oplus U_j}$ on both summands, hence everywhere. So $P_i + P_j = P_{U_i \oplus U_j}$.

11.8 Spectral Resolutions and Functions of a Normal Operator

The last two sections produce an orthonormal basis of eigenvectors. A basis, though, is a choice: permute it, or rotate inside the eigenspace of a repeated eigenvalue, and the basis changes while the operator does not. This section rewrites the same information with nothing chosen — a list of eigenvalues, and the orthogonal projections onto their eigenspaces — and then spends it. Once an operator is written as $\lambda_1P_1 + \cdots + \lambda_kP_k$, any function whatsoever on those k numbers produces a new operator, and powers, square roots and exponentials all become one line of arithmetic on the spectrum.

Throughout, V is a **non-zero** finite-dimensional inner product space over $F = \mathbb{R}$ or $F = \mathbb{C}$, and $T \in \mathcal{L}(V)$. We say that T satisfies

$$(*) \qquad V \text{ has an orthonormal basis of eigenvectors of } T.$$

By Theorem 11.4.2 this holds over $\mathbb{C}$ exactly for the **normal** operators, and by Theorem 11.5.1 it holds over $\mathbb{R}$ exactly for the **self-adjoint** ones. Stating everything for an operator satisfying

$(*)$ covers both fields at once, and keeps in view the only property we ever use.

11.8.1 Grouping an eigenbasis by eigenvalue

Here is the observation the section runs on. Let $(\mathbf{e}_1, \dots, \mathbf{e}_n)$ be an orthonormal eigenbasis of T, with $T\mathbf{e}_j = \mu_j \mathbf{e}_j$. The list $\mu_1, \dots, \mu_n$ repeats: an eigenvalue of geometric multiplicity 3 appears three times. Sort the basis vectors into bundles by the eigenvalue they carry, and each bundle spans one eigenspace. Summing the coordinates of a vector inside one bundle is exactly projecting it onto that eigenspace — orthogonally, because the basis is orthonormal. So T is a weighted sum of perpendicular projections, one weight per **distinct** eigenvalue, and the weights and the projections no longer remember the basis.

A normal operator is a sum of perpendicular projections, weighted by its distinct eigenvalues.

Definition 11.8.1 — Spectral Resolution

Let $T \in \mathcal{L}(V)$ satisfy $(*)$, let $\lambda_1, \dots, \lambda_k$ be the **distinct** eigenvalues of T, and write $E_i = E_{\lambda_i}(T)$ for the corresponding eigenspaces. Let

$$P_i \coloneqq P_{E_i} \in \mathcal{L}(V)$$

be the **orthogonal** projection onto E_i (Definition 10.3.2). The identity

$$T = \lambda_1 P_1 + \lambda_2 P_2 + \cdots + \lambda_k P_k$$

is the **spectral resolution** of T, and the family $(P_1, \dots, P_k)$ is the **resolution of the identity** attached to T.

Two clauses carry weight. The eigenvalues are listed **once each**, so k is the number of distinct eigenvalues and not $\dim V$; and the projections are **orthogonal**, which is the whole content of the definition, since every diagonalizable operator has *some* such expression with oblique projections. That the displayed identity is true, and that the P_i fit together as neatly as one could want, is the next theorem.

Theorem 11.8.1 — The Spectral Resolution and Its Projections

Let $T \in \mathcal{L}(V)$ satisfy $(*)$, with distinct eigenvalues $\lambda_1, \dots, \lambda_k$, eigenspaces $E_i = E_{\lambda_i}(T)$ and $P_i = P_{E_i}$. Then:

(a) $V = E_1 \oplus \cdots \oplus E_k$, and $E_i \perp E_j$ whenever $i \neq j$;
(b) $P_i^* = P_i$ and $P_i^2 = P_i$ for every i, and $P_i P_j = 0$ whenever $i \neq j$;
(c) $P_1 + \cdots + P_k = \mathrm{id}_V$;
(d) $T = \lambda_1 P_1 + \cdots + \lambda_k P_k$;
(e) $TP_i = P_i T = \lambda_i P_i$ for every i.

Idea. Everything is read off one orthonormal eigenbasis. Sorting its vectors by eigenvalue cuts it into k bundles; the only thing to check is that the i-th bundle spans the **whole** of E_i, not just part of it, and that is a coordinate comparison. After that, (a) is the

orthonormality of the basis, (c) and (d) are the coordinate formula $\mathbf{v} = \sum_j \langle \mathbf{v}, \mathbf{e}_j \rangle \mathbf{e}_j$ with its terms grouped, and (b) and (e) are bookkeeping.

Proof. Let $\mathcal{B} = (\mathbf{e}_1, \dots, \mathbf{e}_n)$ be an orthonormal basis of V with $T\mathbf{e}_j = \mu_j \mathbf{e}_j$, which exists by $(*)$. Each $\mathbf{e}_j$ is non-zero, so each μ_j is an eigenvalue of T and therefore equals exactly one λ_i. Put

$$\mathcal{S}_i := \{\, j : \mu_j = \lambda_i \,\},$$

so that $\{1, \dots, n\}$ is the disjoint union of $\mathcal{S}_1, \dots, \mathcal{S}_k$.

Step 1. $E_i = \operatorname{span}(\mathbf{e}_j : j \in \mathcal{S}_i)$. The inclusion $(\supseteq)$ is immediate, since $T\mathbf{e}_j = \lambda_i \mathbf{e}_j$ for $j \in \mathcal{S}_i$. For $(\subseteq)$, let $\mathbf{v} \in E_i$ and write $\mathbf{v} = \sum_j c_j \mathbf{e}_j$ in the basis $\mathcal{B}$. Applying T,

$$\sum_j c_j \mu_j \mathbf{e}_j = T\mathbf{v} = \lambda_i \mathbf{v} = \sum_j c_j \lambda_i \mathbf{e}_j.$$

Coordinates in a basis are unique, so $c_j(\mu_j - \lambda_i) = 0$ for every j, and hence $c_j = 0$ unless $j \in \mathcal{S}_i$. In particular $\mathcal{S}_i \neq \varnothing$, because $E_i \neq \{\mathbf{0}\}$.

Step 2 (a). By Step 1, $V = \operatorname{span}(\mathcal{B}) = E_1 + \cdots + E_k$. If $i \neq j$, then $\mathcal{S}_i$ and $\mathcal{S}_j$ are disjoint and $\mathcal{B}$ is orthonormal, so every spanning vector of E_i is orthogonal to every spanning vector of E_j; hence $E_i \perp E_j$. Pairwise orthogonal subspaces are independent: if $\mathbf{u}_1 + \cdots + \mathbf{u}_k = \mathbf{0}$ with $\mathbf{u}_i \in E_i$, then pairing with $\mathbf{u}_l$ kills every term but one and leaves $\|\mathbf{u}_l\|^2 = 0$, so $\mathbf{u}_l = \mathbf{0}$. By Theorem 1.7.4 the sum is direct.

Step 3 (b). Each P_i is self-adjoint by Theorem 10.3.3 (b), and satisfies $P_i^2 = P_i$ with $\operatorname{im} P_i = E_i$ and $\ker P_i = E_i^{\perp}$ (Definition 10.3.2 and the discussion following it). For $i \neq j$, Step 2 gives $E_j \subseteq E_i^{\perp}$, so $\operatorname{im} P_j \subseteq \ker P_i$ and $P_i P_j = 0$.

Step 4 (c) and (d). By Step 1, $(\mathbf{e}_j : j \in \mathcal{S}_i)$ is an orthonormal basis of E_i, so Theorem 10.3.3 (a) gives

$$P_i \mathbf{v} = \sum_{j \in \mathcal{S}_i} \langle \mathbf{v}, \mathbf{e}_j \rangle \mathbf{e}_j \qquad (\mathbf{v} \in V).$$

Summing over i collects every index j exactly once, so by Theorem 10.2.1,

$$\sum_{i=1}^{k} P_i \mathbf{v} = \sum_{j=1}^{n} \langle \mathbf{v}, \mathbf{e}_j \rangle \mathbf{e}_j = \mathbf{v},$$

which is (c). Multiplying the i-th group by λ_i instead,

$$\begin{aligned} \sum_{i=1}^{k} \lambda_i P_i \mathbf{v} &= \sum_{i=1}^{k} \sum_{j \in \mathcal{S}_i} \langle \mathbf{v}, \mathbf{e}_j \rangle \, \lambda_i \mathbf{e}_j \\ &= \sum_{j=1}^{n} \langle \mathbf{v}, \mathbf{e}_j \rangle \, \mu_j \mathbf{e}_j = T\Big(\sum_{j=1}^{n} \langle \mathbf{v}, \mathbf{e}_j \rangle \mathbf{e}_j \Big) = T\mathbf{v}, \end{aligned}$$

where the second equality uses $\mu_j = \lambda_i$ for $j \in \mathcal{S}_i$, and the third the linearity of T together with $T\mathbf{e}_j = \mu_j \mathbf{e}_j$. This is (d).

Step 5 (e). For $\mathbf{v} \in V$ we have $P_i\mathbf{v} \in E_i$, so $T(P_i\mathbf{v}) = \lambda_i P_i\mathbf{v}$; thus $TP_i = \lambda_i P_i$. In the other order, (d) and (b) give

$$P_i T = P_i\Big(\sum_{j=1}^{k} \lambda_j P_j\Big) = \lambda_i P_i^2 = \lambda_i P_i.$$

This proves the theorem.

■

For matrices the picture is the familiar one, packaged differently. If $\mathbf{A} \in M_n(\mathbb{C})$ is normal, write $\mathbf{A} = \mathbf{U}\mathbf{D}\mathbf{U}^*$ with $\mathbf{U}$ unitary and $\mathbf{D}$ diagonal (Corollary 11.4.3). Grouping the columns $\mathbf{q}_1, \dots, \mathbf{q}_n$ of $\mathbf{U}$ by their eigenvalue turns this into

$$\mathbf{A} = \sum_{i=1}^{k} \lambda_i \mathbf{P}_i, \qquad \mathbf{P}_i = \sum_{j \in \mathcal{S}_i} \mathbf{q}_j \mathbf{q}_j^*,$$

so each $\mathbf{P}_i$ is a sum of rank-one projections and $\operatorname{rank} \mathbf{P}_i = \dim E_i$.

Example. (A Symmetric 3×3 Matrix)

Let $\mathbf{A} = \begin{pmatrix} 1 & 2 & 2 \\ 2 & 1 & 2 \\ 2 & 2 & 1 \end{pmatrix} \in M_3(\mathbb{R})$. Find the spectral resolution of $\mathbf{A}$.

Solution. Write $\mathbf{A} = 2\mathbf{J} - \mathbf{I}$, where $\mathbf{J}$ is the all-ones matrix. Since $\mathbf{J}\mathbf{x} = (x_1 + x_2 + x_3)\mathbf{1}$, we get $\mathbf{J}\mathbf{1} = 3\mathbf{1}$ and $\mathbf{J}\mathbf{x} = \mathbf{0}$ exactly when $x_1 + x_2 + x_3 = 0$. So $\mathbf{J}$ has eigenvalues 3 and 0, and $\mathbf{A}$ has eigenvalues

$$\lambda_1 = 2 \cdot 3 - 1 = 5, \qquad \lambda_2 = 2 \cdot 0 - 1 = -1,$$

with $E_5 = \operatorname{span}(\mathbf{1})$ of dimension 1 and $E_{-1} = \mathbf{1}^{\perp}$ of dimension 2. Since $\|\mathbf{1}\|^2 = 3$, the orthogonal projection onto E_5 is $\mathbf{P}_1 = \frac{1}{3}\mathbf{1}\mathbf{1}^{\top} = \frac{1}{3}\mathbf{J}$, and $\mathbf{P}_2 = \mathbf{I} - \mathbf{P}_1$ by Theorem 11.8.1 (c). Concretely,

$$\mathbf{P}_1 = \frac{1}{3}\begin{pmatrix} 1 & 1 & 1 \\ 1 & 1 & 1 \\ 1 & 1 & 1 \end{pmatrix}, \qquad \mathbf{P}_2 = \frac{1}{3}\begin{pmatrix} 2 & -1 & -1 \\ -1 & 2 & -1 \\ -1 & -1 & 2 \end{pmatrix}.$$

Check. Both are symmetric, both satisfy $\mathbf{P}_i^2 = \mathbf{P}_i$, their product is 0, they sum to $\mathbf{I}$, and

$$5\mathbf{P}_1 - \mathbf{P}_2 = \tfrac{5}{3}\mathbf{J} - \mathbf{I} + \tfrac{1}{3}\mathbf{J} = 2\mathbf{J} - \mathbf{I} = \mathbf{A}.$$

Note that the resolution has two terms, not three: $k = 2$ counts **distinct** eigenvalues, while $\operatorname{rank} \mathbf{P}_2 = 2$ records the multiplicity of -1.

11.8.2 Orthogonal projections versus oblique ones

An expression $T = \sum \lambda_i \pi_i$ with idempotents summing to the identity is not by itself news. In the proof of Theorem 9.8.3 the semisimple part of T is written as $\sum_i \lambda_i \pi_i$, where $\pi_i = h_i(T)$

projects onto the generalized eigenspace $G_{\lambda_i}(T)$ along the sum of the others (Theorem 8.8.1 (d)); when T is diagonalizable, that is a decomposition of T itself, and those π_i satisfy $\pi_i^2 = \pi_i$, $\pi_i\pi_j = 0$ for $i \neq j$ and $\sum_i \pi_i = \mathrm{id}_V$, exactly as in Theorem 11.8.1 (b) and (c). What they do **not** satisfy is $\pi_i^* = \pi_i$, and that single missing condition is the whole difference between Chapter 9 and this section.

Example. (Two Projections That Are Not Orthogonal)

Let $\mathbf{A} = \begin{pmatrix} 1 & 1 \\ 0 & 2 \end{pmatrix} \in M_2(\mathbb{R})$, which is diagonalizable with eigenvalues 1 and 2. Compute the projections $\boldsymbol{\pi}_1, \boldsymbol{\pi}_2$ of Theorem 8.8.1 for $\mathbf{A}$, verify that $\mathbf{A} = \boldsymbol{\pi}_1 + 2\boldsymbol{\pi}_2$, and decide whether they are orthogonal projections.

Solution. The eigenspaces are $E_1 = \mathrm{span}(\mathbf{e}_1)$ and $E_2 = \mathrm{span}\big((1,1)\big)$, read off from $\mathbf{A} - \mathbf{I} = \begin{pmatrix} 0 & 1 \\ 0 & 1 \end{pmatrix}$ and $\mathbf{A} - 2\mathbf{I} = \begin{pmatrix} -1 & 1 \\ 0 & 0 \end{pmatrix}$. Since the eigenvalues are distinct, the generalized eigenspaces are the eigenspaces. With $\mathbf{P} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$ we have $\mathbf{P}^{-1}\mathbf{A}\mathbf{P} = \mathrm{diag}(1,2)$, so

$$\boldsymbol{\pi}_1 = \mathbf{P}\begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}\mathbf{P}^{-1} = \begin{pmatrix} 1 & -1 \\ 0 & 0 \end{pmatrix}, \qquad \boldsymbol{\pi}_2 = \mathbf{I} - \boldsymbol{\pi}_1 = \begin{pmatrix} 0 & 1 \\ 0 & 1 \end{pmatrix}.$$

Both square to themselves, their products vanish in both orders, they sum to $\mathbf{I}$, and

$$1 \cdot \boldsymbol{\pi}_1 + 2 \cdot \boldsymbol{\pi}_2 = \begin{pmatrix} 1 & -1 \\ 0 & 0 \end{pmatrix} + \begin{pmatrix} 0 & 2 \\ 0 & 2 \end{pmatrix} = \mathbf{A}.$$

They are **not** orthogonal projections: $\boldsymbol{\pi}_1^{\top} = \begin{pmatrix} 1 & 0 \\ -1 & 0 \end{pmatrix} \neq \boldsymbol{\pi}_1$. Geometrically, $\boldsymbol{\pi}_1$ projects onto $\mathrm{span}(\mathbf{e}_1)$ **along** $\mathrm{span}((1,1))$, and those two lines meet at $45°$, not at a right angle. Consistently, $\mathbf{A}$ is not normal:

$$\mathbf{A}^{\top}\mathbf{A} = \begin{pmatrix} 1 & 1 \\ 1 & 5 \end{pmatrix} \neq \begin{pmatrix} 2 & 2 \\ 2 & 4 \end{pmatrix} = \mathbf{A}\mathbf{A}^{\top}.$$

Warning. **"Diagonalizable" gives projections; only "normal" makes them orthogonal.** Every diagonalizable operator splits as $\sum \lambda_i \pi_i$ with idempotents that annihilate each other and sum to the identity, and Example (Two Projections That Are Not Orthogonal) is such a splitting for a matrix that is not normal. The projections there are not self-adjoint, so they are not the projections of Definition 11.8.1, and the eigenspaces they project onto are not perpendicular. Whenever an argument needs $\langle P_i\mathbf{u}, \mathbf{v}\rangle = \langle \mathbf{u}, P_i\mathbf{v}\rangle$ — and most of this section does — normality is what pays for it.

11.8.3 What makes a resolution the resolution

The projections in Definition 11.8.1 were built from the eigenspaces, so they are visibly determined by T. It is much more useful to know the converse: that *any* decomposition with the right formal properties has to be that one. This is what lets us recognize a spectral resolution when it turns up by accident, and it is the engine of the uniqueness proof for square roots below.

Theorem 11.8.2 — Uniqueness of the Spectral Resolution

Let V be a non-zero finite-dimensional inner product space over F and let $T \in \mathcal{L}(V)$. Suppose

$$T = \mu_1 Q_1 + \mu_2 Q_2 + \cdots + \mu_m Q_m,$$

where $\mu_1, \ldots, \mu_m \in F$ are **distinct** and $Q_1, \ldots, Q_m \in \mathcal{L}(V)$ are **non-zero** operators satisfying

(R1) $Q_i^* = Q_i$ and $Q_i^2 = Q_i$ for every i;
(R2) $Q_i Q_j = 0$ whenever $i \neq j$;
(R3) $Q_1 + \cdots + Q_m = \mathrm{id}_V$.

Then T satisfies $(*)$, $\mathrm{spec}(T) = \{\mu_1, \ldots, \mu_m\}$, and Q_i is the orthogonal projection onto $E_{\mu_i}(T)$ for every i. In particular m is the number of distinct eigenvalues of T, and the given decomposition is the spectral resolution of T.

Idea. Three moves. ① A self-adjoint idempotent is the orthogonal projection onto its own image: self-adjointness is used here and nowhere else, which is exactly why Example (Two Projections That Are Not Orthogonal) escapes the theorem. ② Conditions (R2) and (R3) then break V into the orthogonal direct sum of the images $U_i = \operatorname{im} Q_i$. ③ On U_i the operator T is multiplication by μ_i, so $U_i \subseteq E_{\mu_i}(T)$; and because the μ_i are distinct, an eigenvector of T cannot spread across two pieces, which upgrades the inclusion to an equality.

Proof. Write $U_i = \operatorname{im} Q_i$, which is non-zero because $Q_i \neq 0$.

Step 1. $Q_i = P_{U_i}$. Fix i and drop the subscript. If $\mathbf{u} \in U$, say $\mathbf{u} = Q\mathbf{x}$, then $Q\mathbf{u} = Q^2\mathbf{x} = Q\mathbf{x} = \mathbf{u}$, so Q is the identity on U. Next, $\ker Q = U^\perp$. Indeed, if $Q\mathbf{w} = \mathbf{0}$, then for every $\mathbf{x}$,

$$\langle \mathbf{w}, Q\mathbf{x} \rangle = \langle Q\mathbf{w}, \mathbf{x} \rangle = 0$$

by Definition 10.6.1 and (R1), so $\mathbf{w} \in U^\perp$; conversely if $\mathbf{w} \in U^\perp$, then $Q\mathbf{w} \in U$ and

$$\|Q\mathbf{w}\|^2 = \langle Q\mathbf{w}, Q\mathbf{w} \rangle = \langle \mathbf{w}, Q^2\mathbf{w} \rangle = \langle \mathbf{w}, Q\mathbf{w} \rangle = 0,$$

using (R1) twice and then $Q\mathbf{w} \in U \perp \mathbf{w}$; so $Q\mathbf{w} = \mathbf{0}$. Finally, for any $\mathbf{v} \in V$,

$$\mathbf{v} = Q\mathbf{v} + (\mathbf{v} - Q\mathbf{v}), \qquad Q\mathbf{v} \in U, \quad Q(\mathbf{v} - Q\mathbf{v}) = Q\mathbf{v} - Q^2\mathbf{v} = \mathbf{0},$$

so $\mathbf{v} - Q\mathbf{v} \in \ker Q = U^\perp$. This is the splitting of $\mathbf{v}$ in $U \oplus U^\perp$ (Theorem 10.3.2), so $Q\mathbf{v} = P_U \mathbf{v}$ by Definition 10.3.2.

Step 2. *$V = U_1 \oplus \cdots \oplus U_m$, orthogonally.* By (R3), every $\mathbf{v}$ equals $\sum_i Q_i \mathbf{v} \in \sum_i U_i$. For $i \neq j$, $\mathbf{u} = Q_i\mathbf{x}$ and $\mathbf{w} = Q_j\mathbf{y}$ satisfy

$$\langle \mathbf{u}, \mathbf{w} \rangle = \langle Q_i\mathbf{x}, Q_j\mathbf{y} \rangle = \langle Q_j Q_i \mathbf{x}, \mathbf{y} \rangle = 0$$

by (R1) and (R2), so $U_i \perp U_j$. As in Step 2 of the proof of Theorem 11.8.1, pairwise orthogonal subspaces are independent, so the sum is direct.

Step 3. *T acts on U_i as multiplication by μ_i.* Let $\mathbf{u} \in U_i$. By Step 1, $Q_i\mathbf{u} = \mathbf{u}$, and for

$j \neq i$, $Q_j\mathbf{u} = Q_jQ_i\mathbf{u} = \mathbf{0}$ by (R2). Hence

$$T\mathbf{u} = \sum_{l=1}^{m} \mu_l Q_l \mathbf{u} = \mu_i \mathbf{u}.$$

Since $U_i \neq \{\mathbf{0}\}$, this makes μ_i an eigenvalue of T, with $U_i \subseteq E_{\mu_i}(T)$.

Step 4. $\operatorname{spec}(T) = \{\mu_1, \dots, \mu_m\}$ *and* $U_i = E_{\mu_i}(T)$. Let λ be an eigenvalue of T with eigenvector $\mathbf{v} \neq \mathbf{0}$. By (R3), $\mathbf{v} = \sum_i Q_i\mathbf{v}$ with $Q_i\mathbf{v} \in U_i$, and by Step 3,

$$\sum_{i=1}^{m} \mu_i Q_i \mathbf{v} = T\mathbf{v} = \lambda\mathbf{v} = \sum_{i=1}^{m} \lambda Q_i \mathbf{v}.$$

Subtracting, $\sum_i (\mu_i - \lambda) Q_i\mathbf{v} = \mathbf{0}$ with the i-th term in U_i, so by the directness of Step 2 every term vanishes: $Q_i\mathbf{v} = \mathbf{0}$ whenever $\mu_i \neq \lambda$. As $\mathbf{v} \neq \mathbf{0}$, some $Q_i\mathbf{v} \neq \mathbf{0}$, and for that i we get $\lambda = \mu_i$. The μ_l being distinct, i is the only index with $\mu_i = \lambda$, so $\mathbf{v} = Q_i\mathbf{v} \in U_i$. Therefore $\operatorname{spec}(T) \subseteq \{\mu_1, \dots, \mu_m\}$ and $E_{\mu_i}(T) \subseteq U_i$; with Step 3 both are equalities.

Step 5. By Steps 1 and 4, $Q_i = P_{U_i} = P_{E_{\mu_i}(T)}$. Choosing an orthonormal basis of each U_i (Theorem 10.2.2) and concatenating gives an orthonormal basis of V by Step 2, made of eigenvectors of T by Step 3; so T satisfies $(*)$. This proves the theorem.

■

Read the other way round, the theorem is the complex spectral theorem again with no basis in sight: over $\mathbb{C}$, an operator is normal **if and only if** it can be written as $\sum \mu_i Q_i$ with distinct μ_i and non-zero self-adjoint idempotents satisfying (R2) and (R3) (Theorem 11.4.2). Conditions (R1)–(R3) are the entire content of the theorem, compressed into three lines of algebra.

Quick check. The matrices $\boldsymbol{\pi}_1, \boldsymbol{\pi}_2$ of Example (Two Projections That Are Not Orthogonal) satisfy $\boldsymbol{\pi}_i^2 = \boldsymbol{\pi}_i$, $\boldsymbol{\pi}_1\boldsymbol{\pi}_2 = \boldsymbol{\pi}_2\boldsymbol{\pi}_1 = 0$ and $\boldsymbol{\pi}_1 + \boldsymbol{\pi}_2 = \mathbf{I}$, and the coefficients 1 and 2 are distinct. Which hypothesis of Theorem 11.8.2 fails, and what does its failure cost?

Solution. Self-adjointness in (R1): $\boldsymbol{\pi}_1^{\top} \neq \boldsymbol{\pi}_1$. Everything else holds. The cost is Step 1 of the proof: $\boldsymbol{\pi}_1$ is a projection onto $\operatorname{span}(\mathbf{e}_1)$, but along $\operatorname{span}((1,1))$ rather than along $\operatorname{span}(\mathbf{e}_1)^{\perp} = \operatorname{span}(\mathbf{e}_2)$, so it is not $P_{\operatorname{span}(\mathbf{e}_1)}$. Consequently the two images are not perpendicular, and the conclusion fails at its strongest point: $\begin{pmatrix} 1 & 1 \\ 0 & 2 \end{pmatrix}$ does not satisfy $(*)$, since it is not normal.

11.8.4 Functions of an operator

Powers are now trivial. Multiplying the resolution by itself and using $P_iP_j = 0$ for $i \neq j$ leaves only the diagonal terms:

$$T^2 = \Big(\sum_i \lambda_i P_i\Big)\Big(\sum_j \lambda_j P_j\Big) = \sum_i \lambda_i^2 P_i,$$

and the same computation repeated gives $T^m = \sum_i \lambda_i^m P_i$. So $p(T) = \sum_i p(\lambda_i) P_i$ for every polynomial p. Stare at that formula and notice what it does **not** use: nothing about p except its k values on the spectrum. Any function at all supplies those.

Definition 11.8.2 — Function of an Operator

Let $T \in \mathcal{L}(V)$ satisfy $(*)$, with distinct eigenvalues $\lambda_1, \dots, \lambda_k$ and spectral resolution $T = \sum_i \lambda_i P_i$. For **any** function $f\colon \operatorname{spec}(T) \to F$, define

$$f(T) \coloneqq \sum_{i=1}^{k} f(\lambda_i)\, P_i \ \in \mathcal{L}(V).$$

In words: apply f to each eigenvalue and reweight the same projections. The function needs no continuity, no differentiability and no formula — it is k numbers. And the definition is unambiguous: the λ_i and the P_i are determined by T alone, by Theorem 11.8.2, so no choice of basis or of eigenvectors enters.

Four instances show the range. Taking $f(\lambda) = \lambda$ returns T. Taking $f \equiv 1$ returns id_V, by Theorem 11.8.1 (c). Taking $f(\lambda) = \overline{\lambda}$ returns T^*, since $P_i^* = P_i$. And if $0 \notin \operatorname{spec}(T)$, taking $f(\lambda) = \lambda^{-1}$ returns T^{-1}, because

$$\Big(\sum_i \lambda_i P_i\Big)\Big(\sum_j \lambda_j^{-1} P_j\Big) = \sum_i P_i = \mathrm{id}_V\,.$$

The notation is, on its face, dangerous. For a polynomial p the symbol $p(T)$ already means something — the operator $a_0\,\mathrm{id}_V + a_1 T + \cdots + a_N T^N$ of Definition 3.4.2, which Chapter 5 studied at length. If Definition 11.8.2 disagreed with it, the whole notation would have to be abandoned. Part (a) below says it does not, and that is the reason the rest of the theorem is safe to use.

Theorem 11.8.3 — Properties of the Functional Calculus

Let $T \in \mathcal{L}(V)$ satisfy $(*)$, with distinct eigenvalues $\lambda_1, \dots, \lambda_k$ and resolution of the identity $(P_1, \dots, P_k)$. Let $f, g\colon \operatorname{spec}(T) \to F$ and $c \in F$, with $f+g$, cf and fg taken pointwise.

(a) **(Compatibility)** For every $p \in F[x]$, the operator $p(T)$ of Definition 3.4.2 equals $\sum_i p(\lambda_i) P_i$; that is, it agrees with Definition 11.8.2 applied to the restriction of p to $\operatorname{spec}(T)$.

(b) **(Algebra homomorphism)** $(f+g)(T) = f(T) + g(T)$, $(cf)(T) = c\,f(T)$, $(fg)(T) = f(T)g(T) = g(T)f(T)$, and $1(T) = \mathrm{id}_V$.

(c) **(Adjoints)** $f(T)^* = \overline{f}(T)$, where $\overline{f}(\lambda) = \overline{f(\lambda)}$. In particular $f(T)$ is self-adjoint when f is real-valued, and unitary when $|f(\lambda_i)| = 1$ for every i.

(d) **(Spectral mapping)** $f(T)$ satisfies $(*)$, with the same orthonormal eigenbasis as T, and $\operatorname{spec}(f(T)) = f(\operatorname{spec}(T))$.

(e) **(Commutation)** If $S \in \mathcal{L}(V)$ commutes with T, then S commutes with every P_i and hence with $f(T)$. In particular T and $f(T)$ commute.

Idea. Everything rests on one multiplication table, $P_i P_j = \delta_{ij} P_i$. It says that the operators $\sum_i c_i P_i$ multiply exactly the way the coefficient lists $(c_1, \dots, c_k)$ multiply coordinatewise, so $\mathcal{L}(V)$ contains a copy of the algebra of all F-valued functions on $\operatorname{spec}(T)$, and $f \mapsto f(T)$ is the obvious map into it. That makes (b) and (c) one-line computations. The one statement needing an argument is (a) — that the copy sitting inside is

the *same* copy Chapter 3 built by substituting T into polynomials — and the argument is to compute the powers of T. For (e), a commuting S preserves each eigenspace, and an operator preserving all the summands of an orthogonal direct sum commutes with the projections onto them.

Proof.

(a) We first show that

$$T^m = \sum_{i=1}^{k} \lambda_i^m P_i \qquad \text{for every integer } m \geq 0,$$

with the usual convention $\lambda^0 = 1$. For $m = 0$ both sides equal id_V, by Theorem 11.8.1 (c). Assuming the formula for m, Theorem 11.8.1 (d) and (b) give

$$\begin{aligned} T^{m+1} = T \cdot T^m &= \Big(\sum_i \lambda_i P_i\Big)\Big(\sum_j \lambda_j^m P_j\Big) \\ &= \sum_{i,j} \lambda_i \lambda_j^m \, P_i P_j = \sum_i \lambda_i^{m+1} P_i, \end{aligned}$$

since $P_i P_j = 0$ for $i \neq j$ and $P_i^2 = P_i$. Now let $p = a_0 + a_1 x + \cdots + a_N x^N$. By Definition 3.4.2 and the formula just proved,

$$\begin{aligned} p(T) = \sum_{m=0}^{N} a_m T^m &= \sum_{m=0}^{N} a_m \sum_{i=1}^{k} \lambda_i^m P_i \\ &= \sum_{i=1}^{k} \Big(\sum_{m=0}^{N} a_m \lambda_i^m \Big) P_i = \sum_{i=1}^{k} p(\lambda_i) P_i, \end{aligned}$$

the middle step being a rearrangement of a finite double sum.

(b) The first two identities are immediate from Definition 11.8.2. For the product, Theorem 11.8.1 (b) gives

$$f(T)g(T) = \sum_{i,j} f(\lambda_i) g(\lambda_j) P_i P_j = \sum_i f(\lambda_i) g(\lambda_i) P_i,$$

which is $(fg)(T)$. The right-hand side is symmetric in f and g, so $f(T)g(T) = g(T)f(T)$. Finally $1(T) = \sum_i P_i = \mathrm{id}_V$ by Theorem 11.8.1 (c).

(c) By Theorem 10.6.2 (a) and (b), and $P_i^* = P_i$,

$$f(T)^* = \sum_{i=1}^{k} \overline{f(\lambda_i)}\, P_i^* = \overline{f}(T).$$

If f is real-valued then $\overline{f} = f$ and $f(T)^* = f(T)$. If $|f(\lambda_i)| = 1$ for all i, then $\overline{f} f \equiv 1$, so by (b) $f(T)^* f(T) = (\overline{f} f)(T) = \mathrm{id}_V$, and likewise $f(T) f(T)^* = \mathrm{id}_V$; so $f(T)$ is unitary (Definition 10.7.2).

(d) Let $\mathcal{B} = (\mathbf{e}_1, \ldots, \mathbf{e}_n)$ be an orthonormal eigenbasis of T, with $T\mathbf{e}_j = \mu_j \mathbf{e}_j$, and fix j. Let i be the index with $\mu_j = \lambda_i$. Then $\mathbf{e}_j \in E_i$, so $P_i \mathbf{e}_j = \mathbf{e}_j$, while $P_l \mathbf{e}_j = \mathbf{0}$

for $l \neq i$ because $E_i \subseteq E_l^{\perp} = \ker P_l$, by Theorem 11.8.1 (a) and Definition 10.3.2. Hence

$$f(T)\mathbf{e}_j = f(\lambda_i)\mathbf{e}_j = f(\mu_j)\,\mathbf{e}_j.$$

So $\mathcal{B}$ is an orthonormal basis of eigenvectors of $f(T)$, which is $(*)$ for $f(T)$. The matrix of $f(T)$ in $\mathcal{B}$ is $\operatorname{diag}(f(\mu_1), \dots, f(\mu_n))$, so its eigenvalues are exactly the numbers $f(\mu_j)$, that is the numbers $f(\lambda_i)$; hence $\operatorname{spec}(f(T)) = f(\operatorname{spec}(T))$.

(e) Suppose $ST = TS$. Each E_i is S-invariant: if $T\mathbf{v} = \lambda_i\mathbf{v}$, then $T(S\mathbf{v}) = S(T\mathbf{v}) = \lambda_i S\mathbf{v}$. Let $\mathbf{v} \in V$ and write $\mathbf{v} = \sum_i P_i\mathbf{v}$ with $P_i\mathbf{v} \in E_i$ (Theorem 11.8.1 (c)). Applying S gives $S\mathbf{v} = \sum_i SP_i\mathbf{v}$ with $SP_i\mathbf{v} \in E_i$, and this is the decomposition of $S\mathbf{v}$ in $E_1 \oplus \cdots \oplus E_k$, which is unique. Comparing it with $S\mathbf{v} = \sum_i P_i(S\mathbf{v})$ gives $P_iS\mathbf{v} = SP_i\mathbf{v}$ for every i, that is $SP_i = P_iS$. Hence S commutes with $f(T) = \sum_i f(\lambda_i)P_i$. Since T commutes with itself, the last claim follows. This proves the theorem.

■

Part (a) is what makes the notation honest. Writing $\sqrt{T}$, e^T and $p(T)$ in the same paragraph is legitimate precisely because the polynomial case is common ground: the new definition extends the old one instead of competing with it. It also reconciles this section with Chapter 9. An operator satisfying $(*)$ is diagonalizable, so every Jordan block of its matrix has size 1, and Definition 9.9.1 consults no derivatives at all — it too returns $\sum_i f(\lambda_i)\mathbf{P}_i$. The two constructions of $f(\mathbf{A})$ agree for normal $\mathbf{A}$, and Chapter 9's extra machinery is precisely the price of dropping normality.

Warning. **Outside the normal case, f on the spectrum is not enough data.** For $\mathbf{A} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$ the only eigenvalue is 0, so the recipe "$f(\mathbf{A}) = \sum_i f(\lambda_i)\mathbf{P}_i$" would read $f(\mathbf{A}) = f(0)\mathbf{I}$ for every f — and with $f(x) = x$ it would announce $\mathbf{A} = 0$. The recipe is not wrong, it is inapplicable: $\mathbf{A}$ is not normal, so there is no resolution of the identity to expand in. Chapter 9's definition of $f(\mathbf{A})$ has to consult $f'(0)$ as well (Definition 9.9.1), and that derivative is exactly what the missing orthogonality would have spared us.

Quick check. Let $T \in \mathcal{L}(V)$ satisfy $(*)$ with $\operatorname{spec}(T) = \{0, 1\}$. Identify T.

Solution. T is the orthogonal projection onto $E_1(T)$. Indeed the spectral resolution reads $T = 0 \cdot P_1 + 1 \cdot P_2 = P_2 = P_{E_1(T)}$. So the operators satisfying $(*)$ with spectrum in $\{0, 1\}$ are exactly the orthogonal projections, together with 0 and id_V for the degenerate spectra $\{0\}$ and $\{1\}$.

11.8.5 Square roots

The function $\lambda \mapsto \sqrt{\lambda}$ is defined on $[0, \infty)$, so Definition 11.8.2 produces a square root of T as soon as the spectrum lies there. The interesting part is that the square root is **unique** once we ask it to be of the same kind, and the uniqueness proof is a direct application of Theorem 11.8.2: a square root's own resolution, squared, has to be T's.

Note first that over $\mathbb{C}$ the hypothesis is stronger than it looks. If T satisfies $(*)$ and $\operatorname{spec}(T) \subseteq \mathbb{R}$, then $f(\lambda) = \lambda$ is real-valued on the spectrum, so $T = f(T)$ is self-adjoint by Theorem 11.8.3 (c). A normal operator with real spectrum is self-adjoint.

Theorem 11.8.4 — The Square Root of a Non-negative Normal Operator

Let V be a non-zero finite-dimensional inner product space over F and let $T \in \mathcal{L}(V)$ satisfy $(*)$ with $\operatorname{spec}(T) \subseteq [0, \infty)$. Then there is **exactly one** operator $S \in \mathcal{L}(V)$ such that

(i) S satisfies $(*)$;
(ii) $\operatorname{spec}(S) \subseteq [0, \infty)$;
(iii) $S^2 = T$.

It is $S = \sum_i \sqrt{\lambda_i}\, P_i$, where $T = \sum_i \lambda_i P_i$ is the spectral resolution of T. This S is self-adjoint, and it commutes with every operator that commutes with T.

Idea. Existence is the functional calculus applied to $\sqrt{\ }$: squaring a function squares its values. Uniqueness is where the work is, and the trick is not to compare S with the candidate directly but to *square S's own resolution.* If $S = \sum_j \mu_j Q_j$, then $S^2 = \sum_j \mu_j^2 Q_j$, and the μ_j^2 are still distinct because the μ_j are distinct **and non-negative**. So $\sum_j \mu_j^2 Q_j$ meets every condition of Theorem 11.8.2 for T, which forces it to be T's spectral resolution term by term.

Proof. Existence. Let $f(\lambda) = \sqrt{\lambda}$ on $\operatorname{spec}(T) \subseteq [0, \infty)$, which takes values in $[0, \infty) \subseteq F$, and put $S = f(T) = \sum_i \sqrt{\lambda_i} P_i$. Then f^2 is the function $\lambda \mapsto \lambda$, so by Theorem 11.8.3 (b) and (a),

$$S^2 = f(T)f(T) = (f^2)(T) = T,$$

giving (iii). By Theorem 11.8.3 (d), S satisfies $(*)$ and $\operatorname{spec}(S) = \{\sqrt{\lambda_1}, \dots, \sqrt{\lambda_k}\} \subseteq [0, \infty)$, giving (i) and (ii). Since f is real-valued, S is self-adjoint by Theorem 11.8.3 (c), and it commutes with everything commuting with T by (e) of the same theorem.

Uniqueness. Let S satisfy (i), (ii) and (iii), and let

$$S = \mu_1 Q_1 + \cdots + \mu_l Q_l$$

be its spectral resolution (Theorem 11.8.1): the μ_j are the distinct eigenvalues of S, and the Q_j are non-zero self-adjoint idempotents with $Q_j Q_{j'} = 0$ for $j \neq j'$ and $\sum_j Q_j = \mathrm{id}_V$. By Theorem 11.8.3 (a) applied to S and $p = x^2$,

$$T = S^2 = \sum_{j=1}^{l} \mu_j^2\, Q_j.$$

The scalars μ_j^2 are **distinct**: the μ_j are distinct by construction, and non-negative by (ii), so $\mu_j^2 = \mu_{j'}^2$ would force $\mu_j = \mu_{j'}$. The family $(Q_1, \dots, Q_l)$ satisfies (R1), (R2) and (R3) of Theorem 11.8.2, and every Q_j is non-zero. That theorem therefore identifies the displayed expression as the spectral resolution of T: after renumbering, $l = k$, $\mu_j^2 = \lambda_j$ and $Q_j = P_j$ for every j. Since $\mu_j \geq 0$ and $\mu_j^2 = \lambda_j$, we get $\mu_j = \sqrt{\lambda_j}$, and hence

$$S = \sum_{j=1}^{k} \sqrt{\lambda_j}\, P_j,$$

which is the operator constructed above. This proves the theorem.

■

The square root is written $\sqrt{T}$, or $T^{1/2}$. Chapter 12 takes the hypothesis $\operatorname{spec}(T) \subseteq [0, \infty)$ as the definition of a **positive** operator, proves that it is equivalent to $\langle T\mathbf{v}, \mathbf{v}\rangle \geq 0$ for all $\mathbf{v}$, and makes this theorem the tool behind polar decomposition and the singular value decomposition; the notation $\mathbf{A}^{1/2}$ in the notation table refers to exactly the operator built here.

Example. (A Square Root, and Three Impostors)

Let $\mathbf{A} = \begin{pmatrix} 10 & 6 \\ 6 & 10 \end{pmatrix} \in M_2(\mathbb{R})$. Find its spectral resolution, compute $\sqrt{\mathbf{A}}$ and $\mathbf{A}^m$, and find a symmetric square root of $\mathbf{A}$ other than $\sqrt{\mathbf{A}}$.

Solution. The resolution. $\mathbf{A}$ is symmetric, hence self-adjoint on $\mathbb{R}^2$. Since $\mathbf{A}(1,1) = (16,16)$ and $\mathbf{A}(1,-1) = (4,-4)$, the eigenvalues are 16 and 4, with eigenlines $\operatorname{span}((1,1))$ and $\operatorname{span}((1,-1))$. Both spanning vectors have squared length 2, so

$$\mathbf{P}_1 = \frac{1}{2}\begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix}, \qquad \mathbf{P}_2 = \frac{1}{2}\begin{pmatrix} 1 & -1 \\ -1 & 1 \end{pmatrix}, \qquad \mathbf{A} = 16\mathbf{P}_1 + 4\mathbf{P}_2.$$

The square root. Both eigenvalues are positive, so Theorem 11.8.4 applies:

$$\sqrt{\mathbf{A}} = 4\mathbf{P}_1 + 2\mathbf{P}_2 = \begin{pmatrix} 2 & 2 \\ 2 & 2 \end{pmatrix} + \begin{pmatrix} 1 & -1 \\ -1 & 1 \end{pmatrix} = \begin{pmatrix} 3 & 1 \\ 1 & 3 \end{pmatrix},$$

and indeed $\begin{pmatrix} 3 & 1 \\ 1 & 3 \end{pmatrix}^2 = \begin{pmatrix} 10 & 6 \\ 6 & 10 \end{pmatrix}$.

Powers. By Theorem 11.8.3 (a), $\mathbf{A}^m = 16^m\mathbf{P}_1 + 4^m\mathbf{P}_2$, that is

$$\mathbf{A}^m = \frac{1}{2}\begin{pmatrix} 16^m + 4^m & 16^m - 4^m \\ 16^m - 4^m & 16^m + 4^m \end{pmatrix}.$$

For $m = 3$ this reads $\begin{pmatrix} 2080 & 2016 \\ 2016 & 2080 \end{pmatrix}$, which is $\mathbf{A}^3$.

An impostor. Changing one sign gives $\mathbf{B} = 4\mathbf{P}_1 - 2\mathbf{P}_2 = \begin{pmatrix} 1 & 3 \\ 3 & 1 \end{pmatrix}$, and $\mathbf{B}^2 = \mathbf{A}$ as well. So $\mathbf{A}$ has more than one symmetric square root; $\mathbf{B}$ fails clause (ii) of Theorem 11.8.4, since $\operatorname{spec}(\mathbf{B}) = \{4, -2\}$. Flipping the other sign, and both, gives $-\mathbf{B}$ and $-\sqrt{\mathbf{A}}$: four symmetric square roots, and exactly one of them has non-negative spectrum.

Warning. **"A square root" and "the square root" are different things.** Uniqueness in Theorem 11.8.4 needs all three clauses. Dropping (ii) admits the three sign-flipped roots of Example (A Square Root, and Three Impostors). Dropping (i) admits more still, and the cheapest witness is the zero operator on $\mathbb{C}^2$. Take

$$\mathbf{S} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}, \qquad \mathbf{S}^2 = \mathbf{0}.$$

Here $\operatorname{spec}(\mathbf{S}) = \{0\} \subseteq [0, \infty)$, so (ii) holds, and (iii) holds by the display, yet $\mathbf{S} \neq \mathbf{0} = \sqrt{\mathbf{0}}$. Only (i) fails: $\mathbf{S}^*\mathbf{S} = \operatorname{diag}(0, 1)$ while $\mathbf{S}\mathbf{S}^* = \operatorname{diag}(1, 0)$. The phrase "**the** square root of T" always means the one satisfying all three.

11.8.6 The exponential and the unitary group

Chapter 9 defined $e^{\mathbf{A}}$ for every $\mathbf{A} \in M_n(\mathbb{C})$ as the sum of the series $\sum_m \mathbf{A}^m/m!$ (Definition 9.9.2) and proved that the series converges (Theorem 9.9.3). We do not redevelop any of that. What the spectral resolution adds is that for a normal matrix the series can be summed by inspection, and that the answer identifies the unitary matrices as the exponentials of the Hermitian ones — the matrix version of $|e^{i\theta}| = 1$.

Theorem 11.8.5 — Unitary Matrices Are Exponentials of Hermitian Matrices

Let $n \geq 1$.

(a) If $\mathbf{A} \in M_n(\mathbb{C})$ is normal with spectral resolution $\mathbf{A} = \sum_i \lambda_i \mathbf{P}_i$, then $e^{\mathbf{A}} = \sum_i e^{\lambda_i} \mathbf{P}_i$.

(b) If $\mathbf{H} \in M_n(\mathbb{C})$ is Hermitian, then $e^{i\mathbf{H}} \in \mathrm{U}(n)$, and $\det e^{i\mathbf{H}} = e^{i \operatorname{tr} \mathbf{H}}$.

(c) Conversely, every $\mathbf{U} \in \mathrm{U}(n)$ equals $e^{i\mathbf{H}}$ for some Hermitian $\mathbf{H}$, which may be chosen with $\operatorname{spec}(\mathbf{H}) \subseteq [0, 2\pi)$.

Idea. For (a), the partial sums of the series collapse: $\mathbf{A}^m = \sum_i \lambda_i^m \mathbf{P}_i$, so each partial sum is a fixed combination of the k scalar partial sums of $\sum_m \lambda_i^m/m!$, whose limits are the numbers e^{λ_i}. For (b) and (c), the resolution turns everything into a statement about k complex numbers: $\mathbf{H}$ Hermitian means real eigenvalues, $e^{i\mathbf{H}}$ then has eigenvalues on the unit circle, and a unitary matrix has eigenvalues on the unit circle, each of which is $e^{i\theta}$ for a unique $\theta \in [0, 2\pi)$. Reading the last sentence backwards constructs $\mathbf{H}$.

Proof.

(a) By Theorem 11.8.3 (a), $\mathbf{A}^m = \sum_i \lambda_i^m \mathbf{P}_i$ for every $m \geq 0$, so for every $N \geq 0$,

$$\sum_{m=0}^{N} \frac{\mathbf{A}^m}{m!} = \sum_{i=1}^{k} \Big(\sum_{m=0}^{N} \frac{\lambda_i^m}{m!} \Big) \mathbf{P}_i.$$

Fix a position (r, s). Its entry on the right is $\sum_i c_{N,i} \, (\mathbf{P}_i)_{rs}$, where $c_{N,i} = \sum_{m \leq N} \lambda_i^m/m!$ and the coefficients $(\mathbf{P}_i)_{rs}$ do not depend on N. Each $c_{N,i} \to e^{\lambda_i}$ as $N \to \infty$ by the scalar exponential series, so the entry converges to $\sum_i e^{\lambda_i} (\mathbf{P}_i)_{rs}$. Hence the series converges entrywise to $\sum_i e^{\lambda_i} \mathbf{P}_i$, and by Definition 9.9.2 this matrix is $e^{\mathbf{A}}$.

(b) $\mathbf{H}$ is normal, so it has a spectral resolution $\mathbf{H} = \sum_j \theta_j \mathbf{P}_j$, and its eigenvalues θ_j are real by Theorem 11.2.1. The scalars $i\theta_j$ are distinct, so $i\mathbf{H} = \sum_j i\theta_j \mathbf{P}_j$ is the spectral resolution of $i\mathbf{H}$ by Theorem 11.8.2, and (a) gives

$$e^{i\mathbf{H}} = \sum_j e^{i\theta_j} \mathbf{P}_j.$$

Each θ_j is real, so $\overline{e^{\,i\theta_j}}\,e^{\,i\theta_j} = |e^{\,i\theta_j}|^2 = 1$. Hence, using $\mathbf{P}_j^* = \mathbf{P}_j$ and $\mathbf{P}_j\mathbf{P}_{j'} = \delta_{jj'}\mathbf{P}_j$ from Theorem 11.8.1 (b),

$$\left(e^{i\mathbf{H}}\right)^* e^{i\mathbf{H}} = \sum_j \overline{e^{\,i\theta_j}}\,e^{\,i\theta_j}\,\mathbf{P}_j = \sum_j \mathbf{P}_j = \mathbf{I},$$

so $e^{i\mathbf{H}} \in \mathrm{U}(n)$ by Definition 10.7.3. For the determinant, Theorem 9.9.4 (e) gives $\det e^{i\mathbf{H}} = e^{\mathrm{tr}(i\mathbf{H})} = e^{\,i\,\mathrm{tr}\,\mathbf{H}}$.

(c) Let $\mathbf{U} \in \mathrm{U}(n)$. Then $\mathbf{U}^*\mathbf{U} = \mathbf{U}\mathbf{U}^* = \mathbf{I}$, so $\mathbf{U}$ is normal; let $\mathbf{U} = \sum_j \nu_j \mathbf{P}_j$ be its spectral resolution. Every eigenvalue has $|\nu_j| = 1$: if $\mathbf{U}\mathbf{x} = \nu_j\mathbf{x}$ with $\mathbf{x} \neq \mathbf{0}$, then $\|\mathbf{x}\| = \|\mathbf{U}\mathbf{x}\| = |\nu_j|\,\|\mathbf{x}\|$ because $\mathbf{U}$ is an isometry (Theorem 10.7.3), and $\|\mathbf{x}\| \neq 0$. So there is a unique $\theta_j \in [0, 2\pi)$ with $\nu_j = e^{\,i\theta_j}$, and the θ_j are distinct because the ν_j are. Put

$$\mathbf{H} \coloneqq \sum_j \theta_j \mathbf{P}_j.$$

The θ_j are real, so $\mathbf{H}^* = \sum_j \theta_j \mathbf{P}_j^* = \mathbf{H}$ by Theorem 10.6.2 (a), (b) and Theorem 11.8.1 (b): $\mathbf{H}$ is Hermitian, with $\mathrm{spec}(\mathbf{H}) = \{\theta_j\} \subseteq [0, 2\pi)$ by Theorem 11.8.2. By (a) applied to $i\mathbf{H}$,

$$e^{i\mathbf{H}} = \sum_j e^{\,i\theta_j}\mathbf{P}_j = \sum_j \nu_j \mathbf{P}_j = \mathbf{U}.$$

This proves the theorem.

■

Part (c) says that the exponential map from Hermitian matrices to $\mathrm{U}(n)$ is **onto**. One consequence belongs to topology rather than algebra, so we only record it: the path $t \mapsto e^{\,it\mathbf{H}}$, $t \in [0, 1]$, stays inside $\mathrm{U}(n)$ and runs from $\mathbf{I}$ to $\mathbf{U}$, so every unitary matrix can be deformed continuously to the identity. Nothing of the sort holds in $\mathrm{O}(n)$, where the determinant is ± 1 and cannot change sign along a path.

Example. (Exponentiating a Hermitian Matrix, and Undoing It)

Let $\mathbf{H} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$. Compute $e^{\,i\theta\mathbf{H}}$ for $\theta \in \mathbb{R}$. Then find a Hermitian $\mathbf{K}$ with $e^{i\mathbf{K}} = \mathbf{Q}$, where $\mathbf{Q} = \frac{1}{\sqrt{2}}\begin{pmatrix} 1 & -1 \\ 1 & 1 \end{pmatrix}$.

Solution. Forwards. $\mathbf{H}$ is symmetric with $\mathbf{H}(1,1) = (1,1)$ and $\mathbf{H}(1,-1) = -(1,-1)$, so its eigenvalues are ± 1 and

$$\mathbf{H} = \mathbf{P}_+ - \mathbf{P}_-, \qquad \mathbf{P}_\pm = \frac{1}{2}\begin{pmatrix} 1 & \pm 1 \\ \pm 1 & 1 \end{pmatrix}.$$

Hence $i\theta\mathbf{H}$ has resolution $i\theta\mathbf{P}_+ - i\theta\mathbf{P}_-$ (for $\theta \neq 0$), and Theorem 11.8.5 (a) gives

$$\begin{aligned} e^{\,i\theta\mathbf{H}} &= e^{\,i\theta}\mathbf{P}_+ + e^{-i\theta}\mathbf{P}_- \\ &= \begin{pmatrix} \cos\theta & i\sin\theta \\ i\sin\theta & \cos\theta \end{pmatrix}, \end{aligned}$$

using $e^{\pm i\theta} = \cos\theta \pm i\sin\theta$. Each row has squared length $\cos^2\theta + \sin^2\theta = 1$ and the two rows are orthogonal, confirming that the result is unitary.

Backwards. $\mathbf{Q}$ is the rotation by $\pi/4$, hence unitary, with $\mathbf{Q}(1,-i) = e^{i\pi/4}(1,-i)$ and $\mathbf{Q}(1,i) = e^{-i\pi/4}(1,i)$. Both eigenvectors have squared length 2, so the spectral projections are

$$\mathbf{R}_+ = \frac{1}{2}\begin{pmatrix} 1 & i \\ -i & 1 \end{pmatrix}, \qquad \mathbf{R}_- = \frac{1}{2}\begin{pmatrix} 1 & -i \\ i & 1 \end{pmatrix}.$$

Writing $e^{-i\pi/4} = e^{i\cdot 7\pi/4}$ to land in $[0, 2\pi)$, the recipe of Theorem 11.8.5 (c) gives

$$\mathbf{K} = \frac{\pi}{4}\mathbf{R}_+ + \frac{7\pi}{4}\mathbf{R}_- = \begin{pmatrix} \pi & -\frac{3\pi i}{4} \\ \frac{3\pi i}{4} & \pi \end{pmatrix},$$

Hermitian with spectrum $\{\pi/4,\ 7\pi/4\}$. Leaving $[0, 2\pi)$, the smaller choice $\frac{\pi}{4}(\mathbf{R}_+ - \mathbf{R}_-) = \frac{\pi}{4}\begin{pmatrix} 0 & i \\ -i & 0 \end{pmatrix}$ works just as well: the Hermitian logarithm is far from unique.

11.8.7 Exercises

11.8.7.1 A. Check your understanding

Exercise A1.

(a) Define the spectral resolution of T, and say which operators have one over $\mathbb{C}$ and which over $\mathbb{R}$.

(b) List the properties of the family $(P_1, \dots, P_k)$ given by Theorem 11.8.1, and say how many terms the resolution of a self-adjoint $T \in \mathcal{L}(\mathbb{R}^5)$ with eigenvalues $2, 2, 2, 7, 7$ has.

(c) True or false: if $T = \mu_1 Q_1 + \mu_2 Q_2$ with $\mu_1 \neq \mu_2$ and Q_1, Q_2 non-zero operators satisfying $Q_i^2 = Q_i$, $Q_1 Q_2 = Q_2 Q_1 = 0$ and $Q_1 + Q_2 = \mathrm{id}_V$, then T is normal. Justify your answer.

(d) Define $f(T)$ for a function f on $\mathrm{spec}(T)$, and say exactly how much information about f it uses.

(e) State Theorem 11.8.3 (a) and explain in one sentence why the rest of the section would be unusable without it.

(f) Give two different self-adjoint square roots of id_V on $\mathbb{R}^2$, and say which one Theorem 11.8.4 singles out and why.

Solution.

(a) For T with an orthonormal basis of eigenvectors, distinct eigenvalues $\lambda_1, \dots, \lambda_k$ and $P_i = P_{E_{\lambda_i}(T)}$ the orthogonal projection onto the i-th eigenspace, the spectral resolution is $T = \sum_i \lambda_i P_i$ (Definition 11.8.1). Over $\mathbb{C}$ the operators with one are exactly the normal operators (Theorem 11.4.2); over $\mathbb{R}$, exactly the self-adjoint ones (Theorem 11.5.1).

(b) Each P_i is self-adjoint and idempotent, $P_i P_j = 0$ for $i \neq j$, $\sum_i P_i = \mathrm{id}_V$, and $TP_i = P_i T = \lambda_i P_i$. The resolution has **two** terms, $T = 2P_1 + 7P_2$, with $\operatorname{rank} P_1 = 3$ and $\operatorname{rank} P_2 = 2$: the resolution counts distinct eigenvalues, not multiplicities.

(c) False. Self-adjointness of the Q_i is missing, and it is the one hypothesis of Theorem 11.8.2 that does the work. The matrices $\boldsymbol{\pi}_1, \boldsymbol{\pi}_2$ of Example (Two Projections That Are Not Orthogonal) satisfy everything listed, with $\mu_1 = 1$ and $\mu_2 = 2$, and $\boldsymbol{\pi}_1 + 2\boldsymbol{\pi}_2 = \begin{pmatrix} 1 & 1 \\ 0 & 2 \end{pmatrix}$, which is not normal.

(d) $f(T) = \sum_i f(\lambda_i) P_i$ (Definition 11.8.2). It uses exactly the k values $f(\lambda_1), \dots, f(\lambda_k)$; two functions agreeing on $\operatorname{spec}(T)$ give the same operator, and f need not be defined, let alone continuous, anywhere else.

(e) For $p \in F[x]$, the operator $\sum_i p(\lambda_i) P_i$ coincides with the operator $p(T)$ of Definition 3.4.2. Without it, the symbol $p(T)$ would carry two unrelated meanings at once, and no computation mixing polynomials with other functions — for instance $(\sqrt{T})^2 = T$ — could be trusted.

(f) id and the reflection $T_{\mathbf{D}}$ with $\mathbf{D} = \operatorname{diag}(1, -1)$, both self-adjoint with square id. Theorem 11.8.4 singles out id, because $\operatorname{spec}(\mathrm{id}) = \{1\} \subseteq [0, \infty)$ while $\operatorname{spec}(T_{\mathbf{D}}) = \{1, -1\}$ is not. (A third root is $-\mathrm{id}$, and a fourth is $T_{\mathbf{D}'}$ with $\mathbf{D}' = \operatorname{diag}(-1, 1)$.)

11.8.7.2 B. Practice

Exercise B1: Write these as $\sum \lambda_i \mathbf{P}_i$.

Find the spectral resolution of each of the following matrices, and check in each case that the projections are self-adjoint, idempotent, mutually annihilating and sum to $\mathbf{I}$.

(a) $\mathbf{A} = \begin{pmatrix} 2 & 1-i \\ 1+i & 3 \end{pmatrix} \in M_2(\mathbb{C})$.

(b) $\mathbf{S} = \begin{pmatrix} 2 & 0 & 1 \\ 0 & 3 & 0 \\ 1 & 0 & 2 \end{pmatrix} \in M_3(\mathbb{R})$.

(c) $\mathbf{U} = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & -1 \\ 1 & 1 \end{pmatrix} \in M_2(\mathbb{C})$.

Solution.

(a) $\mathbf{A}^* = \mathbf{A}$, $\operatorname{tr} \mathbf{A} = 5$ and $\det \mathbf{A} = 6 - (1-i)(1+i) = 4$, so $p_{\mathbf{A}} = x^2 - 5x + 4$ and $\operatorname{spec}(\mathbf{A}) = \{1, 4\}$. From $\mathbf{A} - 4\mathbf{I} = \begin{pmatrix} -2 & 1-i \\ 1+i & -1 \end{pmatrix}$ the first row gives the eigenvector $\mathbf{v}_4 = (1-i, 2)$, with $\|\mathbf{v}_4\|^2 = 2 + 4 = 6$; from $\mathbf{A} - \mathbf{I}$ likewise $\mathbf{v}_1 = (-1+i, 1)$, with $\|\mathbf{v}_1\|^2 = 3$. Hence

$$\mathbf{P}_4 = \frac{\mathbf{v}_4 \mathbf{v}_4^*}{6} = \frac{1}{3} \begin{pmatrix} 1 & 1-i \\ 1+i & 2 \end{pmatrix}, \qquad \mathbf{P}_1 = \frac{1}{3} \begin{pmatrix} 2 & -1+i \\ -1-i & 1 \end{pmatrix},$$

and $\mathbf{A} = 1 \cdot \mathbf{P}_1 + 4 \cdot \mathbf{P}_4$. Both are Hermitian, both square to themselves, $\mathbf{P}_1 \mathbf{P}_4 = 0$, and $\mathbf{P}_1 + \mathbf{P}_4 = \mathbf{I}$.

(b) $\mathbf{S}$ is symmetric, and $\mathbf{S}(1,0,1) = 3(1,0,1)$, $\mathbf{S}(0,1,0) = 3(0,1,0)$, $\mathbf{S}(1,0,-1) = (1,0,-1)$, so $\operatorname{spec}(\mathbf{S}) = \{3, 1\}$ with $E_1 = \operatorname{span}((1,0,-1))$ and $E_3 = \operatorname{span}((1,0,1), (0,1,0))$. Hence

$$\mathbf{P}_1 = \frac{1}{2} \begin{pmatrix} 1 & 0 & -1 \\ 0 & 0 & 0 \\ -1 & 0 & 1 \end{pmatrix}, \qquad \mathbf{P}_3 = \mathbf{I} - \mathbf{P}_1 = \frac{1}{2} \begin{pmatrix} 1 & 0 & 1 \\ 0 & 2 & 0 \\ 1 & 0 & 1 \end{pmatrix},$$

and $\mathbf{S} = \mathbf{P}_1 + 3\mathbf{P}_3$. The stated properties follow from $\mathbf{P}_1^\top = \mathbf{P}_1$, $\mathbf{P}_1^2 = \mathbf{P}_1$ and $\mathbf{P}_3 = \mathbf{I} - \mathbf{P}_1$.

(c) $\mathbf{U}$ is real orthogonal, hence unitary and normal. Since $\mathbf{U}(1,-i) = \frac{1}{\sqrt{2}}(1+i, 1-i) = e^{i\pi/4}(1,-i)$, and similarly $\mathbf{U}(1,i) = e^{-i\pi/4}(1,i)$, we get $\operatorname{spec}(\mathbf{U}) = \{e^{\pm i\pi/4}\}$. Both eigenvectors have squared length 2, so with $\mathbf{v}_\pm = (1, \mp i)$,

$$\mathbf{P}_\pm = \frac{\mathbf{v}_\pm \mathbf{v}_\pm^*}{2} = \frac{1}{2}\begin{pmatrix} 1 & \pm i \\ \mp i & 1 \end{pmatrix}, \qquad \mathbf{U} = e^{i\pi/4}\mathbf{P}_+ + e^{-i\pi/4}\mathbf{P}_-.$$

Both are Hermitian and idempotent, $\mathbf{P}_+\mathbf{P}_- = 0$ and $\mathbf{P}_+ + \mathbf{P}_- = \mathbf{I}$.

Exercise B2: Computing through the resolution.

Let $\mathbf{C} = \begin{pmatrix} 13 & 12 \\ 12 & 13 \end{pmatrix} \in M_2(\mathbb{R})$.

(a) Find the spectral resolution of $\mathbf{C}$.

(b) Hence compute $\sqrt{\mathbf{C}}$, and verify by squaring.

(c) Hence give a closed formula for $\mathbf{C}^m$ and write down $\mathbf{C}^{100}$.

(d) Hence compute $e^{\mathbf{C}}$.

Solution.

(a) $\mathbf{C}(1,1) = 25(1,1)$ and $\mathbf{C}(1,-1) = (1,-1)$, so $\operatorname{spec}(\mathbf{C}) = \{25, 1\}$ and, both spanning vectors having squared length 2,

$$\mathbf{P}_1 = \frac{1}{2}\begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix}, \qquad \mathbf{P}_2 = \frac{1}{2}\begin{pmatrix} 1 & -1 \\ -1 & 1 \end{pmatrix}, \qquad \mathbf{C} = 25\mathbf{P}_1 + \mathbf{P}_2.$$

(b) Both eigenvalues are positive, so by Theorem 11.8.4,

$$\sqrt{\mathbf{C}} = 5\mathbf{P}_1 + 1 \cdot \mathbf{P}_2 = \begin{pmatrix} 3 & 2 \\ 2 & 3 \end{pmatrix},$$

and $\begin{pmatrix} 3 & 2 \\ 2 & 3 \end{pmatrix}^2 = \begin{pmatrix} 13 & 12 \\ 12 & 13 \end{pmatrix} = \mathbf{C}$.

(c) By Theorem 11.8.3 (a), $\mathbf{C}^m = 25^m\mathbf{P}_1 + 1^m\mathbf{P}_2$, that is

$$\mathbf{C}^m = \frac{1}{2}\begin{pmatrix} 25^m + 1 & 25^m - 1 \\ 25^m - 1 & 25^m + 1 \end{pmatrix},$$

so $\mathbf{C}^{100} = \frac{1}{2}\left(\begin{smallmatrix} 25^{100}+1 & 25^{100}-1 \\ 25^{100}-1 & 25^{100}+1 \end{smallmatrix}\right)$. (As a check, $m = 2$ gives $\frac{1}{2}\left(\begin{smallmatrix} 626 & 624 \\ 624 & 626 \end{smallmatrix}\right) = \left(\begin{smallmatrix} 313 & 312 \\ 312 & 313 \end{smallmatrix}\right)$, which is $\mathbf{C}^2$.)

(d) By Theorem 11.8.5 (a),

$$e^{\mathbf{C}} = e^{25}\mathbf{P}_1 + e\,\mathbf{P}_2 = \frac{1}{2}\begin{pmatrix} e^{25} + e & e^{25} - e \\ e^{25} - e & e^{25} + e \end{pmatrix}.$$

Exercise B3: Is it a spectral resolution?.

Determine which of the following displays the spectral resolution of the operator $T_{\mathbf{A}}$ on the stated space. Justify your answer; for those that do not, name the condition of Theorem 11.8.2 that fails and say what the correct resolution is.

(a) On $\mathbb{R}^2$: $\mathbf{A} = \begin{pmatrix} 2 & 0 \\ 0 & -1 \end{pmatrix}$, with $\mu_1 = 2$, $\mathbf{Q}_1 = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}$, $\mu_2 = -1$, $\mathbf{Q}_2 = \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix}$.

(b) On $\mathbb{R}^2$: $\mathbf{A} = 3\mathbf{I}$, with $\mu_1 = \mu_2 = 3$, $\mathbf{Q}_1 = \frac{1}{2}\begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix}$, $\mathbf{Q}_2 = \frac{1}{2}\begin{pmatrix} 1 & -1 \\ -1 & 1 \end{pmatrix}$.

(c) On $\mathbb{R}^2$: $\mathbf{A} = \begin{pmatrix} 3 & 1 \\ 0 & 1 \end{pmatrix}$, with $\mu_1 = 3$, $\mathbf{Q}_1 = \frac{1}{2}\begin{pmatrix} 2 & 1 \\ 0 & 0 \end{pmatrix}$, $\mu_2 = 1$, $\mathbf{Q}_2 = \frac{1}{2}\begin{pmatrix} 0 & -1 \\ 0 & 2 \end{pmatrix}$.

Solution.

(a) Yes. The two matrices are symmetric, idempotent, non-zero, annihilate each other and sum to $\mathbf{I}$, and $2\mathbf{Q}_1 - \mathbf{Q}_2 = \mathbf{A}$; the coefficients 2 and -1 are distinct. By Theorem 11.8.2 this is the spectral resolution, and indeed $E_2 = \operatorname{span}(\mathbf{e}_1)$, $E_{-1} = \operatorname{span}(\mathbf{e}_2)$.

(b) No: the scalars μ_1, μ_2 are not **distinct**, so the hypothesis of Theorem 11.8.2 fails at once. The identity $3\mathbf{Q}_1 + 3\mathbf{Q}_2 = 3\mathbf{I} = \mathbf{A}$ is true but uninformative — the eigenvalue 3 has been split artificially across two projections. The spectral resolution of $3\mathbf{I}$ has a single term, $3\mathbf{I} = 3 \cdot \mathrm{id}$, since $\operatorname{spec}(3\mathbf{I}) = \{3\}$ and $E_3 = \mathbb{R}^2$.

(c) No: $\mathbf{Q}_1$ is not self-adjoint, since $\mathbf{Q}_1^{\top} = \frac{1}{2}\begin{pmatrix} 2 & 0 \\ 1 & 0 \end{pmatrix} \neq \mathbf{Q}_1$, so (R1) fails. Everything else holds: $\mathbf{Q}_1^2 = \mathbf{Q}_1$, $\mathbf{Q}_2 = \mathbf{I} - \mathbf{Q}_1$, $\mathbf{Q}_1\mathbf{Q}_2 = \mathbf{Q}_2\mathbf{Q}_1 = 0$ and $3\mathbf{Q}_1 + \mathbf{Q}_2 = \mathbf{A}$. There is no correct resolution to offer, because $\mathbf{A}$ is not normal: $\mathbf{A}^{\top}\mathbf{A} = \begin{pmatrix} 9 & 3 \\ 3 & 2 \end{pmatrix}$ while $\mathbf{A}\mathbf{A}^{\top} = \begin{pmatrix} 10 & 1 \\ 1 & 1 \end{pmatrix}$. The projections here are onto $E_3 = \operatorname{span}(\mathbf{e}_1)$ along $E_1 = \operatorname{span}((-1, 2))$, two lines that are not perpendicular.

11.8.7.3 C. Going deeper

Exercise C1: The projections are polynomials in the operator.

Let $T \in \mathcal{L}(V)$ satisfy $(*)$, with distinct eigenvalues $\lambda_1, \dots, \lambda_k \in F$ and resolution of the identity $(P_1, \dots, P_k)$.

(a) Prove that $P_i = \ell_i(T)$, where $\ell_i \in F[x]$ is the i-th Lagrange basis polynomial for the nodes $\lambda_1, \dots, \lambda_k$.

(b) Deduce that for every $f\colon \operatorname{spec}(T) \to F$ there is a polynomial p of degree less than k with $f(T) = p(T)$.

(c) Deduce that every operator commuting with T commutes with each P_i, re-proving Theorem 11.8.3 (e) by a different route.

Hint for (a): Definition 5.6.1 produces a polynomial taking prescribed values at prescribed nodes.

Solution.

(a) The λ_i are k distinct elements of F, so Definition 5.6.1 gives $\ell_1, \dots, \ell_k \in F[x]$ of degree $k-1$, and Theorem 5.6.1 (a) gives $\ell_i(\lambda_j) = \delta_{ij}$. By Theorem 11.8.3 (a),

$$\ell_i(T) = \sum_{j=1}^{k} \ell_i(\lambda_j) P_j = \sum_{j=1}^{k} \delta_{ij} P_j = P_i.$$

(b) Let p be the interpolating polynomial of degree less than k with $p(\lambda_i) = f(\lambda_i)$ for every i, which exists by Theorem 5.6.1. By Theorem 11.8.3 (a),

$$p(T) = \sum_{i} p(\lambda_i) P_i = \sum_{i} f(\lambda_i) P_i = f(T).$$

Explicitly, $p = \sum_i f(\lambda_i)\ell_i$.

(c) If $ST = TS$, then S commutes with every polynomial in T by Theorem 5.7.1 (d), in particular with $\ell_i(T) = P_i$.

Exercise C2: When the projections have rank one.

Let $T \in \mathcal{L}(V)$ satisfy $(*)$, with $\dim V = n$ and resolution of the identity $(P_1, \dots, P_k)$.

(a) Prove that $\operatorname{rank} P_i = \dim E_{\lambda_i}(T)$ and that $\sum_i \operatorname{rank} P_i = n$.

(b) Deduce that every P_i has rank 1 if and only if T has n distinct eigenvalues.

(c) Suppose every P_i has rank 1. Prove that every $S \in \mathcal{L}(V)$ commuting with T is a polynomial in T.

Solution.

(a) $\operatorname{im} P_i = E_{\lambda_i}(T)$ by Definition 10.3.2, so $\operatorname{rank} P_i = \dim E_{\lambda_i}(T)$. By Theorem 11.8.1 (a), $V = E_1 \oplus \cdots \oplus E_k$, so the dimensions add to n.

(b) If every $\operatorname{rank} P_i = 1$, then (a) gives $k = n$, so T has n distinct eigenvalues. Conversely, if T has n distinct eigenvalues, then $k = n$ and (a) forces each of the n positive integers $\operatorname{rank} P_i$ to be 1.

(c) By (b), $k = n$ and each E_i is a line, say $E_i = \operatorname{span}(\mathbf{e}_i)$ with $(\mathbf{e}_1, \dots, \mathbf{e}_n)$ an orthonormal eigenbasis. Let $ST = TS$. As in the proof of Theorem 11.8.3 (e), S maps E_i into itself, so $S\mathbf{e}_i = c_i \mathbf{e}_i$ for some $c_i \in F$. Define $f\colon \operatorname{spec}(T) \to F$ by $f(\lambda_i) = c_i$. Then $f(T)\mathbf{e}_i = c_i \mathbf{e}_i = S\mathbf{e}_i$ for every i, and two operators agreeing on a basis are equal, so $S = f(T)$. By Exercise (C1: The projections are polynomials in the operator) (b), $f(T)$ is a polynomial in T.

Exercise C3: What the functional calculus forgets.

Let $T \in \mathcal{L}(V)$ satisfy $(*)$, with distinct eigenvalues $\lambda_1, \dots, \lambda_k$, and let $f, g\colon \operatorname{spec}(T) \to F$.

(a) Prove that $f(T) = 0$ if and only if $f(\lambda_i) = 0$ for every i. Deduce that $f(T) = g(T)$ if and only if $f = g$.

(b) Deduce that $\{p(T) : p \in F[x]\} = \operatorname{span}(P_1, \dots, P_k)$, a subspace of $\mathcal{L}(V)$ of dimen-

sion exactly k.

(c) Deduce that $m_T = (x-\lambda_1)(x-\lambda_2)\cdots(x-\lambda_k)$, so that the minimal polynomial of an operator satisfying $(*)$ has no repeated root.

Solution.

(a) ($\Leftarrow$) is immediate from Definition 11.8.2. For ($\Rightarrow$), fix i and pick $\mathbf{v} \in E_{\lambda_i}(T)$ with $\mathbf{v} \neq \mathbf{0}$, which is possible because λ_i is an eigenvalue. Then $P_i\mathbf{v} = \mathbf{v}$ and $P_j\mathbf{v} = \mathbf{0}$ for $j \neq i$, since $E_i \subseteq \ker P_j$ (Theorem 11.8.1 (a), (b)). Hence

$$\mathbf{0} = f(T)\mathbf{v} = \sum_j f(\lambda_j)P_j\mathbf{v} = f(\lambda_i)\mathbf{v},$$

and $\mathbf{v} \neq \mathbf{0}$ forces $f(\lambda_i) = 0$. For the second claim, apply this to $f - g$, using Theorem 11.8.3 (b).

(b) By Theorem 11.8.3 (a), every $p(T)$ equals $\sum_i p(\lambda_i)P_i$, so the left-hand side is contained in $\operatorname{span}(P_1, \ldots, P_k)$; conversely every $\sum_i c_i P_i$ is $f(T)$ for the function $f(\lambda_i) = c_i$, hence is a polynomial in T by Exercise (C1: The projections are polynomials in the operator) (b). The P_i are linearly independent: if $\sum_i c_i P_i = 0$, that operator is $f(T)$ for $f(\lambda_i) = c_i$, so every $c_i = 0$ by (a). Hence the dimension is k.

(c) Put $p = \prod_i (x - \lambda_i)$, monic of degree k. Since $p(\lambda_i) = 0$ for every i, part (a) gives $p(T) = 0$, so $m_T \mid p$ by Theorem 8.5.1. Conversely $m_T(T) = 0$, so $m_T(\lambda_i) = 0$ for every i by (a), and hence each $x - \lambda_i$ divides m_T (Theorem 5.1.3 (b)). Distinct monic linear polynomials are coprime, since a common divisor would divide their difference, a non-zero constant; so $p = \prod_i (x - \lambda_i)$ divides m_T by Lemma 5.6.3 (b). Two monic polynomials dividing each other are equal, so $m_T = p$, a product of distinct linear factors.

11.9 Circulants and the Discrete Fourier Transform

The spectral theorem of Section 4 gives every normal matrix a unitary of its own, found by solving that matrix's eigenvalue problem. This section does something better for one particular family: it writes down a **single** unitary matrix, before any matrix of the family is named, and that one matrix diagonalizes all of them at once. The family is the circulants, the unitary is built from the n-th roots of unity, and the resulting dictionary between multiplying matrices and multiplying numbers is the discrete Fourier transform.

Two earlier pages pointed here. In Example (Which of these are normal?) (d) a 3×3 matrix whose rows were cyclic shifts of one another turned out to be normal, with the row dot products and the column dot products agreeing entry for entry; Exercise (B2: A circulant, diagonalized) met the same phenomenon again and diagonalized one such matrix by hand. Both times the agreement was described and not explained. It is explained below, and the explanation is the first theorem of the section.

Throughout, the field is $\mathbb{C}$, and **rows, columns and vector entries are numbered** $0, 1, \ldots, n-1$. That is a departure from the rest of the book, and it is worth it: every formula here involves

an index read modulo n, and modular arithmetic starts at 0.

11.9.1 Matrices whose rows walk around

Fix $n \geq 1$ and let $\mathbf{S} \in M_n(\mathbb{C})$ be the matrix with $(\mathbf{S})_{jk} = 1$ when $k \equiv j+1 \pmod{n}$ and $(\mathbf{S})_{jk} = 0$ otherwise: a 1 in each position $(j, j+1)$ for $j \leq n-2$, one more in the corner position $(n-1, 0)$, and zeros elsewhere. For $n = 4$,

$$\mathbf{S} = \begin{pmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 \end{pmatrix}.$$

Applied to a vector, $\mathbf{S}$ moves every entry one place up and sends the top entry around to the bottom: $\mathbf{S}\mathbf{x} = (x_1, x_2, \ldots, x_{n-1}, x_0)$. We call $\mathbf{S}$ the **cyclic shift**. Each row and each column of $\mathbf{S}$ carries exactly one 1, so $\mathbf{S}$ is a permutation matrix (Definition 2.6.2), and shifting n times returns every entry to where it started, so $\mathbf{S}^n = \mathbf{I}$.

Now think of $\mathbf{S}$ as a building block. The powers $\mathbf{I}, \mathbf{S}, \mathbf{S}^2, \ldots, \mathbf{S}^{n-1}$ are the n distinct "rotations of the identity", and a general linear combination of them is the object of this section.

A circulant is a matrix that does not know where the list begins: shift the indices and nothing changes.

Definition 11.9.1 — Circulant matrix

Let $n \geq 1$ and let $\mathbf{c} = (c_0, c_1, \ldots, c_{n-1}) \in \mathbb{C}^n$. The **circulant** with first row $\mathbf{c}$ is the matrix $\mathbf{C} \in M_n(\mathbb{C})$ whose entries are

$$(\mathbf{C})_{jk} = c_{k-j} \qquad (0 \leq j, k \leq n-1),$$

where the subscript $k - j$ is read **modulo** n. The polynomial

$$p_{\mathbf{c}}(x) = c_0 + c_1 x + c_2 x^2 + \cdots + c_{n-1} x^{n-1} \in \mathbb{C}[x]$$

is called the **symbol** of $\mathbf{C}$.

In words: the entry in a given position depends only on how far the column is to the right of the diagonal, counted cyclically. Written out,

$$\mathbf{C} = \begin{pmatrix} c_0 & c_1 & \cdots & c_{n-1} \\ c_{n-1} & c_0 & \cdots & c_{n-2} \\ \vdots & \vdots & \ddots & \vdots \\ c_1 & c_2 & \cdots & c_0 \end{pmatrix},$$

so each row is the row above it moved one step to the right, with the entry that falls off the right-hand end reappearing on the left. The columns behave the same way going down. Note that the data is one vector of length n, not n^2 numbers: a circulant is a very small object wearing a large costume.

Three examples, simplest first. The vector $\mathbf{c} = (1, 0, \ldots, 0)$ gives $\mathbf{C} = \mathbf{I}$, and $\mathbf{c} = (0, 1, 0, \ldots, 0)$ gives $\mathbf{C} = \mathbf{S}$; in both cases the definition is checked by reading off $(\mathbf{C})_{jk} = c_{k-j}$, which is 1

exactly when $k = j$, respectively $k = j + 1$, modulo n. The vector $\mathbf{c} = (1, 1, \ldots, 1)$ gives the all-ones matrix. The 3×3 matrix of Example (Which of these are normal?) (d) is the circulant with first row $(1, 2, 3)$, and the matrix of Exercise (B2: A circulant, diagonalized) is the circulant with first row $(1, 1, 0)$.

Our running example for the whole section is the 4×4 circulant with first row $(1, 2, 3, 4)$:

$$\mathbf{C} = \begin{pmatrix} 1 & 2 & 3 & 4 \\ 4 & 1 & 2 & 3 \\ 3 & 4 & 1 & 2 \\ 2 & 3 & 4 & 1 \end{pmatrix}, \qquad p_{\mathbf{c}}(x) = 1 + 2x + 3x^2 + 4x^3.$$

A non-example by minimal change. Keep the first row $(1, 2, 3, 4)$ but let the entries that fall off the end vanish instead of wrapping around, giving a matrix $\mathbf{B}$ with rows $(1, 2, 3, 4)$, $(0, 1, 2, 3)$, $(0, 0, 1, 2)$, $(0, 0, 0, 1)$. Every diagonal of $\mathbf{B}$ is still constant, and its first row is still $\mathbf{c}$, but $(\mathbf{B})_{10} = 0$ while the definition demands $c_{0-1} = c_3 = 4$. The clause that fails is the one that does all the work here: the subscript must be read modulo n. Matrices with constant diagonals and no wrap-around have their own name and their own theory, and the warning at the end of the section says why they do not fit into this one.

The reason a circulant is worth a name is that it is a polynomial in the shift.

Theorem 11.9.1 — Circulants Are Exactly the Polynomials in the Shift

Let $\mathbf{c} \in \mathbb{C}^n$ and let $\mathbf{C}$ be the circulant with first row $\mathbf{c}$, with symbol $p_{\mathbf{c}}$. Then:

(a) $\mathbf{C} = p_{\mathbf{c}}(\mathbf{S})$; conversely, $q(\mathbf{S})$ is a circulant for every $q \in \mathbb{C}[x]$.
(b) $\mathbf{C}^*$ is the circulant with first row $(\overline{c_0}, \overline{c_{n-1}}, \overline{c_{n-2}}, \ldots, \overline{c_1})$.
(c) $\mathbf{C}$ is normal, and any two circulants of the same size commute.

Idea. For (a), read off the entries of $\mathbf{S}^m$: it has a 1 in position (j, k) exactly when $k = j+m$ modulo n. So $\mathbf{S}^m$ is the circulant that picks out the coefficient c_m, and summing over m rebuilds $\mathbf{C}$ one coefficient at a time. Once (a) is in hand, (b) and (c) are arithmetic with the single relation $\mathbf{S}^* = \mathbf{S}^{n-1}$: the adjoint of a polynomial in $\mathbf{S}$ is again a polynomial in $\mathbf{S}$, and two polynomials in one matrix always commute (Theorem 0.9.9).

Proof.

(a) We claim that $(\mathbf{S}^m)_{jk} = 1$ if $k \equiv j + m \pmod n$ and $(\mathbf{S}^m)_{jk} = 0$ otherwise, for every $m \geq 0$. For $m = 0$ this says $\mathbf{S}^0 = \mathbf{I}$. Assuming it for m, expand one product: $(\mathbf{S}^{m+1})_{jk} = \sum_i (\mathbf{S})_{ji}(\mathbf{S}^m)_{ik}$, and the only non-zero factor $(\mathbf{S})_{ji}$ sits at $i \equiv j + 1$, so the sum is $(\mathbf{S}^m)_{j+1,k}$, which is 1 exactly when $k \equiv j + 1 + m$. This proves the claim by induction. Hence, for each j and k,

$$\big(p_{\mathbf{c}}(\mathbf{S})\big)_{jk} = \sum_{m=0}^{n-1} c_m (\mathbf{S}^m)_{jk} = c_{k-j},$$

because exactly one value of m in $\{0, \ldots, n-1\}$ satisfies $m \equiv k - j \pmod n$. So $p_{\mathbf{c}}(\mathbf{S}) = \mathbf{C}$. Conversely, let $q \in \mathbb{C}[x]$. Dividing by $x^n - 1$ (Theorem 5.1.1) gives $q = h \cdot (x^n - 1) + r$ with $\deg r < n$, and $\mathbf{S}^n = \mathbf{I}$ gives $q(\mathbf{S}) = h(\mathbf{S})(\mathbf{S}^n - \mathbf{I}) + r(\mathbf{S}) =$

$r(\mathbf{S})$, which is the circulant whose first row is the coefficient list of r.

(b) $\mathbf{S}$ is a permutation matrix with real entries, so $\mathbf{S}^* = \mathbf{S}^\top = \mathbf{S}^{-1}$ (Lemma 2.6.6 (b)), and $\mathbf{S}^{-1} = \mathbf{S}^{n-1}$ because $\mathbf{S}^n = \mathbf{I}$. Therefore

$$\mathbf{C}^* = \sum_{m=0}^{n-1} \overline{c_m}\,(\mathbf{S}^*)^m = \sum_{m=0}^{n-1} \overline{c_m}\,\mathbf{S}^{-m}.$$

For $m = 0$ the term is $\overline{c_0}\mathbf{I}$, and for $1 \le m \le n-1$ we have $\mathbf{S}^{-m} = \mathbf{S}^{n-m}$. So the coefficient of $\mathbf{S}^r$ is $\overline{c_0}$ when $r = 0$ and $\overline{c_{n-r}}$ when $1 \le r \le n-1$, which is the stated first row.

(c) By (a) and (b), both $\mathbf{C}$ and $\mathbf{C}^*$ are polynomials in $\mathbf{S}$, and any two polynomials in the same matrix commute (Theorem 0.9.9). Hence $\mathbf{C}^*\mathbf{C} = \mathbf{C}\mathbf{C}^*$. The same argument applies to two circulants $\mathbf{C} = p(\mathbf{S})$ and $\mathbf{C}' = q(\mathbf{S})$.

■

That settles the coincidence noticed in Example (Which of these are normal?) (d) and again in Exercise (B2: A circulant, diagonalized) (a). It is worth seeing it once at the level of entries, because the entries are what those pages compared. For any $\mathbf{A} \in M_n(\mathbb{C})$, writing $\mathbf{a}_0, \dots, \mathbf{a}_{n-1}$ for its columns and $\mathbf{r}_0, \dots, \mathbf{r}_{n-1}$ for its rows, the definition of the matrix product gives

$$(\mathbf{A}^*\mathbf{A})_{jk} = \langle \mathbf{a}_k, \mathbf{a}_j \rangle, \qquad (\mathbf{A}\mathbf{A}^*)_{jk} = \langle \mathbf{r}_j, \mathbf{r}_k \rangle.$$

So "normal" says exactly that the table of column inner products and the table of row inner products agree. Now let $\mathbf{A} = \mathbf{C}$ be a circulant, so that $(\mathbf{C})_{ik} = c_{k-i}$. Re-index the first sum by $t = j - i$ and the second by $t = i - k$; as i runs through all residues modulo n, so does t in each case. This gives

$$\langle \mathbf{a}_k, \mathbf{a}_j \rangle = \sum_{t=0}^{n-1} c_{t+k-j}\,\overline{c_t} = \langle \mathbf{r}_j, \mathbf{r}_k \rangle,$$

all subscripts modulo n. Both tables depend only on $k - j$, and they are literally the same sum. Cyclic shifting is what makes the re-indexing legal, and that is the whole of the coincidence.

Quick check. Which vectors $\mathbf{c} \in \mathbb{C}^n$ give a circulant that is Hermitian? Answer for $n = 4$ with real entries.

Solution. By Theorem 11.9.1 (b), $\mathbf{C}^* = \mathbf{C}$ forces $\overline{c_0} = c_0$ and $\overline{c_{n-m}} = c_m$ for $1 \le m \le n-1$. For $n = 4$ with real entries this reads $c_1 = c_3$, with c_0 and c_2 unconstrained: the symmetric real 4×4 circulants are exactly those whose first row has the form (c_0, c_1, c_2, c_1).

11.9.2 The eigenvectors of the shift

Everything now follows from one eigenvalue problem, the one for $\mathbf{S}$. Since $\mathbf{S}^n = \mathbf{I}$, any eigenvalue λ satisfies $\lambda^n = 1$, so the candidates are the n-th roots of unity of Example (Roots of Unity). There are n of them and $\mathbf{S}$ is an $n \times n$ matrix, which is encouraging. The eigenvectors are equally explicit.

Fix

$$\omega := e^{2\pi i/n},$$

so that $1, \omega, \omega^2, \dots, \omega^{n-1}$ are the n distinct n-th roots of unity, and $\omega^r = 1$ if and only if n divides r (Example (Roots of Unity)).

Theorem 11.9.2 — Eigenvectors of the Cyclic Shift

For $j = 0, 1, \dots, n-1$ let

$$\mathbf{f}_j := \tfrac{1}{\sqrt{n}}\big(1,\ \omega^j,\ \omega^{2j},\ \dots,\ \omega^{(n-1)j}\big) \in \mathbb{C}^n,$$

that is, $(\mathbf{f}_j)_m = \omega^{jm}/\sqrt{n}$. Then $\mathbf{S}\mathbf{f}_j = \omega^j \mathbf{f}_j$. Consequently $\mathbf{S}$ is a unitary matrix with the n distinct eigenvalues $1, \omega, \dots, \omega^{n-1}$, and each eigenspace $E_{\omega^j}(\mathbf{S})$ is the line $\operatorname{span}(\mathbf{f}_j)$.

Idea. The shift moves entry $m+1$ into slot m. If the entries are the successive powers of a fixed number z, that is the same as multiplying the whole vector by z — provided the wrap-around at the end also multiplies by z, which is exactly the condition $z^n = 1$. So the geometric vectors $(1, z, z^2, \dots)$ with $z^n = 1$ are forced on us, and there are n of them.

Proof. Fix j and let $0 \le m \le n-1$. By the description of $\mathbf{S}$, the m-th entry of $\mathbf{S}\mathbf{f}_j$ is the $(m+1)$-st entry of $\mathbf{f}_j$, indices modulo n. For $m < n-1$ this is

$$\frac{\omega^{j(m+1)}}{\sqrt{n}} = \omega^j \cdot \frac{\omega^{jm}}{\sqrt{n}} = \omega^j (\mathbf{f}_j)_m,$$

and for $m = n-1$ it is $(\mathbf{f}_j)_0 = 1/\sqrt{n}$, while $\omega^j (\mathbf{f}_j)_{n-1} = \omega^j \omega^{j(n-1)}/\sqrt{n} = \omega^{jn}/\sqrt{n} = 1/\sqrt{n}$ because $\omega^n = 1$. The two agree, so $\mathbf{S}\mathbf{f}_j = \omega^j \mathbf{f}_j$. Each $\mathbf{f}_j$ is non-zero, since its 0-th entry is $1/\sqrt{n}$, so ω^j is an eigenvalue.

The matrix $\mathbf{S}$ is a real permutation matrix, so $\mathbf{S}^\top \mathbf{S} = \mathbf{I}$ by Lemma 2.6.6 (b), and $\mathbf{S}^* = \mathbf{S}^\top$; hence $\mathbf{S}$ is unitary (Definition 10.7.2). The n numbers $1, \omega, \dots, \omega^{n-1}$ are distinct, so $\mathbf{S}$ has n distinct eigenvalues, and the sum of their eigenspaces is direct (Corollary 8.2.3). Each of those n eigenspaces has dimension at least 1 and their dimensions add up to at most $\dim \mathbb{C}^n = n$, so each has dimension exactly 1. Since $\mathbf{f}_j \in E_{\omega^j}(\mathbf{S})$ is non-zero, that eigenspace is $\operatorname{span}(\mathbf{f}_j)$.

■

The vectors $\mathbf{f}_0, \dots, \mathbf{f}_{n-1}$ are called the **Fourier vectors**. They are already known to be pairwise orthogonal: $\mathbf{S}$ is unitary, hence normal, and eigenvectors of a normal matrix for distinct eigenvalues are orthogonal (Corollary 11.3.4). But the direct computation is short, it produces the normalization at the same time, and it is the computation on which the rest of the section runs. So we do it.

Theorem 11.9.3 — The Fourier Matrix Is Unitary

The list $(\mathbf{f}_0, \mathbf{f}_1, \dots, \mathbf{f}_{n-1})$ is an orthonormal basis of $\mathbb{C}^n$. Equivalently, the **Fourier**

matrix

$$\mathbf{F} := \frac{1}{\sqrt{n}} \begin{pmatrix} 1 & 1 & \cdots & 1 \\ 1 & \omega & \cdots & \omega^{n-1} \\ \vdots & \vdots & & \vdots \\ 1 & \omega^{n-1} & \cdots & \omega^{(n-1)^2} \end{pmatrix}, \qquad (\mathbf{F})_{mj} = \frac{\omega^{mj}}{\sqrt{n}},$$

whose j-th column is $\mathbf{f}_j$, is unitary: $\mathbf{F}^*\mathbf{F} = \mathbf{F}\mathbf{F}^* = \mathbf{I}$.

Proof. Let $0 \le j, k \le n-1$. Since $|\omega| = 1$ we have $\overline{\omega} = \omega^{-1}$, hence $\overline{\omega^{km}} = \omega^{-km}$, and so

$$\langle \mathbf{f}_j, \mathbf{f}_k \rangle = \frac{1}{n} \sum_{m=0}^{n-1} \omega^{jm}\, \overline{\omega^{km}} = \frac{1}{n} \sum_{m=0}^{n-1} \left(\omega^{j-k}\right)^m,$$

the inner product being linear in the first slot and conjugate-linear in the second.

Case $j = k$. Then $\omega^{j-k} = \omega^0 = 1$, so every one of the n terms equals 1 and the sum is n. Hence $\langle \mathbf{f}_j, \mathbf{f}_j \rangle = n/n = 1$, and $\|\mathbf{f}_j\| = 1$.

Case $j \neq k$. Put $z := \omega^{j-k}$. Then $z^n = (\omega^n)^{j-k} = 1$. Also $z \neq 1$: by Example (Roots of Unity), $\omega^{j-k} = 1$ would force n to divide $j-k$, and $0 < |j-k| \le n-1$ makes that impossible. Now use the factorization

$$(z-1)\left(1 + z + z^2 + \cdots + z^{n-1}\right) = z^n - 1 = 0,$$

which is a polynomial identity valid for every complex z. Since $z - 1 \neq 0$, we may divide by it, and

$$\sum_{m=0}^{n-1} z^m = 0.$$

Hence $\langle \mathbf{f}_j, \mathbf{f}_k \rangle = 0$.

So the list is orthonormal; it has $n = \dim \mathbb{C}^n$ members and is independent (Theorem 10.1.4), hence a basis (Theorem 1.6.4). A matrix whose columns form an orthonormal basis of $\mathbb{C}^n$ is unitary (Theorem 10.7.3 (f)), which gives $\mathbf{F}^*\mathbf{F} = \mathbf{F}\mathbf{F}^* = \mathbf{I}$.

■

The second case is where the whole section lives. A sum of n unit complex numbers, spread evenly around the circle, cancels — and it cancels for the cheapest possible reason, that a geometric series with ratio $z \neq 1$ and $z^n = 1$ telescopes to zero.

Example. (The Fourier matrix of size four)

Write out $\mathbf{F}$ for $n = 4$, and check one orthogonality relation by hand.

Solution. For $n = 4$, $\omega = e^{2\pi i/4} = i$, and the powers cycle $i^0 = 1$, $i^1 = i$, $i^2 = -1$, $i^3 = -i$. So

$$\mathbf{F} = \frac{1}{2} \begin{pmatrix} 1 & 1 & 1 & 1 \\ 1 & i & -1 & -i \\ 1 & -1 & 1 & -1 \\ 1 & -i & -1 & i \end{pmatrix}.$$

Take $j = 1$, $k = 3$. Then $\omega^{j-k} = i^{-2} = -1$, and

$$\langle \mathbf{f}_1, \mathbf{f}_3 \rangle = \tfrac{1}{4}\big(1 + (-1) + 1 + (-1)\big) = 0,$$

matching the geometric-series computation with $z = -1$, for which $1 + z + z^2 + z^3 = 0$. Note that $\mathbf{F}$ is symmetric, $\mathbf{F}^{\top} = \mathbf{F}$, but **not** Hermitian: $\mathbf{F}^{*} = \overline{\mathbf{F}} \neq \mathbf{F}$, since $(\mathbf{F})_{12} = i/2$.

11.9.3 One unitary for every circulant

Theorem 11.9.4 — Circulant Diagonalization

Let $\mathbf{C} \in M_n(\mathbb{C})$ be the circulant with first row $\mathbf{c}$ and symbol $p_{\mathbf{c}}$. Then every Fourier vector is an eigenvector of $\mathbf{C}$,

$$\mathbf{C}\mathbf{f}_j = p_{\mathbf{c}}(\omega^j)\,\mathbf{f}_j \qquad (j = 0, 1, \dots, n-1),$$

and consequently

$$\mathbf{F}^{*}\mathbf{C}\mathbf{F} = \operatorname{diag}\big(p_{\mathbf{c}}(1),\ p_{\mathbf{c}}(\omega),\ \dots,\ p_{\mathbf{c}}(\omega^{n-1})\big).$$

The same unitary $\mathbf{F}$ works for every circulant of size n, and $\det \mathbf{C} = \prod_{j=0}^{n-1} p_{\mathbf{c}}(\omega^j)$.

Idea. There is nothing left to prove. A circulant is a polynomial in $\mathbf{S}$ by Theorem 11.9.1, and a polynomial in a matrix acts on an eigenvector of that matrix by the same polynomial applied to the eigenvalue. The point is not the proof but the statement: $\mathbf{F}$ was written down without reference to $\mathbf{c}$, so a single change of orthonormal basis handles the entire family at once.

Proof. By Theorem 11.9.1 (a), $\mathbf{C} = p_{\mathbf{c}}(\mathbf{S})$, and by Theorem 11.9.2, $\mathbf{S}\mathbf{f}_j = \omega^j \mathbf{f}_j$. Iterating the latter gives $\mathbf{S}^m \mathbf{f}_j = \omega^{jm}\mathbf{f}_j$ for every $m \geq 0$, so

$$\mathbf{C}\mathbf{f}_j = \sum_{m=0}^{n-1} c_m\, \mathbf{S}^m \mathbf{f}_j = \Big(\sum_{m=0}^{n-1} c_m \omega^{jm}\Big)\mathbf{f}_j = p_{\mathbf{c}}(\omega^j)\,\mathbf{f}_j.$$

The j-th column of $\mathbf{F}$ is $\mathbf{f}_j$, so the j-th column of $\mathbf{C}\mathbf{F}$ is $p_{\mathbf{c}}(\omega^j)\mathbf{f}_j$, which is the j-th column of $\mathbf{F}\mathbf{D}$ for $\mathbf{D} = \operatorname{diag}(p_{\mathbf{c}}(1), \dots, p_{\mathbf{c}}(\omega^{n-1}))$. Hence $\mathbf{C}\mathbf{F} = \mathbf{F}\mathbf{D}$, and multiplying on the left by $\mathbf{F}^{*} = \mathbf{F}^{-1}$ (Theorem 11.9.3) gives $\mathbf{F}^{*}\mathbf{C}\mathbf{F} = \mathbf{D}$. Taking determinants, $\det \mathbf{C} = \det \mathbf{D} = \prod_j p_{\mathbf{c}}(\omega^j)$, since $\det \mathbf{F}^{*} \det \mathbf{F} = \det(\mathbf{F}^{*}\mathbf{F}) = 1$ (Theorem 6.5.4). ∎

This re-proves normality from the other side, and closes the account opened in Example (Which of these are normal?) (d): $\mathbf{C} = \mathbf{F}\mathbf{D}\mathbf{F}^{*}$ with $\mathbf{F}$ unitary and $\mathbf{D}$ diagonal is precisely the factorization that Corollary 11.4.3 reserves for normal matrices. The eigenvalues $p_{\mathbf{c}}(\omega^j)$ need no characteristic polynomial either: they are n evaluations of a polynomial of degree less than n.

Example. (The running example, diagonalized)

Find the eigenvalues and the determinant of the circulant $\mathbf{C}$ with first row $(1, 2, 3, 4)$, and write down $\mathbf{F}^*\mathbf{C}\mathbf{F}$.

Solution. Here $n = 4$, $\omega = i$ and $p_{\mathbf{c}}(x) = 1 + 2x + 3x^2 + 4x^3$. Evaluate at the four fourth roots of unity, using $i^2 = -1$ and $i^3 = -i$:

$$\begin{aligned} p_{\mathbf{c}}(1) &= 1 + 2 + 3 + 4 = 10, \\ p_{\mathbf{c}}(i) &= 1 + 2i - 3 - 4i = -2 - 2i, \\ p_{\mathbf{c}}(-1) &= 1 - 2 + 3 - 4 = -2, \\ p_{\mathbf{c}}(-i) &= 1 - 2i - 3 + 4i = -2 + 2i. \end{aligned}$$

So $\mathbf{F}^*\mathbf{C}\mathbf{F} = \operatorname{diag}(10,\ -2 - 2i,\ -2,\ -2 + 2i)$ with $\mathbf{F}$ as in Example (The Fourier matrix of size four), and

$$\det \mathbf{C} = 10 \cdot (-2 - 2i) \cdot (-2) \cdot (-2 + 2i) = -20\big(4 + 4\big) = -160,$$

using $(-2 - 2i)(-2 + 2i) = 4 + 4 = 8$. As a check on the first eigenvalue: every row of $\mathbf{C}$ sums to 10, so $\mathbf{C}\mathbf{1} = 10 \cdot \mathbf{1}$, and $\mathbf{f}_0 = \frac{1}{2}\mathbf{1}$.

Quick check. The matrix of Example (The running example, diagonalized) is real, and two of its eigenvalues are not. Why must those two be complex conjugates of each other, and which two are they in general?

Solution. If every c_m is real then $\overline{p_{\mathbf{c}}(z)} = p_{\mathbf{c}}(\overline{z})$ for every z. Taking $z = \omega^j$ and using $\overline{\omega^j} = \omega^{-j} = \omega^{n-j}$,

$$\overline{p_{\mathbf{c}}(\omega^j)} = p_{\mathbf{c}}(\omega^{n-j}),$$

so the eigenvalue attached to $\mathbf{f}_j$ and the one attached to $\mathbf{f}_{n-j}$ are conjugate. Here $n = 4$ and the pair is $j = 1, 3$: $\overline{-2 - 2i} = -2 + 2i$. The eigenvalues for $j = 0$ and, when n is even, $j = n/2$ are their own conjugates, hence real — which is why 10 and -2 came out real. (This is also Theorem 8.2.5, seen here with the eigenvectors named.)

Once every circulant is $\mathbf{F}\mathbf{D}\mathbf{F}^*$, the family closes up on itself.

Corollary 11.9.5 — Circulants Form a Commutative Algebra

Let $\mathcal{C}_n \subseteq M_n(\mathbb{C})$ be the set of circulants of size n. Then:

(a) $\mathcal{C}_n$ is a subspace of $M_n(\mathbb{C})$ of dimension n, with basis $\mathbf{I}, \mathbf{S}, \dots, \mathbf{S}^{n-1}$;

(b) $\mathcal{C}_n$ is closed under products, and any two of its members commute;

(c) $\mathbf{A} \in \mathcal{C}_n$ if and only if $\mathbf{F}^*\mathbf{A}\mathbf{F}$ is diagonal;

(d) a circulant $\mathbf{C}$ is invertible if and only if $p_{\mathbf{c}}(\omega^j) \neq 0$ for every j, and then $\mathbf{C}^{-1}$ is again a circulant.

Proof.

(a) The map $\mathbf{c} \mapsto p_{\mathbf{c}}(\mathbf{S})$ from $\mathbb{C}^n$ to $M_n(\mathbb{C})$ is linear and, by Theorem 11.9.1 (a), its image is exactly $\mathcal{C}_n$. It is injective, because the first row of $p_{\mathbf{c}}(\mathbf{S})$ is $\mathbf{c}$. So $\mathcal{C}_n$ is a subspace of dimension n, and the images $\mathbf{I}, \mathbf{S}, \dots, \mathbf{S}^{n-1}$ of the standard basis form a basis of it.

(b) If $\mathbf{C} = p(\mathbf{S})$ and $\mathbf{C}' = q(\mathbf{S})$, then $\mathbf{C}\mathbf{C}' = (pq)(\mathbf{S})$ (Theorem 0.9.9), which is a circulant by Theorem 11.9.1 (a). Commutativity is part (c) of that theorem.

(c) ($\Rightarrow$) is Theorem 11.9.4. ($\Leftarrow$) Suppose $\mathbf{F}^*\mathbf{A}\mathbf{F} = \mathbf{D} = \operatorname{diag}(d_0, \dots, d_{n-1})$. The n numbers $1, \omega, \dots, \omega^{n-1}$ are distinct, so by Lagrange interpolation (Theorem 5.6.1) there is $q \in \mathbb{C}[x]$ with $q(\omega^j) = d_j$ for every j. By Theorem 11.9.4 applied to the circulant $q(\mathbf{S})$, which has symbol the remainder of q on division by $x^n - 1$,

$$\mathbf{F}^* q(\mathbf{S}) \mathbf{F} = \operatorname{diag}\big(q(1), \dots, q(\omega^{n-1})\big) = \mathbf{D}.$$

Multiplying both sides by $\mathbf{F}$ on the left and $\mathbf{F}^*$ on the right gives $q(\mathbf{S}) = \mathbf{A}$, so $\mathbf{A}$ is a circulant.

(d) From $\mathbf{C} = \mathbf{F}\mathbf{D}\mathbf{F}^*$, $\det \mathbf{C} = \det \mathbf{D}$, so $\mathbf{C}$ is invertible exactly when no diagonal entry $p_{\mathbf{c}}(\omega^j)$ vanishes (Theorem 6.5.2). In that case $\mathbf{C}^{-1} = \mathbf{F}\mathbf{D}^{-1}\mathbf{F}^*$, and $\mathbf{F}^*\mathbf{C}^{-1}\mathbf{F} = \mathbf{D}^{-1}$ is diagonal, so $\mathbf{C}^{-1}$ is a circulant by (c).

■

Part (c) is the sharpest statement of the section: being a circulant is not a statement about the pattern of the entries at all, but a statement about which orthonormal basis diagonalizes the matrix. The pattern was only ever a way of recognizing it.

11.9.4 Multiplying circulants is convolution

A circulant is its first row. So the product of two circulants must be computable from the two first rows, and it is worth knowing what that computation is.

Given $\mathbf{c}, \mathbf{d} \in \mathbb{C}^n$, define their **cyclic convolution** $\mathbf{c} * \mathbf{d} \in \mathbb{C}^n$ by

$$(\mathbf{c} * \mathbf{d})_r := \sum_{l=0}^{n-1} c_l \, d_{r-l} \qquad (r = 0, \dots, n-1),$$

subscripts modulo n. In words: to get entry r, slide the reversed list $\mathbf{d}$ along $\mathbf{c}$ so that the indices add up to r, and add the products. It is the multiplication of polynomials with the exponents read modulo n, and the next theorem says so.

Theorem 11.9.6 — Convolution Theorem

Let $\mathbf{c}, \mathbf{d} \in \mathbb{C}^n$ with circulants $\mathbf{C}, \mathbf{C}'$ and symbols $p_{\mathbf{c}}, p_{\mathbf{d}}$. Then:

(a) $\mathbf{C}\mathbf{C}'$ is the circulant with first row $\mathbf{c} * \mathbf{d}$;

(b) for every j, $p_{\mathbf{c}*\mathbf{d}}(\omega^j) = p_{\mathbf{c}}(\omega^j)\, p_{\mathbf{d}}(\omega^j)$.

In words: convolving the first rows corresponds to multiplying the eigenvalue lists entry by entry.

Idea. Both parts are the identity $p_{\mathbf{c}} p_{\mathbf{d}} \equiv p_{\mathbf{c}*\mathbf{d}} \pmod{x^n - 1}$, looked at twice. Multiplying the two symbols produces a polynomial of degree up to $2n - 2$; reducing the exponents modulo n folds the coefficients back into n slots, and the fold is precisely the

convolution sum. Evaluating at a root of $x^n - 1$ makes the reduction invisible, which is (b); substituting $\mathbf{S}$, for which $\mathbf{S}^n = \mathbf{I}$, makes it invisible as well, which is (a).

Proof. Expand the product of the symbols and collect exponents modulo n:

$$p_{\mathbf{c}}(x)\, p_{\mathbf{d}}(x) = \sum_{l=0}^{n-1} \sum_{m=0}^{n-1} c_l d_m x^{l+m}.$$

For each $r \in \{0, \dots, n-1\}$, the pairs (l, m) with $l + m \equiv r \pmod{n}$ are exactly those with $m \equiv r - l$, one value of m for each l. Hence, working modulo $x^n - 1$ and using $x^{l+m} \equiv x^{(l+m) \bmod n}$,

$$p_{\mathbf{c}}(x)\, p_{\mathbf{d}}(x) \equiv \sum_{r=0}^{n-1} \Big(\sum_{l=0}^{n-1} c_l d_{r-l} \Big) x^r = p_{\mathbf{c}*\mathbf{d}}(x) \pmod{x^n - 1}.$$

(a) Substitute $\mathbf{S}$. Since $\mathbf{S}^n = \mathbf{I}$, the multiple of $x^n - 1$ contributes nothing, so

$$\mathbf{C}\mathbf{C}' = p_{\mathbf{c}}(\mathbf{S})\, p_{\mathbf{d}}(\mathbf{S}) = p_{\mathbf{c}*\mathbf{d}}(\mathbf{S}),$$

the first equality by Theorem 11.9.1 (a) and Theorem 0.9.9. By Theorem 11.9.1 (a) again, $p_{\mathbf{c}*\mathbf{d}}(\mathbf{S})$ is the circulant with first row $\mathbf{c} * \mathbf{d}$, the coefficient list having length n.

(b) Substitute $x = \omega^j$, a root of $x^n - 1$, so that the multiple of $x^n - 1$ again contributes nothing. This gives $p_{\mathbf{c}}(\omega^j) p_{\mathbf{d}}(\omega^j) = p_{\mathbf{c}*\mathbf{d}}(\omega^j)$.

■

Part (b) deserves its own sentence, because it is the reason the discrete Fourier transform is used at all. Define the **discrete Fourier transform** of $\mathbf{c} \in \mathbb{C}^n$ to be the vector of eigenvalues,

$$\widehat{\mathbf{c}} \coloneqq \big(p_{\mathbf{c}}(1),\ p_{\mathbf{c}}(\omega),\ \dots,\ p_{\mathbf{c}}(\omega^{n-1}) \big) = \sqrt{n}\, \mathbf{F}\mathbf{c},$$

the second expression because the j-th entry of $\mathbf{F}\mathbf{c}$ is $n^{-1/2} \sum_m \omega^{jm} c_m$. Then (b) reads

$$\big(\widehat{\mathbf{c} * \mathbf{d}} \big)_j = \widehat{\mathbf{c}}_j\, \widehat{\mathbf{d}}_j \qquad (j = 0, \dots, n-1)\,:$$

the transform turns convolution into entrywise multiplication. Convolution is a tangled sum of n^2 products; after one unitary change of basis it is n ordinary multiplications. Everything the transform buys comes from this line.

Example. (Convolution in size four)

Let $\mathbf{c} = (1, 2, 3, 4)$ and $\mathbf{d} = (1, 1, 0, 0)$. Compute $\mathbf{c} * \mathbf{d}$, and verify Theorem 11.9.6 (b) at all four roots of unity.

Solution. Since $d_0 = d_1 = 1$ and $d_2 = d_3 = 0$, the sum $\sum_l c_l d_{r-l}$ keeps only the terms with $r - l \equiv 0$ or 1, that is $l = r$ and $l = r - 1$. So $(\mathbf{c} * \mathbf{d})_r = c_r + c_{r-1}$, subscripts modulo 4:

$$\mathbf{c} * \mathbf{d} = (1 + 4,\ 2 + 1,\ 3 + 2,\ 4 + 3) = (5, 3, 5, 7).$$

The three symbols are $p_{\mathbf{c}}(x) = 1 + 2x + 3x^2 + 4x^3$, $p_{\mathbf{d}}(x) = 1 + x$ and $p_{\mathbf{c}*\mathbf{d}}(x) = 5 + 3x + 5x^2 + 7x^3$. Evaluating each at $1, i, -1, -i$, with $p_{\mathbf{c}}$ already computed in Example

(The running example, diagonalized):

$$\begin{aligned} j=0: &\quad 10\cdot 2 = 20, && 5+3+5+7 = 20;\\ j=1: &\quad (-2-2i)(1+i) = -4i, && 5+3i-5-7i = -4i;\\ j=2: &\quad (-2)\cdot 0 = 0, && 5-3+5-7 = 0;\\ j=3: &\quad (-2+2i)(1-i) = 4i, && 5-3i-5+7i = 4i. \end{aligned}$$

All four agree. For the middle line, $(-2-2i)(1+i) = -2-2i-2i-2i^2 = -4i$.

11.9.5 Solving a circulant system, and a word about speed

If $\mathbf{Cx} = \mathbf{b}$ with $\mathbf{C}$ an invertible circulant, then in the Fourier basis the system falls apart into n scalar equations. Writing $\mathbf{C} = \mathbf{FDF}^*$ and setting $\mathbf{y} = \mathbf{F}^*\mathbf{x}$, $\mathbf{g} = \mathbf{F}^*\mathbf{b}$, the system becomes $\mathbf{Dy} = \mathbf{g}$, that is $y_j = g_j/\lambda_j$ with $\lambda_j = p_{\mathbf{c}}(\omega^j)$. Then $\mathbf{x} = \mathbf{Fy}$. Three steps: transform, divide, transform back.

Example. (A circulant system)

Solve $\mathbf{Cx} = \mathbf{b}$ for the circulant $\mathbf{C}$ with first row $(1,2,3,4)$ and $\mathbf{b} = (1,1,-1,-1)$.

Solution. The eigenvalues are $\lambda = (10,\ -2-2i,\ -2,\ -2+2i)$ by Example (The running example, diagonalized). First transform $\mathbf{b}$: the j-th entry of $\mathbf{F}^*\mathbf{b}$ is $\frac{1}{2}\sum_m \overline{\omega^{jm}} b_m = \frac{1}{2}\sum_m (-i)^{jm} b_m$, so

$$\begin{aligned} g_0 &= \tfrac{1}{2}(1+1-1-1) = 0,\\ g_1 &= \tfrac{1}{2}\big(1+(-i)-(-1)-(i)\big) = 1-i,\\ g_2 &= \tfrac{1}{2}(1-1-1+1) = 0,\\ g_3 &= \tfrac{1}{2}\big(1+i+1+i\big) = 1+i. \end{aligned}$$

Now divide. The two zero entries stay zero, and

$$y_1 = \frac{1-i}{-2-2i} = \frac{(1-i)(-2+2i)}{8} = \frac{4i}{8} = \frac{i}{2}, \qquad y_3 = \overline{y_1} = -\frac{i}{2},$$

where the middle step multiplies numerator and denominator by $\overline{-2-2i} = -2+2i$, whose product with $-2-2i$ is 8. Finally $\mathbf{x} = \mathbf{Fy}$, whose m-th entry is $\frac{1}{2}(i^m y_1 + i^{3m} y_3) = \frac{1}{2}\cdot\frac{i}{2}\big(i^m - (-i)^m\big)$:

$$\mathbf{x} = \Big(0,\ -\tfrac{1}{2},\ 0,\ \tfrac{1}{2}\Big).$$

Check directly: the second row of $\mathbf{C}$ is $(4,1,2,3)$, and $-\frac{1}{2}+\frac{3}{2} = 1 = b_1$; the third row is $(3,4,1,2)$, and $-2+1 = -1 = b_2$. The answer is real, as it must be: $\mathbf{C}$ and $\mathbf{b}$ are real, so $\mathbf{x} = \mathbf{C}^{-1}\mathbf{b}$ is real, and this shows up in the transform as the conjugate symmetry $y_3 = \overline{y_1}$.

Counted honestly, the recipe above saves something, but not yet very much. Forming $\mathbf{F}^*\mathbf{b}$ as a matrix–vector product costs about n^2 multiplications, and so does forming $\mathbf{Fy}$, so the whole solve costs on the order of n^2. That beats general elimination, which is on the order of n^3, but it is no better than multiplying $\mathbf{b}$ by $\mathbf{C}^{-1}$ once that inverse has been found. What changes the

picture is that $\mathbf{F}$ does not have to be applied as a general matrix. The powers of ω repeat, and splitting the sum $\sum_m \omega^{jm} b_m$ into its even and odd m reduces one transform of length n to two of length $n/2$; iterating brings the cost down to about $n \log n$. That algorithm is the **fast Fourier transform**. It proves no new theorem: the matrix $\mathbf{F}$, the factorization $\mathbf{C} = \mathbf{F}\mathbf{D}\mathbf{F}^*$ and everything above are unchanged, and the fast Fourier transform is only a way of applying $\mathbf{F}$ quickly. Chapter 23 develops it, together with the cost accounting that makes "quickly" precise.

Warning. A **Toeplitz** matrix — one with constant diagonals, $(\mathbf{A})_{jk} = a_{k-j}$ with the subscript **not** reduced modulo n — is not a circulant, and $\mathbf{F}$ does not diagonalize it. Take

$$\mathbf{A} = \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix}.$$

Every diagonal of $\mathbf{A}$ is constant, so $\mathbf{A}$ is Toeplitz, but the circulant with first row $(0,1,0)$ is $\mathbf{S}$, whose second row is $(0,0,1)$, not $(1,0,1)$. And $\mathbf{F}$ fails at the very first column: $\mathbf{f}_0 = \frac{1}{\sqrt{3}}(1,1,1)$ and $\mathbf{A}\mathbf{f}_0 = \frac{1}{\sqrt{3}}(1,2,1)$, which is not a multiple of $\mathbf{f}_0$, so $\mathbf{f}_0$ is not an eigenvector and $\mathbf{F}^*\mathbf{A}\mathbf{F}$ is not diagonal. Normality is not the issue: $\mathbf{A}$ is symmetric, hence normal, and Theorem 11.5.1 does hand it an orthonormal eigenbasis. It is simply a different basis, with the irrational eigenvalues $0, \pm\sqrt{2}$ in place of evaluations of a polynomial at roots of unity. What the wrap-around buys is not diagonalizability; it is the *same* diagonalizing basis for everybody.

11.9.6 Exercises

11.9.6.1 A. Check your understanding

Exercise A1.

(a) Define the circulant with first row $\mathbf{c} = (c_0, \dots, c_{n-1})$, and write down its symbol.

(b) State the eigenvalues and the eigenvectors of the cyclic shift $\mathbf{S}$ on $\mathbb{C}^n$.

(c) Give the eigenvalues of the circulant with first row $\mathbf{c}$, and say how many multiplications are needed to compute all of them from $\mathbf{c}$ by direct evaluation.

(d) Determine whether the following are true, with a reason. (i) Every Toeplitz matrix is a circulant. (ii) Every circulant is normal. (iii) The Fourier matrix $\mathbf{F}$ is Hermitian.

(e) Explain in one sentence why two circulants of the same size commute, without computing any entries.

Solution.

(a) The matrix $\mathbf{C} \in M_n(\mathbb{C})$ with $(\mathbf{C})_{jk} = c_{k-j}$, subscripts modulo n and indices running from 0 to $n-1$ (Definition 11.9.1). Its symbol is $p_{\mathbf{c}}(x) = c_0 + c_1 x + \cdots + c_{n-1}x^{n-1}$.

(b) With $\omega = e^{2\pi i/n}$: the eigenvalues are $1, \omega, \dots, \omega^{n-1}$, all distinct, and ω^j has the one-dimensional eigenspace spanned by $\mathbf{f}_j = n^{-1/2}(1, \omega^j, \dots, \omega^{(n-1)j})$ (Theorem 11.9.2).

(c) The eigenvalues are $p_{\mathbf{c}}(\omega^j)$ for $j = 0, \dots, n-1$ (Theorem 11.9.4). Each evaluation is a sum of n products, so all n of them cost about n^2 multiplications done directly.

(d) (i) False: the 3×3 matrix in the warning above has constant diagonals but is not a circulant. (ii) True, by Theorem 11.9.1 (c); equivalently by Corollary 11.4.3, since $\mathbf{C} = \mathbf{F}\mathbf{D}\mathbf{F}^*$. (iii) False. $\mathbf{F}$ is symmetric, but $\mathbf{F}^* = \overline{\mathbf{F}}$, and for $n = 4$ the entry $(\mathbf{F})_{12} = i/2$ is not real (Example (The Fourier matrix of size four)). $\mathbf{F}$ is Hermitian only for $n = 1, 2$, where all its entries are real.

(e) Both are polynomials in the single matrix $\mathbf{S}$ (Theorem 11.9.1 (a)), and two polynomials in one matrix always commute (Theorem 0.9.9).

11.9.6.2 B. Practice

Exercise B1: Eigenvalues of small circulants.

For each vector $\mathbf{c}$, write down the symbol, compute all eigenvalues of the circulant with first row $\mathbf{c}$, and give its determinant.

(a) $\mathbf{c} = (1, 1, 1)$, $n = 3$.

(b) $\mathbf{c} = (0, 1, 0, 0)$, $n = 4$.

(c) $\mathbf{c} = (2, -1, 0, -1)$, $n = 4$.

Solution.

(a) $p_{\mathbf{c}}(x) = 1 + x + x^2$. With $\omega = e^{2\pi i/3}$, the eigenvalues are $p_{\mathbf{c}}(1) = 3$ and $p_{\mathbf{c}}(\omega^j) = 1 + \omega^j + \omega^{2j}$ for $j = 1, 2$. For $j \neq 0$, $z = \omega^j$ satisfies $z \neq 1$ and $z^3 = 1$, so $1 + z + z^2 = (z^3 - 1)/(z - 1) = 0$ — the geometric-series computation of Theorem 11.9.3 again. The eigenvalues are $3, 0, 0$ and $\det \mathbf{C} = 0$. (This matrix is the all-ones matrix, of rank 1.)

(b) $p_{\mathbf{c}}(x) = x$, so $\mathbf{C} = \mathbf{S}$. The eigenvalues are $\omega^j = i^j$, namely $1, i, -1, -i$, and

$$\det \mathbf{S} = 1 \cdot i \cdot (-1) \cdot (-i) = \big(i \cdot (-i)\big)\big(1 \cdot (-1)\big) = -1.$$

This agrees with the sign of the permutation: $\mathbf{S}$ permutes the coordinates in one 4-cycle, which is odd.

(c) $p_{\mathbf{c}}(x) = 2 - x - x^3$. Then $p_{\mathbf{c}}(1) = 0$; $p_{\mathbf{c}}(i) = 2 - i - i^3 = 2 - i + i = 2$; $p_{\mathbf{c}}(-1) = 2 + 1 + 1 = 4$; $p_{\mathbf{c}}(-i) = 2 + i - i = 2$. The eigenvalues are $0, 2, 4, 2$, and $\det \mathbf{C} = 0$. The kernel contains $\mathbf{f}_0$, that is the all-ones vector, as one sees directly: every row of $\mathbf{C}$ sums to 0.

Exercise B2: Solve a circulant system by transforming.

Let $\mathbf{C}$ be the 4×4 circulant with first row $(3, 1, 0, 1)$ and let $\mathbf{b} = (1, 0, 0, 0)$. Compute the eigenvalues of $\mathbf{C}$, and solve $\mathbf{C}\mathbf{x} = \mathbf{b}$ by transforming, dividing and transforming back. Check your answer against the first two rows of $\mathbf{C}$.

Solution. The symbol is $p_{\mathbf{c}}(x) = 3 + x + x^3$, and with $\omega = i$,

$$p_{\mathbf{c}}(1) = 5, \quad p_{\mathbf{c}}(i) = 3 + i - i = 3, \quad p_{\mathbf{c}}(-1) = 1, \quad p_{\mathbf{c}}(-i) = 3.$$

All four are non-zero, so $\mathbf{C}$ is invertible (Corollary 11.9.5 (d)), with $\det \mathbf{C} = 5 \cdot 3 \cdot 1 \cdot 3 = 45$.

Transform: $(\mathbf{F}^*\mathbf{b})_j = \frac{1}{2}\sum_m \overline{\omega^{jm}} b_m = \frac{1}{2}$ for every j, since $\mathbf{b} = \mathbf{e}_0$. Divide: $y_j = \frac{1}{2}\lambda_j^{-1}$,

giving $\mathbf{y} = \frac{1}{2}(\frac{1}{5}, \frac{1}{3}, 1, \frac{1}{3})$. Transform back: the m-th entry of $\mathbf{x} = \mathbf{F}\mathbf{y}$ is

$$x_m = \tfrac{1}{2}\sum_{j=0}^{3} i^{mj} y_j = \tfrac{1}{4}\Big(\tfrac{1}{5} + \tfrac{i^m}{3} + (-1)^m + \tfrac{i^{3m}}{3}\Big).$$

For $m = 1$ and $m = 3$ the two middle terms cancel, since $i^m + i^{3m} = i^m + \overline{i^m}$ is 0 when $i^m = \pm i$; the bracket is $\frac{1}{5} - 1$, so $x_1 = x_3 = -\frac{1}{5}$. For $m = 0$ the bracket is $\frac{1}{5} + \frac{1}{3} + 1 + \frac{1}{3} = \frac{28}{15}$, so $x_0 = \frac{7}{15}$. For $m = 2$ it is $\frac{1}{5} - \frac{1}{3} + 1 - \frac{1}{3} = \frac{8}{15}$, so $x_2 = \frac{2}{15}$. Hence

$$\mathbf{x} = \Big(\tfrac{7}{15},\ -\tfrac{1}{5},\ \tfrac{2}{15},\ -\tfrac{1}{5}\Big).$$

Check: row 0 of $\mathbf{C}$ is $(3, 1, 0, 1)$ and $3 \cdot \frac{7}{15} - \frac{1}{5} - \frac{1}{5} = \frac{21-3-3}{15} = 1$; row 1 is $(1, 3, 1, 0)$ and $\frac{7}{15} - \frac{3}{5} + \frac{2}{15} = \frac{7-9+2}{15} = 0$.

Exercise B3: The convolution theorem in an example.

Let $\mathbf{c} = (1, 0, 2, 0)$ and $\mathbf{d} = (0, 1, 0, 3)$ in $\mathbb{C}^4$.

(a) Compute $\mathbf{c} * \mathbf{d}$.

(b) Verify $p_{\mathbf{c}*\mathbf{d}}(\omega^j) = p_{\mathbf{c}}(\omega^j)p_{\mathbf{d}}(\omega^j)$ for $j = 0, 1, 2, 3$.

(c) Hence write down the first row of the product of the two circulants, without multiplying any matrices.

Solution.

(a) Only $c_0 = 1$ and $c_2 = 2$ are non-zero, so $(\mathbf{c} * \mathbf{d})_r = d_r + 2d_{r-2}$, subscripts modulo 4. With $\mathbf{d} = (0, 1, 0, 3)$:

$$\mathbf{c} * \mathbf{d} = (0 + 0,\ 1 + 6,\ 0 + 0,\ 3 + 2) = (0, 7, 0, 5).$$

(b) The symbols are $p_{\mathbf{c}}(x) = 1 + 2x^2$, $p_{\mathbf{d}}(x) = x + 3x^3$ and $p_{\mathbf{c}*\mathbf{d}}(x) = 7x + 5x^3$. With $\omega = i$:

$$\begin{aligned}
j = 0: &\quad 3 \cdot 4 = 12, && 7 + 5 = 12;\\
j = 1: &\quad (-1)(-2i) = 2i, && 7i - 5i = 2i;\\
j = 2: &\quad 3 \cdot (-4) = -12, && -7 - 5 = -12;\\
j = 3: &\quad (-1)(2i) = -2i, && -7i + 5i = -2i.
\end{aligned}$$

Here $p_{\mathbf{c}}(i) = 1 + 2i^2 = -1$ and $p_{\mathbf{d}}(i) = i + 3i^3 = i - 3i = -2i$, and similarly at the other roots. All four rows agree.

(c) By Theorem 11.9.6 (a), the product is the circulant with first row $\mathbf{c}*\mathbf{d} = (0, 7, 0, 5)$.

11.9.6.3 C. Going deeper

Exercise C1: What commutes with the shift.

Let $\mathbf{A} \in M_n(\mathbb{C})$ satisfy $\mathbf{AS} = \mathbf{SA}$. Prove that $\mathbf{A}$ is a circulant. *Hint: consider the eigenspaces of* $\mathbf{S}$.

Solution. By Theorem 11.9.2, $\mathbf{S}$ has the n distinct eigenvalues ω^j, and $E_{\omega^j}(\mathbf{S}) = \operatorname{span}(\mathbf{f}_j)$ is one-dimensional. Since $\mathbf{A}$ commutes with $\mathbf{S}$, each eigenspace of $\mathbf{S}$ is invariant under $\mathbf{A}$ (Theorem 8.9.1). So $\mathbf{A}\mathbf{f}_j \in \operatorname{span}(\mathbf{f}_j)$, that is $\mathbf{A}\mathbf{f}_j = d_j\mathbf{f}_j$ for some $d_j \in \mathbb{C}$.

Therefore the j-th column of $\mathbf{AF}$ is $d_j\mathbf{f}_j$, which is the j-th column of $\mathbf{FD}$ for $\mathbf{D} = \operatorname{diag}(d_0, \dots, d_{n-1})$. Hence $\mathbf{AF} = \mathbf{FD}$ and $\mathbf{F}^*\mathbf{AF} = \mathbf{D}$ is diagonal, so $\mathbf{A}$ is a circulant by Corollary 11.9.5 (c). This proves the converse of Theorem 11.9.1 (c) for the single matrix $\mathbf{S}$: the commutant of the cyclic shift is exactly the algebra of circulants.

Exercise C2: Determinant and invertibility.

Let $\mathbf{C}$ be the circulant with first row $\mathbf{c} \in \mathbb{C}^n$ and symbol $p_{\mathbf{c}}$.

(a) Prove that $\det \mathbf{C} = \prod_{j=0}^{n-1} p_{\mathbf{c}}(\omega^j)$, and use it to compute the determinant of the $n \times n$ all-ones matrix for every $n \geq 2$.

(b) Prove that $\mathbf{C}$ is invertible if and only if $p_{\mathbf{c}}$ and $x^n - 1$ are coprime in $\mathbb{C}[x]$.

(c) Give an example of a 4×4 circulant with integer entries, none of them 0, whose determinant is 0.

Solution.

(a) This is the last claim of Theorem 11.9.4: from $\mathbf{C} = \mathbf{FDF}^*$ and $\det(\mathbf{F}^*)\det(\mathbf{F}) = \det(\mathbf{F}^*\mathbf{F}) = 1$, multiplicativity of the determinant (Theorem 6.5.4) gives $\det \mathbf{C} = \det \mathbf{D}$, which is the product of the diagonal entries $p_{\mathbf{c}}(\omega^j)$.
For the all-ones matrix, $\mathbf{c} = (1, 1, \dots, 1)$ and $p_{\mathbf{c}}(x) = 1 + x + \cdots + x^{n-1}$. Then $p_{\mathbf{c}}(1) = n$, while for $1 \leq j \leq n-1$ the number $z = \omega^j$ satisfies $z^n = 1$ and $z \neq 1$, so $p_{\mathbf{c}}(z) = (z^n - 1)/(z - 1) = 0$. Hence $\det \mathbf{C} = n \cdot 0 \cdots 0 = 0$ for every $n \geq 2$, as it must be, since all the rows are equal.

(b) By (a), $\det \mathbf{C} \neq 0$ if and only if $p_{\mathbf{c}}(\omega^j) \neq 0$ for every j, that is, if and only if $p_{\mathbf{c}}$ and $x^n - 1$ have no common root, the roots of $x^n - 1$ being exactly $1, \omega, \dots, \omega^{n-1}$ (Example (Roots of Unity)). Over $\mathbb{C}$, having no common root is the same as having no common non-constant factor: such a factor would have a root by Theorem 5.5.1, and that root would be common to both; conversely a common root α makes $x - \alpha$ a common factor. So invertibility of $\mathbf{C}$ is equivalent to $p_{\mathbf{c}}$ and $x^n - 1$ being coprime (Definition 5.2.3). Combined with Theorem 6.5.2, this is the statement asked for.

(c) Take $\mathbf{c} = (1, 2, 1, 2)$, so

$$\mathbf{C} = \begin{pmatrix} 1 & 2 & 1 & 2 \\ 2 & 1 & 2 & 1 \\ 1 & 2 & 1 & 2 \\ 2 & 1 & 2 & 1 \end{pmatrix}, \qquad p_{\mathbf{c}}(x) = 1 + 2x + x^2 + 2x^3.$$

Here $p_{\mathbf{c}}(i) = 1 + 2i - 1 - 2i = 0$, so $\det \mathbf{C} = 0$ by (a). The reason is visible without any of the theory — rows 0 and 2 are equal — and the Fourier picture names a kernel vector: $\mathbf{C}\mathbf{f}_1 = \mathbf{0}$, and since $\mathbf{C}$ is real, the real and imaginary parts of $\mathbf{f}_1$ are in the kernel too, giving $\mathbf{C}(1, 0, -1, 0) = \mathbf{0}$.

Exercise C3: The real orthogonal form of a real circulant.

Let $\mathbf{C} \in M_4(\mathbb{R})$ be the circulant with first row $(1, 2, 3, 4)$, with eigenvalues $10, -2 -$

$2i, -2, -2+2i$ as in Example (The running example, diagonalized). Put

$$\mathbf{g} \coloneqq \sqrt{2}\,\operatorname{Re}\mathbf{f}_1, \qquad \mathbf{h} \coloneqq \sqrt{2}\,\operatorname{Im}\mathbf{f}_1,$$

the real and imaginary parts taken entrywise.

(a) Write $\mathbf{g}$ and $\mathbf{h}$ out, and show that $(\mathbf{f}_0, \mathbf{f}_2, \mathbf{g}, \mathbf{h})$ is an orthonormal basis of $\mathbb{R}^4$.

(b) Writing $a + bi \coloneqq -2 + 2i$, prove that $\mathbf{C}\mathbf{g} = a\mathbf{g} + b\mathbf{h}$ and $\mathbf{C}\mathbf{h} = -b\mathbf{g} + a\mathbf{h}$.

(c) Hence write down the matrix of $\mathbf{C}$ in the ordered basis of (a), and identify it as an instance of Theorem 11.5.3.

Hint for (b): apply $\mathbf{C}$ to $\mathbf{f}_3 = (\mathbf{g} - i\mathbf{h})/\sqrt{2}$ and compare real and imaginary parts.

Solution.

(a) With $\omega = i$, $\mathbf{f}_1 = \frac{1}{2}(1, i, -1, -i)$, so

$$\mathbf{g} = \tfrac{1}{\sqrt{2}}(1, 0, -1, 0), \qquad \mathbf{h} = \tfrac{1}{\sqrt{2}}(0, 1, 0, -1).$$

Also $\mathbf{f}_0 = \frac{1}{2}(1,1,1,1)$ and $\mathbf{f}_2 = \frac{1}{2}(1,-1,1,-1)$ are real, so all four vectors lie in $\mathbb{R}^4$. Each has norm 1: for instance $\|\mathbf{g}\|^2 = \frac{1}{2}(1+1) = 1$ and $\|\mathbf{f}_0\|^2 = \frac{1}{4}\cdot 4 = 1$. They are pairwise orthogonal for the real dot product. First $\mathbf{g}\cdot\mathbf{h} = 0$, because the non-zero entries sit in different slots, and $\mathbf{f}_0 \cdot \mathbf{f}_2 = \frac{1}{4}(1-1+1-1) = 0$. The four remaining pairings are

$$\mathbf{f}_0 \cdot \mathbf{g} = \tfrac{1}{2\sqrt{2}}(1-1) = 0, \quad \mathbf{f}_2 \cdot \mathbf{g} = \tfrac{1}{2\sqrt{2}}(1-1) = 0,$$
$$\mathbf{f}_0 \cdot \mathbf{h} = \tfrac{1}{2\sqrt{2}}(1-1) = 0, \quad \mathbf{f}_2 \cdot \mathbf{h} = \tfrac{1}{2\sqrt{2}}(-1+1) = 0.$$

Four orthonormal vectors are independent (Theorem 10.1.4) and there are $\dim \mathbb{R}^4 = 4$ of them, so they form a basis (Theorem 1.6.4).

(b) From $\mathbf{f}_1 = \frac{1}{\sqrt{2}}(\mathbf{g} + i\mathbf{h})$ and $\mathbf{f}_3 = \overline{\mathbf{f}_1}$ we get $\mathbf{f}_3 = \frac{1}{\sqrt{2}}(\mathbf{g} - i\mathbf{h})$. Its eigenvalue is $p_{\mathbf{c}}(\omega^3) = p_{\mathbf{c}}(-i) = -2 + 2i = a + bi$, so $a = -2$ and $b = 2$, and $\mathbf{C}\mathbf{f}_3 = (a+bi)\mathbf{f}_3$ reads

$$\tfrac{1}{\sqrt{2}}\big(\mathbf{C}\mathbf{g} - i\,\mathbf{C}\mathbf{h}\big) = \tfrac{1}{\sqrt{2}}(a+bi)(\mathbf{g} - i\mathbf{h}) = \tfrac{1}{\sqrt{2}}\big((a\mathbf{g} + b\mathbf{h}) + i(b\mathbf{g} - a\mathbf{h})\big).$$

Both $\mathbf{C}\mathbf{g}$ and $\mathbf{C}\mathbf{h}$ are real vectors, because $\mathbf{C}$, $\mathbf{g}$ and $\mathbf{h}$ are real. Comparing real parts gives $\mathbf{C}\mathbf{g} = a\mathbf{g} + b\mathbf{h}$, and comparing imaginary parts gives $-\mathbf{C}\mathbf{h} = b\mathbf{g} - a\mathbf{h}$, that is $\mathbf{C}\mathbf{h} = -b\mathbf{g} + a\mathbf{h}$. With $a = -2$ and $b = 2$,

$$\mathbf{C}\mathbf{g} = -2\mathbf{g} + 2\mathbf{h}, \qquad \mathbf{C}\mathbf{h} = -2\mathbf{g} - 2\mathbf{h}.$$

A direct check: $\sqrt{2}\,\mathbf{C}\mathbf{g} = \mathbf{C}(1,0,-1,0) = (1-3,\ 4-2,\ 3-1,\ 2-4) = (-2,2,2,-2)$, while $\sqrt{2}\,(-2\mathbf{g} + 2\mathbf{h}) = (-2,2,2,-2)$.

(c) Reading the coordinates of the images off (b), the matrix in the ordered basis $(\mathbf{f}_0, \mathbf{f}_2, \mathbf{g}, \mathbf{h})$ is

$$\begin{pmatrix} 10 & 0 & 0 & 0 \\ 0 & -2 & 0 & 0 \\ 0 & 0 & -2 & -2 \\ 0 & 0 & 2 & -2 \end{pmatrix} = (10) \oplus (-2) \oplus \mathbf{\Lambda}(-2+2i),$$

since $\mathbf{\Lambda}(a+bi)$ has rows $(a,-b)$ and (b,a). This is exactly the shape promised by Theorem 11.5.3 for a real normal operator: two 1×1 blocks for the real eigenvalues, and one rotation-scaling block for the conjugate pair, with $b=2>0$. The change of basis is orthogonal, because the basis is orthonormal.

11.10 The Sylvester Equation

Chapter 7 wrote an operator with an invariant subspace as a block triangular matrix, with a corner block $\mathbf{C}$ recording how the subspace fails to have an invariant complement (Theorem 7.1.7). Chapter 9 spent its length on what to do when that corner cannot be cleared. The question of *when* it can be cleared has an exact answer, and the answer is a linear equation in the unknown matrix $\mathbf{X}$:

$$\mathbf{AX}-\mathbf{XB}=\mathbf{C}.$$

Chapter 7 already turned this equation into an ordinary linear system with the Kronecker product, and stopped one step short of the criterion because that step needs eigenvalues. We have eigenvalues now, and Schur's factorization of Section 1 to organize them. This section proves the criterion, uses it to clear corners, and reads off what it says about the matrices that commute with a given one.

Throughout, the field is $\mathbb{C}$ unless stated otherwise, and $\mathbf{A}\in M_m(\mathbb{C})$, $\mathbf{B}\in M_n(\mathbb{C})$, while the unknown $\mathbf{X}$ and the data $\mathbf{C}$ live in $M_{m\times n}(\mathbb{C})$.

11.10.1 The Sylvester operator

The left-hand side of the equation is linear in $\mathbf{X}$: replacing $\mathbf{X}$ by $\mathbf{X}+\mathbf{X}'$ or by $c\mathbf{X}$ does the same to $\mathbf{AX}-\mathbf{XB}$, because matrix multiplication is bilinear (Theorem 0.9.4). So the whole question is about one linear map, and it deserves a name.

Solving $\mathbf{AX}-\mathbf{XB}=\mathbf{C}$ means inverting a single linear operator on the space of $m\times n$ matrices.

Definition 11.10.1 — Sylvester operator

Let $\mathbf{A}\in M_m(F)$ and $\mathbf{B}\in M_n(F)$. The **Sylvester operator** of the pair $(\mathbf{A},\mathbf{B})$ is

$$\mathcal{S}_{\mathbf{A},\mathbf{B}}\colon M_{m\times n}(F)\to M_{m\times n}(F),\qquad \mathcal{S}_{\mathbf{A},\mathbf{B}}(\mathbf{X})=\mathbf{AX}-\mathbf{XB}.$$

The equation $\mathbf{AX}-\mathbf{XB}=\mathbf{C}$, for a given $\mathbf{C}\in M_{m\times n}(F)$, is the **Sylvester equation**.

In words: $\mathcal{S}_{\mathbf{A},\mathbf{B}}$ multiplies by $\mathbf{A}$ on the left, multiplies by $\mathbf{B}$ on the right, and subtracts. It is an operator on a space of dimension mn, not on F^m or F^n, and that is the only thing that makes the equation look harder than $\mathbf{Ax}=\mathbf{b}$.

Three special cases are worth keeping in view.

1. **$\mathbf{B}=\mathbf{0}$.** Then $\mathcal{S}_{\mathbf{A},\mathbf{0}}(\mathbf{X})=\mathbf{AX}$, and the equation is n copies of $\mathbf{Ax}=\mathbf{b}$, one for each column of $\mathbf{X}$ (Exercise (B2: One-sided equations)). It is uniquely solvable for every $\mathbf{C}$ exactly when $\mathbf{A}$ is invertible, that is, when $0\notin\operatorname{spec}(\mathbf{A})$. Since $\operatorname{spec}(\mathbf{0})=\{0\}$, this already matches the criterion we are heading for.

2. $\mathbf{B} = \mathbf{A}$ **and** $\mathbf{C} = \mathbf{0}$**.** Then $\ker \mathcal{S}_{\mathbf{A},\mathbf{A}}$ is the **commutant** of $\mathbf{A}$, the set of matrices commuting with $\mathbf{A}$. This is the question Chapter 7 opened with, and Chapter 9 §04 studied it for a single Jordan or Weyr block.
3. $m = n = 1$**.** Then $\mathcal{S}_{a,b}(x) = (a-b)x$, which is invertible exactly when $a \neq b$. The general criterion will be this one, run over all pairs of eigenvalues.

Non-example by minimal change. The map $\mathbf{X} \mapsto \mathbf{AX} - \mathbf{XB} - \mathbf{X}^{\top}$ is still linear on $M_n(F)$, but it is not a Sylvester operator: the transpose is not of the form "multiply on one side". Everything below uses the two-sided product shape and nothing else.

Chapter 7 already wrote the matrix of $\mathcal{S}_{\mathbf{A},\mathbf{B}}$. Stacking the columns of $\mathbf{X}$ with the vectorization vec of Definition 7.4.2 and applying the vec identity Theorem 7.4.4 twice, once with $\mathbf{B} = \mathbf{I}_n$ and once with $\mathbf{A} = \mathbf{I}_m$,

$$\begin{aligned} \operatorname{vec}\left(\mathcal{S}_{\mathbf{A},\mathbf{B}}(\mathbf{X})\right) &= \mathbf{K}\ \operatorname{vec}\mathbf{X}, \\ \mathbf{K} &\coloneqq \mathbf{I}_n \otimes \mathbf{A} - \mathbf{B}^{\top} \otimes \mathbf{I}_m. \end{aligned} \tag{11.10.1}$$

Here $\mathbf{K} \in M_{mn}(F)$, and $\operatorname{vec}\colon M_{m\times n}(F) \to F^{mn}$ is an isomorphism. So Eq. 11.10.1 says that $\mathbf{K}$ *is* the matrix of $\mathcal{S}_{\mathbf{A},\mathbf{B}}$ with respect to the basis of matrix units ordered column by column. In particular $\mathcal{S}_{\mathbf{A},\mathbf{B}}$ is invertible if and only if $\mathbf{K}$ is.

That is exactly where Chapter 7 left the problem. What it could not do was compute the eigenvalues of $\mathbf{K}$.

11.10.2 The spectrum of a Kronecker sum

Chapter 7 proved how the Kronecker product treats rank, trace and determinant (Theorem 7.4.3) and how it treats products, transposes and inverses (Theorem 7.4.1). It proved nothing about eigenvalues, and Exercise (C2: Kronecker sums) got only as far as the case where both factors are already triangular. Schur closes the gap, because over $\mathbb{C}$ every matrix can be made triangular unitarily, and the mixed product rule carries a pair of unitary conjugations through the Kronecker product in one step.

Lemma 11.10.1 — The Eigenvalues of a Kronecker Sum

Let $\mathbf{A} \in M_m(\mathbb{C})$ with eigenvalues $\lambda_1, \dots, \lambda_m$ and let $\mathbf{B} \in M_n(\mathbb{C})$ with eigenvalues $\mu_1, \dots, \mu_n$, each list repeated according to algebraic multiplicity. Then the mn eigenvalues of

$$\mathbf{K} = \mathbf{I}_n \otimes \mathbf{A} - \mathbf{B}^{\top} \otimes \mathbf{I}_m \in M_{mn}(\mathbb{C}),$$

listed with algebraic multiplicity, are the mn differences $\lambda_i - \mu_j$ $(1 \le i \le m,\ 1 \le j \le n)$.

Idea. Triangularize both ingredients at once. Schur (Corollary 11.1.3) writes $\mathbf{A} = \mathbf{UTU}^{*}$ and $\mathbf{B}^{\top} = \mathbf{VSV}^{*}$ with $\mathbf{T}, \mathbf{S}$ upper triangular. The mixed product rule then conjugates *both* summands of $\mathbf{K}$ by the single unitary matrix $\mathbf{V} \otimes \mathbf{U}$, because $\mathbf{I}_n \otimes \mathbf{A}$ and $\mathbf{B}^{\top} \otimes \mathbf{I}_m$ each have one trivial factor to absorb the other conjugation. What is left is $\mathbf{I}_n \otimes \mathbf{T} - \mathbf{S} \otimes \mathbf{I}_m$, and a Kronecker product with one triangular and one identity factor is triangular, so the eigenvalues are visible on the diagonal.

Proof. By Corollary 11.1.3 there are a unitary $\mathbf{U} \in M_m(\mathbb{C})$ and an upper triangular $\mathbf{T} \in M_m(\mathbb{C})$ with $\mathbf{A} = \mathbf{U}\mathbf{T}\mathbf{U}^*$ and $t_{ii} = \lambda_i$. By Proposition 8.10.5 (b), $p_{\mathbf{B}^\top} = p_{\mathbf{B}}$, so $\mathbf{B}^\top$ has eigenvalue list $\mu_1, \dots, \mu_n$; applying Corollary 11.1.3 to $\mathbf{B}^\top$ gives a unitary $\mathbf{V} \in M_n(\mathbb{C})$ and an upper triangular $\mathbf{S} \in M_n(\mathbb{C})$ with $\mathbf{B}^\top = \mathbf{V}\mathbf{S}\mathbf{V}^*$ and $s_{jj} = \mu_j$.

Put $\mathbf{W} = \mathbf{V} \otimes \mathbf{U} \in M_{mn}(\mathbb{C})$. Conjugating every entry of $\mathbf{A} \otimes \mathbf{B}$ conjugates every block $a_{ij}\mathbf{B}$, so $\overline{\mathbf{A} \otimes \mathbf{B}} = \overline{\mathbf{A}} \otimes \overline{\mathbf{B}}$ (Definition 7.4.1), and combining this with Theorem 7.4.1 (d) gives $(\mathbf{A} \otimes \mathbf{B})^* = \mathbf{A}^* \otimes \mathbf{B}^*$ whenever the product is defined. Hence $\mathbf{W}^* = \mathbf{V}^* \otimes \mathbf{U}^*$, and by the mixed product rule Theorem 7.4.1 (c),

$$\mathbf{W}^*\mathbf{W} = (\mathbf{V}^*\mathbf{V}) \otimes (\mathbf{U}^*\mathbf{U}) = \mathbf{I}_n \otimes \mathbf{I}_m = \mathbf{I}_{mn},$$

so $\mathbf{W}$ is unitary. Using the mixed product rule twice more,

$$\mathbf{W}(\mathbf{I}_n \otimes \mathbf{T})\mathbf{W}^* = (\mathbf{V}\mathbf{I}_n\mathbf{V}^*) \otimes (\mathbf{U}\mathbf{T}\mathbf{U}^*) = \mathbf{I}_n \otimes \mathbf{A},$$
$$\mathbf{W}(\mathbf{S} \otimes \mathbf{I}_m)\mathbf{W}^* = (\mathbf{V}\mathbf{S}\mathbf{V}^*) \otimes (\mathbf{U}\mathbf{I}_m\mathbf{U}^*) = \mathbf{B}^\top \otimes \mathbf{I}_m.$$

Subtracting, $\mathbf{W}(\mathbf{I}_n \otimes \mathbf{T} - \mathbf{S} \otimes \mathbf{I}_m)\mathbf{W}^* = \mathbf{K}$, so $\mathbf{K}$ is similar to

$$\mathbf{R} \coloneqq \mathbf{I}_n \otimes \mathbf{T} - \mathbf{S} \otimes \mathbf{I}_m.$$

$\mathbf{R}$ is upper triangular. Label the rows and columns of an $mn \times mn$ matrix by pairs as in Definition 7.4.1: row $(j-1)m + i$ with $1 \le j \le n$, $1 \le i \le m$, and likewise column $(l-1)m + k$. In those labels the entries of the two summands are

$$(\mathbf{I}_n \otimes \mathbf{T})_{(j-1)m+i,\,(l-1)m+k} = \delta_{jl}\, t_{ik},$$
$$(\mathbf{S} \otimes \mathbf{I}_m)_{(j-1)m+i,\,(l-1)m+k} = s_{jl}\, \delta_{ik}.$$

The first is non-zero only when $j = l$ and $i \le k$, since $\mathbf{T}$ is upper triangular; then $(j-1)m + i \le (l-1)m + k$. The second is non-zero only when $j \le l$ and $i = k$; if $j = l$ the two labels are equal, and if $j < l$ then

$$(j-1)m + i \le (j-1)m + m = jm \le (l-1)m < (l-1)m + k,$$

using $i \le m$, $j \le l - 1$ and $k \ge 1$. So each summand vanishes below the diagonal, and so does $\mathbf{R}$.

The diagonal. Taking $j = l$ and $i = k$ above, the diagonal entry of $\mathbf{R}$ in position $(j-1)m + i$ is $t_{ii} - s_{jj} = \lambda_i - \mu_j$. As (i, j) runs over all mn pairs, so does the position $(j-1)m + i$, by division with remainder.

By Theorem 8.7.4 (a), applied to the operator $T_{\mathbf{R}}$ on $\mathbb{C}^{mn}$ and the standard basis, $p_{\mathbf{R}} = \prod_{i,j} \big(x - (\lambda_i - \mu_j)\big)$. Since $\mathbf{K} \sim \mathbf{R}$, Theorem 6.10.3 gives $p_{\mathbf{K}} = p_{\mathbf{R}}$. This proves the lemma.

■

Two remarks on what the proof used. The hypothesis $F = \mathbb{C}$ entered once, in Schur, and through Schur it is the Fundamental Theorem of Algebra again. And the unitarity of $\mathbf{W}$ was a convenience, not a necessity: any similarity triangularizing $\mathbf{A}$ and $\mathbf{B}^\top$ would do, but Schur hands us one for free and the Kronecker product of two unitary matrices is unitary, which is worth recording on its own.

11.10.3 When the equation is uniquely solvable

The criterion now costs one line.

Theorem 11.10.2 — Sylvester's Theorem

Let $\mathbf{A} \in M_m(\mathbb{C})$ and $\mathbf{B} \in M_n(\mathbb{C})$. The following are equivalent.

(a) $\operatorname{spec}(\mathbf{A}) \cap \operatorname{spec}(\mathbf{B}) = \varnothing$: the two matrices have **no common eigenvalue**.

(b) The Sylvester operator $\mathcal{S}_{\mathbf{A},\mathbf{B}} \colon \mathbf{X} \mapsto \mathbf{AX} - \mathbf{XB}$ is invertible on $M_{m\times n}(\mathbb{C})$.

(c) For every $\mathbf{C} \in M_{m\times n}(\mathbb{C})$, the equation $\mathbf{AX} - \mathbf{XB} = \mathbf{C}$ has **exactly one** solution $\mathbf{X}$.

(d) The only $\mathbf{X} \in M_{m\times n}(\mathbb{C})$ with $\mathbf{AX} = \mathbf{XB}$ is $\mathbf{X} = \mathbf{0}$.

Proof. By Eq. 11.10.1 the isomorphism vec turns $\mathcal{S}_{\mathbf{A},\mathbf{B}}$ into the matrix $\mathbf{K} = \mathbf{I}_n \otimes \mathbf{A} - \mathbf{B}^{\top} \otimes \mathbf{I}_m$: a matrix $\mathbf{X}$ solves $\mathbf{AX} - \mathbf{XB} = \mathbf{C}$ if and only if the vector $\operatorname{vec}\mathbf{X}$ solves $\mathbf{Ky} = \operatorname{vec}\mathbf{C}$, and every $\mathbf{y} \in \mathbb{C}^{mn}$ and every $\mathbf{z} \in \mathbb{C}^{mn}$ arise this way. Transported through vec, statements (b), (c) and (d) say respectively that $\mathbf{K}$ is invertible, that $\mathbf{Ky} = \mathbf{z}$ has exactly one solution for every $\mathbf{z}$, and that $\mathbf{Ky} = \mathbf{0}$ forces $\mathbf{y} = \mathbf{0}$. These three are equivalent by Theorem 2.4.4, parts (a), (e) and (b): (e) gives existence for every $\mathbf{z}$, and (b) upgrades it to uniqueness, since two solutions differ by a member of the null space.

It remains to match (a) with (b). By Theorem 8.2.6, $\mathbf{K}$ is invertible if and only if $0 \notin \operatorname{spec}(\mathbf{K})$. By Lemma 11.10.1, $\operatorname{spec}(\mathbf{K}) = \{\lambda_i - \mu_j\}$, where $\lambda_1, \dots, \lambda_m$ and $\mu_1, \dots, \mu_n$ list the eigenvalues of $\mathbf{A}$ and of $\mathbf{B}$. So $0 \in \operatorname{spec}(\mathbf{K})$ if and only if $\lambda_i = \mu_j$ for some pair (i, j), that is, if and only if $\mathbf{A}$ and $\mathbf{B}$ have a common eigenvalue. Negating both sides matches (a) with (b), and the proof is complete. ∎

This is the statement Chapter 7 promised. At the end of Example (A Sylvester Equation as a Linear System) it was said that over $\mathbb{C}$ the equation $\mathbf{AX} - \mathbf{XB} = \mathbf{C}$ is uniquely solvable for every $\mathbf{C}$ exactly when $\mathbf{A}$ and $\mathbf{B}$ have no common eigenvalue, and that the criterion needs eigenvalues and would be proved in Chapter 11. Parts (a) and (c) of Theorem 11.10.2 are that sentence, and the eigenvalues it needed were supplied by Lemma 11.10.1. The quantitative version — *how badly* conditioned the equation is when the spectra are close but disjoint — is a separate matter, and belongs with perturbation theory in Chapter 19.

Part (d) is the version used most often in practice, because it is a statement with no data in it: to show that some matrix is zero, exhibit it as a solution of $\mathbf{AX} = \mathbf{XB}$ for a pair with disjoint spectra. The corollary on commutants below is that move and nothing else.

Example. (Solving a Sylvester Equation)

Over $\mathbb{C}$, solve $\mathbf{AX} - \mathbf{XB} = \mathbf{C}$ for

$$\mathbf{A} = \begin{pmatrix} 2 & 1 \\ 0 & 3 \end{pmatrix}, \quad \mathbf{B} = \begin{pmatrix} 1 & 0 \\ 2 & -1 \end{pmatrix}, \quad \mathbf{C} = \begin{pmatrix} 4 & -2 \\ 0 & 4 \end{pmatrix}.$$

Solution. The matrix $\mathbf{A}$ is upper triangular, so $\operatorname{spec}(\mathbf{A}) = \{2, 3\}$ (Theorem 8.7.4); $\mathbf{B}$ is lower triangular, so $\operatorname{spec}(\mathbf{B}) = \{1, -1\}$. The spectra are disjoint, and by Theorem 11.10.2 there is exactly one solution.

To find it, use Eq. 11.10.1. Here $\mathbf{B}^\top = \begin{pmatrix} 1 & 2 \\ 0 & -1 \end{pmatrix}$, so by Definition 7.4.1

$$\mathbf{I}_2 \otimes \mathbf{A} = \begin{pmatrix} 2 & 1 & 0 & 0 \\ 0 & 3 & 0 & 0 \\ 0 & 0 & 2 & 1 \\ 0 & 0 & 0 & 3 \end{pmatrix}, \qquad \mathbf{B}^\top \otimes \mathbf{I}_2 = \begin{pmatrix} 1 & 0 & 2 & 0 \\ 0 & 1 & 0 & 2 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & -1 \end{pmatrix},$$

and their difference is

$$\mathbf{K} = \begin{pmatrix} 1 & 1 & -2 & 0 \\ 0 & 2 & 0 & -2 \\ 0 & 0 & 3 & 1 \\ 0 & 0 & 0 & 4 \end{pmatrix}.$$

Its diagonal entries are $1, 2, 3, 4$, which are the four differences $2 - 1$, $3 - 1$, $2 - (-1)$, $3 - (-1)$, as Lemma 11.10.1 predicts; none is zero, confirming invertibility.

With $\operatorname{vec} \mathbf{X} = (x_{11}, x_{21}, x_{12}, x_{22})$ and $\operatorname{vec} \mathbf{C} = (4, 0, -2, 4)$, back substitution in $\mathbf{K} \operatorname{vec} \mathbf{X} = \operatorname{vec} \mathbf{C}$ gives $4x_{22} = 4$, so $x_{22} = 1$; then $3x_{12} + 1 = -2$, so $x_{12} = -1$; then $2x_{21} - 2 = 0$, so $x_{21} = 1$; then $x_{11} + 1 + 2 = 4$, so $x_{11} = 1$. Hence

$$\mathbf{X} = \begin{pmatrix} 1 & -1 \\ 1 & 1 \end{pmatrix}.$$

Check: $\mathbf{AX} = \begin{pmatrix} 3 & -1 \\ 3 & 3 \end{pmatrix}$ and $\mathbf{XB} = \begin{pmatrix} -1 & 1 \\ 3 & -1 \end{pmatrix}$, and their difference is $\mathbf{C}$.

Quick check. Let $\mathbf{A} \in M_3(\mathbb{C})$ have eigenvalues $1, 2, 2$ and let $\mathbf{B} \in M_2(\mathbb{C})$ have eigenvalues $0, 3$. List the eigenvalues of $\mathcal{S}_{\mathbf{A},\mathbf{B}}$ with multiplicity, and decide whether $\mathbf{AX} - \mathbf{XB} = \mathbf{C}$ is uniquely solvable for every $\mathbf{C} \in M_{3\times 2}(\mathbb{C})$.

Solution. By Lemma 11.10.1 the six eigenvalues are the differences $\lambda_i - \mu_j$:

$$1 - 0 = 1, \quad 2 - 0 = 2, \quad 2 - 0 = 2, \quad 1 - 3 = -2, \quad 2 - 3 = -1, \quad 2 - 3 = -1.$$

None is zero — equivalently $\operatorname{spec}(\mathbf{A}) = \{1, 2\}$ and $\operatorname{spec}(\mathbf{B}) = \{0, 3\}$ are disjoint — so by Theorem 11.10.2 the equation has exactly one solution for every $\mathbf{C}$.

Warning. **The criterion depends on the sign.** For the equation $\mathbf{AX} + \mathbf{XB} = \mathbf{C}$, which is the form Chapter 7 used in Example (A Sylvester Equation as a Linear System), the relevant operator is $\mathcal{S}_{\mathbf{A},-\mathbf{B}}$, and $\operatorname{spec}(-\mathbf{B}) = \{-\mu_j\}$. So the condition is $\lambda_i + \mu_j \neq 0$ for all i, j, **not** $\operatorname{spec}(\mathbf{A}) \cap \operatorname{spec}(\mathbf{B}) = \varnothing$. The two conditions are genuinely different: with $\mathbf{A} = \operatorname{diag}(1, 2)$ and $\mathbf{B} = \begin{pmatrix} -1 & 5 \\ 0 & 3 \end{pmatrix}$ the spectra $\{1, 2\}$ and $\{-1, 3\}$ are disjoint, yet $1 + (-1) = 0$, so $\mathbf{AX} + \mathbf{XB} = \mathbf{C}$ is not solvable for every $\mathbf{C}$. Read the sign off the equation before quoting the criterion.

11.10.4 Clearing the corner

We can now answer the question the section opened with.

Corollary 11.10.3 — Block Diagonalization by a Sylvester Solution

Let $\mathbf{A} \in M_m(F)$, $\mathbf{B} \in M_n(F)$ and $\mathbf{C} \in M_{m\times n}(F)$, and put

$$\mathbf{M} = \begin{pmatrix} \mathbf{A} & \mathbf{C} \\ \mathbf{0} & \mathbf{B} \end{pmatrix} \in M_{m+n}(F).$$

(a) If $\mathbf{X} \in M_{m\times n}(F)$ satisfies $\mathbf{AX} - \mathbf{XB} = -\mathbf{C}$, then with $\mathbf{P} = \begin{pmatrix} \mathbf{I}_m & \mathbf{X} \\ \mathbf{0} & \mathbf{I}_n \end{pmatrix}$ we have $\mathbf{P}^{-1}\mathbf{MP} = \mathbf{A} \oplus \mathbf{B}$. In particular $\mathbf{M} \sim \mathbf{A} \oplus \mathbf{B}$.

(b) Conversely, if $\mathbf{P}^{-1}\mathbf{MP} = \mathbf{A} \oplus \mathbf{B}$ for some $\mathbf{X} \in M_{m\times n}(F)$ and the matrix $\mathbf{P}$ built from it as in (a), then that $\mathbf{X}$ satisfies $\mathbf{AX} - \mathbf{XB} = -\mathbf{C}$.

(c) If $F = \mathbb{C}$ and $\operatorname{spec}(\mathbf{A}) \cap \operatorname{spec}(\mathbf{B}) = \varnothing$, then a solution $\mathbf{X}$ exists, and it is unique; so $\mathbf{M} \sim \mathbf{A} \oplus \mathbf{B}$ for **every** corner $\mathbf{C}$.

Idea. The matrices $\begin{pmatrix} \mathbf{I}_m & \mathbf{X} \\ \mathbf{0} & \mathbf{I}_n \end{pmatrix}$ are exactly the changes of basis that add multiples of the first block of basis vectors to the second and leave the first alone. Conjugating $\mathbf{M}$ by one of them cannot touch the two diagonal blocks or create anything below the diagonal; all it can do is move the corner, and the block multiplication shows it moves the corner by $\mathbf{AX} - \mathbf{XB}$. So the corner can be driven to $\mathbf{0}$ precisely when $-\mathbf{C}$ lies in the image of the Sylvester operator.

Proof.

(a) First, $\mathbf{P}$ is invertible with

$$\mathbf{P}^{-1} = \begin{pmatrix} \mathbf{I}_m & -\mathbf{X} \\ \mathbf{0} & \mathbf{I}_n \end{pmatrix},$$

since multiplying the two matrices in either order gives $\mathbf{I}_{m+n}$ by Theorem 7.1.1, the partitions being conformable. The same theorem gives

$$\mathbf{MP} = \begin{pmatrix} \mathbf{A} & \mathbf{AX} + \mathbf{C} \\ \mathbf{0} & \mathbf{B} \end{pmatrix},$$

and then

$$\mathbf{P}^{-1}\mathbf{MP} = \begin{pmatrix} \mathbf{A} & \mathbf{AX} + \mathbf{C} - \mathbf{XB} \\ \mathbf{0} & \mathbf{B} \end{pmatrix}.$$

By hypothesis $\mathbf{AX} - \mathbf{XB} = -\mathbf{C}$, so the corner is $\mathbf{0}$ and the result is $\mathbf{A} \oplus \mathbf{B}$ (Definition 7.1.2).

(b) The computation in (a) used nothing about $\mathbf{X}$ until the last sentence. So if that $\mathbf{P}$ satisfies $\mathbf{P}^{-1}\mathbf{MP} = \mathbf{A} \oplus \mathbf{B}$, comparing the corners of the two sides gives $\mathbf{AX} + \mathbf{C} - \mathbf{XB} = \mathbf{0}$, which is the equation.

(c) By Theorem 11.10.2 ((a) $\Rightarrow$ (c)), the equation $\mathbf{AX} - \mathbf{XB} = -\mathbf{C}$ has exactly one solution. Apply (a).

■

Example. (Clearing a Corner)

Block-diagonalize

$$\mathbf{M} = \begin{pmatrix} 2 & 1 & -4 & 2 \\ 0 & 3 & 0 & -4 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 2 & -1 \end{pmatrix} \in M_4(\mathbb{Q}).$$

Solution. Partition $\mathbf{M}$ into 2×2 blocks. The diagonal blocks are the matrices $\mathbf{A}$ and $\mathbf{B}$ of Example (Solving a Sylvester Equation), and the corner is

$$\begin{pmatrix} -4 & 2 \\ 0 & -4 \end{pmatrix} = -\mathbf{C}$$

for the $\mathbf{C}$ of that example. So the equation to solve is $\mathbf{AX} - \mathbf{XB} = -(-\mathbf{C}) = \mathbf{C}$, which is the one already solved there, with the unique solution $\mathbf{X} = \begin{pmatrix} 1 & -1 \\ 1 & 1 \end{pmatrix}$. By Corollary 11.10.3 (a), taking

$$\mathbf{P} = \begin{pmatrix} 1 & 0 & 1 & -1 \\ 0 & 1 & 1 & 1 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}$$

gives $\mathbf{P}^{-1}\mathbf{M}\mathbf{P} = \mathbf{A} \oplus \mathbf{B}$, that is,

$$\mathbf{P}^{-1}\mathbf{M}\mathbf{P} = \begin{pmatrix} 2 & 1 & 0 & 0 \\ 0 & 3 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 2 & -1 \end{pmatrix}.$$

The eigenvalues $2, 3, 1, -1$ are of course unchanged; what has changed is that the space has been split into two invariant pieces of dimension 2.

Remark. Part (b) restricts the shape of $\mathbf{P}$, and one may ask whether that is a real restriction: if $\mathbf{M}$ is similar to $\mathbf{A} \oplus \mathbf{B}$ by *any* invertible matrix, must the Sylvester equation be solvable? The answer is yes over every field. This is **Roth's removal rule**, and the proof is not a block computation: it goes through the characteristic matrix and the criterion $\mathbf{A} \sim \mathbf{B}$ if and only if $x\mathbf{I} - \mathbf{A} \approx x\mathbf{I} - \mathbf{B}$ over $F[x]$ (Theorem 9.7.5). We do not need it here and do not prove it; nothing later in the book depends on it.

Primary decomposition, seen again. Put Corollary 11.10.3 next to Schur and a familiar theorem drops out with no extra work. Let $\mathbf{A} \in M_N(\mathbb{C})$ have distinct eigenvalues $\lambda_1, \dots, \lambda_k$ with algebraic multiplicities $a_1, \dots, a_k$. By Corollary 11.1.3 we may prescribe the order of the diagonal in a Schur factorization, so choose the order that lists all copies of λ_1 first, then all copies of λ_2, and so on. Partitioning the resulting triangular matrix along $N = a_1 + \cdots + a_k$ makes it block upper triangular with diagonal blocks $\mathbf{T}_1, \dots, \mathbf{T}_k$, where $\mathbf{T}_i$ is triangular with the single diagonal value λ_i, so $\operatorname{spec}(\mathbf{T}_i) = \{\lambda_i\}$. Now peel the blocks off one at a time: $\operatorname{spec}(\mathbf{T}_1)$ is disjoint from the spectrum of the rest, so Corollary 11.10.3 (c) splits off $\mathbf{T}_1$, and induction

on k finishes. The conclusion is that $\mathbf{A} \sim \mathbf{T}_1 \oplus \cdots \oplus \mathbf{T}_k$ with $\operatorname{spec}(\mathbf{T}_i) = \{\lambda_i\}$ — the matrix form of the primary decomposition of Theorem 8.8.1, here obtained from a triangular form and a linear equation rather than from the kernel-splitting lemma.

11.10.5 Commuting with a matrix of disjoint spectra

Here is the promised use of Theorem 11.10.2 (d). It says that disjoint spectra force a block structure on anything that commutes.

Corollary 11.10.4 — Disjoint Spectra Split the Commutant

Let $\mathbf{A}_1 \in M_{n_1}(\mathbb{C}), \dots, \mathbf{A}_r \in M_{n_r}(\mathbb{C})$ have **pairwise disjoint** spectra, and put $\mathbf{D} = \mathbf{A}_1 \oplus \cdots \oplus \mathbf{A}_r \in M_N(\mathbb{C})$, $N = n_1 + \cdots + n_r$. Let $\mathbf{Z} \in M_N(\mathbb{C})$ satisfy $\mathbf{DZ} = \mathbf{ZD}$, and partition $\mathbf{Z}$ into blocks $\mathbf{Z}_{pq} \in M_{n_p \times n_q}(\mathbb{C})$ for the partition $N = n_1 + \cdots + n_r$. Then

$$\mathbf{Z}_{pq} = \mathbf{0} \quad \text{for all } p \neq q,$$

so $\mathbf{Z} = \mathbf{Z}_{11} \oplus \cdots \oplus \mathbf{Z}_{rr}$ is block **diagonal**, and each diagonal block satisfies $\mathbf{A}_p \mathbf{Z}_{pp} = \mathbf{Z}_{pp} \mathbf{A}_p$.

Proof. By Theorem 7.1.1, the (p, q) block of $\mathbf{DZ}$ is $\mathbf{A}_p \mathbf{Z}_{pq}$ and the (p, q) block of $\mathbf{ZD}$ is $\mathbf{Z}_{pq} \mathbf{A}_q$, because $\mathbf{D}$ has only one non-zero block in each block row and in each block column. So $\mathbf{DZ} = \mathbf{ZD}$ is equivalent to

$$\mathbf{A}_p \mathbf{Z}_{pq} = \mathbf{Z}_{pq} \mathbf{A}_q \qquad (1 \leq p, q \leq r).$$

Let $p \neq q$. Then $\operatorname{spec}(\mathbf{A}_p) \cap \operatorname{spec}(\mathbf{A}_q) = \varnothing$ by hypothesis, so Theorem 11.10.2 ((a) $\Rightarrow$ (d)) forces $\mathbf{Z}_{pq} = \mathbf{0}$. The diagonal equations $\mathbf{A}_p \mathbf{Z}_{pp} = \mathbf{Z}_{pp} \mathbf{A}_p$ are the remaining cases $p = q$, and they carry no information beyond commuting.

■

Read the statement twice, because a similar-sounding claim is false.

Warning. **It is the disjointness of the spectra that does the work, not the block diagonal shape.** Nothing here says that a matrix commuting with a block diagonal matrix is block diagonal, and nothing here says that a commutant consists of triangular matrices. Both fail as soon as two diagonal blocks share an eigenvalue. Chapter 9 §04 computes the commutant of $\mathbf{J} = \mathbf{J}_2(0) \oplus \mathbf{J}_1(0)$ explicitly and finds it to be

$$\left\{ \begin{pmatrix} a & b & c \\ 0 & a & 0 \\ 0 & h & i \end{pmatrix} : a, b, c, h, i \in F \right\},$$

which contains matrices with a non-zero entry **below** the diagonal, in position $(3, 2)$. That does not contradict Corollary 11.10.4: the two blocks $\mathbf{J}_2(0)$ and $\mathbf{J}_1(0)$ have the same spectrum $\{0\}$, so the corollary has nothing to say about them. What is true for a single repeated eigenvalue is weaker and needs a different normal form: the commutant of a basic **Weyr** matrix is block upper triangular for the Weyr partition (Proposition 9.4.6),

and the Jordan form has no such property. Note too that even when Corollary 11.10.4 applies, it says nothing about the diagonal blocks $\mathbf{Z}_{pp}$ themselves, which range over the whole commutant of $\mathbf{A}_p$.

The corollary is the reason spectral separation is so useful. Combined with the primary decomposition above, it says that over $\mathbb{C}$ the commutant of any matrix splits along its distinct eigenvalues: after the change of basis that block-diagonalizes $\mathbf{A}$ by spectrum, everything commuting with $\mathbf{A}$ becomes block diagonal too, and the hard part of describing a commutant is always the single-eigenvalue part. The pleasant case of the same phenomenon appeared in Theorem 11.7.1, where the pieces are honest eigenspaces and the splitting is orthogonal.

11.10.6 Lyapunov's equation

One specialization is important enough to have its own name.

Definition 11.10.2 — Lyapunov equation

Let $\mathbf{A} \in M_n(\mathbb{C})$ and $\mathbf{Q} \in M_n(\mathbb{C})$. The **Lyapunov equation** for the pair $(\mathbf{A}, \mathbf{Q})$ is

$$\mathbf{A}\mathbf{X} + \mathbf{X}\mathbf{A}^* = -\mathbf{Q},$$

with unknown $\mathbf{X} \in M_n(\mathbb{C})$. Call $\mathbf{A}$ **stable** when every $\lambda \in \operatorname{spec}(\mathbf{A})$ has $\operatorname{Re}\lambda < 0$.

This is the Sylvester equation with $\mathbf{B} = -\mathbf{A}^*$, since $\mathbf{A}\mathbf{X} - \mathbf{X}(-\mathbf{A}^*) = \mathbf{A}\mathbf{X} + \mathbf{X}\mathbf{A}^*$. To apply Theorem 11.10.2 we need $\operatorname{spec}(-\mathbf{A}^*)$.

The eigenvalues of $\mathbf{A}^*$ are the conjugates of those of $\mathbf{A}$. Indeed $\det(\mathbf{M}^*) = \overline{\det \mathbf{M}}$ for every $\mathbf{M} \in M_n(\mathbb{C})$, because $\det(\mathbf{M}^\top) = \det \mathbf{M}$ (Theorem 6.4.5) and the determinant is a sum of products of entries with coefficients ± 1 (Definition 6.4.1), so conjugating every entry conjugates the value. Applying this to $\mathbf{M} = \lambda\mathbf{I} - \mathbf{A}$, whose conjugate transpose is $\overline{\lambda}\mathbf{I} - \mathbf{A}^*$, gives $\det(\overline{\lambda}\mathbf{I} - \mathbf{A}^*) = \overline{\det(\lambda\mathbf{I} - \mathbf{A})}$. So one determinant vanishes exactly when the other does, and $\lambda \in \operatorname{spec}(\mathbf{A})$ if and only if $\overline{\lambda} \in \operatorname{spec}(\mathbf{A}^*)$ (Theorem 8.2.1).

Therefore $\operatorname{spec}(-\mathbf{A}^*) = \{-\overline{\lambda} : \lambda \in \operatorname{spec}(\mathbf{A})\}$, and Theorem 11.10.2 says the Lyapunov equation has exactly one solution for every $\mathbf{Q}$ precisely when

$$\lambda + \overline{\mu} \neq 0 \qquad \text{for all } \lambda, \mu \in \operatorname{spec}(\mathbf{A}).$$

If $\mathbf{A}$ is stable this holds, because then $\operatorname{Re}(\lambda + \overline{\mu}) = \operatorname{Re}\lambda + \operatorname{Re}\mu < 0$. So a stable matrix gives a uniquely solvable Lyapunov equation, whatever $\mathbf{Q}$ is.

What makes the equation important is a statement we are not yet equipped to prove. Call a Hermitian matrix $\mathbf{X}$ **positive definite** when $\mathbf{x}^*\mathbf{X}\mathbf{x} > 0$ for every non-zero $\mathbf{x} \in \mathbb{C}^n$. Then: *if $\mathbf{A}$ is stable and $\mathbf{Q}$ is positive definite, the unique solution $\mathbf{X}$ of $\mathbf{A}\mathbf{X} + \mathbf{X}\mathbf{A}^* = -\mathbf{Q}$ is positive definite; and conversely, if some positive definite $\mathbf{X}$ solves the equation for some positive definite $\mathbf{Q}$, then $\mathbf{A}$ is stable.* Positivity is the subject of Chapter 12, where the tools to handle $\mathbf{x}^*\mathbf{X}\mathbf{x}$ are built, and the consequence for differential equations — that a stable $\mathbf{A}$ makes every solution of $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x}$ decay, with $\mathbf{x}^*\mathbf{X}\mathbf{x}$ as the quantity that measures the decay — belongs to Chapter 15. We record the equation here because its *solvability*, which is the part Sylvester's theorem settles, is exactly what makes the rest possible.

11.10.7 Exercises

11.10.7.1 A. Check your understanding

Exercise A1.

(a) Define the Sylvester operator of a pair $(\mathbf{A}, \mathbf{B})$ with $\mathbf{A} \in M_m(F)$, $\mathbf{B} \in M_n(F)$, and state the dimension of the space it acts on.

(b) Write down the matrix of the Sylvester operator with respect to the vectorization vec, and say which Chapter 7 result produces it.

(c) State the criterion for $\mathbf{AX} - \mathbf{XB} = \mathbf{C}$ to have exactly one solution for every $\mathbf{C}$, over $\mathbb{C}$.

(d) True or false: if $\mathbf{AX} - \mathbf{XB} = \mathbf{C}$ has at least one solution for every $\mathbf{C}$, then that solution is unique. Justify your answer.

(e) True or false: if $\operatorname{spec}(\mathbf{A}) \cap \operatorname{spec}(\mathbf{B}) = \varnothing$, then $\mathbf{AX} + \mathbf{XB} = \mathbf{C}$ has exactly one solution for every $\mathbf{C}$. Justify your answer.

Solution.

(a) $\mathcal{S}_{\mathbf{A},\mathbf{B}}(\mathbf{X}) = \mathbf{AX} - \mathbf{XB}$ for $\mathbf{X} \in M_{m\times n}(F)$ (Definition 11.10.1). It acts on $M_{m\times n}(F)$, of dimension mn.

(b) $\mathbf{K} = \mathbf{I}_n \otimes \mathbf{A} - \mathbf{B}^{\top} \otimes \mathbf{I}_m$, by Eq. 11.10.1; it comes from the vec identity Theorem 7.4.4 applied twice, with $\operatorname{vec}(\mathbf{AX}) = (\mathbf{I}_n \otimes \mathbf{A}) \operatorname{vec} \mathbf{X}$ and $\operatorname{vec}(\mathbf{XB}) = (\mathbf{B}^{\top} \otimes \mathbf{I}_m) \operatorname{vec} \mathbf{X}$.

(c) Exactly when $\mathbf{A}$ and $\mathbf{B}$ have no common eigenvalue, that is $\operatorname{spec}(\mathbf{A}) \cap \operatorname{spec}(\mathbf{B}) = \varnothing$ (Theorem 11.10.2).

(d) True. Existence for every $\mathbf{C}$ says $\mathcal{S}_{\mathbf{A},\mathbf{B}}$ is surjective; an operator on the finite-dimensional space $M_{m\times n}(F)$ is surjective if and only if it is injective (Theorem 2.4.4 through vec, or Rank–Nullity), and injectivity is uniqueness.

(e) False. The criterion for the $+$ form is $\lambda + \mu \neq 0$ for all $\lambda \in \operatorname{spec}(\mathbf{A})$, $\mu \in \operatorname{spec}(\mathbf{B})$, since $\mathbf{AX} + \mathbf{XB} = \mathcal{S}_{\mathbf{A},-\mathbf{B}}(\mathbf{X})$. With $\mathbf{A} = \operatorname{diag}(1, 2)$ and $\mathbf{B} = \operatorname{diag}(-1, 3)$ the spectra are disjoint but $1 + (-1) = 0$, so the equation is not uniquely solvable.

11.10.7.2 B. Practice

Exercise B1: A Sylvester equation by vectorization.

Over $\mathbb{Q}$, let

$$\mathbf{A} = \begin{pmatrix} 3 & 1 \\ 0 & 1 \end{pmatrix}, \qquad \mathbf{B} = \begin{pmatrix} -1 & 0 \\ 1 & 0 \end{pmatrix}, \qquad \mathbf{C} = \begin{pmatrix} 2 & 1 \\ 0 & -2 \end{pmatrix}.$$

(a) Compute $\operatorname{spec}(\mathbf{A})$ and $\operatorname{spec}(\mathbf{B})$, and decide whether $\mathbf{AX} - \mathbf{XB} = \mathbf{C}$ has exactly one solution.

(b) Write down $\mathbf{K} = \mathbf{I}_2 \otimes \mathbf{A} - \mathbf{B}^{\top} \otimes \mathbf{I}_2$, and check that its diagonal entries are the four differences $\lambda_i - \mu_j$.

(c) Solve the equation.

Solution.

(a) $\mathbf{A}$ is upper triangular with diagonal $3, 1$, so $\operatorname{spec}(\mathbf{A}) = \{3, 1\}$ (Theorem 8.7.4). For $\mathbf{B}$, $p_{\mathbf{B}} = \det \begin{pmatrix} x+1 & 0 \\ -1 & x \end{pmatrix} = x(x+1)$, so $\operatorname{spec}(\mathbf{B}) = \{0, -1\}$. The spectra are disjoint, so by Theorem 11.10.2 there is exactly one solution for this (or any) $\mathbf{C}$.

(b) $\mathbf{B}^{\top} = \begin{pmatrix} -1 & 1 \\ 0 & 0 \end{pmatrix}$, so

$$\mathbf{I}_2 \otimes \mathbf{A} = \begin{pmatrix} 3 & 1 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 3 & 1 \\ 0 & 0 & 0 & 1 \end{pmatrix}, \qquad \mathbf{B}^{\top} \otimes \mathbf{I}_2 = \begin{pmatrix} -1 & 0 & 1 & 0 \\ 0 & -1 & 0 & 1 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix},$$

and

$$\mathbf{K} = \begin{pmatrix} 4 & 1 & -1 & 0 \\ 0 & 2 & 0 & -1 \\ 0 & 0 & 3 & 1 \\ 0 & 0 & 0 & 1 \end{pmatrix}.$$

Its diagonal is $4, 2, 3, 1$, and the differences $\lambda_i - \mu_j$ are $3-(-1) = 4$, $1-(-1) = 2$, $3-0 = 3$, $1-0 = 1$, as Lemma 11.10.1 asserts.

(c) With $\operatorname{vec} \mathbf{X} = (x_{11}, x_{21}, x_{12}, x_{22})$ and $\operatorname{vec} \mathbf{C} = (2, 0, 1, -2)$, back substitution gives $x_{22} = -2$; then $3x_{12} + x_{22} = 1$, so $x_{12} = 1$; then $2x_{21} - x_{22} = 0$, so $x_{21} = -1$; then $4x_{11} + x_{21} - x_{12} = 2$, so $x_{11} = 1$. Hence

$$\mathbf{X} = \begin{pmatrix} 1 & 1 \\ -1 & -2 \end{pmatrix}.$$

Check: $\mathbf{AX} = \begin{pmatrix} 2 & 1 \\ -1 & -2 \end{pmatrix}$ and $\mathbf{XB} = \begin{pmatrix} 0 & 0 \\ -1 & 0 \end{pmatrix}$, and their difference is $\mathbf{C}$.

Exercise B2: Block-diagonalizing a 3×3 matrix.

Let

$$\mathbf{M} = \begin{pmatrix} 2 & 1 & 2 \\ 0 & 2 & 3 \\ 0 & 0 & 5 \end{pmatrix} \in M_3(\mathbb{Q}).$$

(a) Partition $\mathbf{M}$ as $3 = 2 + 1$, name the blocks $\mathbf{A}$, $\mathbf{B}$, $\mathbf{C}$, and explain why Corollary 11.10.3 applies.

(b) Solve the corresponding Sylvester equation.

(c) Write down $\mathbf{P}$ and verify that $\mathbf{P}^{-1}\mathbf{M}\mathbf{P} = \mathbf{A} \oplus \mathbf{B}$.

Solution.

(a) The blocks are $\mathbf{A} = \begin{pmatrix} 2 & 1 \\ 0 & 2 \end{pmatrix}$, $\mathbf{B} = (5)$ and $\mathbf{C} = \begin{pmatrix} 2 \\ 3 \end{pmatrix}$. Both diagonal blocks are triangular, so $\operatorname{spec}(\mathbf{A}) = \{2\}$ and $\operatorname{spec}(\mathbf{B}) = \{5\}$ (Theorem 8.7.4); these are disjoint, so Corollary 11.10.3 (c) applies and a unique $\mathbf{X} \in M_{2\times 1}(\mathbb{Q})$ exists.

(b) With $\mathbf{X} = \mathbf{x} = (x_1, x_2)$, the equation $\mathbf{A}\mathbf{x} - 5\mathbf{x} = -\mathbf{C}$ reads $(\mathbf{A} - 5\mathbf{I}_2)\mathbf{x} = -\mathbf{C}$, that

is

$$\begin{pmatrix} -3 & 1 \\ 0 & -3 \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \end{pmatrix} = \begin{pmatrix} -2 \\ -3 \end{pmatrix}.$$

The second row gives $x_2 = 1$, and the first then gives $-3x_1 + 1 = -2$, so $x_1 = 1$. Hence $\mathbf{x} = (1, 1)$.

(c) Taking

$$\mathbf{P} = \begin{pmatrix} 1 & 0 & 1 \\ 0 & 1 & 1 \\ 0 & 0 & 1 \end{pmatrix}, \qquad \mathbf{P}^{-1} = \begin{pmatrix} 1 & 0 & -1 \\ 0 & 1 & -1 \\ 0 & 0 & 1 \end{pmatrix},$$

we get $\mathbf{MP} = \begin{pmatrix} 2 & 1 & 5 \\ 0 & 2 & 5 \\ 0 & 0 & 5 \end{pmatrix}$ and then

$$\mathbf{P}^{-1}\mathbf{MP} = \begin{pmatrix} 2 & 1 & 0 \\ 0 & 2 & 0 \\ 0 & 0 & 5 \end{pmatrix} = \mathbf{A} \oplus \mathbf{B},$$

as Corollary 11.10.3 (a) predicts.

Exercise B3: Which equations are uniquely solvable?.

Determine, for each of the following, whether the stated equation has exactly one solution $\mathbf{X} \in M_2(\mathbb{C})$ for **every** right-hand side $\mathbf{C} \in M_2(\mathbb{C})$. Justify your answer.

(a) $\mathbf{AX} - \mathbf{XB} = \mathbf{C}$ with $\mathbf{A} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$, $\mathbf{B} = \begin{pmatrix} 2 & 0 \\ 0 & 3 \end{pmatrix}$.

(b) $\mathbf{AX} - \mathbf{XB} = \mathbf{C}$ with $\mathbf{A} = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}$, $\mathbf{B} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$.

(c) $\mathbf{AX} + \mathbf{XB} = \mathbf{C}$ with $\mathbf{A} = \begin{pmatrix} 1 & 0 \\ 0 & 2 \end{pmatrix}$, $\mathbf{B} = \begin{pmatrix} -1 & 5 \\ 0 & 3 \end{pmatrix}$.

(d) $\mathbf{AX} - \mathbf{XB} = \mathbf{C}$ with $\mathbf{A} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$, $\mathbf{B} = \begin{pmatrix} 1 & 0 \\ 2 & 1 \end{pmatrix}$.

(e) $\mathbf{AX} - \mathbf{XB} = \mathbf{C}$ with $\mathbf{A} \in M_2(\mathbb{C})$ nilpotent and $\mathbf{B} \in M_2(\mathbb{C})$ invertible.

Solution.

(a) Yes. $\operatorname{spec}(\mathbf{A}) = \{1\}$ and $\operatorname{spec}(\mathbf{B}) = \{2, 3\}$ are disjoint (Theorem 8.7.4), so Theorem 11.10.2 applies.

(b) No. Both characteristic polynomials are $x^2 + 1$, so $\operatorname{spec}(\mathbf{A}) = \operatorname{spec}(\mathbf{B}) = \{i, -i\}$, which is as far from disjoint as possible. A witness is easy to produce here: $\mathbf{X} = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$ gives $\mathbf{AX} = \begin{pmatrix} 0 & -1 \\ -1 & 0 \end{pmatrix} = \mathbf{XB}$, so $\mathbf{X}$ is a non-zero member of $\ker \mathcal{S}_{\mathbf{A},\mathbf{B}}$ and condition (d) of Theorem 11.10.2 fails.

(c) No. This is the $+$ form, so the operator is $\mathcal{S}_{\mathbf{A},-\mathbf{B}}$ and the condition is $\lambda + \mu \neq 0$. Here $\operatorname{spec}(\mathbf{A}) = \{1, 2\}$ and $\operatorname{spec}(\mathbf{B}) = \{-1, 3\}$, and $1 + (-1) = 0$.

(d) No. Both are triangular with diagonal $1, 1$, so $\operatorname{spec}(\mathbf{A}) = \operatorname{spec}(\mathbf{B}) = \{1\}$.

(e) Yes. A nilpotent matrix has $\operatorname{spec}(\mathbf{A}) = \{0\}$, since $\mathbf{A}^k = \mathbf{0}$ forces $\lambda^k = 0$ for every eigenvalue λ; and $0 \notin \operatorname{spec}(\mathbf{B})$ because $\mathbf{B}$ is invertible (Theorem 8.2.6). So the

spectra are disjoint.

11.10.7.3 C. Going deeper

Exercise C1: Eigenvectors of the Sylvester operator.

Let $\mathbf{A} \in M_m(\mathbb{C})$ and $\mathbf{B} \in M_n(\mathbb{C})$, and let $\mathcal{S} = \mathcal{S}_{\mathbf{A},\mathbf{B}}$.

(a) Suppose $\mathbf{A}\mathbf{x} = \lambda\mathbf{x}$ with $\mathbf{x} \in \mathbb{C}^m$ non-zero, and suppose $\mathbf{y} \in \mathbb{C}^n$ is a left eigenvector of $\mathbf{B}$ for μ, so that $\mathbf{y}^\top\mathbf{B} = \mu\mathbf{y}^\top$ (Definition 8.10.1). Prove that $\mathbf{x}\mathbf{y}^\top \neq \mathbf{0}$ and that $\mathcal{S}(\mathbf{x}\mathbf{y}^\top) = (\lambda - \mu)\,\mathbf{x}\mathbf{y}^\top$.

(b) Deduce that every difference $\lambda - \mu$ with $\lambda \in \operatorname{spec}(\mathbf{A})$ and $\mu \in \operatorname{spec}(\mathbf{B})$ is an eigenvalue of $\mathcal{S}$.

(c) Hence give a second proof that $\mathcal{S}$ is not invertible when $\mathbf{A}$ and $\mathbf{B}$ have a common eigenvalue, one that uses no Kronecker products.

Solution.

(a) Choose i with $x_i \neq 0$ and j with $y_j \neq 0$; these exist because $\mathbf{x}$ and $\mathbf{y}$ are non-zero. The (i,j) entry of $\mathbf{x}\mathbf{y}^\top$ is $x_i y_j \neq 0$, so $\mathbf{x}\mathbf{y}^\top \neq \mathbf{0}$. For the eigenvalue equation, associativity of matrix multiplication (Theorem 0.9.4) gives

$$\mathcal{S}(\mathbf{x}\mathbf{y}^\top) = (\mathbf{A}\mathbf{x})\mathbf{y}^\top - \mathbf{x}(\mathbf{y}^\top\mathbf{B}) = \lambda\mathbf{x}\mathbf{y}^\top - \mu\mathbf{x}\mathbf{y}^\top,$$

which is $(\lambda - \mu)\mathbf{x}\mathbf{y}^\top$.

(b) Let $\lambda \in \operatorname{spec}(\mathbf{A})$ and $\mu \in \operatorname{spec}(\mathbf{B})$. A right eigenvector $\mathbf{x}$ for λ exists by Definition 8.2.1, and a left eigenvector $\mathbf{y}$ for μ exists by Proposition 8.10.5 (b). By (a), $\mathbf{x}\mathbf{y}^\top$ is a non-zero matrix with $\mathcal{S}(\mathbf{x}\mathbf{y}^\top) = (\lambda - \mu)\mathbf{x}\mathbf{y}^\top$, so $\lambda - \mu$ is an eigenvalue of $\mathcal{S}$ with eigenvector $\mathbf{x}\mathbf{y}^\top$.

(c) If $\lambda \in \operatorname{spec}(\mathbf{A}) \cap \operatorname{spec}(\mathbf{B})$, apply (b) with $\mu = \lambda$: then 0 is an eigenvalue of $\mathcal{S}$, so $\ker \mathcal{S} \neq \{\mathbf{0}\}$ and $\mathcal{S}$ is not invertible. This shows one implication of Theorem 11.10.2 directly. (It does not give the converse: knowing every $\lambda - \mu$ is an eigenvalue does not by itself show there are no others.)

Exercise C2: The kernel when the spectra meet.

Let $\mathbf{A} \in M_m(\mathbb{C})$ and $\mathbf{B} \in M_n(\mathbb{C})$ have eigenvalue lists $\lambda_1, \dots, \lambda_m$ and $\mu_1, \dots, \mu_n$ with algebraic multiplicity, and let $d = \#\{(i,j) : \lambda_i = \mu_j\}$.

(a) Prove that $\dim\ker \mathcal{S}_{\mathbf{A},\mathbf{B}} \geq 1$ if and only if $d \geq 1$.

(b) Prove that $\dim\ker \mathcal{S}_{\mathbf{A},\mathbf{B}} \leq d$.

(c) Show that the inequality in (b) can be strict, by computing $\ker \mathcal{S}_{\mathbf{A},\mathbf{B}}$ for $\mathbf{A} = \mathbf{B} = \mathbf{J}_2(0)$.

Solution.

(a) $d \geq 1$ says exactly that $\mathbf{A}$ and $\mathbf{B}$ have a common eigenvalue, and by Theorem 11.10.2 ((a) $\Leftrightarrow$ (d)) that is exactly the failure of $\ker \mathcal{S}_{\mathbf{A},\mathbf{B}} = \{\mathbf{0}\}$.

(b) The operator $\mathcal{S}_{\mathbf{A},\mathbf{B}}$ has matrix $\mathbf{K}$ (Eq. 11.10.1), so $\dim\ker \mathcal{S}_{\mathbf{A},\mathbf{B}} = g_{\mathbf{K}}(0)$, the

geometric multiplicity of 0 as an eigenvalue of $\mathbf{K}$ (when $0 \notin \operatorname{spec}(\mathbf{K})$ both sides are 0 and there is nothing to prove). By Lemma 11.10.1 the eigenvalue list of $\mathbf{K}$ consists of the mn differences $\lambda_i - \mu_j$, so the algebraic multiplicity is $a_{\mathbf{K}}(0) = d$. By Theorem 8.3.1, $g_{\mathbf{K}}(0) \le a_{\mathbf{K}}(0) = d$.

(c) Here $m = n = 2$ and $\lambda_1 = \lambda_2 = \mu_1 = \mu_2 = 0$, so $d = 4$. The kernel is the commutant of $\mathbf{J} = \mathbf{J}_2(0)$: writing $\mathbf{X} = \begin{pmatrix} p & q \\ r & s \end{pmatrix}$,

$$\mathbf{JX} = \begin{pmatrix} r & s \\ 0 & 0 \end{pmatrix}, \qquad \mathbf{XJ} = \begin{pmatrix} 0 & p \\ 0 & r \end{pmatrix},$$

so $\mathbf{JX} = \mathbf{XJ}$ forces $r = 0$ and $s = p$, and leaves q free. Hence $\ker \mathcal{S}_{\mathbf{J},\mathbf{J}} = \operatorname{span}(\mathbf{I}_2, \mathbf{J})$, of dimension $2 < 4 = d$.

Exercise C3: Only the scalars commute with everything.

Let F be a field, $n \ge 2$, and let $\mathbf{E}_{ij} \in M_n(F)$ be the matrix unit with 1 in position (i, j) and 0 elsewhere.

(a) Suppose $\mathbf{A} \in M_n(F)$ satisfies $\mathbf{AE}_{ij} = \mathbf{E}_{ij}\mathbf{A}$ for all $i \ne j$. Prove that $\mathbf{A} = c\mathbf{I}_n$ for some $c \in F$.

(b) Deduce that the only matrices commuting with every $\mathbf{X} \in M_n(F)$ are the scalar matrices, that is, $\ker \mathcal{S}_{\mathbf{A},\mathbf{A}} = M_n(F)$ forces $\mathbf{A}$ scalar.

(c) Deduce that the only matrices commuting with every **invertible** matrix are again the scalar matrices.

Hint for (c): $\mathbf{I}_n + \mathbf{E}_{ij}$ *is invertible when* $i \ne j$.

Solution.

(a) Fix $i \ne j$. By Theorem 0.9.2, $\mathbf{AE}_{ij}$ has column j equal to $\mathbf{Ae}_i$, that is column i of $\mathbf{A}$, and all other columns zero; while $\mathbf{E}_{ij}\mathbf{A}$ has row i equal to row j of $\mathbf{A}$, and all other rows zero. Compare entries.
Take $k \ne i$. The (k, j) entry of $\mathbf{AE}_{ij}$ is a_{ki}, and the (k, j) entry of $\mathbf{E}_{ij}\mathbf{A}$ is 0, because row $k \ne i$ of $\mathbf{E}_{ij}\mathbf{A}$ is zero. Hence $a_{ki} = 0$ whenever $k \ne i$. Since $n \ge 2$, every index i has some $j \ne i$ available, so this holds for every i, and $\mathbf{A}$ is diagonal. Now the (i, j) entry: on the left it is a_{ii} (the i-th entry of column i of $\mathbf{A}$), and on the right it is a_{jj} (the j-th entry of row j of $\mathbf{A}$). So $a_{ii} = a_{jj}$ for all $i \ne j$. Writing c for this common value, $\mathbf{A} = c\mathbf{I}_n$.

(b) If $\mathbf{AX} = \mathbf{XA}$ for every $\mathbf{X} \in M_n(F)$, then in particular for $\mathbf{X} = \mathbf{E}_{ij}$ with $i \ne j$, so (a) gives $\mathbf{A} = c\mathbf{I}_n$. Conversely every scalar matrix commutes with everything. Hence $\ker \mathcal{S}_{\mathbf{A},\mathbf{A}} = M_n(F)$ if and only if $\mathbf{A}$ is scalar.

(c) For $i \ne j$ we have $\mathbf{E}_{ij}^2 = \mathbf{0}$, so $(\mathbf{I}_n + \mathbf{E}_{ij})(\mathbf{I}_n - \mathbf{E}_{ij}) = \mathbf{I}_n$ and $\mathbf{I}_n + \mathbf{E}_{ij}$ is invertible. If $\mathbf{A}$ commutes with every invertible matrix, it commutes with $\mathbf{I}_n + \mathbf{E}_{ij}$, hence with $\mathbf{E}_{ij}$ (subtract $\mathbf{AI}_n = \mathbf{I}_n\mathbf{A}$), for all $i \ne j$. By (a), $\mathbf{A} = c\mathbf{I}_n$.

11.11 How Far from Normal

Every theorem so far in this chapter has been a yes-or-no statement. An operator either commutes with its adjoint or it does not; there either is an orthonormal basis of eigenvectors or there is not. That is unsatisfying, because the two matrices $\begin{pmatrix} 1 & 10^{-6} \\ 0 & 2 \end{pmatrix}$ and $\begin{pmatrix} 1 & 10^{6} \\ 0 & 2 \end{pmatrix}$ are both non-normal, and no one would want to treat them alike. This section replaces the yes-or-no answer with a number. The number comes out of Schur's theorem almost for free, once we know that the Frobenius norm cannot tell one orthonormal basis from another, and it turns out to measure exactly the mass that a Schur factorization is forced to leave above the diagonal.

Throughout, $\mathbf{A} \in M_n(\mathbb{C})$ and $\mathbb{C}^n$ carries the standard inner product. Eigenvalues are always counted **in** $\mathbb{C}$ and **with algebraic multiplicity**, so that an $n \times n$ matrix always has a list of exactly n of them (Corollary 5.5.5).

11.11.1 The Frobenius norm, officially

Chapter 10 made $M_{m\times n}(F)$ into an inner product space in its first section, by declaring

$$\langle \mathbf{A}, \mathbf{B} \rangle = \operatorname{tr}(\mathbf{B}^* \mathbf{A}),$$

the **Frobenius inner product**, and observing that it is nothing but the standard inner product of F^{mn} after the entries are listed in a single column. Its induced norm (Definition 10.1.3) was named there too, but never given a symbol, and we have already borrowed one on the quiet in Exercise (C2: The Frobenius norm is unitarily invariant). It is time to make it official, because the whole of this section is written in it.

For $\mathbf{A} \in M_{m\times n}(\mathbb{C})$, the **Frobenius norm** of $\mathbf{A}$ is

$$\|\mathbf{A}\|_F := \sqrt{\langle \mathbf{A}, \mathbf{A} \rangle} = \Big(\sum_{i,j} |a_{ij}|^2 \Big)^{1/2}.$$

The subscript F is there because $\|\cdot\|$ with no subscript already means the norm of a *vector*, and a matrix will shortly be asked to be both. Two remarks on the formula. First, it treats $\mathbf{A}$ as a list of mn numbers and forgets that they are arranged in a rectangle: it is blind to the difference between $\begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}$ and $\begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$. Second, it is computable with no eigenvalues, no row reduction and no choices: add up mn squared moduli.

The trace form of the same quantity is the one that does the work.

> *Quick check.* Why is $\|\mathbf{A}\|_F^2 = \operatorname{tr}(\mathbf{A}^*\mathbf{A})$?

> *Solution.* The (j,j) entry of $\mathbf{A}^*\mathbf{A}$ is $\sum_i \overline{a_{ij}} a_{ij} = \sum_i |a_{ij}|^2$, the squared length of the j-th column. Summing over j sweeps every entry of $\mathbf{A}$ exactly once, so $\operatorname{tr}(\mathbf{A}^*\mathbf{A}) = \sum_{i,j} |a_{ij}|^2$. Equivalently, it is $\langle \mathbf{A}, \mathbf{A} \rangle$ read off the definition of the Frobenius inner product.

Now the property that makes the Frobenius norm the right yardstick in a chapter about orthonormal bases: unitary factors are invisible to it.

Lemma 11.11.1 — Unitary Invariance of the Frobenius Norm

Let $\mathbf{A} \in M_{m\times n}(\mathbb{C})$, let $\mathbf{U} \in \mathrm{U}(m)$ and let $\mathbf{V} \in \mathrm{U}(n)$. Then

$$\|\mathbf{UA}\|_F = \|\mathbf{A}\|_F = \|\mathbf{AV}\|_F.$$

In particular, if $\mathbf{A}$ is square and $\mathbf{U}$ is unitary then $\|\mathbf{U}^*\mathbf{AU}\|_F = \|\mathbf{A}\|_F$.

Proof. Using $\|\mathbf{B}\|_F^2 = \mathrm{tr}(\mathbf{B}^*\mathbf{B})$, then $(\mathbf{UA})^* = \mathbf{A}^*\mathbf{U}^*$ and $\mathbf{U}^*\mathbf{U} = \mathbf{I}_m$,

$$\|\mathbf{UA}\|_F^2 = \mathrm{tr}(\mathbf{A}^*\mathbf{U}^*\mathbf{UA}) = \mathrm{tr}(\mathbf{A}^*\mathbf{A}) = \|\mathbf{A}\|_F^2.$$

For the right-hand factor, Theorem 0.9.6 (3) lets the $\mathbf{V}$ travel around the trace, and $\mathbf{VV}^* = \mathbf{I}_n$:

$$\|\mathbf{AV}\|_F^2 = \mathrm{tr}(\mathbf{V}^*\mathbf{A}^*\mathbf{AV}) = \mathrm{tr}(\mathbf{A}^*\mathbf{AVV}^*) = \|\mathbf{A}\|_F^2.$$

Both norms are non-negative reals, so equality of the squares gives equality of the norms. For the last statement, $\mathbf{U}^*$ is unitary too, since $(\mathbf{U}^*)^*\mathbf{U}^* = \mathbf{UU}^* = \mathbf{I}$; apply the first equality to the left factor $\mathbf{U}^*$ and the second to the right factor $\mathbf{U}$.

■

The consequence to keep in mind is this. If $T \in \mathcal{L}(V)$ is an operator on a finite-dimensional complex inner product space and we compute $\|[T]_{\mathcal{B}}^{\mathcal{B}}\|_F$ in an **orthonormal** basis $\mathcal{B}$, the answer does not depend on which orthonormal basis we chose, because two such matrices differ by a unitary similarity (Theorem 3.7.3). So the Frobenius norm is a property of T, not of our coordinates — exactly like the trace and the determinant, and unlike, say, the largest entry.

11.11.2 Schur's inequality

Here is the observation the section is built on. Write a matrix in a Schur form $\mathbf{A} = \mathbf{UTU}^*$. The diagonal of $\mathbf{T}$ holds the eigenvalues, so $\sum_i |\lambda_i|^2$ is the Frobenius mass sitting *on* the diagonal of $\mathbf{T}$. The rest of $\mathbf{T}$ sits strictly above it. And by Lemma 11.11.1 the total mass of $\mathbf{T}$ is the total mass of $\mathbf{A}$. Rearranged, that is a theorem.

Theorem 11.11.2 — Schur's Inequality

Let $\mathbf{A} \in M_n(\mathbb{C})$ have eigenvalues $\lambda_1, \dots, \lambda_n$, listed with algebraic multiplicity. Then

$$\sum_{i=1}^{n} |\lambda_i|^2 \;\le\; \|\mathbf{A}\|_F^2,$$

with **equality if and only if $\mathbf{A}$ is normal**.

Idea. Schur-triangularize, then count. ① $\mathbf{A} = \mathbf{UTU}^*$ with $\mathbf{T}$ upper triangular and the λ_i on its diagonal (Corollary 11.1.3). ② The Frobenius norm does not notice the $\mathbf{U}$'s, so $\|\mathbf{A}\|_F = \|\mathbf{T}\|_F$. ③ Splitting $\|\mathbf{T}\|_F^2$ into its diagonal part and its strictly upper part gives the inequality on the nose, with the strictly upper part as the exact surplus. ④ For the equality case, that surplus vanishes exactly when $\mathbf{T}$ is diagonal, and "triangular

and normal" and "diagonal" were shown to be the same thing in Lemma 11.4.1.

Proof. By Corollary 11.1.3 there are a unitary $\mathbf{U}$ and an upper triangular $\mathbf{T} = (t_{ij})$ with $\mathbf{A} = \mathbf{U}\mathbf{T}\mathbf{U}^*$ and $t_{ii} = \lambda_i$ for every i. Since $t_{ij} = 0$ whenever $i > j$, the entries of $\mathbf{T}$ fall into the diagonal ones and the strictly upper ones, so by Lemma 11.11.1

$$\begin{aligned} \|\mathbf{A}\|_F^2 = \|\mathbf{T}\|_F^2 &= \sum_{i=1}^{n} |t_{ii}|^2 + \sum_{i<j} |t_{ij}|^2 \\ &= \sum_{i=1}^{n} |\lambda_i|^2 + \sum_{i<j} |t_{ij}|^2. \end{aligned} \tag{11.11.1}$$

The second sum is a sum of non-negative reals, so it is ≥ 0, and the inequality follows. Moreover equality holds if and only if that sum is 0, which happens if and only if $t_{ij} = 0$ for all $i < j$, that is, if and only if **this** $\mathbf{T}$ is diagonal.

($\Leftarrow$) Suppose $\mathbf{A}$ is normal. Then so is $\mathbf{T} = \mathbf{U}^*\mathbf{A}\mathbf{U}$: using $\mathbf{U}\mathbf{U}^* = \mathbf{I}$ in the middle of each product,

$$\mathbf{T}^*\mathbf{T} = \mathbf{U}^*\mathbf{A}^*\mathbf{A}\mathbf{U} = \mathbf{U}^*\mathbf{A}\mathbf{A}^*\mathbf{U} = \mathbf{T}\mathbf{T}^*.$$

A normal upper triangular matrix is diagonal (Lemma 11.4.1), so $\mathbf{T}$ is diagonal and Eq. 11.11.1 gives equality.

($\Rightarrow$) Suppose equality holds. Then, as noted, $\mathbf{T}$ is diagonal, so $\mathbf{A} = \mathbf{U}\mathbf{T}\mathbf{U}^*$ exhibits $\mathbf{A}$ as unitarily diagonalizable, and Corollary 11.4.3 makes $\mathbf{A}$ normal.

This proves the inequality and both halves of the equality case. ∎

Notice that the proof never had to worry about *which* Schur factorization was used. The two sides of the inequality — the eigenvalue list and $\|\mathbf{A}\|_F$ — are determined by $\mathbf{A}$ alone, so the surplus $\sum_{i<j}|t_{ij}|^2$ in Eq. 11.11.1 comes out the same for every triangularization of $\mathbf{A}$, even though the individual entries t_{ij} certainly do not. That is worth a second look, and we will look at it in a moment.

Example. (Both sides of Schur's inequality)

Verify Theorem 11.11.2 for

$$\mathbf{A} = \begin{pmatrix} 0 & 1 \\ 2 & 0 \end{pmatrix},$$

and locate the surplus inside an explicit Schur factorization (Corollary 11.1.3).

Solution. Here $\operatorname{tr}\mathbf{A} = 0$ and $\det\mathbf{A} = -2$, so $p_{\mathbf{A}} = x^2 - 2$ and the eigenvalues are $\pm\sqrt{2}$. Thus

$$\sum_i |\lambda_i|^2 = 2 + 2 = 4, \qquad \|\mathbf{A}\|_F^2 = 0 + 1 + 4 + 0 = 5,$$

and indeed $4 < 5$. The inequality is strict, so Theorem 11.11.2 already says that $\mathbf{A}$ is not normal — no product of matrices needed.

For the factorization, solve $(\mathbf{A} - \sqrt{2}\mathbf{I})\mathbf{x} = \mathbf{0}$: the first row reads $-\sqrt{2}x_1 + x_2 = 0$, giving

the eigenvector $(1, \sqrt{2})$ of norm $\sqrt{3}$. Take

$$\mathbf{q}_1 = \tfrac{1}{\sqrt{3}}(1, \sqrt{2}), \qquad \mathbf{q}_2 = \tfrac{1}{\sqrt{3}}(-\sqrt{2}, 1),$$

a pair of orthonormal vectors, and let $\mathbf{U}$ have them as columns. Then

$$\mathbf{U}^*\mathbf{A}\mathbf{U} = \begin{pmatrix} \sqrt{2} & -1 \\ 0 & -\sqrt{2} \end{pmatrix} = \mathbf{T}.$$

Its Frobenius mass is $2+1+2 = 5 = \|\mathbf{A}\|_F^2$, as Lemma 11.11.1 promises, and the split of Eq. 11.11.1 reads $5 = 4+1$: the whole surplus is the single entry -1 above the diagonal.

Quick check. The real matrix $\mathbf{A} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$ has $\|\mathbf{A}\|_F^2 = 2$ and no real eigenvalue at all. Does Theorem 11.11.2 fail for it?

Solution. No, because the eigenvalues are counted in $\mathbb{C}$. They are i and $-i$, so $\sum_i |\lambda_i|^2 = 1 + 1 = 2 = \|\mathbf{A}\|_F^2$: equality, which is exactly right, since $\mathbf{A}^\top\mathbf{A} = \mathbf{A}\mathbf{A}^\top = \mathbf{I}$ makes $\mathbf{A}$ normal. Restricting the eigenvalue list to $\mathbb{R}$ would leave the left-hand side empty and the statement meaningless; this is one more place where the Fundamental Theorem of Algebra (Theorem 5.5.1) is doing silent work.

11.11.3 The departure from normality

Schur's inequality has a slack term, and the slack term is the interesting object. It is non-negative for every matrix; it vanishes exactly on the normal ones; and, both of its ingredients being unitary-similarity invariants, it survives a change of orthonormal basis. Those are precisely the properties one wants of a measurement, so we name it.

The departure from normality is the Frobenius mass that no Schur factorization can push onto the diagonal.

Definition 11.11.1 — Departure from Normality

Let $\mathbf{A} \in M_n(\mathbb{C})$ have eigenvalues $\lambda_1, \dots, \lambda_n$, listed with algebraic multiplicity. The **departure from normality** of $\mathbf{A}$ is the non-negative real number $\Delta(\mathbf{A})$ defined by

$$\Delta(\mathbf{A})^2 := \|\mathbf{A}\|_F^2 - \sum_{i=1}^{n} |\lambda_i|^2.$$

Clause by clause: the quantity on the right is a real number because $\|\mathbf{A}\|_F^2$ and each $|\lambda_i|^2$ are real; it is **non-negative** by Theorem 11.11.2, which is what allows us to take its non-negative square root and call the result $\Delta(\mathbf{A})$; and the eigenvalue list, though it comes with no preferred order, contributes a sum that does not care about the order. So $\Delta(\mathbf{A})$ is well defined, with no choices made anywhere.

Two facts come straight from Theorem 11.11.2 and its proof.

- $\Delta(\mathbf{A}) = 0$ **if and only if $\mathbf{A}$ is normal.** This is the equality case, restated.

- $\Delta(\mathbf{A}) = \left(\sum_{i<j}|t_{ij}|^2\right)^{1/2}$ **for every** Schur factorization $\mathbf{A} = \mathbf{UTU}^*$, by Eq. 11.11.1. So $\Delta(\mathbf{A})$ is the length of the strictly upper triangular part of $\mathbf{T}$, and the remark after Theorem 11.11.2 says that this length is the same for all of them, even though the entries are not.

And one more, which is the reason the number deserves to be called a measurement rather than a coincidence: $\Delta(\mathbf{U}^*\mathbf{AU}) = \Delta(\mathbf{A})$ for every unitary $\mathbf{U}$. Both ingredients are unitary-similarity invariants — the Frobenius norm by Lemma 11.11.1, the eigenvalue list because similar matrices have the same characteristic polynomial (Theorem 6.10.3). Exercise (C1: Unitary similarity preserves the defect, ordinary similarity does not) asks for the details, and for an example showing that ordinary similarity wrecks the number completely.

Example. (The defect of a Jordan block)

Compute $\Delta(\mathbf{J}_k(\lambda))$ for the $k \times k$ Jordan block with eigenvalue λ.

Solution. The matrix $\mathbf{J}_k(\lambda)$ has λ in each of its k diagonal positions and 1 in each of the $k-1$ superdiagonal positions, and zeros elsewhere, so

$$\|\mathbf{J}_k(\lambda)\|_F^2 = k|\lambda|^2 + (k-1).$$

It is upper triangular, so its eigenvalue list is λ repeated k times (Theorem 8.7.4), giving $\sum_i|\lambda_i|^2 = k|\lambda|^2$. Subtracting,

$$\Delta(\mathbf{J}_k(\lambda))^2 = k-1, \qquad \Delta(\mathbf{J}_k(\lambda)) = \sqrt{k-1}.$$

Three things are worth reading off. The answer does not depend on λ: sliding a Jordan block up and down the complex plane does not make it more or less normal. It is 0 exactly when $k = 1$, agreeing with the fact that a 1×1 matrix is normal. And it grows with the block, which matches what Theorem 11.3.5 gave us in Section 3: a normal operator has no Jordan block of size larger than 1 (Theorem 9.3.1). Here the defect is counting exactly the superdiagonal ones that normality forbids.

A minimal-change non-example makes the same point on a smaller scale. The matrix $\mathrm{diag}(1,3)$ is normal, so its defect is 0. Change the single entry in position $(1,2)$ from 0 to 2:

$$\mathbf{A} = \begin{pmatrix} 1 & 2 \\ 0 & 3 \end{pmatrix}, \qquad \|\mathbf{A}\|_F^2 = 14, \qquad \sum_i|\lambda_i|^2 = 1+9 = 10,$$

so $\Delta(\mathbf{A}) = 2$. The eigenvalues did not move — a triangular matrix wears them on its diagonal — and the entire change went into the defect. That is the general picture for triangular matrices: for them, Δ is just the length of everything above the diagonal.

The defect also bounds something one might actually want to know. Fix a Schur factorization $\mathbf{A} = \mathbf{UTU}^*$ (Corollary 11.1.3), write $\mathbf{D}$ for the diagonal part of $\mathbf{T}$, and put $\mathbf{N} = \mathbf{UDU}^*$, which is normal by Corollary 11.4.3. Then

$$\|\mathbf{A} - \mathbf{N}\|_F = \|\mathbf{T} - \mathbf{D}\|_F = \Delta(\mathbf{A}),$$

the first step by Lemma 11.11.1. So $\Delta(\mathbf{A})$ is an upper bound for the Frobenius distance from $\mathbf{A}$ to the set of normal matrices. It is not that distance.

Warning. **Δ is a defect, not a distance.** It is tempting to read $\Delta(\mathbf{A})$ as "how far $\mathbf{A}$ is from the nearest normal matrix", and the displayed bound above makes the temptation worse. But the bound can be strict. Take $\mathbf{A} = \mathbf{J}_2(0) = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$, so that $\Delta(\mathbf{A}) = 1$ by Example (The defect of a Jordan block). The symmetric — hence normal — matrix $\mathbf{N} = \frac{1}{2}\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$ satisfies

$$\|\mathbf{A} - \mathbf{N}\|_F = \left\| \tfrac{1}{2}\begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} \right\|_F = \tfrac{1}{\sqrt{2}} < 1.$$

So some normal matrix is strictly nearer to $\mathbf{A}$ than $\Delta(\mathbf{A})$. What $\Delta(\mathbf{A})$ measures is the mass that survives *triangularization*, which is a genuine and useful quantity, but it is an upper bound for the distance and not the distance itself.

11.11.4 Eigenvalues that will not sit still

Here is why anyone outside this chapter cares. Eigenvalues are computed, in practice, from data that is only approximately right, so the question "if I move the matrix a little, how far do the eigenvalues move?" is not academic. For a normal matrix the answer is "just as little". For a matrix with a large defect it can be "enormously further". The following pair of 2×2 matrices shows the whole phenomenon with nothing but the quadratic formula.

Example. (A perturbation that moves the eigenvalues a thousand times as far)

Fix a real number $M > 0$ and a real ε with $0 < \varepsilon < M$. Compare the effect of adding ε to the lower-left entry of each of

$$\mathbf{A} = \begin{pmatrix} 1 & M \\ 0 & 1 \end{pmatrix} \qquad \text{and} \qquad \mathbf{N} = \begin{pmatrix} 1 & M \\ -M & 1 \end{pmatrix}.$$

Compute the defects of $\mathbf{A}$ and $\mathbf{N}$, the eigenvalues of both perturbed matrices exactly, and the distance each eigenvalue travels.

Solution. The two defects. The matrix $\mathbf{A}$ is upper triangular with both diagonal entries 1, so its eigenvalue list is $1, 1$ and

$$\Delta(\mathbf{A})^2 = (1 + M^2 + 1) - (1 + 1) = M^2, \qquad \Delta(\mathbf{A}) = M.$$

The matrix $\mathbf{N}$ is normal: $\mathbf{N}^\top\mathbf{N} = \mathbf{N}\mathbf{N}^\top = (1 + M^2)\mathbf{I}$, a direct multiplication. So $\Delta(\mathbf{N}) = 0$. Its eigenvalues are $1 \pm Mi$, since $p_{\mathbf{N}} = (x-1)^2 + M^2$. The two matrices have the same diagonal and the same entry M in the corner we are leaving alone; where they differ is that one has defect M and the other defect 0.

The non-normal one. Perturbing the corner gives $\mathbf{A}_\varepsilon = \begin{pmatrix} 1 & M \\ \varepsilon & 1 \end{pmatrix}$, with

$$p_{\mathbf{A}_\varepsilon} = (x-1)^2 - M\varepsilon, \qquad \lambda_\pm = 1 \pm \sqrt{M\varepsilon}.$$

The perturbation has size $\|\mathbf{A}_\varepsilon - \mathbf{A}\|_F = \varepsilon$, and each eigenvalue has moved a distance

$\sqrt{M\varepsilon}$, which is $\sqrt{M/\varepsilon}$ times the size of the perturbation. With $M = 100$ and $\varepsilon = 10^{-4}$, the perturbation is one ten-thousandth and the eigenvalues move by $\sqrt{100 \cdot 10^{-4}} = 1/10$: a thousandfold amplification.

The normal one. Perturbing the same corner gives $\mathbf{N}_\varepsilon = \begin{pmatrix} 1 & M \\ -M+\varepsilon & 1 \end{pmatrix}$, with

$$p_{\mathbf{N}_\varepsilon} = (x-1)^2 + M(M-\varepsilon), \qquad \mu_\pm = 1 \pm i\sqrt{M^2 - M\varepsilon},$$

the square root being a real number because $\varepsilon < M$. The eigenvalue $1 + Mi$ has moved to $1 + i\sqrt{M^2 - M\varepsilon}$, a distance of

$$M - \sqrt{M^2 - M\varepsilon} = \frac{M\varepsilon}{M + \sqrt{M^2 - M\varepsilon}} \le \frac{M\varepsilon}{M} = \varepsilon,$$

where the middle equality multiplies top and bottom by $M + \sqrt{M^2 - M\varepsilon}$ and the last step uses $\sqrt{M^2 - M\varepsilon} \ge 0$. So here the eigenvalues move by **at most** the size of the perturbation. The same denominator is at most $2M$, so the movement is also at least $\varepsilon/2$: with $M = 100$ and $\varepsilon = 10^{-4}$ it is a shade over $\varepsilon/2$.

The contrast is not an accident of these two matrices, and it is not a theorem we can prove here either. The general statement — that for a diagonalizable $\mathbf{A}$ every eigenvalue of a perturbed $\mathbf{A} + \mathbf{E}$ lies within $\kappa\|\mathbf{E}\|$ of some eigenvalue of $\mathbf{A}$, where κ measures how far from unitary the diagonalizing matrix is, and that $\kappa = 1$ exactly in the normal case — is the Bauer–Fike theorem. It needs matrix norms and a little analysis, and Chapter 19 develops both and proves it. What the example above establishes on its own is modest and exact: of two 2×2 matrices with the same diagonal and the same large off-diagonal entry, the one with defect 0 amplifies a corner perturbation by a factor of at most 1, and the one with defect M amplifies it by $\sqrt{M/\varepsilon}$. The defect is not bookkeeping.

Remark. The amplification $\sqrt{M\varepsilon}$ in Example (A perturbation that moves the eigenvalues a thousand times as far) has a square root in it, and that square root is the signature of a repeated eigenvalue. The unperturbed $\mathbf{A}$ has the single eigenvalue 1 twice over with only one eigenvector, so it is a Jordan block in disguise; splitting a double root is what costs the square root. A matrix with well-separated eigenvalues and a large defect behaves less dramatically.

11.11.5 The characterizations collected

Schur's inequality gives a normality test of a new kind. Every earlier test compared two matrix products or ranged over all vectors; this one compares two numbers, and one of them is a trace.

Theorem 11.11.3 — Normality as a Trace Identity

Let $\mathbf{A} \in M_n(\mathbb{C})$ have eigenvalues $\lambda_1, \dots, \lambda_n$, listed with algebraic multiplicity. Then $\mathbf{A}$ is normal if and only if

$$\operatorname{tr}(\mathbf{A}^*\mathbf{A}) = \sum_{i=1}^{n} |\lambda_i|^2.$$

Proof. We showed above that $\operatorname{tr}(\mathbf{A}^*\mathbf{A}) = \|\mathbf{A}\|_F^2$. So the displayed equation is the equality case of Theorem 11.11.2, which holds exactly when $\mathbf{A}$ is normal. ∎

Small as it is, this is the first criterion in the chapter that never asks for $\mathbf{A}\mathbf{A}^*$. If the spectrum is already known — from the characteristic polynomial, or because the matrix arrived in triangular form — normality costs one sum of n^2 squared moduli and one sum of n more.

We can now put every description of normality in one place. Sections 3 and 4 proved most of them; this section adds the last one; and one equivalence, the converse of Corollary 11.4.5, has not been proved anywhere and is proved here.

Theorem 11.11.4 — Normality: The Complete List

Let $\mathbf{A} \in M_n(\mathbb{C})$ have eigenvalues $\lambda_1, \dots, \lambda_n$, listed with algebraic multiplicity, and put

$$\mathbf{H} = \tfrac{1}{2}(\mathbf{A} + \mathbf{A}^*), \qquad \mathbf{K} = \tfrac{1}{2i}(\mathbf{A} - \mathbf{A}^*),$$

both of which are Hermitian, with $\mathbf{A} = \mathbf{H} + i\mathbf{K}$. The following are equivalent.

(a) $\mathbf{A}^*\mathbf{A} = \mathbf{A}\mathbf{A}^*$, that is, $\mathbf{A}$ is normal.
(b) $\|\mathbf{A}\mathbf{x}\| = \|\mathbf{A}^*\mathbf{x}\|$ for every $\mathbf{x} \in \mathbb{C}^n$.
(c) $\langle \mathbf{A}\mathbf{x}, \mathbf{A}\mathbf{y}\rangle = \langle \mathbf{A}^*\mathbf{x}, \mathbf{A}^*\mathbf{y}\rangle$ for all $\mathbf{x}, \mathbf{y} \in \mathbb{C}^n$.
(d) $\mathbf{H}\mathbf{K} = \mathbf{K}\mathbf{H}$.
(e) $\mathbb{C}^n$ has an orthonormal basis of eigenvectors of $\mathbf{A}$.
(f) $\mathbf{A} = \mathbf{U}\mathbf{D}\mathbf{U}^*$ for some unitary $\mathbf{U}$ and some diagonal $\mathbf{D}$.
(g) $\mathbf{A}^* = p(\mathbf{A})$ for some polynomial $p \in \mathbb{C}[x]$.
(h) $\sum_{i=1}^{n} |\lambda_i|^2 = \|\mathbf{A}\|_F^2$.

Proof. Let $T = T_{\mathbf{A}}$ on $\mathbb{C}^n$ with its standard inner product, for which the standard basis is orthonormal; then $T^* = T_{\mathbf{A}^*}$ by Theorem 10.6.3, and T is normal exactly when $\mathbf{A}$ is.

(a), (b), (c) and (d) are equivalent by Theorem 11.3.1 applied to T, whose four conditions are these four read for T instead of $\mathbf{A}$. (a) $\Leftrightarrow$ (e) is Theorem 11.4.2, again for T. (a) $\Leftrightarrow$ (f) is Corollary 11.4.3. (a) $\Leftrightarrow$ (h) is Theorem 11.11.3, since $\|\mathbf{A}\|_F^2 = \operatorname{tr}(\mathbf{A}^*\mathbf{A})$. (a) $\Rightarrow$ (g) is Corollary 11.4.5, applied to T and read back as matrices.

It remains to prove (g) $\Rightarrow$ (a). Suppose $\mathbf{A}^* = p(\mathbf{A})$ with $p = c_0 + c_1 x + \cdots + c_d x^d$. Every power of $\mathbf{A}$ commutes with $\mathbf{A}$, hence so does any linear combination of powers:

$$p(\mathbf{A})\mathbf{A} = \sum_{k=0}^{d} c_k \mathbf{A}^{k+1} = \mathbf{A}\, p(\mathbf{A}).$$

Substituting $\mathbf{A}^*$ for $p(\mathbf{A})$ on both sides gives $\mathbf{A}^*\mathbf{A} = \mathbf{A}\mathbf{A}^*$, which is (a). This closes the loop and proves the theorem. ∎

This list is the summary result of the chapter, and it is worth reading as a whole rather than

as eight separate facts. Conditions (a) and (d) are algebraic: one equation between products. Conditions (b) and (c) are metric: $\mathbf{A}$ and $\mathbf{A}^*$ distort lengths and angles identically. Conditions (e) and (f) are geometric: the eigenvectors can be chosen perpendicular. Condition (g) is a surprise, and says that for a normal matrix the adjoint carries no information beyond $\mathbf{A}$ itself. And condition (h) is quantitative: it is the only one on the list that comes with a *number* attached, so that when it fails one can ask by how much. That number is $\Delta(\mathbf{A})$, and it is the reason this section exists.

The operator versions of (a)–(g) hold verbatim on any finite-dimensional complex inner product space, by passing to the matrix in an orthonormal basis. So does (h), once $\|\cdot\|_F$ is read as the Frobenius norm of that matrix, which Lemma 11.11.1 showed does not depend on which orthonormal basis is used.

11.11.6 Exercises

11.11.6.1 A. Check your understanding

Exercise A1.

(a) Define the Frobenius norm of a matrix, and give the expression for $\|\mathbf{A}\|_F^2$ as a trace.

(b) State Theorem 11.11.2, including the equality case and how the eigenvalues are counted.

(c) Define $\Delta(\mathbf{A})$, and say why the definition needs Theorem 11.11.2 before it can be made.

(d) True or false: $\Delta(\mathbf{A})$ equals the Frobenius distance from $\mathbf{A}$ to the nearest normal matrix. Justify your answer.

(e) True or false: if $\mathbf{A}$ and $\mathbf{B}$ are similar then $\Delta(\mathbf{A}) = \Delta(\mathbf{B})$. Justify your answer.

(f) Name the two facts about the Frobenius norm and about triangular matrices that the proof of Theorem 11.11.2 rests on.

Solution.

(a) $\|\mathbf{A}\|_F = \left(\sum_{i,j}|a_{ij}|^2\right)^{1/2}$, the norm induced by the Frobenius inner product $\langle \mathbf{A}, \mathbf{B}\rangle = \operatorname{tr}(\mathbf{B}^*\mathbf{A})$ of Chapter 10. As a trace, $\|\mathbf{A}\|_F^2 = \operatorname{tr}(\mathbf{A}^*\mathbf{A})$.

(b) For $\mathbf{A} \in M_n(\mathbb{C})$ with eigenvalues $\lambda_1, \dots, \lambda_n$ listed **in $\mathbb{C}$ and with algebraic multiplicity**, $\sum_i |\lambda_i|^2 \le \|\mathbf{A}\|_F^2$, with equality if and only if $\mathbf{A}$ is normal.

(c) $\Delta(\mathbf{A})^2 = \|\mathbf{A}\|_F^2 - \sum_i |\lambda_i|^2$, and $\Delta(\mathbf{A})$ is its non-negative square root. Without Theorem 11.11.2 the right-hand side might be negative, and there would be no real square root to take.

(d) False. It is an upper bound for that distance, as the paragraph before the warning shows, but the warning gives $\mathbf{A} = \mathbf{J}_2(0)$ with $\Delta(\mathbf{A}) = 1$ and a normal matrix at distance $1/\sqrt{2}$.

(e) False. The matrices $\begin{pmatrix} 1 & 1 \\ 0 & 2 \end{pmatrix}$ and $\operatorname{diag}(1, 2)$ are similar, since the first is diagonalizable with eigenvalues 1 and 2, yet their defects are 1 and 0. What is true is that Δ is unchanged by **unitary** similarity; see Exercise (C1: Unitary similarity preserves the defect, ordinary similarity does not).

(f) That the Frobenius norm is unchanged by unitary factors (Lemma 11.11.1), so that $\|\mathbf{A}\|_F = \|\mathbf{T}\|_F$; and that a normal upper triangular matrix is diagonal (Lemma 11.4.1), which is what makes the equality case work in the direction ($\Leftarrow$).

11.11.6.2 B. Practice

Exercise B1: Computing the defect.

For each matrix below, compute $\|\mathbf{A}\|_F^2$, the eigenvalue list, and $\Delta(\mathbf{A})$. State in each case whether the matrix is normal, and say how you know without multiplying $\mathbf{A}$ by $\mathbf{A}^*$.

(a) $\begin{pmatrix} 3 & 4 \\ 0 & 5 \end{pmatrix}$

(b) $\begin{pmatrix} 1 & 1 \\ -1 & 1 \end{pmatrix}$

(c) $\mathbf{J}_3(2)$

(d) $\begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 0 & 0 \end{pmatrix}$

Solution.

(a) $\|\mathbf{A}\|_F^2 = 9 + 16 + 25 = 50$. The matrix is upper triangular, so its eigenvalues are 3 and 5 (Theorem 8.7.4) and $\sum_i |\lambda_i|^2 = 34$. Hence $\Delta(\mathbf{A})^2 = 16$ and $\Delta(\mathbf{A}) = 4$. Since $\Delta(\mathbf{A}) \neq 0$, the matrix is not normal (Theorem 11.11.2).

(b) $\|\mathbf{A}\|_F^2 = 1+1+1+1 = 4$. Here $\operatorname{tr}\mathbf{A} = 2$ and $\det\mathbf{A} = 1+1 = 2$, so $p_{\mathbf{A}} = x^2 - 2x + 2$ and the eigenvalues are $1 \pm i$, each of modulus $\sqrt{2}$. Then $\sum_i |\lambda_i|^2 = 2 + 2 = 4$, so $\Delta(\mathbf{A}) = 0$ and the matrix **is** normal.

(c) $\|\mathbf{J}_3(2)\|_F^2 = 3 \cdot 4 + 2 = 14$, the eigenvalue is 2 three times, and $\sum_i |\lambda_i|^2 = 12$. So $\Delta^2 = 2$ and $\Delta = \sqrt{2}$, which is $\sqrt{k-1}$ with $k = 3$, as Example (The defect of a Jordan block) says. Not normal.

(d) $\|\mathbf{A}\|_F^2 = 3$. The matrix is the cyclic shift, with $p_{\mathbf{A}} = x^3 - 1$ (expand along the first row, or note $\mathbf{A}^3 = \mathbf{I}$ and $\mathbf{A} \neq \mathbf{I}$ with $\mathbf{A}$ having no repeated eigenvalue). Its eigenvalues are the three cube roots of unity, each of modulus 1, so $\sum_i |\lambda_i|^2 = 3$ and $\Delta(\mathbf{A}) = 0$: normal.

Exercise B2: Verifying Schur's inequality.

Let

$$\mathbf{A} = \begin{pmatrix} 1 & 1 & 1 \\ 0 & 2 & 1 \\ 0 & 0 & 3 \end{pmatrix}.$$

(a) Compute both sides of Theorem 11.11.2 for $\mathbf{A}$ and verify the inequality.

(b) Hence determine whether $\mathbf{A}$ is normal, without computing $\mathbf{A}^*\mathbf{A}$ or $\mathbf{A}\mathbf{A}^*$.

(c) Write down a normal matrix $\mathbf{N}$ with $\|\mathbf{A} - \mathbf{N}\|_F = \Delta(\mathbf{A})$, and verify the equality.

Solution.

(a) $\|\mathbf{A}\|_F^2 = 1+1+1+4+1+9 = 17$. The matrix is upper triangular, so its eigenvalues are $1, 2, 3$ (Theorem 8.7.4) and $\sum_i |\lambda_i|^2 = 1 + 4 + 9 = 14$. Indeed $14 \leq 17$.

(b) The inequality is strict, so by the equality case of Theorem 11.11.2 the matrix is not normal. Equivalently $\Delta(\mathbf{A}) = \sqrt{17 - 14} = \sqrt{3} \neq 0$.

(c) Since $\mathbf{A}$ is already upper triangular, $\mathbf{A} = \mathbf{I}\mathbf{A}\mathbf{I}^*$ is a Schur factorization (Corollary 11.1.3) with $\mathbf{U} = \mathbf{I}$ and $\mathbf{T} = \mathbf{A}$. The construction before the warning takes $\mathbf{N}$ to be the diagonal part, $\mathbf{N} = \operatorname{diag}(1, 2, 3)$, which is normal. Then $\mathbf{A} - \mathbf{N}$ has the three entries 1 above the diagonal and zeros elsewhere, so $\|\mathbf{A}-\mathbf{N}\|_F = \sqrt{3} = \Delta(\mathbf{A})$.

Exercise B3: The nearest symmetric matrix.

Let $\mathbf{A} \in M_n(\mathbb{R})$ and write $\mathbf{S} = \frac{1}{2}(\mathbf{A} + \mathbf{A}^\top)$ and $\mathbf{W} = \frac{1}{2}(\mathbf{A} - \mathbf{A}^\top)$, so that $\mathbf{A} = \mathbf{S} + \mathbf{W}$ with $\mathbf{S}^\top = \mathbf{S}$ and $\mathbf{W}^\top = -\mathbf{W}$.

(a) Prove that $\langle \mathbf{B}, \mathbf{C} \rangle = 0$ in the Frobenius inner product whenever $\mathbf{B} \in M_n(\mathbb{R})$ is symmetric and $\mathbf{C} \in M_n(\mathbb{R})$ is skew-symmetric.

(b) Deduce that $\|\mathbf{A} - \mathbf{B}\|_F \geq \|\mathbf{W}\|_F$ for every symmetric $\mathbf{B} \in M_n(\mathbb{R})$, with equality only for $\mathbf{B} = \mathbf{S}$. Hence $\mathbf{S}$ is the nearest symmetric matrix to $\mathbf{A}$.

(c) Carry this out for $\mathbf{A} = \begin{pmatrix} 2 & 4 \\ 0 & -2 \end{pmatrix}$, and compare the resulting distance with $\Delta(\mathbf{A})$.

Solution.

(a) For real matrices $\langle \mathbf{B}, \mathbf{C} \rangle = \operatorname{tr}(\mathbf{C}^\top \mathbf{B})$. Since $\mathbf{C}^\top = -\mathbf{C}$, this is $-\operatorname{tr}(\mathbf{C}\mathbf{B})$. On the other hand $\operatorname{tr}(\mathbf{C}\mathbf{B}) = \operatorname{tr}\big((\mathbf{C}\mathbf{B})^\top\big)$ by Theorem 0.9.6 (2), and $(\mathbf{C}\mathbf{B})^\top = \mathbf{B}^\top \mathbf{C}^\top = -\mathbf{B}\mathbf{C}$, so $\operatorname{tr}(\mathbf{C}\mathbf{B}) = -\operatorname{tr}(\mathbf{B}\mathbf{C}) = -\operatorname{tr}(\mathbf{C}\mathbf{B})$, the last step by Theorem 0.9.6 (3). A number equal to its own negative is 0, so $\operatorname{tr}(\mathbf{C}\mathbf{B}) = 0$ and $\langle \mathbf{B}, \mathbf{C} \rangle = 0$.

(b) Let $\mathbf{B}$ be symmetric. Then $\mathbf{A} - \mathbf{B} = (\mathbf{S} - \mathbf{B}) + \mathbf{W}$, where $\mathbf{S} - \mathbf{B}$ is symmetric and $\mathbf{W}$ is skew-symmetric, so the two are orthogonal by (a) and Pythagoras (Theorem 10.1.3) gives

$$\|\mathbf{A} - \mathbf{B}\|_F^2 = \|\mathbf{S} - \mathbf{B}\|_F^2 + \|\mathbf{W}\|_F^2 \geq \|\mathbf{W}\|_F^2.$$

Equality forces $\|\mathbf{S} - \mathbf{B}\|_F = 0$, that is $\mathbf{B} = \mathbf{S}$ (Theorem 10.1.2 (a)). So $\mathbf{S}$ is the unique nearest symmetric matrix, at distance $\|\mathbf{W}\|_F$.

(c) Here $\mathbf{S} = \begin{pmatrix} 2 & 2 \\ 2 & -2 \end{pmatrix}$ and $\mathbf{W} = \begin{pmatrix} 0 & 2 \\ -2 & 0 \end{pmatrix}$, so the distance from $\mathbf{A}$ to the symmetric matrices is $\|\mathbf{W}\|_F = \sqrt{8} = 2\sqrt{2}$. For the defect, $\|\mathbf{A}\|_F^2 = 4 + 16 + 4 = 24$, and $\mathbf{A}$ is triangular with eigenvalues 2 and -2, so $\sum_i |\lambda_i|^2 = 8$ and $\Delta(\mathbf{A}) = 4$. A symmetric matrix is normal, so this again exhibits a normal matrix strictly closer than $\Delta(\mathbf{A})$: $2\sqrt{2} \approx 2.83 < 4$.

11.11.6.3 C. Going deeper

Exercise C1: Unitary similarity preserves the defect, ordinary similarity does not.

(a) Prove that $\Delta(\mathbf{U}^*\mathbf{A}\mathbf{U}) = \Delta(\mathbf{A})$ for every $\mathbf{A} \in M_n(\mathbb{C})$ and every unitary $\mathbf{U}$.

(b) Give $\mathbf{A}, \mathbf{B} \in M_2(\mathbb{C})$ that are similar with $\Delta(\mathbf{A}) \neq \Delta(\mathbf{B})$, exhibiting an explicit $\mathbf{P}$ with $\mathbf{P}^{-1}\mathbf{A}\mathbf{P} = \mathbf{B}$.

(c) Deduce that two similar matrices with different defects cannot be unitarily similar, and use this to show that $\begin{pmatrix} 1 & 1 \\ 0 & 2 \end{pmatrix}$ and $\operatorname{diag}(1, 2)$ are not unitarily similar.

Solution.

(a) Put $\mathbf{B} = \mathbf{U}^*\mathbf{A}\mathbf{U}$. By Lemma 11.11.1, $\|\mathbf{B}\|_F = \|\mathbf{A}\|_F$. Also $\mathbf{B}$ is similar to $\mathbf{A}$, so $p_{\mathbf{B}} = p_{\mathbf{A}}$ (Theorem 6.10.3) and the two matrices have the same eigenvalue list with multiplicities. Both terms in Definition 11.11.1 therefore agree, so $\Delta(\mathbf{B})^2 = \Delta(\mathbf{A})^2$, and the defects are equal since both are non-negative.

(b) Take $\mathbf{A} = \begin{pmatrix} 1 & 1 \\ 0 & 2 \end{pmatrix}$ and $\mathbf{B} = \operatorname{diag}(1, 2)$. Then $\|\mathbf{A}\|_F^2 = 1+1+4 = 6$ with eigenvalues $1, 2$, so $\Delta(\mathbf{A})^2 = 6 - 5 = 1$ and $\Delta(\mathbf{A}) = 1$, while $\Delta(\mathbf{B}) = 0$ because $\mathbf{B}$ is diagonal, hence normal. They are similar: eigenvectors of $\mathbf{A}$ are $(1, 0)$ for $\lambda = 1$ and $(1, 1)$ for $\lambda = 2$, so with $\mathbf{P} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$, whose inverse is $\begin{pmatrix} 1 & -1 \\ 0 & 1 \end{pmatrix}$, we get $\mathbf{P}^{-1}\mathbf{A}\mathbf{P} = \mathbf{B}$ by direct multiplication.

(c) By (a), unitarily similar matrices have equal defects. So if $\Delta(\mathbf{A}) \neq \Delta(\mathbf{B})$ then no unitary $\mathbf{U}$ can satisfy $\mathbf{U}^*\mathbf{A}\mathbf{U} = \mathbf{B}$. The pair in (b) has defects 1 and 0, so it is similar but not unitarily similar. (This is the failure of "diagonalizable" to imply "unitarily diagonalizable", seen through a number instead of through Example (Diagonalizable, and no orthonormal eigenbasis).)

Exercise C2: Equality plus a single eigenvalue forces a scalar.

Let $\mathbf{A} \in M_n(\mathbb{C})$ satisfy $\|\mathbf{A}\|_F^2 = \sum_{i=1}^n |\lambda_i|^2$, and suppose $\mathbf{A}$ has **only one** distinct eigenvalue λ, so that $p_{\mathbf{A}} = (x - \lambda)^n$.

(a) Prove that $\mathbf{A} = \lambda\mathbf{I}$.

(b) Deduce that a normal matrix whose characteristic polynomial is x^n is the zero matrix.

(c) Show that the hypothesis of equality cannot be dropped, by computing Δ for a matrix with $p_{\mathbf{A}} = (x - \lambda)^n$ that is not $\lambda\mathbf{I}$.

Solution.

(a) By the equality case of Theorem 11.11.2, $\mathbf{A}$ is normal. So by Corollary 11.4.3 there are a unitary $\mathbf{U}$ and a diagonal $\mathbf{D}$ with $\mathbf{A} = \mathbf{U}\mathbf{D}\mathbf{U}^*$, the diagonal of $\mathbf{D}$ being the eigenvalue list of $\mathbf{A}$. That list is λ repeated n times, so $\mathbf{D} = \lambda\mathbf{I}$ and

$$\mathbf{A} = \mathbf{U}(\lambda\mathbf{I})\mathbf{U}^* = \lambda\mathbf{U}\mathbf{U}^* = \lambda\mathbf{I}.$$

(b) A normal matrix satisfies the equality hypothesis (Theorem 11.11.2 again), and $p_{\mathbf{A}} = x^n$ says its only eigenvalue is 0. By (a), $\mathbf{A} = 0 \cdot \mathbf{I} = 0$. In words: a normal nilpotent matrix is zero, which is Theorem 11.3.5 seen from the quantitative side.

(c) Take $\mathbf{A} = \mathbf{J}_n(\lambda)$ with $n \geq 2$. Its characteristic polynomial is $(x - \lambda)^n$ and it is

not $\lambda\mathbf{I}$, and $\Delta(\mathbf{A}) = \sqrt{n-1} \neq 0$ by Example (The defect of a Jordan block). So equality in Theorem 11.11.2 fails, exactly as it must.

Exercise C3: The commutator is at least as big as the defect squared.

For $\mathbf{A} \in M_n(\mathbb{C})$ write $[\mathbf{A}, \mathbf{A}^*] = \mathbf{A}\mathbf{A}^* - \mathbf{A}^*\mathbf{A}$.

(a) Prove that $\|[\mathbf{A}, \mathbf{A}^*]\|_F$ is unchanged when $\mathbf{A}$ is replaced by $\mathbf{U}^*\mathbf{A}\mathbf{U}$ with $\mathbf{U}$ unitary.

(b) Let $\mathbf{T} = \begin{pmatrix} \lambda_1 & b \\ 0 & \lambda_2 \end{pmatrix}$. Compute $[\mathbf{T}, \mathbf{T}^*]$ and show that

$$\|[\mathbf{T}, \mathbf{T}^*]\|_F^2 = 2|b|^4 + 2|b|^2|\lambda_1 - \lambda_2|^2.$$

(c) Deduce that every $\mathbf{A} \in M_2(\mathbb{C})$ satisfies $\|[\mathbf{A}, \mathbf{A}^*]\|_F \geq \sqrt{2}\,\Delta(\mathbf{A})^2$, and determine exactly when equality holds.

Hint for (c): Schur-triangularize, and use (a) to move the computation to the triangular factor.

Solution.

(a) Put $\mathbf{B} = \mathbf{U}^*\mathbf{A}\mathbf{U}$, so $\mathbf{B}^* = \mathbf{U}^*\mathbf{A}^*\mathbf{U}$. Inserting $\mathbf{U}\mathbf{U}^* = \mathbf{I}$ between the factors,

$$[\mathbf{B}, \mathbf{B}^*] = \mathbf{U}^*(\mathbf{A}\mathbf{A}^* - \mathbf{A}^*\mathbf{A})\mathbf{U} = \mathbf{U}^*[\mathbf{A}, \mathbf{A}^*]\mathbf{U},$$

and Lemma 11.11.1 gives $\|[\mathbf{B}, \mathbf{B}^*]\|_F = \|[\mathbf{A}, \mathbf{A}^*]\|_F$.

(b) Multiplying out,

$$\mathbf{T}\mathbf{T}^* = \begin{pmatrix} |\lambda_1|^2 + |b|^2 & b\overline{\lambda_2} \\ \lambda_2\overline{b} & |\lambda_2|^2 \end{pmatrix},$$

$$\mathbf{T}^*\mathbf{T} = \begin{pmatrix} |\lambda_1|^2 & \overline{\lambda_1}b \\ \lambda_1\overline{b} & |b|^2 + |\lambda_2|^2 \end{pmatrix}.$$

Subtracting,

$$[\mathbf{T}, \mathbf{T}^*] = \begin{pmatrix} |b|^2 & b\,\overline{(\lambda_2 - \lambda_1)} \\ \overline{b}\,(\lambda_2 - \lambda_1) & -|b|^2 \end{pmatrix}.$$

Its four squared moduli are $|b|^4$, $|b|^2|\lambda_1 - \lambda_2|^2$, $|b|^2|\lambda_1 - \lambda_2|^2$ and $|b|^4$. Adding them gives the stated formula.

(c) Let $\mathbf{A} \in M_2(\mathbb{C})$ and write $\mathbf{A} = \mathbf{U}\mathbf{T}\mathbf{U}^*$ as in Corollary 11.1.3, with $\mathbf{T}$ upper triangular of the shape in (b) and λ_1, λ_2 the eigenvalues of $\mathbf{A}$. By Eq. 11.11.1, $\Delta(\mathbf{A})^2 = |b|^2$. By (a) and (b),

$$\|[\mathbf{A}, \mathbf{A}^*]\|_F^2 = 2|b|^4 + 2|b|^2|\lambda_1 - \lambda_2|^2 \geq 2|b|^4 = 2\,\Delta(\mathbf{A})^4,$$

and taking non-negative square roots gives $\|[\mathbf{A}, \mathbf{A}^*]\|_F \geq \sqrt{2}\,\Delta(\mathbf{A})^2$.

Equality holds exactly when $|b|^2|\lambda_1 - \lambda_2|^2 = 0$, that is, when $b = 0$ or $\lambda_1 = \lambda_2$. The first case says $\Delta(\mathbf{A}) = 0$, that is, $\mathbf{A}$ is normal, and then both sides are 0. So equality holds if and only if $\mathbf{A}$ is normal or its two eigenvalues coincide.

Chapter 12

Positive Matrices and the Singular Value Decomposition

A matrix that is not square has no eigenvalues. There is no equation $\mathbf{Av} = \lambda\mathbf{v}$ to write down, because $\mathbf{Av}$ and $\mathbf{v}$ live in different spaces, and everything Chapters 8 to 11 built on that equation is unavailable. Yet the geometric picture that opened Chapter 11 survives untouched: push the unit sphere of F^n through any $\mathbf{A} \in M_{m\times n}(F)$, square or not, and what comes out is an ellipsoid. It has semi-axes, they are perpendicular, and the directions they came from were perpendicular too. Reading that picture as a factorization gives $\mathbf{A} = \mathbf{U\Sigma V}^*$, the **singular value decomposition**: every matrix whatsoever maps some orthonormal basis to an orthogonal set. It is the most used factorization in applied linear algebra, and this chapter's business is to earn it and then spend it.

The road runs through positivity. A non-square $\mathbf{A}$ has no eigenvalues, but $\mathbf{A}^*\mathbf{A}$ does, and $\mathbf{A}^*\mathbf{A}$ is self-adjoint with a non-negative quadratic form — it is a **positive semidefinite** matrix, the analogue of a non-negative number. Chapter 11 left that class unexamined; here it comes first, with its many equivalent tests, its square root, and the triangular factorization that elimination finds. From the square root comes the absolute value $|\mathbf{A}|$, from $|\mathbf{A}|$ the polar decomposition $\mathbf{A} = \mathbf{W}|\mathbf{A}|$, and from the spectral theorem applied to $\mathbf{A}^*\mathbf{A}$ the singular value decomposition itself. Once it is in hand, a series of questions that look unrelated turn out to have one answer: what are orthonormal bases of the four fundamental subspaces, what is the best rank-k approximation of a matrix, what should $\mathbf{A}^{-1}$ mean when $\mathbf{A}$ is not invertible, and when is a projection orthogonal. **The field is $\mathbb{R}$ or $\mathbb{C}$ throughout**, as in Chapters 10 and 11, and every statement says which one it needs.

What you need. From Chapter 11, the two spectral theorems and their matrix forms (Theorem 11.4.2, Corollary 11.4.3, Theorem 11.5.1, Corollary 11.5.2, Corollary 11.5.4, Theorem 11.5.5), the elementary theory of self-adjoint operators (Theorem 11.2.1, Theorem 11.2.3, Theorem 11.2.6, Exercise (C1: The operator S^*S)), commuting families (Corollary 11.7.2, Corollary 11.7.3), and the functional calculus with its square root (Definition 11.8.1, Theorem 11.8.1, Theorem 11.8.3, Theorem 11.8.4), together with the Frobenius norm and its unitary invariance (Lemma 11.11.1). From Chapter 10, the adjoint and what it does to the four subspaces (Definition 10.6.1, Theorem 10.6.2, Theorem 10.6.3, Theorem 10.6.5, Corollary 10.6.6), orthogonal decompositions and projections (Theorem 10.3.2, Definition 10.3.2, Theorem 10.3.3, Theorem 10.3.5), least squares (Theorem 10.4.2, Corollary 10.4.4, Theorem 10.4.5, Lemma 10.4.3), Gram matrices (Definition 10.2.3, Theorem 10.2.5), isometries (Definition 10.7.1, Theorem 10.7.3, Definition 10.7.2) and the QR factorization (Theorem 10.8.1). From Chapter 7, block multiplication and Schur

complements (Theorem 7.1.1, Definition 7.3.1, Theorem 7.3.1, Theorem 7.3.2, Theorem 7.3.3, Theorem 7.3.4). From Chapter 6, multiplicativity of the determinant, triangular determinants and the non-negativity of Gram determinants (Theorem 6.5.4, Theorem 6.4.6, Corollary 6.7.3). From Chapter 5, Lagrange interpolation (Theorem 5.6.1). From Chapter 3, projections along a complement (Definition 3.10.1, Theorem 3.10.1). From Chapter 2, the $\text{Ł}\mathbf{D}\text{Ł}^\top$ factorization and the invertible matrix theorem it started (Theorem 2.6.8, Theorem 2.4.4).

12.0.1 Roadmap

- **Positive semidefinite and positive definite matrices.** The definition, the real-versus-complex asymmetry that trips everyone, and the full list of equivalent tests, ending in Sylvester's criterion and the trap that comes with it.
- **The square root and Cholesky.** The unique positive square root, why it is a polynomial in the matrix, the absolute value $|\mathbf{A}|$, and the factorization $\mathbf{A} = \text{Ł}\text{Ł}^*$ whose algorithm is itself the test for definiteness.
- **Gram matrices.** A matrix is a Gram matrix exactly when it is positive semidefinite; the Gram determinant as a squared volume, and distance to a subspace computed two ways.
- **Two forms at once.** A positive definite form and a self-adjoint one can be diagonalized simultaneously — by congruence, not by similarity — and the generalized eigenvalue problem $\mathbf{Bx} = \lambda\mathbf{Ax}$ follows.
- **The Loewner order.** What $\mathbf{A} \succeq \mathbf{B}$ means, what monotonicity survives it (traces, determinants, inverses), and the chapter's negative result: squaring does not.
- **Blocks and Schur complements.** Testing a block matrix for positive definiteness one block at a time, and the Fischer and Hadamard determinant inequalities that fall out.
- **Products entry by entry.** The Schur product theorem — the Hadamard product of positive matrices is positive — and Oppenheim's inequality.
- **The singular value decomposition.** Every matrix is $\mathbf{U}\mathbf{\Sigma}\mathbf{V}^*$; the singular values are determined, the unitaries are not, and the compact form reads off orthonormal bases of all four fundamental subspaces.
- **Polar decomposition and Takagi.** $\mathbf{A} = \mathbf{W}|\mathbf{A}|$ is $z = e^{i\theta}r$ for matrices; $\mathbf{W}$ is the nearest unitary matrix to $\mathbf{A}$; and a complex symmetric matrix factors as $\mathbf{U}\mathbf{\Sigma}\mathbf{U}^\top$.
- **Low-rank approximation.** Truncating the singular value sum gives the best approximation of each rank, in the Frobenius norm, with an error one can write down.
- **The pseudoinverse.** Inverting the non-zero singular values defines $\mathbf{A}^+$; it is pinned down by four conditions, and $\mathbf{A}^+\mathbf{b}$ is the minimum-norm least-squares solution promised in Chapter 10.
- **Projections revisited.** An idempotent is an orthogonal projection exactly when it is self-adjoint; everything else is oblique, and the obliqueness is a measurable angle.

12.0.2 Named moves

- **Test with $\langle\mathbf{Ax}, \mathbf{x}\rangle$.** Positivity is a statement about one scalar function of one vector. Most proofs in the first half of the chapter consist of evaluating that function at a cleverly chosen $\mathbf{x}$ — a standard basis vector, a vector supported on a few coordinates, an eigenvector, or $\mathbf{Sy}$ for a substitution $\mathbf{S}$.
- **Factor as $\mathbf{B}^*\mathbf{B}$.** Every positive semidefinite matrix is one, and that form turns a statement about the matrix into a statement about lengths: $\langle\mathbf{B}^*\mathbf{Bx}, \mathbf{x}\rangle = \|\mathbf{Bx}\|^2$. It is also what makes every positive semidefinite matrix a Gram matrix.
- **Diagonalize, do it to the eigenvalues, come back.** The square root, the pseudoinverse

and the whole functional calculus are this one move. The work is always in checking that the result does not depend on the diagonalization chosen.

- **Apply the spectral theorem to $\mathbf{A}^*\mathbf{A}$.** When the matrix in front of you is not square, not normal, or not even an operator, this is the way in. The singular value decomposition is nothing but the spectral theorem for $\mathbf{A}^*\mathbf{A}$, read back through $\mathbf{A}$.
- **Truncate the sum.** Writing $\mathbf{A} = \sum_i \sigma_i \mathbf{u}_i \mathbf{v}_i^*$ turns a matrix into a sum of rank-one pieces ordered by importance. Cutting the sum short gives the compact form, the best low-rank approximation and the pseudoinverse, three times from one idea.

12.1 Positive Semidefinite and Positive Definite Matrices

Chapter 11 sorted the operators that have an orthonormal eigenbasis. Among them the self-adjoint ones are the matrix analogue of the real numbers, since they are exactly the operators fixed by starring. Inside the real numbers sits a smaller and even more useful set, the non-negative ones, and this section finds its matrix analogue. The answer turns out to have three faces — a sign condition on the spectrum, a sign condition on a scalar function, and a factorization — and the whole of the rest of the chapter is built on the fact that the three agree.

Throughout, $F = \mathbb{R}$ or $F = \mathbb{C}$, and F^n carries the standard inner product $\langle \mathbf{x}, \mathbf{y} \rangle = \mathbf{y}^*\mathbf{x}$.

12.1.1 Which self-adjoint matrices deserve to be called non-negative?

A real number t is non-negative in three equivalent ways: $t \geq 0$; $tx^2 \geq 0$ for every real x; and $t = s^2$ for some real s. Each of the three has a matrix reading. "Every eigenvalue is ≥ 0" copies the first. "$\langle \mathbf{A}\mathbf{x}, \mathbf{x} \rangle \geq 0$ for every $\mathbf{x}$" copies the second, because $\langle \mathbf{A}\mathbf{x}, \mathbf{x} \rangle$ is the one scalar a matrix attaches to a single vector. "$\mathbf{A} = \mathbf{B}^*\mathbf{B}$" copies the third, with the star doing what nothing does for numbers but everything does for matrices.

It is not obvious that the three agree, and for a general matrix they do not: they all fail for $\begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$ in different ways. What makes them agree is self-adjointness, and the middle condition is the one to take as the definition, because it is the one that says something about every vector at once.

A matrix is positive semidefinite when its quadratic form never goes negative.

Definition 12.1.1 — Positive Semidefinite and Positive Definite

Let $\mathbf{A} \in M_n(F)$. Then $\mathbf{A}$ is **positive semidefinite**, written $\mathbf{A} \succeq 0$, if

(P1) $\mathbf{A}$ is **Hermitian**, that is $\mathbf{A}^* = \mathbf{A}$ (over $\mathbb{R}$: symmetric, $\mathbf{A}^\top = \mathbf{A}$); and
(P2) $\langle \mathbf{A}\mathbf{x}, \mathbf{x} \rangle \geq 0$ for **every** $\mathbf{x} \in F^n$.

It is **positive definite**, written $\mathbf{A} \succ 0$, if (P1) holds and $\langle \mathbf{A}\mathbf{x}, \mathbf{x} \rangle > 0$ for every **non-zero**

$\mathbf{x} \in F^n$.

The same words apply to an operator $T \in \mathcal{L}(V)$ on a finite-dimensional inner product space: T is positive semidefinite if $T^* = T$ and $\langle T\mathbf{v}, \mathbf{v}\rangle \geq 0$ for every $\mathbf{v} \in V$, and positive definite if the inequality is strict for $\mathbf{v} \neq \mathbf{0}$.

In words: (P1) puts $\mathbf{A}$ in the class where the analogy with real numbers is available at all, and (P2) says that the number $\langle \mathbf{Ax}, \mathbf{x}\rangle = \mathbf{x}^*\mathbf{Ax}$ is never negative. The word **every** in (P2) is the whole content; a single vector proves nothing. In the definite case the vector $\mathbf{x} = \mathbf{0}$ has to be excluded, since $\langle \mathbf{A0}, \mathbf{0}\rangle = 0$ for every $\mathbf{A}$ whatsoever.

Clause (P1) is also what makes clause (P2) meaningful. For a Hermitian $\mathbf{A}$, the number $\langle \mathbf{Ax}, \mathbf{x}\rangle$ is **real** for every $\mathbf{x}$, over $\mathbb{C}$ as well as over $\mathbb{R}$ (Proposition 10.6.7), so comparing it with 0 is legitimate. Without (P1) the number can be a genuine complex number, and "≥ 0" would be meaningless.

Positive definite implies positive semidefinite, since a condition that holds strictly for $\mathbf{x} \neq \mathbf{0}$ holds weakly for $\mathbf{x} = \mathbf{0}$ too. The reverse fails, and the smallest witness is $\operatorname{diag}(1, 0)$.

Before any examples, the trap.

Warning. **Over $\mathbb{R}$, clause (P1) has to be assumed; over $\mathbb{C}$ it comes free.** Let $\mathbf{A} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$, the quarter turn of $\mathbb{R}^2$. Then $\langle \mathbf{Ax}, \mathbf{x}\rangle = -x_2x_1 + x_1x_2 = 0$ for every $\mathbf{x} \in \mathbb{R}^2$, so (P2) holds in the strongest possible way, and yet $\mathbf{A}^\top = -\mathbf{A} \neq \mathbf{A}$. A real matrix can pass the quadratic-form test and be nowhere near symmetric, because over $\mathbb{R}$ the quadratic form cannot see the skew part of a matrix at all (Exercise (C3: What the real quadratic form does determine)). So a real definition that dropped (P1) would call the quarter turn positive semidefinite, and none of the theorems below would survive.

Over $\mathbb{C}$ the situation is the opposite, and it is worth recording once.

Proposition 12.1.1 — Over $\mathbb{C}$, positivity implies Hermitian

Let $\mathbf{A} \in M_n(\mathbb{C})$ satisfy $\langle \mathbf{Ax}, \mathbf{x}\rangle \in \mathbb{R}$ for every $\mathbf{x} \in \mathbb{C}^n$ — in particular, let $\langle \mathbf{Ax}, \mathbf{x}\rangle \geq 0$ for every $\mathbf{x}$. Then $\mathbf{A}^* = \mathbf{A}$.

Proof. Put $\mathbf{S} = \mathbf{A} - \mathbf{A}^*$. For every $\mathbf{x}$, moving the star across (Lemma 10.4.1) and using conjugate symmetry,

$$\langle \mathbf{A}^*\mathbf{x}, \mathbf{x}\rangle = \langle \mathbf{x}, \mathbf{Ax}\rangle = \overline{\langle \mathbf{Ax}, \mathbf{x}\rangle} = \langle \mathbf{Ax}, \mathbf{x}\rangle,$$

the last equality because the number is real. Hence $\langle \mathbf{Sx}, \mathbf{x}\rangle = 0$ for every $\mathbf{x} \in \mathbb{C}^n$, and Theorem 11.2.6 gives $\mathbf{S} = 0$.

■

So over $\mathbb{C}$ one may state the definition with (P2) alone; over $\mathbb{R}$ one may not. We keep (P1) in the definition for both fields, so that a single sentence covers them and so that no reader has to remember which field licenses which shortcut.

Now the examples, all checked against (P1) and (P2) in turn.

Example. (Five Positive Matrices)

Decide which of the following are positive semidefinite, and which are positive definite.

(a) $\mathbf{I}_n$, and more generally $\mathbf{D} = \operatorname{diag}(d_1, \dots, d_n)$ with every d_i real.
(b) $\mathbf{x}\mathbf{x}^*$ for a fixed $\mathbf{x} \in F^n$.
(c) The Gram matrix $\mathbf{G}$ of a list $(\mathbf{v}_1, \dots, \mathbf{v}_k)$ in an inner product space.
(d) The zero matrix $0 \in M_n(F)$.
(e) $\begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$.

Solution.

(a) $\mathbf{D}^* = \mathbf{D}$ because the d_i are real, so (P1) holds. For (P2),

$$\langle \mathbf{D}\mathbf{x}, \mathbf{x} \rangle = \mathbf{x}^* \mathbf{D} \mathbf{x} = \sum_{i=1}^{n} d_i |x_i|^2.$$

So $\mathbf{D} \succeq 0$ exactly when every $d_i \geq 0$, and $\mathbf{D} \succ 0$ exactly when every $d_i > 0$: if some $d_i < 0$, the vector $\mathbf{e}_i$ refutes (P2), and if some $d_i = 0$, the vector $\mathbf{e}_i$ refutes definiteness. In particular $\mathbf{I}_n \succ 0$, with $\langle \mathbf{x}, \mathbf{x} \rangle = \|\mathbf{x}\|^2$.

(b) $(\mathbf{x}\mathbf{x}^*)^* = \mathbf{x}^{**}\mathbf{x}^* = \mathbf{x}\mathbf{x}^*$, so (P1) holds. For (P2), using $\langle \mathbf{u}, \mathbf{w} \rangle = \mathbf{w}^*\mathbf{u}$ twice,

$$\mathbf{y}^*(\mathbf{x}\mathbf{x}^*)\mathbf{y} = (\mathbf{y}^*\mathbf{x})(\mathbf{x}^*\mathbf{y}) = \langle \mathbf{x}, \mathbf{y} \rangle \, \overline{\langle \mathbf{x}, \mathbf{y} \rangle} = |\langle \mathbf{x}, \mathbf{y} \rangle|^2 \geq 0.$$

So $\mathbf{x}\mathbf{x}^* \succeq 0$. It is never positive definite for $n \geq 2$, since any $\mathbf{y} \neq \mathbf{0}$ orthogonal to $\mathbf{x}$ makes the value 0; and for $\mathbf{x} = \mathbf{0}$ it is the zero matrix.

(c) $\mathbf{G}^* = \mathbf{G}$ by Theorem 10.2.5 (a), and $\mathbf{x}^*\mathbf{G}\mathbf{x} = \|\sum_j x_j \mathbf{v}_j\|^2 \geq 0$ by part (b) of the same theorem. So $\mathbf{G} \succeq 0$ always, and by (c) of that theorem $\mathbf{G} \succ 0$ exactly when the list is linearly independent.

(d) $0^* = 0$ and $\langle 0\mathbf{x}, \mathbf{x} \rangle = 0 \geq 0$, so $0 \succeq 0$. This is the degenerate case, and it matters: it is the bottom of the order introduced in Section 5, and it shows that (P2) can hold with equality everywhere.

(e) Symmetric, so (P1) holds; but $\langle \mathbf{A}\mathbf{e}_2, \mathbf{e}_2 \rangle = -1 < 0$. Not positive semidefinite. This is (a) with $d_2 = -1$.

Example (e) is the non-example by minimal change: keep (P1), change one diagonal entry, and (P2) fails at one standard basis vector. The quarter turn of the warning is the other kind of non-example, keeping (P2) and losing (P1).

Two remarks on the name and the convention. "Definite" is the older word, from the theory of quadratic forms: the form $q(\mathbf{x}) = \mathbf{x}^*\mathbf{A}\mathbf{x}$ has a *definite* sign. "Semi" weakens the sign to allow zeros. Some authors write "positive" for what we call positive semidefinite and "strictly positive" for positive definite; the words differ but the two classes are the same two classes everywhere.

Warning. **A positive matrix is not a matrix with positive entries.** The all-ones matrix $\mathbf{J} \in M_2(\mathbb{R})$ has every entry positive and is positive semidefinite, but $\begin{pmatrix} 1 & 2 \\ 2 & 1 \end{pmatrix}$ has every entry positive and is **not**: at $\mathbf{x} = (1, -1)$ its form is $1 - 2 - 2 + 1 = -2$. Conversely

diag$(1,1)$ has a zero entry and is positive definite. Entrywise positivity is a different subject, the one Chapter 8 met through stochastic matrices, and it shares only a word with this one.

12.1.2 Positivity survives a change of variable

Before the equivalences, one small result that will be used in almost every proof of this chapter. The quadratic form $\mathbf{x} \mapsto \mathbf{x}^*\mathbf{A}\mathbf{x}$ is attached to $\mathbf{A}$; substituting $\mathbf{x} = \mathbf{S}\mathbf{y}$ turns it into the quadratic form of $\mathbf{S}^*\mathbf{A}\mathbf{S}$. The operation $\mathbf{A} \mapsto \mathbf{S}^*\mathbf{A}\mathbf{S}$ is called **congruence**, and Chapter 13 studies it for its own sake. Here we need only that it preserves the sign.

Proposition 12.1.2 — Congruence preserves positivity

Let $\mathbf{A} \in M_n(F)$ be Hermitian and $\mathbf{S} \in M_{n\times m}(F)$. Then $\mathbf{S}^*\mathbf{A}\mathbf{S} \in M_m(F)$ is Hermitian, and:

(a) if $\mathbf{A} \succeq 0$, then $\mathbf{S}^*\mathbf{A}\mathbf{S} \succeq 0$;

(b) if $\mathbf{A} \succ 0$ and $\operatorname{nul}(\mathbf{S}) = \{\mathbf{0}\}$, then $\mathbf{S}^*\mathbf{A}\mathbf{S} \succ 0$. In particular, for $m = n$ and $\mathbf{S}$ invertible, $\mathbf{A} \succ 0$ if and only if $\mathbf{S}^*\mathbf{A}\mathbf{S} \succ 0$.

Proof. $(\mathbf{S}^*\mathbf{A}\mathbf{S})^* = \mathbf{S}^*\mathbf{A}^*\mathbf{S}^{**} = \mathbf{S}^*\mathbf{A}\mathbf{S}$, so the matrix is Hermitian. For every $\mathbf{y} \in F^m$,

$$\mathbf{y}^*(\mathbf{S}^*\mathbf{A}\mathbf{S})\mathbf{y} = (\mathbf{S}\mathbf{y})^*\mathbf{A}(\mathbf{S}\mathbf{y}) = \langle \mathbf{A}(\mathbf{S}\mathbf{y}), \mathbf{S}\mathbf{y}\rangle. \tag{$*$}$$

(a) If $\mathbf{A} \succeq 0$, the right-hand side of $(*)$ is ≥ 0 for every $\mathbf{y}$.

(b) If $\mathbf{A} \succ 0$ and $\operatorname{nul}(\mathbf{S}) = \{\mathbf{0}\}$, then $\mathbf{y} \neq \mathbf{0}$ forces $\mathbf{S}\mathbf{y} \neq \mathbf{0}$, so the right-hand side of $(*)$ is > 0. For the last claim, take $\mathbf{S}$ invertible: one direction is what we just proved, and the other is the same statement applied to $\mathbf{S}^{-1}$ and the matrix $\mathbf{S}^*\mathbf{A}\mathbf{S}$, since $(\mathbf{S}^{-1})^*(\mathbf{S}^*\mathbf{A}\mathbf{S})\mathbf{S}^{-1} = \mathbf{A}$.

■

12.1.3 The equivalent descriptions

The characterization needs one determinant identity, which is worth stating on its own because it also describes every coefficient of a characteristic polynomial. Recall from Definition 6.7.1 that $\mathbf{A}_{I,I}$ denotes the submatrix of $\mathbf{A}$ on the rows and columns indexed by I; its determinant is a **principal minor** of $\mathbf{A}$, and $\mathbf{A}_{I,I}$ is a **principal submatrix**.

Lemma 12.1.3 — Shifting by $t\mathbf{I}$, minor by minor

Let $\mathbf{A} \in M_n(F)$ and $t \in F$. Then

$$\det(\mathbf{A} + t\mathbf{I}_n) = \sum_{k=0}^{n} E_k(\mathbf{A})\, t^{\,n-k},$$

where $E_0(\mathbf{A}) = 1$ and, for $1 \le k \le n$, $E_k(\mathbf{A}) = \sum_{|I|=k} \det \mathbf{A}_{I,I}$ is the sum of all $k \times k$ principal minors of $\mathbf{A}$.

Idea. Column j of $\mathbf{A} + t\mathbf{I}$ is $\mathbf{a}_j + t\mathbf{e}_j$, a sum of two columns, and the determinant is linear in each column separately. Expanding all n columns turns one determinant into 2^n of them, one for each choice of which columns contribute their $t\mathbf{e}_j$. A determinant with $\mathbf{e}_j$ in column j collapses under cofactor expansion to the determinant with row j and column j deleted, and doing that for every chosen column leaves exactly a principal submatrix.

Proof. Write $\mathbf{a}_1, \dots, \mathbf{a}_n$ for the columns of $\mathbf{A}$, so that column j of $\mathbf{A} + t\mathbf{I}$ is $\mathbf{a}_j + t\mathbf{e}_j$. The determinant is linear in each column with the others fixed (Theorem 6.4.3). Applying that in column 1, then in column 2, and so on through column n,

$$\det(\mathbf{A} + t\mathbf{I}) = \sum_{S \subseteq \{1,\dots,n\}} t^{|S|} \det \mathbf{M}_S,$$

where $\mathbf{M}_S$ is the matrix whose j-th column is $\mathbf{e}_j$ for $j \in S$ and $\mathbf{a}_j$ for $j \notin S$.

Fix S and let $j \in S$. Expanding $\det \mathbf{M}_S$ along column j (Theorem 6.6.1 (a)) leaves one term, since that column is $\mathbf{e}_j$: the entry is 1 in row j and 0 elsewhere, and its cofactor is $(-1)^{j+j} M_{jj} = M_{jj}$. So $\det \mathbf{M}_S$ equals the determinant of $\mathbf{M}_S$ with row j and column j deleted, which is a matrix of the same shape on the index set $\{1, \dots, n\} \setminus \{j\}$. Repeating this for each $j \in S$ deletes every row and column indexed by S and leaves

$$\det \mathbf{M}_S = \det \mathbf{A}_{S^c, S^c}, \qquad S^c = \{1, \dots, n\} \setminus S.$$

Collecting the subsets by $k = |S^c|$, so that $|S| = n - k$, gives the stated formula. ∎

Remark. Running the same expansion over $F[x]$ with the indeterminate $-x$ in place of t, and multiplying by $(-1)^n$, turns this into $p_{\mathbf{A}}(x) = \sum_k (-1)^k E_k(\mathbf{A}) x^{n-k}$: the coefficients of the characteristic polynomial are, up to sign, the sums of principal minors. The cases $k = 1$ and $k = n$ recover $\operatorname{tr} \mathbf{A}$ and $\det \mathbf{A}$ from Theorem 6.10.2.

Here is the main theorem of the section.

Theorem 12.1.4 — Characterizations of Positive Semidefiniteness

Let $\mathbf{A} \in M_n(F)$ be Hermitian. The following are equivalent.

(a) $\mathbf{A} \succeq 0$.
(b) Every eigenvalue of $\mathbf{A}$ is a non-negative real number.
(c) $\mathbf{A} = \mathbf{B}^*\mathbf{B}$ for some $\mathbf{B} \in M_n(F)$.
(d) $\mathbf{A} = \mathbf{C}^2$ for exactly one $\mathbf{C} \in M_n(F)$ with $\mathbf{C} \succeq 0$.
(e) Every principal minor of $\mathbf{A}$ is ≥ 0.

Idea. The spectral theorem makes (a) and (b) two readings of one diagonal matrix, since an orthonormal change of basis does not change the sign of a quadratic form. From (b)

the square root of Chapter 11 produces $\mathbf{C}$, and $\mathbf{C}$ is its own $\mathbf{B}$. The step $(c) \Rightarrow (a)$ is the identity $\langle \mathbf{B}^*\mathbf{B}\mathbf{x}, \mathbf{x}\rangle = \|\mathbf{B}\mathbf{x}\|^2$, one line of moving $\mathbf{B}^*$ across. For (e), a principal submatrix is what the form does to vectors supported on a few coordinates, which gives $(a) \Rightarrow (e)$ at once; the return trip uses Lemma 12.1.3 to show that $\det(\mathbf{A} + t\mathbf{I}) > 0$ for every $t > 0$, so that no $-t$ can be an eigenvalue.

Proof. **(a) $\Leftrightarrow$ (b).** ($\Rightarrow$) Let $\mathbf{A}\mathbf{v} = \lambda\mathbf{v}$ with $\mathbf{v} \neq \mathbf{0}$. By Theorem 11.2.1, $\lambda \in \mathbb{R}$, and

$$0 \leq \langle \mathbf{A}\mathbf{v}, \mathbf{v}\rangle = \langle \lambda\mathbf{v}, \mathbf{v}\rangle = \lambda\|\mathbf{v}\|^2,$$

so $\lambda \geq 0$, as $\|\mathbf{v}\|^2 > 0$. ($\Leftarrow$) By Corollary 11.4.3 (over $\mathbb{C}$) or Corollary 11.5.2 (over $\mathbb{R}$), $\mathbf{A} = \mathbf{U}\mathbf{D}\mathbf{U}^*$ with $\mathbf{U}$ unitary and $\mathbf{D} = \operatorname{diag}(\lambda_1, \dots, \lambda_n)$ the eigenvalues. Put $\mathbf{y} = \mathbf{U}^*\mathbf{x}$. Then

$$\langle \mathbf{A}\mathbf{x}, \mathbf{x}\rangle = \mathbf{x}^*\mathbf{U}\mathbf{D}\mathbf{U}^*\mathbf{x} = \mathbf{y}^*\mathbf{D}\mathbf{y} = \sum_i \lambda_i |y_i|^2 \geq 0,$$

every term being a product of two non-negative reals.

(b) $\Rightarrow$ (d). A Hermitian matrix has an orthonormal basis of eigenvectors, so the operator $T_{\mathbf{A}}$ on F^n satisfies the hypothesis of Theorem 11.8.4, whose spectral condition $\operatorname{spec}(T_{\mathbf{A}}) \subseteq [0, \infty)$ is exactly (b). That theorem gives a unique $\mathbf{C}$ with an orthonormal eigenbasis, non-negative spectrum and $\mathbf{C}^2 = \mathbf{A}$, and it is self-adjoint; by the equivalence just proved, applied to $\mathbf{C}$, this says $\mathbf{C} \succeq 0$. Conversely any $\mathbf{C} \succeq 0$ with $\mathbf{C}^2 = \mathbf{A}$ is Hermitian with non-negative spectrum, hence is that one. So there is exactly one such $\mathbf{C}$.

(d) $\Rightarrow$ (c). Take $\mathbf{B} = \mathbf{C}$; then $\mathbf{B}^*\mathbf{B} = \mathbf{C}^*\mathbf{C} = \mathbf{C}^2 = \mathbf{A}$.

(c) $\Rightarrow$ (a). Conjugate-transposing twice, $(\mathbf{B}^*\mathbf{B})^* = \mathbf{B}^*(\mathbf{B}^*)^* = \mathbf{B}^*\mathbf{B}$, which is (P1). And for every $\mathbf{x}$,

$$\langle \mathbf{B}^*\mathbf{B}\mathbf{x}, \mathbf{x}\rangle = \mathbf{x}^*\mathbf{B}^*\mathbf{B}\mathbf{x} = (\mathbf{B}\mathbf{x})^*(\mathbf{B}\mathbf{x}) = \|\mathbf{B}\mathbf{x}\|^2 \;\geq\; 0,$$

which is (P2). Both facts are recorded in operator form in Exercise (C1: The operator S^*S) (a), applied to the map $\mathbf{x} \mapsto \mathbf{B}\mathbf{x}$.

(a) $\Rightarrow$ (e). Let $I = \{i_1 < \cdots < i_k\}$. Given $\mathbf{y} \in F^k$, let $\mathbf{x} \in F^n$ have $x_{i_p} = y_p$ and all other entries 0. Then $\mathbf{x}^*\mathbf{A}\mathbf{x} = \mathbf{y}^*\mathbf{A}_{I,I}\mathbf{y}$, because the terms $\overline{x_i}a_{ij}x_j$ with $i \notin I$ or $j \notin I$ vanish. So $\mathbf{A}_{I,I}$ is Hermitian and satisfies (P2), that is $\mathbf{A}_{I,I} \succeq 0$. By the equivalence (a) $\Leftrightarrow$ (b) applied to $\mathbf{A}_{I,I}$, all its eigenvalues are ≥ 0. Diagonalizing it as $\mathbf{A}_{I,I} = \mathbf{U}\mathbf{D}\mathbf{U}^*$ as above, with $\mathbf{U}^* = \mathbf{U}^{-1}$, and taking determinants (Theorem 6.5.4, Corollary 6.5.6),

$$\det \mathbf{A}_{I,I} = \det \mathbf{D} = \lambda_1 \cdots \lambda_k \geq 0.$$

(e) $\Rightarrow$ (b). Let $t > 0$ be real. Every $E_k(\mathbf{A}) \geq 0$ by hypothesis and $E_0(\mathbf{A}) = 1$, so Lemma 12.1.3 gives

$$\det(\mathbf{A} + t\mathbf{I}) = \sum_{k=0}^{n} E_k(\mathbf{A})\, t^{\,n-k} \geq t^{\,n} > 0.$$

In particular $\mathbf{A} + t\mathbf{I}$ is invertible (Theorem 6.5.3), so $-t$ is not an eigenvalue of $\mathbf{A}$ (Theorem 8.2.6 applied to $\mathbf{A} + t\mathbf{I}$). As $t > 0$ was arbitrary and every eigenvalue of $\mathbf{A}$

is real (Theorem 11.2.1), no eigenvalue is negative. This closes the cycle and proves the theorem.

■

Item (c) is the one to keep in mind: **every positive semidefinite matrix is a Gram matrix**, since $\mathbf{B}^*\mathbf{B}$ is the Gram matrix of the columns of $\mathbf{B}$ (Definition 10.2.3). Section 3 turns that remark into a theorem. Item (d) names the square root, which Section 2 develops. Item (b) is how one *thinks*; item (e) is, for small matrices, how one *computes*.

12.1.4 The definite case, and Sylvester's criterion

The definite versions of (a), (b) and (c) are proved by putting "strict" in front of the same arguments. The new item is a test that can be run by hand on a numerical matrix without finding a single eigenvalue.

Theorem 12.1.5 — Characterizations of Positive Definiteness, with Sylvester's Criterion

Let $\mathbf{A} \in M_n(F)$ be Hermitian, and for $1 \le k \le n$ let $\mathbf{A}_k$ be its leading principal submatrix, the top-left $k \times k$ corner. The following are equivalent.

(a) $\mathbf{A} \succ 0$.
(b) Every eigenvalue of $\mathbf{A}$ is a positive real number.
(c) $\mathbf{A} = \mathbf{B}^*\mathbf{B}$ for some **invertible** $\mathbf{B} \in M_n(F)$.
(d) **(Sylvester's criterion)** $\det \mathbf{A}_k > 0$ for every $k = 1, \dots, n$.

Idea. Steps (a) ⇔ (b) ⇔ (c) repeat the previous proof with strict inequalities. For (a) ⇒ (d), a leading principal submatrix inherits definiteness, and a determinant is a product of eigenvalues. The content is (d) ⇒ (a), and it is an induction on n that peels off the last row and column. The inductive hypothesis makes the corner $\mathbf{A}_{n-1}$ definite, hence invertible, and one shear — the congruence by $\mathbf{S} = \begin{pmatrix} \mathbf{I} & -\mathbf{A}_{n-1}^{-1}\mathbf{b} \\ \mathbf{0}^\top & 1 \end{pmatrix}$, which is exactly the block elimination of Chapter 7 — clears the border and turns $\mathbf{A}$ into $\mathbf{A}_{n-1} \oplus (s)$ with one scalar s left over. Determinants identify the sign of s, and Proposition 12.1.2 carries the verdict back.

Proof. **(a) ⇔ (b).** As in Theorem 12.1.4, with $\ge$ replaced by $>$ throughout: for (⇒), $0 < \lambda\|\mathbf{v}\|^2$ forces $\lambda > 0$; for (⇐), $\sum_i \lambda_i |y_i|^2 > 0$ whenever $\mathbf{y} = \mathbf{U}^*\mathbf{x} \neq \mathbf{0}$, which happens exactly when $\mathbf{x} \neq \mathbf{0}$ because $\mathbf{U}^*$ is invertible.

(b) ⇒ (c). Let $\mathbf{C} \succeq 0$ with $\mathbf{C}^2 = \mathbf{A}$ (Theorem 12.1.4 (d)). Since every eigenvalue of $\mathbf{A}$ is positive, $0 \notin \operatorname{spec}(\mathbf{A})$ and $\mathbf{A}$ is invertible (Theorem 8.2.6). If $\mathbf{C}\mathbf{x} = \mathbf{0}$ then $\mathbf{A}\mathbf{x} = \mathbf{C}^2\mathbf{x} = \mathbf{0}$, so $\mathbf{x} = \mathbf{0}$; hence $\mathbf{C}$ is invertible too (Theorem 2.4.4). Take $\mathbf{B} = \mathbf{C}$.

(c) ⇒ (a). For $\mathbf{x} \neq \mathbf{0}$, $\mathbf{B}\mathbf{x} \neq \mathbf{0}$, so $\langle \mathbf{B}^*\mathbf{B}\mathbf{x}, \mathbf{x} \rangle = \|\mathbf{B}\mathbf{x}\|^2 > 0$.

(a) ⇒ (d). As in the proof of (a) ⇒ (e) of Theorem 12.1.4 with $I = \{1, \dots, k\}$, the corner $\mathbf{A}_k$ satisfies $\mathbf{y}^*\mathbf{A}_k\mathbf{y} = \mathbf{x}^*\mathbf{A}\mathbf{x} > 0$ for $\mathbf{y} \neq \mathbf{0}$, so $\mathbf{A}_k \succ 0$. Its eigenvalues are positive, and $\det \mathbf{A}_k$ is their product, computed as in the proof of Theorem 12.1.4, so

$\det \mathbf{A}_k > 0$.

(d) $\Rightarrow$ (a). Induct on n. For $n = 1$, $\mathbf{A} = (a_{11})$ with $a_{11} = \det \mathbf{A}_1 > 0$, and $\langle \mathbf{A}x, x\rangle = a_{11}|x|^2 > 0$ for $x \neq 0$.

Let $n \geq 2$, and write

$$\mathbf{A} = \begin{pmatrix} \mathbf{A}' & \mathbf{b} \\ \mathbf{b}^* & d \end{pmatrix}, \qquad \mathbf{A}' = \mathbf{A}_{n-1},\ \mathbf{b} \in F^{n-1},\ d \in \mathbb{R}.$$

The leading principal submatrices of $\mathbf{A}'$ are $\mathbf{A}_1, \dots, \mathbf{A}_{n-1}$, so the inductive hypothesis gives $\mathbf{A}' \succ 0$; in particular $\mathbf{A}'$ is invertible, since $\det \mathbf{A}' = \det \mathbf{A}_{n-1} > 0$. Put

$$\mathbf{S} = \begin{pmatrix} \mathbf{I}_{n-1} & -\mathbf{A}'^{-1}\mathbf{b} \\ \mathbf{0}^\top & 1 \end{pmatrix}, \qquad s = d - \mathbf{b}^*\mathbf{A}'^{-1}\mathbf{b}.$$

Block multiplication (Theorem 7.1.1), together with $(\mathbf{A}'^{-1})^* = \mathbf{A}'^{-1}$ because $\mathbf{A}'$ is Hermitian, gives

$$\mathbf{S}^*\mathbf{A}\mathbf{S} = \begin{pmatrix} \mathbf{A}' & \mathbf{0} \\ \mathbf{0}^\top & s \end{pmatrix}. \tag{$*$}$$

Both $\mathbf{S}$ and $\mathbf{S}^*$ are triangular with 1s on the diagonal, so $\det \mathbf{S} = \det \mathbf{S}^* = 1$ by Theorem 6.4.6. Taking determinants in $(*)$ with Theorem 6.5.4 and Theorem 6.8.4,

$$0 < \det \mathbf{A} = \det(\mathbf{S}^*\mathbf{A}\mathbf{S}) = s \det \mathbf{A}',$$

and $\det \mathbf{A}' > 0$, so $s > 0$. The right-hand side of $(*)$ is therefore positive definite: for $\mathbf{y} = (\mathbf{y}', y_n) \neq \mathbf{0}$,

$$\mathbf{y}^* \begin{pmatrix} \mathbf{A}' & \mathbf{0} \\ \mathbf{0}^\top & s \end{pmatrix} \mathbf{y} = \mathbf{y}'^*\mathbf{A}'\mathbf{y}' + s|y_n|^2 > 0,$$

since the two terms are ≥ 0 and not both zero. Finally $\mathbf{S}$ is invertible, so Proposition 12.1.2 (b) turns $\mathbf{S}^*\mathbf{A}\mathbf{S} \succ 0$ back into $\mathbf{A} \succ 0$. This completes the induction and proves the theorem.

■

The number $s = d - \mathbf{b}^*\mathbf{A}'^{-1}\mathbf{b}$ in that proof is the Schur complement $\mathbf{A}/\mathbf{A}'$ of Definition 7.3.1, and $(*)$ is the block **LDU** factorization of Theorem 7.3.1 written as a congruence. Section 6 replaces the scalar s by a block and gets the general test.

Warning. **For semidefiniteness, the leading principal minors are not enough.** Sylvester's criterion has no "$\geq$" version. Take

$$\mathbf{A} = \begin{pmatrix} 0 & 0 \\ 0 & -1 \end{pmatrix}.$$

Its leading principal minors are $\det \mathbf{A}_1 = 0$ and $\det \mathbf{A}_2 = 0$, both ≥ 0, and yet $\langle \mathbf{A}\mathbf{e}_2, \mathbf{e}_2\rangle = -1$, so $\mathbf{A}$ is not positive semidefinite. What Theorem 12.1.4 (e) demands is **all** principal minors, and the one this matrix fails is $\det \mathbf{A}_{\{2\},\{2\}} = -1 < 0$. The leading corners simply never look at the second coordinate on its own. This is the single most common error about the subject: for the strict test n minors suffice, for the weak test one needs all $2^n - 1$ of them.

Quick check. Is $\mathbf{A} = \begin{pmatrix} 1 & 2 \\ 2 & 4 \end{pmatrix}$ positive semidefinite? Is it positive definite? Which minors did you use?

Solution. It is positive semidefinite but not positive definite. The principal minors are 1, 4 and $\det \mathbf{A} = 4 - 4 = 0$, all ≥ 0, so Theorem 12.1.4 (e) applies. It is not definite, since $\det \mathbf{A}_2 = 0$ violates Sylvester's criterion; concretely $\mathbf{A}(2, -1) = \mathbf{0}$, so $\langle \mathbf{Ax}, \mathbf{x} \rangle = 0$ at the non-zero $\mathbf{x} = (2, -1)$. One can also see everything at once from $\mathbf{A} = \mathbf{b}\mathbf{b}^\top$ with $\mathbf{b} = (1, 2)$, which is Example (Five Positive Matrices) (b).

12.1.5 Two by two, and where these matrices come from

The 2×2 case is worth memorizing, because it is the one that appears inside larger arguments.

Example. (The 2×2 Test)

Let $\mathbf{A} = \begin{pmatrix} a & b \\ \overline{b} & d \end{pmatrix}$ be Hermitian, so $a, d \in \mathbb{R}$ and $b \in F$. State and justify the tests for $\mathbf{A} \succ 0$ and for $\mathbf{A} \succeq 0$.

Solution. $\mathbf{A} \succ 0$ if and only if $a > 0$ and $ad - |b|^2 > 0$. This is Sylvester's criterion, Theorem 12.1.5 (d): the two leading principal minors are a and $\det \mathbf{A} = ad - |b|^2$.

$\mathbf{A} \succeq 0$ if and only if $a \geq 0$, $d \geq 0$ and $ad - |b|^2 \geq 0$. This is Theorem 12.1.4 (e): the principal minors are a, d and $\det \mathbf{A}$, and all three are needed. Dropping $d \geq 0$ readmits $\operatorname{diag}(0, -1)$.

Note what the second condition says: $|b|^2 \leq ad$, so an off-diagonal entry can never be larger in modulus than the geometric mean of the two diagonal entries it sits between. For $\mathbf{A} = \begin{pmatrix} 2 & 1+i \\ 1-i & 3 \end{pmatrix}$ over $\mathbb{C}$: $a = 2 > 0$ and $ad - |b|^2 = 6 - 2 = 4 > 0$, so $\mathbf{A} \succ 0$.

Where do positive semidefinite matrices come from? Almost always from item (c) of Theorem 12.1.4, and the standard source is data.

Example. (A Covariance-style Matrix)

Three quantities are measured on four occasions, and each column of

$$\mathbf{X} = \begin{pmatrix} 2 & 1 & 0 \\ -1 & 1 & 1 \\ -1 & -1 & 0 \\ 0 & -1 & -1 \end{pmatrix} \in M_{4\times 3}(\mathbb{R})$$

has been adjusted to sum to 0. Show that $\mathbf{A} = \mathbf{X}^\top \mathbf{X}$ is positive definite, and check the verdict against Sylvester's criterion.

Solution. Multiplying out, a_{ij} is the dot product of columns i and j of $\mathbf{X}$:

$$\mathbf{A} = \begin{pmatrix} 6 & 2 & -1 \\ 2 & 4 & 2 \\ -1 & 2 & 2 \end{pmatrix}.$$

The columns of $\mathbf{X}$ are linearly independent: if $\mathbf{Xx} = \mathbf{0}$, rows 1 and 3 read $2x_1 + x_2 = 0$ and $-x_1 - x_2 = 0$, which force $x_1 = x_2 = 0$, and then row 2 reads $x_3 = 0$. So $\operatorname{nul}(\mathbf{X}) = \{\mathbf{0}\}$, and taking $\mathbf{S} = \mathbf{X}$ in Proposition 12.1.2 (b) with the positive definite matrix $\mathbf{I}_4$ gives $\mathbf{A} = \mathbf{X}^{\top}\mathbf{I}_4\mathbf{X} \succ 0$. Equivalently, $\langle \mathbf{Ax}, \mathbf{x} \rangle = \|\mathbf{Xx}\|^2 > 0$ for $\mathbf{x} \neq \mathbf{0}$.

Sylvester's criterion agrees: $\det \mathbf{A}_1 = 6$, $\det \mathbf{A}_2 = 24 - 4 = 20$, and expanding along the first row,

$$\det \mathbf{A} = 6(8-4) - 2(4+2) + (-1)(4+4) = 24 - 12 - 8 = 4,$$

all positive. The reason the two routes must agree is that $\mathbf{A}$ is the Gram matrix of the columns of $\mathbf{X}$, and Theorem 10.2.5 (d) already said that its determinant is positive exactly when those columns are independent.

12.1.6 The invertible matrix theorem grows

Chapter 2 listed eight conditions equivalent to invertibility (Theorem 2.4.4); Chapter 3 restated them for operators (Theorem 3.5.7); Chapter 6 added the determinant (Theorem 6.5.3) and Chapter 8 the eigenvalue 0 (Theorem 8.2.6). Positivity adds a pair, and they are the ones used whenever a square system is attacked through least squares.

Theorem 12.1.6 — Invertible Matrix Theorem, with Positive Definiteness

Let $\mathbf{A} \in M_n(F)$ with $F = \mathbb{R}$ or $F = \mathbb{C}$. The following are equivalent, and each is equivalent to each of the conditions of Theorem 2.4.4, Theorem 6.5.3 and Theorem 8.2.6.

(a) $\mathbf{A}$ is invertible.
(b) $\mathbf{A}^*\mathbf{A} \succ 0$.
(c) $\mathbf{A}\mathbf{A}^* \succ 0$.

For a general $\mathbf{A} \in M_{m\times n}(F)$, one always has $\mathbf{A}^*\mathbf{A} \succeq 0$, with $\mathbf{A}^*\mathbf{A} \succ 0$ if and only if the columns of $\mathbf{A}$ are linearly independent.

Proof. Let $\mathbf{A} \in M_{m\times n}(F)$. Then $\mathbf{A}^*\mathbf{A}$ is positive semidefinite by Theorem 12.1.4 ((c) $\Rightarrow$ (a)). Whether it is definite is decided by the identity $\langle \mathbf{A}^*\mathbf{Ax}, \mathbf{x} \rangle = \mathbf{x}^*\mathbf{A}^*\mathbf{Ax} = \|\mathbf{Ax}\|^2$, computed in the proof of Theorem 12.1.4 ((c) $\Rightarrow$ (a)) and recorded in operator form in Exercise (C1: The operator S^*S) (a): the left side is > 0 for every $\mathbf{x} \neq \mathbf{0}$ exactly when $\mathbf{Ax} \neq \mathbf{0}$ for every $\mathbf{x} \neq \mathbf{0}$, that is, exactly when $\operatorname{nul}(\mathbf{A}) = \{\mathbf{0}\}$, that is, exactly when the columns of $\mathbf{A}$ are linearly independent. The same conclusion comes from Lemma 10.4.3, which says $\operatorname{nul}(\mathbf{A}^*\mathbf{A}) = \operatorname{nul}(\mathbf{A})$ and so lets one read the condition off $\mathbf{A}$ directly.

Now let $\mathbf{A}$ be square. Then "$\operatorname{nul}(\mathbf{A}) = \{\mathbf{0}\}$" is item (b) of Theorem 2.4.4, which gives (a) $\Leftrightarrow$ (b). Also $\mathbf{A}$ is invertible if and only if $\mathbf{A}^*$ is, since $(\mathbf{A}^{-1})^*$ is a two-sided inverse

of $\mathbf{A}^*$ and conversely; applying (a) $\Leftrightarrow$ (b) to $\mathbf{A}^*$ therefore gives (a) $\Leftrightarrow$ (c).

■

The two new items look like a detour — why test $\mathbf{A}^*\mathbf{A}$ when $\mathbf{A}$ itself is available? Because $\mathbf{A}^*\mathbf{A}$ is Hermitian and positive, and everything in this chapter applies to it. Chapter 10 already used it once, in the normal equations of least squares; Section 8 will use it again, to build the singular value decomposition of a matrix that is not even square, and that decomposition supplies the last item of the list: a square matrix is invertible exactly when none of its singular values is zero.

12.1.7 Exercises

12.1.7.1 A. Check your understanding

Exercise A1.

(a) State the definition of $\mathbf{A} \succeq 0$ and of $\mathbf{A} \succ 0$, including every quantifier and the field.

(b) Explain why clause (P1) cannot be dropped from the real definition, with a concrete matrix.

(c) True or false: if $\mathbf{A}$ is Hermitian and every leading principal minor of $\mathbf{A}$ is ≥ 0, then $\mathbf{A} \succeq 0$. Justify your answer.

(d) Write down the three conditions of the 2×2 test for $\mathbf{A} \succeq 0$.

(e) Name the item of Theorem 12.1.4 that says every positive semidefinite matrix is a Gram matrix.

Solution.

(a) $\mathbf{A} \in M_n(F)$ with $F = \mathbb{R}$ or $\mathbb{C}$ is positive semidefinite if $\mathbf{A}^* = \mathbf{A}$ and $\langle \mathbf{Ax}, \mathbf{x} \rangle \geq 0$ for **every** $\mathbf{x} \in F^n$; positive definite if $\mathbf{A}^* = \mathbf{A}$ and $\langle \mathbf{Ax}, \mathbf{x} \rangle > 0$ for every **non-zero** $\mathbf{x} \in F^n$ (Definition 12.1.1).

(b) Because over $\mathbb{R}$ the quadratic form does not see the skew part. The quarter turn $\begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$ has $\langle \mathbf{Ax}, \mathbf{x} \rangle = 0$ for every $\mathbf{x} \in \mathbb{R}^2$ and is not symmetric.

(c) False. $\operatorname{diag}(0, -1)$ has leading principal minors 0 and 0, and $\langle \mathbf{Ae}_2, \mathbf{e}_2 \rangle = -1$. All principal minors are needed (Theorem 12.1.4 (e)).

(d) With $\mathbf{A} = \begin{pmatrix} a & b \\ \overline{b} & d \end{pmatrix}$ Hermitian: $a \geq 0$, $d \geq 0$ and $ad - |b|^2 \geq 0$.

(e) Item (c): $\mathbf{A} = \mathbf{B}^*\mathbf{B}$, and $\mathbf{B}^*\mathbf{B}$ is the Gram matrix of the columns of $\mathbf{B}$.

12.1.7.2 B. Practice

Exercise B1: Determine the definiteness.

For each matrix below, determine whether it is positive definite, positive semidefinite but not positive definite, or neither. Justify your answer.

(a) $\begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix}$ over $\mathbb{R}$.

(b) $\begin{pmatrix} 0 & 0 \\ 0 & -1 \end{pmatrix}$ over $\mathbb{R}$.

(c) $\begin{pmatrix} 2 & -1 & 0 \\ -1 & 2 & -1 \\ 0 & -1 & 2 \end{pmatrix}$ over $\mathbb{R}$.

(d) The all-ones matrix $\mathbf{J} \in M_3(\mathbb{R})$.

(e) $\begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}$ over $\mathbb{R}$.

(f) $\begin{pmatrix} 2 & 1+i \\ 1-i & 1 \end{pmatrix}$ over $\mathbb{C}$.

Solution.

(a) Positive definite. Symmetric, with leading principal minors 2 and $4 - 1 = 3$, both positive (Theorem 12.1.5 (d)).

(b) Neither. The leading principal minors are 0 and 0, which tempts one into "semidefinite", but the principal minor $\det \mathbf{A}_{\{2\},\{2\}} = -1$ is negative, and $\langle \mathbf{A}\mathbf{e}_2, \mathbf{e}_2 \rangle = -1 < 0$.

(c) Positive definite. Symmetric, with leading principal minors 2, $4 - 1 = 3$ and $2 \cdot 3 - (-1)(-2) = 4$, all positive.

(d) Positive semidefinite, not positive definite. $\mathbf{J} = \mathbf{1}\mathbf{1}^{\top}$, which is Example (Five Positive Matrices) (b) with $\mathbf{x} = \mathbf{1}$; so $\langle \mathbf{J}\mathbf{x}, \mathbf{x} \rangle = |\langle \mathbf{x}, \mathbf{1} \rangle|^2 \geq 0$. It vanishes at the non-zero $\mathbf{x} = (1, -1, 0)$, so it is not definite. (Equivalently, $\det \mathbf{J} = 0$.)

(e) Neither: it is not symmetric, so (P1) fails and it is not in the class at all. Its quadratic form is identically 0, which shows how little the form sees over $\mathbb{R}$.

(f) Positive semidefinite, not positive definite. Hermitian, with $a = 2 \geq 0$, $d = 1 \geq 0$ and $ad - |b|^2 = 2 - 2 = 0$. The determinant is 0, so definiteness fails; indeed $\mathbf{A}(1 + i, -2) = \mathbf{0}$.

Exercise B2: A parameter.

For which $t \in \mathbb{R}$ is

$$\mathbf{A}(t) = \begin{pmatrix} 1 & t & 0 \\ t & 2 & t \\ 0 & t & 3 \end{pmatrix}$$

positive definite? Justify your answer.

Solution. $\mathbf{A}(t)$ is symmetric for every real t, so Sylvester's criterion applies (Theorem 12.1.5 (d)). The leading principal minors are

$$\det \mathbf{A}_1 = 1, \qquad \det \mathbf{A}_2 = 2 - t^2, \qquad \det \mathbf{A}_3 = 6 - 4t^2,$$

the last by expansion along the first row: $1 \cdot (6 - t^2) - t \cdot (3t - 0) = 6 - 4t^2$. All three are positive exactly when $t^2 < 2$ and $t^2 < 3/2$, that is when $t^2 < 3/2$. Hence $\mathbf{A}(t) \succ 0$ if and only if $|t| < \sqrt{6}/2$.

At $t = \sqrt{6}/2$ the matrix is positive semidefinite but singular, and for $|t| > \sqrt{6}/2$ the determinant is negative, so $\mathbf{A}(t)$ has an odd number of negative eigenvalues and is not even semidefinite.

Exercise B3: The inverse of a positive definite matrix.

Let $\mathbf{A} \in M_n(F)$ with $\mathbf{A} \succ 0$. Prove that $\mathbf{A}$ is invertible and that $\mathbf{A}^{-1} \succ 0$.

Solution. By Theorem 12.1.5 (b), every eigenvalue of $\mathbf{A}$ is positive, so $0 \notin \operatorname{spec}(\mathbf{A})$ and $\mathbf{A}$ is invertible (Theorem 8.2.6). Then $(\mathbf{A}^{-1})^* = (\mathbf{A}^*)^{-1} = \mathbf{A}^{-1}$, so $\mathbf{A}^{-1}$ is Hermitian. Apply Proposition 12.1.2 (b) with $\mathbf{S} = \mathbf{A}^{-1}$, which is invertible:

$$\mathbf{S}^*\mathbf{A}\mathbf{S} = \mathbf{A}^{-1}\mathbf{A}\mathbf{A}^{-1} = \mathbf{A}^{-1} \succ 0.$$

(Alternatively: the eigenvalues of $\mathbf{A}^{-1}$ are the reciprocals $1/\lambda_i$ of those of $\mathbf{A}$, hence positive, and Theorem 12.1.5 (b) applies again.)

12.1.7.3 C. Going deeper

Exercise C1: Zero trace forces zero.

Let $\mathbf{A} \in M_n(F)$ with $\mathbf{A} \succeq 0$.

(a) Prove that $a_{ii} \geq 0$ for every i, and that $\operatorname{tr}\mathbf{A} \geq 0$.

(b) Prove that if $\operatorname{tr}\mathbf{A} = 0$ then $\mathbf{A} = 0$.

(c) Deduce that if $\mathbf{A} \succeq 0$ and $-\mathbf{A} \succeq 0$, then $\mathbf{A} = 0$.

Solution.

(a) $a_{ii} = \mathbf{e}_i^*\mathbf{A}\mathbf{e}_i = \langle \mathbf{A}\mathbf{e}_i, \mathbf{e}_i\rangle \geq 0$ by (P2). Summing, $\operatorname{tr}\mathbf{A} = \sum_i a_{ii} \geq 0$.

(b) Write $\mathbf{A} = \mathbf{U}\mathbf{D}\mathbf{U}^*$ with $\mathbf{U}$ unitary and $\mathbf{D} = \operatorname{diag}(\lambda_1, \ldots, \lambda_n)$ the eigenvalues (Corollary 11.4.3, Corollary 11.5.2). Then $\operatorname{tr}\mathbf{A} = \operatorname{tr}(\mathbf{D}\mathbf{U}^*\mathbf{U}) = \operatorname{tr}\mathbf{D} = \sum_i \lambda_i$ by Theorem 0.9.6, and each $\lambda_i \geq 0$ by Theorem 12.1.4 (b). A sum of non-negative reals is 0 only if every term is 0, so $\mathbf{D} = 0$ and hence $\mathbf{A} = 0$.
Alternatively, without eigenvalues: by (a) each $a_{ii} \geq 0$, so $\operatorname{tr}\mathbf{A} = 0$ forces every $a_{ii} = 0$. Writing $\mathbf{A} = \mathbf{B}^*\mathbf{B}$ (Theorem 12.1.4 (c)), the i-th diagonal entry is $\|\mathbf{b}_i\|^2$ for the i-th column $\mathbf{b}_i$ of $\mathbf{B}$; so every column of $\mathbf{B}$ is $\mathbf{0}$, that is $\mathbf{B} = 0$ and $\mathbf{A} = 0$.

(c) If both $\mathbf{A} \succeq 0$ and $-\mathbf{A} \succeq 0$, then by (a) $\operatorname{tr}\mathbf{A} \geq 0$ and $\operatorname{tr}(-\mathbf{A}) = -\operatorname{tr}\mathbf{A} \geq 0$, so $\operatorname{tr}\mathbf{A} = 0$ and (b) gives $\mathbf{A} = 0$.

Exercise C2: The cone of positive matrices.

Let $\mathcal{P}_n \subseteq M_n(F)$ be the set of positive semidefinite matrices.

(a) Prove that if $\mathbf{A}, \mathbf{B} \in \mathcal{P}_n$ and $c \geq 0$ is real, then $\mathbf{A} + \mathbf{B} \in \mathcal{P}_n$ and $c\mathbf{A} \in \mathcal{P}_n$. (A set with these two properties is a **convex cone**: it contains $(1-t)\mathbf{A} + t\mathbf{B}$ for $0 \leq t \leq 1$ as well.)

(b) Prove that $\mathcal{P}_n$ contains no line through 0: if $\mathbf{A} \in \mathcal{P}_n$ and $-\mathbf{A} \in \mathcal{P}_n$ then $\mathbf{A} = 0$.

(c) Prove that $\mathcal{P}_n$ is closed under congruence: if $\mathbf{A} \in \mathcal{P}_n$ and $\mathbf{S} \in M_n(F)$, then $\mathbf{S}^*\mathbf{A}\mathbf{S} \in \mathcal{P}_n$. Give an example showing that $\mathcal{P}_n$ is **not** closed under multiplication.

Hint for (c): for the example, two positive semidefinite matrices whose product is not even Hermitian will do.

Solution.

(a) Sums and real multiples of Hermitian matrices are Hermitian. For every $\mathbf{x}$,

$$\langle (\mathbf{A}+\mathbf{B})\mathbf{x}, \mathbf{x}\rangle = \langle \mathbf{A}\mathbf{x}, \mathbf{x}\rangle + \langle \mathbf{B}\mathbf{x}, \mathbf{x}\rangle \geq 0,$$

and $\langle c\mathbf{A}\mathbf{x}, \mathbf{x}\rangle = c\langle \mathbf{A}\mathbf{x}, \mathbf{x}\rangle \geq 0$ since $c \geq 0$. Convexity follows by taking $c = 1-t$ and $c = t$ and adding.

(b) This is Exercise (C1: Zero trace forces zero) (c).

(c) Immediate from Proposition 12.1.2 (a). For the failure of multiplicativity, take

$$\mathbf{A} = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}, \qquad \mathbf{B} = \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix},$$

both positive semidefinite ($\mathbf{A} = \mathbf{e}_1\mathbf{e}_1^{\top}$ and $\mathbf{B} = \mathbf{1}\mathbf{1}^{\top}$). Then

$$\mathbf{A}\mathbf{B} = \begin{pmatrix} 1 & 1 \\ 0 & 0 \end{pmatrix},$$

which is not symmetric, so it is not positive semidefinite — it fails (P1), never mind (P2). Section 2 shows what does survive: $\operatorname{tr}(\mathbf{A}\mathbf{B}) \geq 0$, and $\mathbf{A}\mathbf{B} \succeq 0$ whenever $\mathbf{A}$ and $\mathbf{B}$ commute.

Exercise C3: The largest entry sits on the diagonal.

Let $\mathbf{A} \in M_n(F)$ with $\mathbf{A} \succeq 0$.

(a) Prove that $|a_{ij}|^2 \leq a_{ii}a_{jj}$ for all i, j.

(b) Deduce that if $a_{ii} = 0$ for some i, then the whole i-th row and i-th column of $\mathbf{A}$ are zero.

(c) Deduce that $\max_{i,j}|a_{ij}| = \max_i a_{ii}$.

Hint for (a): look at a 2×2 principal submatrix.

Solution.

(a) For $i = j$ the claim is $a_{ii}^2 \leq a_{ii}^2$. For $i \neq j$, take $I = \{i, j\}$. By the proof of Theorem 12.1.4 ((a) $\Rightarrow$ (e)), $\mathbf{A}_{I,I} \succeq 0$, and Example (The 2×2 Test) gives $a_{ii}a_{jj} - |a_{ij}|^2 = \det \mathbf{A}_{I,I} \geq 0$.

(b) If $a_{ii} = 0$, then (a) gives $|a_{ij}|^2 \leq 0 \cdot a_{jj} = 0$ for every j, so $a_{ij} = 0$; and $a_{ji} = \overline{a_{ij}} = 0$ since $\mathbf{A}$ is Hermitian.

(c) Let $M = \max_i a_{ii}$, a maximum of non-negative reals by Exercise (C1: Zero trace forces zero) (a). By (a), $|a_{ij}| \leq \sqrt{a_{ii}a_{jj}} \leq M$ for all i, j, so $\max_{i,j}|a_{ij}| \leq M$. The

reverse inequality holds because the diagonal entries are among the entries. Hence the two maxima are equal.

12.2 Square Roots and the Cholesky Factorization

A non-negative real number has exactly one non-negative square root, and it is the reason "non-negative" is a useful class of numbers at all: it lets us take lengths, define standard deviations, and undo a squaring. Section 1 produced the matrix analogue as one clause of a theorem. This section makes it an object with a name, adds the one property the clause did not mention — that the square root is a **polynomial** in the matrix — and then turns the same idea into the triangular factorization that elimination discovers, the one Chapter 2 promised and could not yet explain.

Throughout, $F = \mathbb{R}$ or $F = \mathbb{C}$, and all matrices are over F.

12.2.1 The positive square root

Theorem 12.1.4 (d) already says that a positive semidefinite $\mathbf{A}$ has exactly one positive semidefinite square root. That is an existence-and-uniqueness statement, so by the usual convention it deserves a notation.

The square root of a positive matrix is what you get by taking square roots of its eigenvalues and leaving the eigenvectors alone.

Theorem 12.2.1 — The Positive Square Root

Let $\mathbf{A} \in M_n(F)$ with $\mathbf{A} \succeq 0$. Then there is exactly one $\mathbf{C} \in M_n(F)$ with $\mathbf{C} \succeq 0$ and $\mathbf{C}^2 = \mathbf{A}$. We write $\mathbf{C} = \mathbf{A}^{1/2}$, also $\sqrt{\mathbf{A}}$. Moreover:

(a) $\mathbf{A}^{1/2} = p(\mathbf{A})$ for some polynomial p with real coefficients (the nodes λ_i and the values $\sqrt{\lambda_i}$ are real, so the interpolation of Theorem 5.6.1 may be run over $\mathbb{R}$, and $\mathbb{R}[x] \subseteq \mathbb{C}[x]$);

(b) $\mathbf{A}^{1/2}\mathbf{B} = \mathbf{B}\mathbf{A}^{1/2}$ for **every** $\mathbf{B} \in M_n(F)$ with $\mathbf{A}\mathbf{B} = \mathbf{B}\mathbf{A}$;

(c) $\operatorname{nul}(\mathbf{A}^{1/2}) = \operatorname{nul}(\mathbf{A})$ and $\operatorname{rank}\mathbf{A}^{1/2} = \operatorname{rank}\mathbf{A}$; in particular $\mathbf{A}^{1/2}$ is invertible if and only if $\mathbf{A}$ is.

The eigenvalues of $\mathbf{A}^{1/2}$ are the non-negative square roots of those of $\mathbf{A}$, with the same eigenvectors.

Idea. Existence and uniqueness are Section 1. What is new is (a), and it is the reason (b) is free. On the spectrum, the square root is just a function $\lambda \mapsto \sqrt{\lambda}$ defined at finitely many points, and a function defined at finitely many points is a polynomial — that is Lagrange interpolation from Chapter 5. The functional calculus of Chapter 11 says that applying a polynomial to $\mathbf{A}$ and applying the corresponding function to the spectrum are the same operation, so the interpolating polynomial evaluated at $\mathbf{A}$ *is* the

square root. Once $\mathbf{A}^{1/2}$ is a polynomial in $\mathbf{A}$, anything commuting with $\mathbf{A}$ commutes with it, with no further work.

Proof. Existence and uniqueness are Theorem 12.1.4 (d).

(a) Let $\lambda_1, \dots, \lambda_k$ be the **distinct** eigenvalues of $\mathbf{A}$ and let $\mathbf{A} = \sum_i \lambda_i \mathbf{P}_i$ be its spectral resolution (Definition 11.8.1, Theorem 11.8.1), which exists because a Hermitian matrix has an orthonormal basis of eigenvectors. Every λ_i is a non-negative real number by Theorem 12.1.4 (b), so the numbers $\sqrt{\lambda_i}$ are defined and real. Let $f(\lambda) = \sqrt{\lambda}$ on $\operatorname{spec}(\mathbf{A})$. By Theorem 11.8.3 (b) and (a),

$$f(\mathbf{A})^2 = (f^2)(\mathbf{A}) = \mathbf{A},$$

and by (c) and (d) of the same theorem $f(\mathbf{A})$ is Hermitian with spectrum $\{\sqrt{\lambda_1}, \dots, \sqrt{\lambda_k}\} \subseteq [0, \infty)$, so $f(\mathbf{A}) \succeq 0$ by Theorem 12.1.4 (b). Uniqueness gives $f(\mathbf{A}) = \mathbf{A}^{1/2}$.
The numbers $\lambda_1, \dots, \lambda_k$ are distinct, so by Lagrange interpolation (Theorem 5.6.1) there is a polynomial p of degree at most $k-1$, with real coefficients, such that $p(\lambda_i) = \sqrt{\lambda_i}$ for every i. By Theorem 11.8.3 (a), $p(\mathbf{A}) = \sum_i p(\lambda_i)\mathbf{P}_i = f(\mathbf{A}) = \mathbf{A}^{1/2}$.

(b) Suppose $\mathbf{AB} = \mathbf{BA}$. Then $\mathbf{B}$ commutes with every power of $\mathbf{A}$, hence with every polynomial in $\mathbf{A}$, hence with $p(\mathbf{A}) = \mathbf{A}^{1/2}$.

(c) If $\mathbf{A}^{1/2}\mathbf{x} = \mathbf{0}$ then $\mathbf{Ax} = \mathbf{A}^{1/2}(\mathbf{A}^{1/2}\mathbf{x}) = \mathbf{0}$. Conversely, if $\mathbf{Ax} = \mathbf{0}$, then since $\mathbf{A}^{1/2}$ is Hermitian,

$$\|\mathbf{A}^{1/2}\mathbf{x}\|^2 = \langle \mathbf{A}^{1/2}\mathbf{x}, \mathbf{A}^{1/2}\mathbf{x} \rangle = \langle \mathbf{Ax}, \mathbf{x} \rangle = 0,$$

so $\mathbf{A}^{1/2}\mathbf{x} = \mathbf{0}$. Hence the two null spaces agree, and the ranks agree by Theorem 2.5.7. Invertibility is the case $\operatorname{nul} = \{\mathbf{0}\}$ (Theorem 2.4.4).

The last sentence is the spectral mapping statement of Theorem 11.8.3 (d) for $f = \sqrt{\cdot}$. ∎

Two routes to the same matrix, then, and both are worth practicing: assemble $\sum_i \sqrt{\lambda_i}\mathbf{P}_i$ from the projections, or find one interpolating polynomial and substitute.

Example. (Two Square Roots)

Compute $\mathbf{A}^{1/2}$ for

(a) $\mathbf{A} = \begin{pmatrix} 13 & 12 \\ 12 & 13 \end{pmatrix}$;

(b) $\mathbf{B} = \begin{pmatrix} 2 & 1 & 1 \\ 1 & 2 & 1 \\ 1 & 1 & 2 \end{pmatrix}$,

in each case by the spectral resolution and by a polynomial.

Solution.

(a) $\mathbf{A}$ is symmetric. Since $\mathbf{A}(1,1) = (25, 25)$ and $\mathbf{A}(1,-1) = (1,-1)$, the eigenvalues

are 25 and 1, with eigenlines spanned by $(1,1)$ and $(1,-1)$. Both are positive, so $\mathbf{A} \succ 0$. The orthogonal projections onto the two eigenlines are

$$\mathbf{P}_1 = \tfrac{1}{2}\begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix}, \qquad \mathbf{P}_2 = \tfrac{1}{2}\begin{pmatrix} 1 & -1 \\ -1 & 1 \end{pmatrix},$$

so $\mathbf{A} = 25\mathbf{P}_1 + \mathbf{P}_2$ and

$$\mathbf{A}^{1/2} = 5\mathbf{P}_1 + 1 \cdot \mathbf{P}_2 = \begin{pmatrix} 3 & 2 \\ 2 & 3 \end{pmatrix}.$$

By the polynomial route: we need p with $p(25) = 5$ and $p(1) = 1$. The line through the two points is $p(x) = \frac{1}{6}x + \frac{5}{6}$, and

$$\tfrac{1}{6}\mathbf{A} + \tfrac{5}{6}\mathbf{I} = \tfrac{1}{6}\begin{pmatrix} 18 & 12 \\ 12 & 18 \end{pmatrix} = \begin{pmatrix} 3 & 2 \\ 2 & 3 \end{pmatrix}.$$

Check: $\begin{pmatrix} 3 & 2 \\ 2 & 3 \end{pmatrix}^2 = \begin{pmatrix} 13 & 12 \\ 12 & 13 \end{pmatrix}$.

(b) Here $\mathbf{B} = \mathbf{I} + \mathbf{J}$ with $\mathbf{J}$ the all-ones matrix. Since $\mathbf{J1} = 3\mathbf{1}$ and $\mathbf{Jx} = \mathbf{0}$ for every $\mathbf{x}$ with entries summing to 0, the eigenvalues of $\mathbf{J}$ are 3 and 0, so those of $\mathbf{B}$ are 4 and 1; both are positive, so $\mathbf{B} \succ 0$. We need p with $p(4) = 2$ and $p(1) = 1$, namely $p(x) = \frac{1}{3}x + \frac{2}{3}$, giving

$$\mathbf{B}^{1/2} = \tfrac{1}{3}\mathbf{B} + \tfrac{2}{3}\mathbf{I} = \tfrac{1}{3}\begin{pmatrix} 4 & 1 & 1 \\ 1 & 4 & 1 \\ 1 & 1 & 4 \end{pmatrix}.$$

Check by squaring: the diagonal entry of the square is $\frac{1}{9}(16 + 1 + 1) = 2$ and an off-diagonal entry is $\frac{1}{9}(4 + 4 + 1) = 1$, which reproduces $\mathbf{B}$. Only two distinct eigenvalues appear, so a polynomial of degree 1 suffices even though $\mathbf{B}$ is 3×3.

Warning. **$\mathbf{A}^{1/2}$ is not the entrywise square root, and it is not the only square root.** For $\mathbf{A} = \begin{pmatrix} 13 & 12 \\ 12 & 13 \end{pmatrix}$ the entrywise roots $\begin{pmatrix} \sqrt{13} & \sqrt{12} \\ \sqrt{12} & \sqrt{13} \end{pmatrix}$ form a matrix whose square is not $\mathbf{A}$. And $\mathbf{A}$ has other square roots: $-\mathbf{A}^{1/2}$ is one, and $5\mathbf{P}_1 - \mathbf{P}_2 = \begin{pmatrix} 2 & 3 \\ 3 & 2 \end{pmatrix}$ is another symmetric one. The word **positive** in "positive square root" is what makes the object unique; drop it and this $\mathbf{A}$, whose two eigenvalues are distinct and positive, has four symmetric square roots, one for each choice of sign on each eigenline. When an eigenvalue repeats there are infinitely many, symmetric ones included: every reflection $\left(\begin{smallmatrix} \cos\theta & \sin\theta \\ \sin\theta & -\cos\theta \end{smallmatrix}\right)$ is a symmetric square root of $\mathbf{I}_2$.

Quick check. Let $\mathbf{A} \succeq 0$ and let $\mathbf{U}$ be unitary. What is $(\mathbf{U}^*\mathbf{A}\mathbf{U})^{1/2}$?

Solution. $\mathbf{U}^*\mathbf{A}^{1/2}\mathbf{U}$. It is positive semidefinite by Proposition 12.1.2 (a), since $\mathbf{A}^{1/2} \succeq 0$, and its square is $\mathbf{U}^*\mathbf{A}^{1/2}\mathbf{U}\mathbf{U}^*\mathbf{A}^{1/2}\mathbf{U} = \mathbf{U}^*\mathbf{A}\mathbf{U}$ because $\mathbf{U}\mathbf{U}^* = \mathbf{I}$. Uniqueness in Theorem 12.2.1 does the rest. In words: the square root does not care which orthonormal coordinates we use, which is exactly what one wants of an operation defined on the spectrum.

12.2.2 The absolute value of a matrix

A complex number has a modulus $|z| = \sqrt{\bar{z}z}$, and the polar form $z = e^{i\theta}|z|$ splits it into a rotation and a non-negative stretch. Section 9 will split a matrix the same way, and the stretching factor it needs is built now. For **any** matrix, square or not, $\mathbf{A}^*\mathbf{A}$ is positive semidefinite (Theorem 12.1.6), so it has a square root.

Definition 12.2.1 — Absolute Value of a Matrix

Let $\mathbf{A} \in M_{m\times n}(F)$. The **absolute value** of $\mathbf{A}$ is

$$|\mathbf{A}| := (\mathbf{A}^*\mathbf{A})^{1/2} \in M_n(F),$$

the unique positive semidefinite square root of $\mathbf{A}^*\mathbf{A}$.

Note the size: $|\mathbf{A}|$ is $n \times n$, not $m \times n$, because $\mathbf{A}^*\mathbf{A}$ acts on the domain of $\mathbf{A}$. It is well defined because $\mathbf{A}^*\mathbf{A} \succeq 0$ and Theorem 12.2.1 gives exactly one root.

Proposition 12.2.2 — What the absolute value preserves

Let $\mathbf{A} \in M_{m\times n}(F)$. Then for every $\mathbf{x} \in F^n$,

$$\||\mathbf{A}|\mathbf{x}\| = \|\mathbf{A}\mathbf{x}\|.$$

Consequently $\operatorname{nul}|\mathbf{A}| = \operatorname{nul}\mathbf{A}$ and $\operatorname{rank}|\mathbf{A}| = \operatorname{rank}\mathbf{A}$.

Proof. Since $|\mathbf{A}|$ is Hermitian and $|\mathbf{A}|^2 = \mathbf{A}^*\mathbf{A}$,

$$\||\mathbf{A}|\mathbf{x}\|^2 = \langle |\mathbf{A}|^2\mathbf{x}, \mathbf{x}\rangle = \langle \mathbf{A}^*\mathbf{A}\mathbf{x}, \mathbf{x}\rangle = \|\mathbf{A}\mathbf{x}\|^2,$$

using Lemma 10.4.1 twice. Both sides are non-negative reals, so the norms agree. Hence $|\mathbf{A}|\mathbf{x} = \mathbf{0}$ if and only if $\mathbf{A}\mathbf{x} = \mathbf{0}$, and the rank statement follows by Theorem 2.5.7. ∎

So $|\mathbf{A}|$ does exactly what $\mathbf{A}$ does to lengths, and nothing else. That single identity is the whole engine of the polar decomposition: the map $|\mathbf{A}|\mathbf{x} \mapsto \mathbf{A}\mathbf{x}$ preserves norms, so it extends to a unitary matrix, and $\mathbf{A} = \mathbf{W}|\mathbf{A}|$ follows.

Example. (Two Absolute Values)

Compute $|\mathbf{A}|$ for $\mathbf{A} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$ and for $\mathbf{B} = \begin{pmatrix} 3 & 0 \\ 4 & 0 \end{pmatrix}$, both over $\mathbb{R}$.

Solution. For the quarter turn, $\mathbf{A}^\top\mathbf{A} = \mathbf{I}$, so $|\mathbf{A}| = \mathbf{I}^{1/2} = \mathbf{I}$. This is right: a rotation changes no length, so the matrix that does the same thing to lengths and nothing else is the identity.

For $\mathbf{B}$, $\mathbf{B}^\top\mathbf{B} = \begin{pmatrix} 25 & 0 \\ 0 & 0 \end{pmatrix}$, whose positive square root is $|\mathbf{B}| = \begin{pmatrix} 5 & 0 \\ 0 & 0 \end{pmatrix}$. Check Proposition 12.2.2: $\|\mathbf{Bx}\| = \|(3x_1, 4x_1)\| = 5|x_1| = \||\mathbf{B}|\mathbf{x}\|$. Both have rank 1 and null space $\operatorname{span}(\mathbf{e}_2)$.

Warning. **$|\mathbf{A}|$ is not the entrywise absolute value, and $|\mathbf{AB}| \neq |\mathbf{A}||\mathbf{B}|$.** For the quarter turn above, the entrywise absolute value is $\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$, while $|\mathbf{A}| = \mathbf{I}$. For the product rule, take

$$\mathbf{A} = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}, \qquad \mathbf{B} = \begin{pmatrix} 0 & 0 \\ 1 & 1 \end{pmatrix}.$$

Then $\mathbf{AB} = 0$, so $|\mathbf{AB}| = 0$, while $|\mathbf{A}| = \mathbf{A}$ and $|\mathbf{B}| = \frac{1}{\sqrt{2}}\begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix}$, giving

$$|\mathbf{A}||\mathbf{B}| = \frac{1}{\sqrt{2}}\begin{pmatrix} 1 & 1 \\ 0 & 0 \end{pmatrix} \neq 0.$$

That product is not even Hermitian, so it could not be the absolute value of anything. The modulus of a product of **numbers** is the product of the moduli because numbers commute; matrices do not.

12.2.3 Cholesky: elimination on a positive definite matrix

Chapter 2 ran elimination on a symmetric matrix and found that the two triangular factors are secretly the same one: $\mathbf{A} = \text{Ł}\mathbf{D}\text{Ł}^\top$ (Theorem 2.6.8). It then observed that when every entry of $\mathbf{D}$ is positive one can split $\mathbf{D} = \mathbf{D}^{1/2}\mathbf{D}^{1/2}$ and write $\mathbf{A} = (\text{Ł}\mathbf{D}^{1/2})(\text{Ł}\mathbf{D}^{1/2})^\top$, called this the **Cholesky factorization**, and promised that Chapter 12 would connect it with positive definite matrices. Here is the connection, and it is the best kind: the hypothesis "every entry of $\mathbf{D}$ is positive" is not an extra assumption at all. It holds exactly when $\mathbf{A}$ is positive definite, and it can be checked while the elimination runs.

Theorem 12.2.3 — Cholesky Factorization

Let $\mathbf{A} \in M_n(F)$ be Hermitian. Then $\mathbf{A} \succ 0$ if and only if

$$\mathbf{A} = \text{Ł}\text{Ł}^*$$

for some lower triangular $\text{Ł} \in M_n(F)$ whose diagonal entries are **real and strictly positive**. In that case Ł is unique.

Idea. ($\Leftarrow$) is one line: such an Ł is invertible, and $\text{Ł}\text{Ł}^* = (\text{Ł}^*)^*\text{Ł}^*$ is Theorem 12.1.5 (c) with $\mathbf{B} = \text{Ł}^*$.

($\Rightarrow$) is Chapter 2's elimination with its hypothesis supplied, run symmetrically. One pass clears the first column and the first row at once and leaves a smaller matrix that is again positive definite, so an induction produces $\mathbf{A} = \mathbf{M}\mathbf{D}\mathbf{M}^*$ with $\mathbf{M}$ unit lower triangular and every pivot $d_k > 0$. Absorbing $\mathbf{D}^{1/2}$ into $\mathbf{M}$ finishes it. For uniqueness,

strip the positive diagonal off each candidate Ł; what is left is an LU factorization of $\mathbf{A}$, and Chapter 2 already proved those unique.

Proof. ($\Leftarrow$) Suppose $\mathbf{A} = \text{Ł}\text{Ł}^*$ with Ł lower triangular and every $\ell_{kk} > 0$. Then Ł is invertible by Lemma 2.6.2, hence so is Ł^*, and $\mathbf{A} = (\text{Ł}^*)^*\text{Ł}^*$ is positive definite by Theorem 12.1.5 ((c) $\Rightarrow$ (a)).

($\Rightarrow$) Suppose $\mathbf{A} \succ 0$.

Claim. There are a unit lower triangular $\mathbf{M} \in M_n(F)$ and a diagonal $\mathbf{D} = \operatorname{diag}(d_1, \dots, d_n)$ whose entries are **real and strictly positive**, with $\mathbf{A} = \mathbf{M}\mathbf{D}\mathbf{M}^*$.

Proof. Induction on n. For $n = 1$, the single entry is $a_{11} = \langle \mathbf{A}\mathbf{e}_1, \mathbf{e}_1 \rangle > 0$ by (P2) of Definition 12.1.1 in its strict form, so $\mathbf{M} = (1)$ and $\mathbf{D} = (a_{11})$ will do.

Let $n \geq 2$. Since $\mathbf{A}^* = \mathbf{A}$, we may write

$$\mathbf{A} = \begin{pmatrix} \alpha & \mathbf{c}^* \\ \mathbf{c} & \mathbf{A}' \end{pmatrix}, \qquad \alpha = a_{11}, \quad \mathbf{c} \in F^{n-1}, \quad \mathbf{A}' \in M_{n-1}(F) \text{ Hermitian.}$$

Here $\alpha = \langle \mathbf{A}\mathbf{e}_1, \mathbf{e}_1 \rangle > 0$, so α^{-1} exists and is a positive real number. Put

$$\mathbf{S} \coloneqq \mathbf{A}' - \alpha^{-1}\mathbf{c}\mathbf{c}^*,$$

which is Hermitian, since $(\mathbf{c}\mathbf{c}^*)^* = \mathbf{c}\mathbf{c}^*$ and α is real.

The smaller matrix is again positive definite. Let $\mathbf{y} \in F^{n-1}$ with $\mathbf{y} \neq \mathbf{0}$, set $t = -\alpha^{-1}\mathbf{c}^*\mathbf{y}$ and $\mathbf{x} = (t, \mathbf{y}) \in F^n$, which is non-zero because $\mathbf{y}$ is. Multiplying out in blocks (Theorem 7.1.1),

$$\langle \mathbf{A}\mathbf{x}, \mathbf{x} \rangle = \mathbf{x}^*\mathbf{A}\mathbf{x} = \alpha|t|^2 + \bar{t}\,\mathbf{c}^*\mathbf{y} + \mathbf{y}^*\mathbf{c}\,t + \mathbf{y}^*\mathbf{A}'\mathbf{y}.$$

With $\mathbf{c}^*\mathbf{y} = -\alpha t$ and $\mathbf{y}^*\mathbf{c} = \overline{\mathbf{c}^*\mathbf{y}} = -\alpha\bar{t}$, the first three terms are

$$\alpha|t|^2 - \alpha|t|^2 - \alpha|t|^2 = -\alpha|t|^2 = -\alpha^{-1}|\mathbf{c}^*\mathbf{y}|^2,$$

so $\langle \mathbf{A}\mathbf{x}, \mathbf{x} \rangle = \mathbf{y}^*\big(\mathbf{A}' - \alpha^{-1}\mathbf{c}\mathbf{c}^*\big)\mathbf{y} = \langle \mathbf{S}\mathbf{y}, \mathbf{y} \rangle$. The left side is > 0 because $\mathbf{A} \succ 0$ and $\mathbf{x} \neq \mathbf{0}$. Hence $\mathbf{S} \succ 0$.

The induction step. By the induction hypothesis, $\mathbf{S} = \mathbf{M}'\mathbf{D}'(\mathbf{M}')^*$ with $\mathbf{M}' \in M_{n-1}(F)$ unit lower triangular and $\mathbf{D}' = \operatorname{diag}(d_2, \dots, d_n)$ real with positive entries. Put

$$\mathbf{M} = \begin{pmatrix} 1 & \mathbf{0}^\top \\ \alpha^{-1}\mathbf{c} & \mathbf{M}' \end{pmatrix}, \qquad \mathbf{D} = \begin{pmatrix} \alpha & \mathbf{0}^\top \\ \mathbf{0} & \mathbf{D}' \end{pmatrix}.$$

Then $\mathbf{M}$ is unit lower triangular and $\mathbf{D}$ is diagonal with the positive real entries $\alpha, d_2, \dots, d_n$. Block multiplication (Theorem 7.1.1) gives

$$\mathbf{M}\mathbf{D}\mathbf{M}^* = \begin{pmatrix} \alpha & \mathbf{0}^\top \\ \mathbf{c} & \mathbf{M}'\mathbf{D}' \end{pmatrix} \begin{pmatrix} 1 & \alpha^{-1}\mathbf{c}^* \\ \mathbf{0} & (\mathbf{M}')^* \end{pmatrix} = \begin{pmatrix} \alpha & \mathbf{c}^* \\ \mathbf{c} & \alpha^{-1}\mathbf{c}\mathbf{c}^* + \mathbf{M}'\mathbf{D}'(\mathbf{M}')^* \end{pmatrix},$$

and $\alpha^{-1}\mathbf{c}\mathbf{c}^* + \mathbf{M}'\mathbf{D}'(\mathbf{M}')^* = \alpha^{-1}\mathbf{c}\mathbf{c}^* + \mathbf{S} = \mathbf{A}'$. So $\mathbf{M}\mathbf{D}\mathbf{M}^* = \mathbf{A}$, which proves the claim.

■

The claim is one pass of elimination performed symmetrically, and $d_1 = \alpha, d_2, \dots, d_n$ are its pivots. Over $\mathbb{R}$ it is the $\mathrm{L}\mathbf{D}\mathrm{L}^{\top}$ factorization of Theorem 2.6.8 with the hypothesis that makes every pivot positive.

Write $d_1, \dots, d_n$ for the diagonal entries of $\mathbf{D}$, all of them positive real numbers. Then $\mathbf{D}^{1/2} \coloneqq \operatorname{diag}(\sqrt{d_1}, \dots, \sqrt{d_n})$ is a real matrix, and putting

$$\mathrm{L} = \mathbf{M}\mathbf{D}^{1/2}$$

gives a lower triangular matrix — its (i,j)-entry is $m_{ij}\sqrt{d_j}$, which vanishes for $i < j$ — whose k-th diagonal entry is $\sqrt{d_k} > 0$, and

$$\mathrm{L}\mathrm{L}^{*} = \mathbf{M}\mathbf{D}^{1/2}(\mathbf{D}^{1/2})^{*}\mathbf{M}^{*} = \mathbf{M}\mathbf{D}\mathbf{M}^{*} = \mathbf{A}.$$

Uniqueness. Suppose $\mathbf{A} = \mathrm{L}_1\mathrm{L}_1^{*} = \mathrm{L}_2\mathrm{L}_2^{*}$, with each L_i lower triangular with positive diagonal entries. Split off the diagonal: write $\mathbf{\Delta}_i = \operatorname{diag}((\mathrm{L}_i)_{11}, \dots, (\mathrm{L}_i)_{nn})$, a real diagonal matrix with positive entries, and $\mathbf{M}_i = \mathrm{L}_i\mathbf{\Delta}_i^{-1}$, which is lower triangular with every diagonal entry 1. Then $\mathrm{L}_i = \mathbf{M}_i\mathbf{\Delta}_i$ and

$$\mathbf{A} = \mathbf{M}_i\mathbf{\Delta}_i^2\mathbf{M}_i^{*} = \mathbf{M}_i\big(\mathbf{\Delta}_i^2\mathbf{M}_i^{*}\big).$$

The second factor is upper triangular, its (k,l)-entry being $(\mathbf{\Delta}_i^2)_{kk}\overline{(\mathbf{M}_i)_{lk}}$, which vanishes for $k > l$. So for $i = 1$ and $i = 2$ this displays an LU factorization of $\mathbf{A}$, which is invertible: L_1 is triangular with non-zero diagonal, hence invertible by Lemma 2.6.2, and $\mathbf{A} = \mathrm{L}_1\mathrm{L}_1^{*}$ is a product of two invertible matrices. By Theorem 2.6.5 the two agree:

$$\mathbf{M}_1 = \mathbf{M}_2 \qquad \text{and} \qquad \mathbf{\Delta}_1^2\mathbf{M}_1^{*} = \mathbf{\Delta}_2^2\mathbf{M}_2^{*}.$$

Canceling the invertible $\mathbf{M}_1^{*} = \mathbf{M}_2^{*}$ gives $\mathbf{\Delta}_1^2 = \mathbf{\Delta}_2^2$, and since both have positive diagonal entries, $\mathbf{\Delta}_1 = \mathbf{\Delta}_2$. Hence $\mathrm{L}_1 = \mathbf{M}_1\mathbf{\Delta}_1 = \mathbf{M}_2\mathbf{\Delta}_2 = \mathrm{L}_2$. This proves the theorem.

■

Remark. The pivots are determinant ratios. For $i, j \le k$, a term of $(\mathbf{M}\mathbf{D}\mathbf{M}^{*})_{ij} = \sum_l m_{il}(\mathbf{D}\mathbf{M}^{*})_{lj}$ with $l > k$ has $l > i$ and so $m_{il} = 0$; the sum therefore stops at $l = k$, which says that the leading principal submatrices multiply: $\mathbf{A}_k = \mathbf{M}_k\mathbf{D}_k(\mathbf{M}^{*})_k = \mathbf{M}_k\mathbf{D}_k\mathbf{M}_k^{*}$. Taking determinants with Theorem 6.5.4 and Theorem 6.4.6 gives $\det \mathbf{A}_k = d_1 \cdots d_k$, so $d_1 = \det \mathbf{A}_1$ and $d_k = \det \mathbf{A}_k / \det \mathbf{A}_{k-1}$ for $k \ge 2$. Read the other way, this is Sylvester's criterion (Theorem 12.1.5 (d)) appearing inside the elimination: the leading minors are positive exactly when the pivots are.

Reading the equation $\mathbf{A} = \mathrm{L}\mathrm{L}^{*}$ entry by entry turns it into a recipe, and the recipe is the standard way to factor by hand. Comparing the (j,j) entry of both sides gives $a_{jj} = \sum_{k<j}|\ell_{jk}|^2$, and comparing the (i,j) entry for $i > j$ gives $a_{ij} = \sum_{k<j}\ell_{ik}\overline{\ell_{jk}}$. Solving each for its one new unknown, column by column:

$$\ell_{jj} = \Big(a_{jj} - \textstyle\sum_{k<j}|\ell_{jk}|^2\Big)^{1/2},$$
$$\ell_{ij} = \Big(a_{ij} - \textstyle\sum_{k<j}\ell_{ik}\overline{\ell_{jk}}\Big)/\ell_{jj} \qquad (i > j).$$

Example. (A Cholesky Factorization, and One That Fails)

Factor

$$\mathbf{A} = \begin{pmatrix} 4 & -2 & 6 \\ -2 & 5 & -1 \\ 6 & -1 & 26 \end{pmatrix}$$

as $\text{Ł}\text{Ł}^\top$, and run the same algorithm on the matrix $\mathbf{A}'$ obtained from $\mathbf{A}$ by changing the $(3,3)$ entry to 9.

Solution. Column 1. $\ell_{11} = \sqrt{4} = 2$; then $\ell_{21} = -2/2 = -1$ and $\ell_{31} = 6/2 = 3$.

Column 2. $\ell_{22} = \sqrt{5 - (-1)^2} = \sqrt{4} = 2$; then

$$\ell_{32} = \frac{a_{32} - \ell_{31}\ell_{21}}{\ell_{22}} = \frac{-1 - 3(-1)}{2} = 1.$$

Column 3. $\ell_{33} = \sqrt{26 - 3^2 - 1^2} = \sqrt{16} = 4$. So

$$\text{Ł} = \begin{pmatrix} 2 & 0 & 0 \\ -1 & 2 & 0 \\ 3 & 1 & 4 \end{pmatrix},$$

and multiplying back confirms $\text{Ł}\text{Ł}^\top = \mathbf{A}$. The diagonal entries $2, 2, 4$ are positive, so $\mathbf{A} \succ 0$ by Theorem 12.2.3; their squares $4, 4, 16$ are the pivots $d_k = \det \mathbf{A}_k / \det \mathbf{A}_{k-1}$, consistent with $\det \mathbf{A}_1 = 4$, $\det \mathbf{A}_2 = 16$, $\det \mathbf{A} = 256$.

The failure. For $\mathbf{A}'$, columns 1 and 2 are unchanged, and the last step asks for

$$\ell_{33} = \sqrt{9 - 3^2 - 1^2} = \sqrt{-1},$$

which is not a positive real number. The algorithm stops, and by Theorem 12.2.3 its stopping is a proof: $\mathbf{A}'$ is not positive definite. Indeed $\det \mathbf{A}' = -16 < 0$, so Sylvester's criterion fails at $k = 3$.

The example shows the practical point. **The algorithm is the test.** To decide whether a numerical Hermitian matrix is positive definite, one does not compute eigenvalues and one does not compute n determinants; one starts the Cholesky recursion and watches whether every quantity under a square root stays positive. Sylvester's criterion guarantees that this verdict is correct, because $d_1 \cdots d_k = \det \mathbf{A}_k$.

Remark. Two remarks on cost, both of which belong properly to Chapter 23. First, Cholesky does about half the arithmetic of a general LU factorization, because it computes only Ł and never the second triangular factor. Second, and less obvious, it needs no pivoting: the recursion above never divides by something that positive definiteness allows to be zero, so the row swaps that Chapter 2 introduced for stability are simply not required here. Positive definiteness is the one structural hypothesis under which elimination is unconditionally safe.

Warning. **Cholesky needs definiteness, not just semidefiniteness, for uniqueness.** The matrix $\mathbf{A} = \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix}$ is positive semidefinite and does factor as $\text{Ł}\text{Ł}^\top$, for instance with $\text{Ł} = \mathbf{A}$. But the diagonal entry $\ell_{11} = 0$ is not positive, so Theorem 12.2.3

does not apply — and indeed uniqueness fails, since $\begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix}$ and $\begin{pmatrix} 0 & 0 \\ 0 & -1 \end{pmatrix}$ are two different lower triangular matrices Ł with $\text{Ł}\text{Ł}^\top = \mathbf{A}$. Also note that the Ł of Cholesky is **not** the Ł of Chapter 2's LU factorization: the latter is unit lower triangular, and the two differ by the factor $\mathbf{D}^{1/2}$.

Quick check. Let $\mathbf{A} \succ 0$ with Cholesky factor Ł. What is $\det \mathbf{A}$ in terms of Ł, and what is the Cholesky factor of $\mathbf{A}^{-1}$?

Solution. $\det \mathbf{A} = \det \text{Ł} \det \text{Ł}^* = |\ell_{11} \cdots \ell_{nn}|^2 = (\ell_{11} \cdots \ell_{nn})^2$, by Theorem 6.5.4 and Theorem 6.4.6, the last step because the ℓ_{kk} are positive reals. For the inverse, $\mathbf{A}^{-1} = (\text{Ł}\text{Ł}^*)^{-1} = (\text{Ł}^*)^{-1}\text{Ł}^{-1} = \mathbf{M}\mathbf{M}^*$ with $\mathbf{M} = (\text{Ł}^*)^{-1}$, which is **upper** triangular; so this is not itself a Cholesky factorization. The Cholesky factor of $\mathbf{A}^{-1}$ is a different matrix, which is why solving $\mathbf{A}\mathbf{x} = \mathbf{b}$ is done by two triangular substitutions with Ł rather than by inverting anything.

12.2.4 Exercises

12.2.4.1 A. Check your understanding

Exercise A1.

(a) State what $\mathbf{A}^{1/2}$ is, including the two conditions that pin it down.

(b) Define $|\mathbf{A}|$ for $\mathbf{A} \in M_{m\times n}(F)$ and say what size it is.

(c) State the Cholesky factorization theorem.

(d) True or false: every Hermitian matrix has exactly one Hermitian square root. Justify your answer.

(e) Explain in one sentence why the Cholesky algorithm is a test for positive definiteness.

Solution.

(a) For $\mathbf{A} \succeq 0$, $\mathbf{A}^{1/2}$ is the unique matrix $\mathbf{C}$ with $\mathbf{C} \succeq 0$ and $\mathbf{C}^2 = \mathbf{A}$ (Theorem 12.2.1). Both conditions are needed: positivity, and squaring to $\mathbf{A}$.

(b) $|\mathbf{A}| = (\mathbf{A}^*\mathbf{A})^{1/2}$, which is $n \times n$, the size of the domain of $\mathbf{A}$ (Definition 12.2.1).

(c) A Hermitian $\mathbf{A}$ is positive definite if and only if $\mathbf{A} = \text{Ł}\text{Ł}^*$ with Ł lower triangular with positive real diagonal entries, and then Ł is unique (Theorem 12.2.3).

(d) False, twice over. A Hermitian matrix with a negative eigenvalue has no Hermitian square root at all, since $\mathbf{C}^2 \succeq 0$ always. And a positive semidefinite $\mathbf{A}$ with two distinct eigenvalues has at least two Hermitian square roots, $\pm\mathbf{A}^{1/2}$. Uniqueness needs the root itself to be positive semidefinite.

(e) Because the algorithm computes $\ell_{jj}^2 = \det \mathbf{A}_j / \det \mathbf{A}_{j-1}$ one step at a time, so it produces a positive real ℓ_{jj} at every step exactly when Sylvester's criterion holds.

12.2.4.2 B. Practice

Exercise B1: Square roots.

Compute $\mathbf{A}^{1/2}$ for each of the following, and in each case give a polynomial p with $p(\mathbf{A}) = \mathbf{A}^{1/2}$.

(a) $\mathbf{A} = \begin{pmatrix} 5 & 4 \\ 4 & 5 \end{pmatrix}$.

(b) $\mathbf{A} = \begin{pmatrix} 10 & -6 \\ -6 & 10 \end{pmatrix}$.

Solution.

(a) $\mathbf{A}(1,1) = (9,9)$ and $\mathbf{A}(1,-1) = (1,-1)$, so the eigenvalues are 9 and 1 with eigenlines $\operatorname{span}((1,1))$ and $\operatorname{span}((1,-1))$; both positive, so $\mathbf{A} \succ 0$. With $\mathbf{P}_1, \mathbf{P}_2$ the projections onto those lines,

$$\mathbf{A}^{1/2} = 3\mathbf{P}_1 + \mathbf{P}_2 = \begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix}.$$

For the polynomial, solve $p(9) = 3$, $p(1) = 1$: $p(x) = \frac{1}{4}x + \frac{3}{4}$, and $\frac{1}{4}\mathbf{A} + \frac{3}{4}\mathbf{I} = \begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix}$. Check: $\begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix}^2 = \begin{pmatrix} 5 & 4 \\ 4 & 5 \end{pmatrix}$.

(b) $\mathbf{A}(1,-1) = (16,-16)$ and $\mathbf{A}(1,1) = (4,4)$, so the eigenvalues are 16 and 4. Then

$$\mathbf{A}^{1/2} = 4 \cdot \tfrac{1}{2}\begin{pmatrix} 1 & -1 \\ -1 & 1 \end{pmatrix} + 2 \cdot \tfrac{1}{2}\begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix} = \begin{pmatrix} 3 & -1 \\ -1 & 3 \end{pmatrix}.$$

For the polynomial, $p(16) = 4$ and $p(4) = 2$ give $p(x) = \frac{1}{6}x + \frac{4}{3}$, and $\frac{1}{6}\mathbf{A} + \frac{4}{3}\mathbf{I} = \begin{pmatrix} 3 & -1 \\ -1 & 3 \end{pmatrix}$. Check: $\begin{pmatrix} 3 & -1 \\ -1 & 3 \end{pmatrix}^2 = \begin{pmatrix} 10 & -6 \\ -6 & 10 \end{pmatrix}$.

Exercise B2: Cholesky, and a planted failure.

(a) Find the Cholesky factor of $\mathbf{A} = \begin{pmatrix} 1 & 2 & -1 \\ 2 & 5 & 1 \\ -1 & 1 & 14 \end{pmatrix}$, and hence write down $\det \mathbf{A}$.

(b) Run the same algorithm on $\mathbf{A}' = \begin{pmatrix} 1 & 2 & -1 \\ 2 & 5 & 1 \\ -1 & 1 & 9 \end{pmatrix}$ and say what the outcome proves.

Solution.

(a) $\ell_{11} = \sqrt{1} = 1$, $\ell_{21} = 2$, $\ell_{31} = -1$. Then $\ell_{22} = \sqrt{5-4} = 1$ and

$$\ell_{32} = \frac{1 - (-1)(2)}{1} = 3.$$

Finally $\ell_{33} = \sqrt{14 - 1 - 9} = \sqrt{4} = 2$. So

$$L = \begin{pmatrix} 1 & 0 & 0 \\ 2 & 1 & 0 \\ -1 & 3 & 2 \end{pmatrix},$$

and $LL^{\top} = \mathbf{A}$. All diagonal entries are positive, so $\mathbf{A} \succ 0$. By the Quick check above, $\det \mathbf{A} = (1 \cdot 1 \cdot 2)^2 = 4$.

(b) Columns 1 and 2 are identical, and the last step asks for $\ell_{33} = \sqrt{9 - 1 - 9} = \sqrt{-1}$. The algorithm fails, so $\mathbf{A}'$ is not positive definite (Theorem 12.2.3). Confirming by Sylvester: $\det \mathbf{A}'_1 = 1$, $\det \mathbf{A}'_2 = 1$, and $\det \mathbf{A}' = 1 \cdot 44 - 2 \cdot 19 - 7 = -1 < 0$.

Exercise B3: An absolute value.

Let $\mathbf{A} = \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix} \in M_2(\mathbb{R})$. Compute $|\mathbf{A}|$, verify $\||\mathbf{A}|\mathbf{x}\| = \|\mathbf{A}\mathbf{x}\|$ directly, and determine whether $|\mathbf{A}| = \mathbf{A}$.

Solution. $\mathbf{A}^{\top}\mathbf{A} = \begin{pmatrix} 2 & 2 \\ 2 & 2 \end{pmatrix}$, whose eigenvalues are 4 and 0 with eigenlines $\operatorname{span}((1,1))$ and $\operatorname{span}((1,-1))$. Hence

$$|\mathbf{A}| = 2 \cdot \tfrac{1}{2} \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix} + 0 = \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix} = \mathbf{A}.$$

Directly: $\mathbf{A}\mathbf{x} = (x_1 + x_2)(1,1)$, so $\|\mathbf{A}\mathbf{x}\| = \sqrt{2}\,|x_1 + x_2|$, and the same computation applies to $|\mathbf{A}| = \mathbf{A}$. The equality $|\mathbf{A}| = \mathbf{A}$ is no accident: $\mathbf{A} \succeq 0$ here, and for a positive semidefinite $\mathbf{A}$ one has $\mathbf{A}^*\mathbf{A} = \mathbf{A}^2$, so $|\mathbf{A}| = (\mathbf{A}^2)^{1/2} = \mathbf{A}$ by uniqueness in Theorem 12.2.1.

12.2.4.3 C. Going deeper

Exercise C1: The trace of a product of positive matrices.

Let $\mathbf{A}, \mathbf{B} \in M_n(F)$ with $\mathbf{A} \succeq 0$ and $\mathbf{B} \succeq 0$.

(a) Prove that $\operatorname{tr}(\mathbf{A}\mathbf{B}) = \operatorname{tr}(\mathbf{A}^{1/2}\mathbf{B}\mathbf{A}^{1/2})$, and deduce that $\operatorname{tr}(\mathbf{A}\mathbf{B}) \geq 0$.

(b) Prove that $\operatorname{tr}(\mathbf{A}\mathbf{B}) = 0$ if and only if $\mathbf{A}\mathbf{B} = 0$.

Hint for (b): a positive semidefinite matrix of trace 0 *is* 0.

Solution.

(a) By Theorem 0.9.6, $\operatorname{tr}(\mathbf{X}\mathbf{Y}) = \operatorname{tr}(\mathbf{Y}\mathbf{X})$. With $\mathbf{X} = \mathbf{A}^{1/2}$ and $\mathbf{Y} = \mathbf{A}^{1/2}\mathbf{B}$,

$$\operatorname{tr}(\mathbf{A}\mathbf{B}) = \operatorname{tr}(\mathbf{A}^{1/2}\mathbf{A}^{1/2}\mathbf{B}) = \operatorname{tr}(\mathbf{A}^{1/2}\mathbf{B}\mathbf{A}^{1/2}).$$

Now $\mathbf{A}^{1/2}\mathbf{B}\mathbf{A}^{1/2} = (\mathbf{A}^{1/2})^*\mathbf{B}\mathbf{A}^{1/2} \succeq 0$ by Proposition 12.1.2 (a), since $\mathbf{A}^{1/2}$ is Hermitian. The trace of a positive semidefinite matrix is ≥ 0 by Exercise (C1: Zero trace forces zero) (a). Hence $\operatorname{tr}(\mathbf{A}\mathbf{B}) \geq 0$.

(b) ($\Leftarrow$) is clear. ($\Rightarrow$) Suppose $\operatorname{tr}(\mathbf{AB}) = 0$. By (a), $\mathbf{C} := \mathbf{A}^{1/2}\mathbf{B}\mathbf{A}^{1/2} \succeq 0$ and $\operatorname{tr}\mathbf{C} = 0$, so $\mathbf{C} = 0$ by Exercise (C1: Zero trace forces zero) (b). Put $\mathbf{M} = \mathbf{B}^{1/2}\mathbf{A}^{1/2}$. Then

$$\mathbf{M}^*\mathbf{M} = \mathbf{A}^{1/2}\mathbf{B}^{1/2}\mathbf{B}^{1/2}\mathbf{A}^{1/2} = \mathbf{A}^{1/2}\mathbf{B}\mathbf{A}^{1/2} = \mathbf{C} = 0,$$

so $\mathbf{M} = 0$ by Lemma 10.4.3 (its null space is all of F^n, hence so is $\operatorname{nul}\mathbf{M}$). Therefore

$$\mathbf{AB} = \mathbf{A}^{1/2}(\mathbf{A}^{1/2}\mathbf{B}^{1/2})\mathbf{B}^{1/2} = \mathbf{A}^{1/2}\mathbf{M}^*\mathbf{B}^{1/2} = 0.$$

Exercise C2: Commuting positive matrices.

Let $\mathbf{A} \in M_n(F)$ with $\mathbf{A} \succeq 0$.

(a) Prove **without** using Theorem 12.2.1 (a) that if $\mathbf{BA} = \mathbf{AB}$, then $\mathbf{BA}^{1/2} = \mathbf{A}^{1/2}\mathbf{B}$. *Hint: show that* $\mathbf{B}$ *maps each eigenspace of* $\mathbf{A}$ *into itself.*

(b) Let $\mathbf{B} \succeq 0$ with $\mathbf{AB} = \mathbf{BA}$. Prove that $\mathbf{AB} \succeq 0$ and that $(\mathbf{AB})^{1/2} = \mathbf{A}^{1/2}\mathbf{B}^{1/2}$.

Solution.

(a) Let $\lambda \in \operatorname{spec}(\mathbf{A})$ and $\mathbf{Av} = \lambda\mathbf{v}$. Then $\mathbf{A}(\mathbf{Bv}) = \mathbf{B}(\mathbf{Av}) = \lambda\mathbf{Bv}$, so $\mathbf{B}$ maps $E_\lambda(\mathbf{A})$ into itself. Since $\mathbf{A} \succeq 0$, its distinct eigenvalues $\lambda_1, \dots, \lambda_k$ are non-negative reals, and $\mathbf{A}^{1/2} = \sum_i \sqrt{\lambda_i}\,\mathbf{P}_i$ with $\mathbf{P}_i$ the orthogonal projection onto $E_{\lambda_i}(\mathbf{A})$ (proof of Theorem 12.2.1). For $\mathbf{v} \in E_{\lambda_j}(\mathbf{A})$ we have $\mathbf{P}_i\mathbf{v} = \mathbf{0}$ for $i \neq j$ and $\mathbf{P}_j\mathbf{v} = \mathbf{v}$, so $\mathbf{A}^{1/2}\mathbf{v} = \sqrt{\lambda_j}\,\mathbf{v}$. Now $F^n = E_{\lambda_1}(\mathbf{A}) \oplus \cdots \oplus E_{\lambda_k}(\mathbf{A})$ (Theorem 11.8.1), so it suffices to check $\mathbf{BA}^{1/2}\mathbf{v} = \mathbf{A}^{1/2}\mathbf{Bv}$ for $\mathbf{v} \in E_{\lambda_j}(\mathbf{A})$. The left side is $\sqrt{\lambda_j}\,\mathbf{Bv}$; the right side is $\mathbf{A}^{1/2}(\mathbf{Bv}) = \sqrt{\lambda_j}\,\mathbf{Bv}$ as well, because $\mathbf{Bv} \in E_{\lambda_j}(\mathbf{A})$ by the first sentence. Hence $\mathbf{BA}^{1/2} = \mathbf{A}^{1/2}\mathbf{B}$.

(b) By (a), $\mathbf{A}^{1/2}$ commutes with $\mathbf{B}$. Applying (a) once more, this time to $\mathbf{B} \succeq 0$ with the commuting matrix $\mathbf{A}^{1/2}$, gives that $\mathbf{A}^{1/2}$ commutes with $\mathbf{B}^{1/2}$. Put $\mathbf{C} = \mathbf{A}^{1/2}\mathbf{B}^{1/2}$. Then

$$\mathbf{C}^* = (\mathbf{B}^{1/2})^*(\mathbf{A}^{1/2})^* = \mathbf{B}^{1/2}\mathbf{A}^{1/2} = \mathbf{C},$$

so $\mathbf{C}$ is Hermitian, and $\mathbf{C}^2 = \mathbf{A}^{1/2}\mathbf{B}^{1/2}\mathbf{A}^{1/2}\mathbf{B}^{1/2} = \mathbf{AB}$ after one commutation. It remains to see $\mathbf{C} \succeq 0$. The matrices $\mathbf{A}^{1/2}$ and $\mathbf{B}^{1/2}$ are commuting Hermitian matrices, so by Corollary 11.7.2 (over $\mathbb{C}$) or Corollary 11.7.3 (over $\mathbb{R}$) there is a unitary $\mathbf{U}$ with $\mathbf{U}^*\mathbf{A}^{1/2}\mathbf{U} = \operatorname{diag}(\alpha_i)$ and $\mathbf{U}^*\mathbf{B}^{1/2}\mathbf{U} = \operatorname{diag}(\beta_i)$, all $\alpha_i, \beta_i \geq 0$. Then $\mathbf{U}^*\mathbf{CU} = \operatorname{diag}(\alpha_i\beta_i) \succeq 0$, so $\mathbf{C} \succeq 0$ by Proposition 12.1.2 (a). Hence $\mathbf{AB} = \mathbf{C}^2 \succeq 0$ and, by uniqueness in Theorem 12.2.1, $(\mathbf{AB})^{1/2} = \mathbf{C} = \mathbf{A}^{1/2}\mathbf{B}^{1/2}$.

Exercise C3: Why definiteness is needed.

(a) Give a positive semidefinite $\mathbf{A} \in M_2(\mathbb{R})$, not positive definite, together with two different lower triangular $\mathbf{L}$ satisfying $\mathbf{A} = \mathbf{L}\mathbf{L}^\top$. Which hypothesis of Theorem 12.2.3 fails?

(b) Prove that if $\mathbf{A} \succeq 0$ then $\mathbf{A} + t\mathbf{I} \succ 0$ for every real $t > 0$, and hence that every positive semidefinite matrix is a limit of positive definite ones in the entrywise sense.

Solution.

(a) Take $\mathbf{A} = \operatorname{diag}(0, 1)$. Then $Ł_1 = \operatorname{diag}(0, 1)$ and $Ł_2 = \operatorname{diag}(0, -1)$ are both lower triangular with $Ł_i Ł_i^{\top} = \mathbf{A}$. The hypothesis that fails is that the diagonal entries of $Ł$ be strictly positive: $\ell_{11} = 0$ here, which is exactly the first pivot vanishing. Uniqueness in Theorem 12.2.3 is not available without it.

(b) $\mathbf{A} + t\mathbf{I}$ is Hermitian, and for $\mathbf{x} \neq \mathbf{0}$,

$$\langle (\mathbf{A} + t\mathbf{I})\mathbf{x}, \mathbf{x} \rangle = \langle \mathbf{A}\mathbf{x}, \mathbf{x} \rangle + t\|\mathbf{x}\|^2 \geq t\|\mathbf{x}\|^2 > 0,$$

so $\mathbf{A} + t\mathbf{I} \succ 0$. Each entry of $\mathbf{A} + t\mathbf{I}$ differs from the corresponding entry of $\mathbf{A}$ by t or by 0, so letting t decrease to 0 recovers $\mathbf{A}$ entry by entry. This is the standard device for extending a statement from positive definite to positive semidefinite matrices whenever the statement survives taking limits; Theorem 12.1.4 already used it in the form $\det(\mathbf{A} + t\mathbf{I}) > 0$.

12.3 Gram Matrices

Chapter 10 attached to every list of vectors the matrix of its pairwise inner products and read three facts off it: it is Hermitian, its quadratic form is a squared length, and it is invertible exactly when the list is independent (Definition 10.2.3, Theorem 10.2.5). One question was left standing. Given a square matrix, is it the Gram matrix of *something*? The answer is the shortest possible one: exactly when it is positive semidefinite. This section proves that, and then spends it twice — the determinant of a Gram matrix is a squared volume, and a ratio of two Gram determinants is a distance to a subspace.

Throughout, $F = \mathbb{R}$ or $F = \mathbb{C}$ and all inner product spaces are over F. When the list must be named we write $\mathbf{G}(\mathbf{v}_1, \dots, \mathbf{v}_k)$ for its Gram matrix, whose entries are $\langle \mathbf{v}_j, \mathbf{v}_i \rangle$ as in Definition 10.2.3.

12.3.1 Which matrices are Gram matrices?

Half of the answer is already proved. By Theorem 10.2.5 (a) and (b), a Gram matrix $\mathbf{G}$ is Hermitian and satisfies

$$\mathbf{x}^* \mathbf{G} \mathbf{x} = \Big\| \sum_j x_j \mathbf{v}_j \Big\|^2 \;\geq\; 0$$

for every $\mathbf{x} \in F^k$. That is word for word the definition of positive semidefiniteness (Definition 12.1.1). So being positive semidefinite is **necessary**. The content of the next theorem is that nothing else is needed, and this is where the chapter's second signature move earns its keep: a positive semidefinite matrix factors as $\mathbf{B}^*\mathbf{B}$, and the columns of $\mathbf{B}$ are then the list we were looking for.

Theorem 12.3.1 — Gram Matrices Are Exactly the Positive Semidefinite Matrices

Let $\mathbf{G} \in M_k(F)$. The following are equivalent.

(a) $\mathbf{G}$ is the Gram matrix of some list of k vectors in some inner product space over F;

(b) $\mathbf{G}$ is the Gram matrix of some list of k vectors in F^r with the standard inner product, where $r = \operatorname{rank} \mathbf{G}$;

(c) $\mathbf{G} \succeq 0$.

Moreover the list is unique up to an isometry: if $(\mathbf{v}_1, \dots, \mathbf{v}_k)$ in V and $(\mathbf{w}_1, \dots, \mathbf{w}_k)$ in W have the same Gram matrix, then there is an isometry from $\operatorname{span}(\mathbf{v}_1, \dots, \mathbf{v}_k)$ onto $\operatorname{span}(\mathbf{w}_1, \dots, \mathbf{w}_k)$ carrying $\mathbf{v}_j$ to $\mathbf{w}_j$ for every j.

Idea.

(a) $\Rightarrow$ (c) is the display above. For (c) $\Rightarrow$ (b), diagonalize: the spectral theorem writes $\mathbf{G} = \mathbf{U}\mathbf{D}\mathbf{U}^*$ with $\mathbf{D}$ diagonal and, by Theorem 12.1.4, with non-negative diagonal. Then $\mathbf{D}^{1/2}\mathbf{U}^*$ is a square root of $\mathbf{G}$ in the $\mathbf{B}^*\mathbf{B}$ sense, and its rows beyond the r-th are zero, so the columns already live in F^r. For the uniqueness clause, the Gram matrix *is* the recipe for every inner product among the vectors, so the obvious map $\sum a_j \mathbf{v}_j \mapsto \sum a_j \mathbf{w}_j$ has no choice but to preserve them; the only thing needing care is that it is well defined, and part (b) of Theorem 10.2.5 says precisely that.

Proof.

(b) $\Rightarrow$ (a) is immediate, since F^r with the standard inner product is an inner product space.

(c) $\Rightarrow$ (c). Let $\mathbf{G}$ be the Gram matrix of $(\mathbf{v}_1, \dots, \mathbf{v}_k)$. By Theorem 10.2.5 (a), $\mathbf{G}^* = \mathbf{G}$, and by (b) of the same theorem $\mathbf{x}^*\mathbf{G}\mathbf{x} = \|\sum_j x_j \mathbf{v}_j\|^2 \geq 0$ for every $\mathbf{x} \in F^k$. Hence $\mathbf{G} \succeq 0$ by Definition 12.1.1.

(d) $\Rightarrow$ (b). Since $\mathbf{G}$ is Hermitian, the spectral theorem for matrices gives a unitary $\mathbf{U}$ and a diagonal $\mathbf{D}$ with $\mathbf{G} = \mathbf{U}\mathbf{D}\mathbf{U}^*$ (Corollary 11.4.3 over $\mathbb{C}$; Corollary 11.5.2 over $\mathbb{R}$, with $\mathbf{U}$ orthogonal and $\mathbf{D}$ real). The diagonal entries of $\mathbf{D}$ are the eigenvalues of $\mathbf{G}$, so they are real and ≥ 0 by Theorem 12.1.4, and we may prescribe their order: let $d_1, \dots, d_r > 0$ and $d_{r+1} = \cdots = d_k = 0$. Here r is the number of non-zero eigenvalues, which is $\operatorname{rank} \mathbf{G}$, because $\mathbf{G}$ and $\mathbf{D}$ have the same rank.

Put $\mathbf{B} = \mathbf{D}^{1/2}\mathbf{U}^* \in M_k(F)$, where $\mathbf{D}^{1/2} = \operatorname{diag}(\sqrt{d_1}, \dots, \sqrt{d_k})$. Then

$$\mathbf{B}^*\mathbf{B} = \mathbf{U}\mathbf{D}^{1/2}\mathbf{D}^{1/2}\mathbf{U}^* = \mathbf{U}\mathbf{D}\mathbf{U}^* = \mathbf{G},$$

using $(\mathbf{D}^{1/2})^* = \mathbf{D}^{1/2}$. Rows $r+1, \dots, k$ of $\mathbf{B}$ are zero, since row p of $\mathbf{D}^{1/2}\mathbf{U}^*$ is $\sqrt{d_p}$ times row p of $\mathbf{U}^*$. Let $\mathbf{B}' \in M_{r \times k}(F)$ consist of the first r rows of $\mathbf{B}$; deleting zero rows changes no entry of $\mathbf{B}^*\mathbf{B}$, so $(\mathbf{B}')^*\mathbf{B}' = \mathbf{G}$ as well. Let $\mathbf{v}_1, \dots, \mathbf{v}_k \in F^r$ be the columns of $\mathbf{B}'$. With the standard inner product $\langle \mathbf{x}, \mathbf{y} \rangle = \mathbf{y}^*\mathbf{x}$ on F^r,

$$\langle \mathbf{v}_j, \mathbf{v}_i \rangle = \mathbf{v}_i^*\mathbf{v}_j = \big((\mathbf{B}')^*\mathbf{B}'\big)_{ij} = (\mathbf{G})_{ij},$$

so $\mathbf{G}$ is the Gram matrix of $(\mathbf{v}_1, \dots, \mathbf{v}_k)$.

The uniqueness clause. Let $(\mathbf{v}_1, \dots, \mathbf{v}_k)$ in V and $(\mathbf{w}_1, \dots, \mathbf{w}_k)$ in W both have Gram matrix $\mathbf{G}$, and put $U = \operatorname{span}(\mathbf{v}_1, \dots, \mathbf{v}_k)$ and $U' = \operatorname{span}(\mathbf{w}_1, \dots, \mathbf{w}_k)$. Define $T\colon U \to U'$

by

$$T\Big(\sum_j a_j \mathbf{v}_j\Big) = \sum_j a_j \mathbf{w}_j.$$

This is well defined: if $\sum_j a_j \mathbf{v}_j = \sum_j b_j \mathbf{v}_j$, let $\mathbf{x} \in F^k$ be the vector with entries $x_j = a_j - b_j$; then Theorem 10.2.5 (b), applied to each list in turn, gives

$$\Big\|\sum_j x_j \mathbf{w}_j\Big\|^2 = \mathbf{x}^* \mathbf{G} \mathbf{x} = \Big\|\sum_j x_j \mathbf{v}_j\Big\|^2 = 0,$$

so $\sum_j a_j \mathbf{w}_j = \sum_j b_j \mathbf{w}_j$. The same display with every $b_j = 0$ shows $\|T\mathbf{u}\| = \|\mathbf{u}\|$ for every $\mathbf{u} \in U$, so T is an isometry (Definition 10.7.1); it is linear and surjective by its definition on spanning vectors. This proves the theorem.

■

Three consequences are worth naming at once.

First, the corollary promised in Chapter 6 is now proved from the right principle. Corollary 6.7.3 said that $\det(\mathbf{A}\mathbf{A}^\top) \geq 0$ for real $\mathbf{A}$, with equality exactly when the rows of $\mathbf{A}$ are dependent, and it proved this by writing the determinant as a sum of squares of minors. The structural reason is the theorem above: $\mathbf{A}\mathbf{A}^\top$ is a Gram matrix, hence positive semidefinite, hence has non-negative eigenvalues, and its determinant is their product. Positivity of the determinant is not an accident of Cauchy–Binet; it is one shadow of a much stronger property, and the other shadows come free — **every** principal minor of a Gram matrix is ≥ 0 too, since a principal submatrix of $\mathbf{G}(\mathbf{v}_1, \dots, \mathbf{v}_k)$ is the Gram matrix of a sublist.

Second, the smallest space that can hold a realization of $\mathbf{G}$ has dimension $\operatorname{rank} \mathbf{G}$, and no smaller one will do: a list of k vectors in a space of dimension s has a Gram matrix of rank at most s, because $\mathbf{G} = \mathbf{A}^*\mathbf{A}$ for the $s \times k$ coordinate matrix $\mathbf{A}$ of the list and $\operatorname{rank}(\mathbf{A}^*\mathbf{A}) = \operatorname{rank} \mathbf{A} \leq s$ by Corollary 10.6.6 (b).

Third, the theorem is a free source of examples in both directions: any vectors at all produce a positive semidefinite table, and conversely positivity is a real constraint on a table of numbers — a stronger one than most readers expect.

Warning. **Plausible-looking symmetric tables need not be Gram matrices.** The condition is not "symmetric with non-negative diagonal", and it is not even "every 2×2 principal minor is ≥ 0". Take

$$\mathbf{G} = \begin{pmatrix} 5 & -3 & -3 \\ -3 & 5 & -3 \\ -3 & -3 & 5 \end{pmatrix}.$$

Its three 2×2 principal minors are all $25 - 9 = 16 > 0$, so any two of the three vectors would be a legitimate pair. But $\mathbf{G}(1,1,1)^\top = (-1,-1,-1)^\top$, so -1 is an eigenvalue and $\mathbf{G} \not\succeq 0$: no three vectors in any inner product space have this table. In words, three vectors of squared length 5 cannot be **pairwise** at an angle with cosine $-3/5$; two of them can.

Quick check. Is the $k \times k$ matrix with every entry equal to 1 a Gram matrix? If so, exhibit a list; if not, say which clause fails.

Solution. It is. Take $\mathbf{v}_1 = \cdots = \mathbf{v}_k = \mathbf{v}$ for any unit vector $\mathbf{v}$: then $\langle \mathbf{v}_j, \mathbf{v}_i \rangle = 1$ for all i, j. Consistently, the matrix has rank 1, and Theorem 12.3.1 (b) predicts a realization in F^1; the list $(1, 1, \ldots, 1)$ in F is one.

12.3.2 The Gram determinant is a squared volume

Chapter 6 defined the volume of a parallelepiped spanned by n vectors of $\mathbb{R}^n$ as $|\det|$ of the matrix of their coordinates (Definition 6.9.1). That definition needs a **square** matrix, so it says nothing about two vectors in $\mathbb{R}^3$. The missing notion was already present in Chapter 6's motivation, though: volume is base times height. Turning that into a definition costs one line, now that we have distances to subspaces.

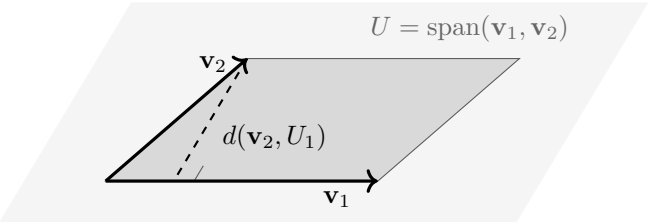
Definition 12.3.1 — Volume of a list

Let $(\mathbf{v}_1, \ldots, \mathbf{v}_k)$ be a list in an inner product space V over F. Its **k-dimensional volume** $\operatorname{vol}(\mathbf{v}_1, \ldots, \mathbf{v}_k) \geq 0$ is defined recursively by

$$\operatorname{vol}(\mathbf{v}_1) = \|\mathbf{v}_1\|, \qquad \operatorname{vol}(\mathbf{v}_1, \ldots, \mathbf{v}_k) = \operatorname{vol}(\mathbf{v}_1, \ldots, \mathbf{v}_{k-1}) \cdot d(\mathbf{v}_k, U_{k-1}),$$

where $U_{k-1} = \operatorname{span}(\mathbf{v}_1, \ldots, \mathbf{v}_{k-1})$ and $d(\cdot, \cdot)$ is the distance of Definition 10.3.3.

In words: the volume of the last vector's parallelepiped is the volume of the one below it, times the height of the last vector above the subspace the others span. For $k = 2$ this is base times height for a parallelogram, and it is 0 exactly when $\mathbf{v}_2$ lies on the line through $\mathbf{v}_1$.



base times height: $\operatorname{vol}(\mathbf{v}_1, \mathbf{v}_2) = \|\mathbf{v}_1\|\, d(\mathbf{v}_2, U_1)$

The recursion is easy to state and awkward to compute with, because each step needs a projection. The Gram determinant computes all of it at once.

Lemma 12.3.2 — Bordering a Gram matrix

Let $(\mathbf{v}_1, \ldots, \mathbf{v}_k)$ be a list in an inner product space V, let $U = \operatorname{span}(\mathbf{v}_1, \ldots, \mathbf{v}_k)$, and let $\mathbf{w} \in V$. Then

$$\det \mathbf{G}(\mathbf{v}_1, \ldots, \mathbf{v}_k, \mathbf{w}) = \det \mathbf{G}(\mathbf{v}_1, \ldots, \mathbf{v}_k) \cdot d(\mathbf{w}, U)^2.$$

Idea. Replace $\mathbf{w}$ by $\mathbf{w} - P_U \mathbf{w}$. That is a column operation on the *list*, and a column operation on the list is a congruence $\mathbf{G} \mapsto \mathbf{E}^* \mathbf{G} \mathbf{E}$ on the Gram matrix, with $\mathbf{E}$ unitriangular, so the determinant does not move. After the replacement the last vector is

orthogonal to all the others, and the Gram matrix has become block diagonal.

Proof. First record how the Gram matrix responds to a change of list. If $\mathbf{u}_j = \sum_t e_{tj}\mathbf{v}_t$ for a matrix $\mathbf{E} = (e_{tj})$, then by sesquilinearity

$$\langle \mathbf{u}_j, \mathbf{u}_i \rangle = \sum_t \sum_s e_{tj}\overline{e_{si}}\langle \mathbf{v}_t, \mathbf{v}_s \rangle,$$

which is the (i,j)-entry of $\mathbf{E}^*\mathbf{G}\mathbf{E}$; that is, $\mathbf{G}(\mathbf{u}_1,\dots,\mathbf{u}_m) = \mathbf{E}^*\mathbf{G}(\mathbf{v}_1,\dots,\mathbf{v}_k)\mathbf{E}$.

Now write $\mathbf{w} = \mathbf{p} + \mathbf{h}$ with $\mathbf{p} = P_U\mathbf{w} \in U$ and $\mathbf{h} = \mathbf{w} - \mathbf{p} \in U^{\perp}$, which is possible by Theorem 10.3.2 (a). Since $\mathbf{p} \in U$, there are scalars $c_1,\dots,c_k$ with $\mathbf{p} = \sum_t c_t\mathbf{v}_t$. Let $\mathbf{E} \in M_{k+1}(F)$ be the identity matrix with its last column replaced by $(-c_1,\dots,-c_k,1)$. Applying the rule above to the list $(\mathbf{v}_1,\dots,\mathbf{v}_k,\mathbf{w})$ and this $\mathbf{E}$ turns it into $(\mathbf{v}_1,\dots,\mathbf{v}_k,\mathbf{h})$, so

$$\mathbf{G}(\mathbf{v}_1,\dots,\mathbf{v}_k,\mathbf{h}) = \mathbf{E}^*\,\mathbf{G}(\mathbf{v}_1,\dots,\mathbf{v}_k,\mathbf{w})\,\mathbf{E}.$$

The matrix $\mathbf{E}$ is triangular with ones on the diagonal, so $\det\mathbf{E} = 1$ by Theorem 6.4.6, and $\det(\mathbf{E}^*) = \overline{\det\mathbf{E}} = 1$. By Theorem 6.5.4 the two Gram determinants are equal.

Finally, $\mathbf{h} \in U^{\perp}$ gives $\langle \mathbf{h}, \mathbf{v}_i \rangle = \langle \mathbf{v}_i, \mathbf{h} \rangle = 0$ for every i, so

$$\mathbf{G}(\mathbf{v}_1,\dots,\mathbf{v}_k,\mathbf{h}) = \begin{pmatrix} \mathbf{G}(\mathbf{v}_1,\dots,\mathbf{v}_k) & \mathbf{0} \\ \mathbf{0} & \|\mathbf{h}\|^2 \end{pmatrix},$$

whose determinant is $\det\mathbf{G}(\mathbf{v}_1,\dots,\mathbf{v}_k)\cdot\|\mathbf{h}\|^2$ by cofactor expansion along the last row. Since $\|\mathbf{h}\| = \|\mathbf{w} - P_U\mathbf{w}\| = d(\mathbf{w},U)$ by Definition 10.3.3, this proves the lemma. ∎

The recursion names the vectors in a particular order, and the last one plays a special role. The value does not depend on that choice: Theorem 12.3.3 below identifies $\mathrm{vol}(\mathbf{v}_1,\dots,\mathbf{v}_k)^2$ with $\det\mathbf{G}$, and permuting the list permutes the rows of $\mathbf{G}$ and the columns in the same way, which leaves the determinant unchanged (Theorem 6.5.1 (a) applied once to the rows and once to the columns, so the two sign changes cancel). So the volume is an invariant of the list as a set of vectors, and we are free to order it however a computation prefers.

Theorem 12.3.3 — The Gram Determinant Is the Squared Volume

Let $(\mathbf{v}_1,\dots,\mathbf{v}_k)$ be a list in an inner product space over F. Then

$$\det\mathbf{G}(\mathbf{v}_1,\dots,\mathbf{v}_k) = \mathrm{vol}(\mathbf{v}_1,\dots,\mathbf{v}_k)^2.$$

In particular, if $\mathbf{A} \in M_{m\times k}(F)$ has columns $\mathbf{v}_1,\dots,\mathbf{v}_k \in F^m$, then $\mathrm{vol}(\mathbf{v}_1,\dots,\mathbf{v}_k) = \sqrt{\det(\mathbf{A}^*\mathbf{A})}$.

Proof. Induction on k. For $k = 1$, $\mathbf{G}(\mathbf{v}_1) = (\|\mathbf{v}_1\|^2)$ and $\mathrm{vol}(\mathbf{v}_1) = \|\mathbf{v}_1\|$.

Let $k \geq 2$ and assume the statement for $k-1$. With $U_{k-1} = \mathrm{span}(\mathbf{v}_1,\dots,\mathbf{v}_{k-1})$,

Lemma 12.3.2 and then the induction hypothesis give

$$\begin{aligned}\det \mathbf{G}(\mathbf{v}_1,\dots,\mathbf{v}_k) &= \det \mathbf{G}(\mathbf{v}_1,\dots,\mathbf{v}_{k-1}) \cdot d(\mathbf{v}_k, U_{k-1})^2 \\ &= \operatorname{vol}(\mathbf{v}_1,\dots,\mathbf{v}_{k-1})^2 \cdot d(\mathbf{v}_k, U_{k-1})^2,\end{aligned}$$

and the right-hand side is $\operatorname{vol}(\mathbf{v}_1,\dots,\mathbf{v}_k)^2$ by Definition 12.3.1.

For the last claim, $\langle \mathbf{v}_j, \mathbf{v}_i\rangle = \mathbf{v}_i^* \mathbf{v}_j = (\mathbf{A}^*\mathbf{A})_{ij}$ in F^m with the standard inner product, so $\mathbf{G}(\mathbf{v}_1,\dots,\mathbf{v}_k) = \mathbf{A}^*\mathbf{A}$, and the volume is the non-negative square root of its determinant.

■

Two checks that the definition is the right one. If $k = m$ and $F = \mathbb{R}$, then $\mathbf{A}$ is square and $\det(\mathbf{A}^\top\mathbf{A}) = (\det \mathbf{A})^2$ by Theorem 6.5.4 and Theorem 6.4.5, so $\operatorname{vol}(\mathbf{v}_1,\dots,\mathbf{v}_m) = |\det \mathbf{A}|$: Definition 12.3.1 agrees with Definition 6.9.1 whenever both apply. And for $k = 2$ in $\mathbb{R}^3$, Exercise (C1: Area of a triangle in space) *defined* the area of a parallelogram in space to be $\sqrt{\det(\mathbf{A}^\top\mathbf{A})}$ and promised a justification from inner products; the theorem is that justification, since base times height is what an area should be.

The volume vanishes exactly when the list is dependent, which is Theorem 10.2.5 (d) read through the theorem: a flat parallelepiped has no volume.

12.3.3 Distance to a subspace, by determinants

Dividing in Lemma 12.3.2 gives a formula for a distance with no projection in sight.

Theorem 12.3.4 — Distance by Gram Determinants

Let U be a finite-dimensional subspace of an inner product space V, let $(\mathbf{v}_1,\dots,\mathbf{v}_k)$ be a **basis** of U, and let $\mathbf{w} \in V$. Then

$$d(\mathbf{w}, U)^2 = \frac{\det \mathbf{G}(\mathbf{v}_1,\dots,\mathbf{v}_k,\mathbf{w})}{\det \mathbf{G}(\mathbf{v}_1,\dots,\mathbf{v}_k)}.$$

Proof. The list $(\mathbf{v}_1,\dots,\mathbf{v}_k)$ is independent, so $\det \mathbf{G}(\mathbf{v}_1,\dots,\mathbf{v}_k) > 0$ by Theorem 10.2.5 (d) and the quotient is defined. Dividing the identity of Lemma 12.3.2 by it gives the formula.

■

No orthonormal basis, no Gram–Schmidt and no projection: two determinants and a division. The price is a $(k+1)\times(k+1)$ determinant in the numerator, so for large k the projection route of Chapter 10 is faster. The quotient is also a ratio of squared volumes, $\operatorname{vol}(\mathbf{v}_1,\dots,\mathbf{v}_k,\mathbf{w})^2 / \operatorname{vol}(\mathbf{v}_1,\dots,\mathbf{v}_k)^2$: volume over base area, which is the height.

Example. (The same distance twice)

In $\mathbb{R}^3$ with the dot product, let $U = \{(x,y,z) : x+y+z = 0\}$ and $\mathbf{w} = (1,2,3)$.

Compute $d(\mathbf{w}, U)$ by Theorem 12.3.4, and compare with Example (Distance from a point to a plane).

Solution. The vectors $\mathbf{v}_1 = (1, -1, 0)$ and $\mathbf{v}_2 = (0, 1, -1)$ lie in U and are independent, and $\dim U = 2$, so they are a basis of U. Their inner products are $\langle \mathbf{v}_1, \mathbf{v}_1 \rangle = 2$, $\langle \mathbf{v}_2, \mathbf{v}_2 \rangle = 2$, $\langle \mathbf{v}_1, \mathbf{v}_2 \rangle = -1$, and with $\mathbf{w}$: $\langle \mathbf{w}, \mathbf{w} \rangle = 14$, $\langle \mathbf{w}, \mathbf{v}_1 \rangle = 1 - 2 = -1$, $\langle \mathbf{w}, \mathbf{v}_2 \rangle = 2 - 3 = -1$. Hence

$$\mathbf{G}(\mathbf{v}_1, \mathbf{v}_2) = \begin{pmatrix} 2 & -1 \\ -1 & 2 \end{pmatrix}, \qquad \mathbf{G}(\mathbf{v}_1, \mathbf{v}_2, \mathbf{w}) = \begin{pmatrix} 2 & -1 & -1 \\ -1 & 2 & -1 \\ -1 & -1 & 14 \end{pmatrix}.$$

The first determinant is $4 - 1 = 3$. Expanding the second along the first row,

$$2(28 - 1) + 1(-14 - 1) - 1(1 + 2) = 54 - 15 - 3 = 36.$$

So $d(\mathbf{w}, U)^2 = 36/3 = 12$ and $d(\mathbf{w}, U) = 2\sqrt{3}$. Example (Distance from a point to a plane) obtained $\|(2, 2, 2)\| = 2\sqrt{3}$ by projecting onto the normal line. The two routes never meet on the page, and they agree.

Remark. The numerator 36 is the squared volume of the parallelepiped on $\mathbf{v}_1, \mathbf{v}_2, \mathbf{w}$, and the denominator 3 is the squared area of its base. The determinant of the coordinate matrix of $(\mathbf{v}_1, \mathbf{v}_2, \mathbf{w})$ is 6, and indeed $6^2 = 36$: Theorem 12.3.3 in the square case.

12.3.4 Exercises

12.3.4.1 A. Check your understanding

Exercise A1.

(a) State the criterion for a matrix $\mathbf{G} \in M_k(F)$ to be the Gram matrix of some list of vectors.

(b) Determine whether the following statement is correct, and justify your answer: every symmetric matrix with non-negative entries is a Gram matrix.

(c) A list of 5 vectors in $\mathbb{R}^3$ has a 5×5 Gram matrix. What are the possible values of its rank, and what is its determinant?

(d) Write down the formula for $d(\mathbf{w}, U)$ in terms of Gram determinants, saying what list is used.

(e) Define the k-dimensional volume of a list, and say what Theorem 12.3.3 asserts about it.

Solution.

(a) $\mathbf{G}$ is a Gram matrix if and only if $\mathbf{G} \succeq 0$ (Theorem 12.3.1). The list may then be taken in F^r with $r = \operatorname{rank} \mathbf{G}$.

(b) Incorrect. $\begin{pmatrix} 1 & 2 \\ 2 & 1 \end{pmatrix}$ has non-negative entries and eigenvalues 3 and -1, so it is not positive semidefinite and by Theorem 12.3.1 it is no Gram matrix. (Concretely: two unit vectors cannot have inner product 2, by Cauchy–Schwarz, Theorem 10.1.5.)

(c) The rank is $\operatorname{rank} \mathbf{G} = \dim \operatorname{span}(\mathbf{v}_1, \dots, \mathbf{v}_5) \le 3$, so it is $0, 1, 2$ or 3; in particular

$\mathbf{G}$ is singular and $\det \mathbf{G} = 0$. (A list of 5 vectors in a 3-dimensional space is dependent, so Theorem 10.2.5 (d) gives $\det \mathbf{G} = 0$ directly.)

(d) If $(\mathbf{v}_1, \dots, \mathbf{v}_k)$ is a **basis** of U, then

$$d(\mathbf{w}, U)^2 = \frac{\det \mathbf{G}(\mathbf{v}_1, \dots, \mathbf{v}_k, \mathbf{w})}{\det \mathbf{G}(\mathbf{v}_1, \dots, \mathbf{v}_k)}$$

by Theorem 12.3.4.

(e) $\operatorname{vol}(\mathbf{v}_1) = \|\mathbf{v}_1\|$ and $\operatorname{vol}(\mathbf{v}_1, \dots, \mathbf{v}_k) = \operatorname{vol}(\mathbf{v}_1, \dots, \mathbf{v}_{k-1})\, d(\mathbf{v}_k, \operatorname{span}(\mathbf{v}_1, \dots, \mathbf{v}_{k-1}))$ (Definition 12.3.1). Theorem 12.3.3 says $\det \mathbf{G}(\mathbf{v}_1, \dots, \mathbf{v}_k) = \operatorname{vol}(\mathbf{v}_1, \dots, \mathbf{v}_k)^2$.

12.3.4.2 B. Practice

Exercise B1: Which are Gram matrices?.

Determine which of the following are Gram matrices of some list of vectors in some real inner product space. For those that are, exhibit a list; for those that are not, give a reason.

(i) $\begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix}$

(ii) $\begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$

(iii) $\begin{pmatrix} 2 & -1 & -1 \\ -1 & 2 & -1 \\ -1 & -1 & 2 \end{pmatrix}$

(iv) $\begin{pmatrix} 1 & 0 & 1 \\ 0 & 1 & 1 \\ 1 & 1 & 1 \end{pmatrix}$

Solution.

(i) Yes. It is symmetric with eigenvalues 1 and 3, both > 0, so it is positive definite and Theorem 12.3.1 applies. A list: $\mathbf{v}_1 = (1, 1, 0)$, $\mathbf{v}_2 = (1, 0, 1)$ in $\mathbb{R}^3$, whose Gram matrix is exactly this.

(ii) No. It is not symmetric, so it is not Hermitian and Definition 12.1.1 fails at once; a Gram matrix over $\mathbb{R}$ is symmetric by Theorem 10.2.5 (a).

(iii) Yes. Its rank is 2: the rows sum to zero, and the top-left 2×2 minor is $3 \neq 0$. Its eigenvalues are 0 (eigenvector $(1, 1, 1)$) and 3 (twice, on the plane $x + y + z = 0$), all ≥ 0. A list in $\mathbb{R}^2$, as Theorem 12.3.1 (b) promises with $r = 2$: the three vectors $(\sqrt{2}, 0)$, $(-\frac{1}{\sqrt{2}}, \sqrt{\frac{3}{2}})$, $(-\frac{1}{\sqrt{2}}, -\sqrt{\frac{3}{2}})$, three vectors of length $\sqrt{2}$ at 120° to each other.

(iv) No. It is symmetric, but its leading principal minors are $1, 1, -1$, and the determinant of a positive semidefinite matrix is ≥ 0 (its eigenvalues are ≥ 0). So it is not positive semidefinite, and by Theorem 12.3.1 it is not a Gram matrix. (Its eigenvalues are 1 and $1 \pm \sqrt{2}$, one of which is negative.)

Exercise B2: A volume two ways.

In $\mathbb{R}^3$, let $\mathbf{v}_1 = (1,1,0)$, $\mathbf{v}_2 = (1,0,1)$, $\mathbf{v}_3 = (0,1,1)$. Compute $\mathrm{vol}(\mathbf{v}_1,\mathbf{v}_2,\mathbf{v}_3)$ with Theorem 12.3.3, and check the answer against Definition 6.9.1.

Solution. The pairwise dot products give

$$\mathbf{G} = \begin{pmatrix} 2 & 1 & 1 \\ 1 & 2 & 1 \\ 1 & 1 & 2 \end{pmatrix},$$

and expanding along the first row, $\det \mathbf{G} = 2(4-1) - 1(2-1) + 1(1-2) = 6 - 1 - 1 = 4$. By Theorem 12.3.3, $\mathrm{vol}(\mathbf{v}_1,\mathbf{v}_2,\mathbf{v}_3) = \sqrt{4} = 2$.

Directly, the matrix $\mathbf{A}$ with these columns has $\det \mathbf{A} = 1(0-1) - 1(1-0) + 0 = -2$, so Definition 6.9.1 gives $|-2| = 2$. The two agree, as they must, since $\det(\mathbf{A}^{\top}\mathbf{A}) = (\det \mathbf{A})^2$.

Exercise B3: A distance in $\mathbb{R}^4$.

In $\mathbb{R}^4$ with the dot product, let $U = \mathrm{span}\big((1,1,0,0),(0,1,1,0)\big)$ and $\mathbf{w} = (1,0,0,1)$. Find $d(\mathbf{w}, U)$ using Theorem 12.3.4.

Solution. Write $\mathbf{v}_1 = (1,1,0,0)$ and $\mathbf{v}_2 = (0,1,1,0)$; they are independent, hence a basis of U. The inner products are $\langle \mathbf{v}_1,\mathbf{v}_1\rangle = \langle \mathbf{v}_2,\mathbf{v}_2\rangle = 2$, $\langle \mathbf{v}_1,\mathbf{v}_2\rangle = 1$, $\langle \mathbf{w},\mathbf{w}\rangle = 2$, $\langle \mathbf{w},\mathbf{v}_1\rangle = 1$, $\langle \mathbf{w},\mathbf{v}_2\rangle = 0$. So

$$\mathbf{G}(\mathbf{v}_1,\mathbf{v}_2) = \begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix}, \qquad \mathbf{G}(\mathbf{v}_1,\mathbf{v}_2,\mathbf{w}) = \begin{pmatrix} 2 & 1 & 1 \\ 1 & 2 & 0 \\ 1 & 0 & 2 \end{pmatrix},$$

with determinants 3 and $2(4) - 1(2) + 1(-2) = 4$. Hence $d(\mathbf{w},U)^2 = 4/3$ and $d(\mathbf{w},U) = 2/\sqrt{3}$.

Check. The projection is $P_U\mathbf{w} = \tfrac{1}{3}(2,1,-1,0)$, so $\mathbf{w} - P_U\mathbf{w} = \tfrac{1}{3}(1,-1,1,3)$, of norm $\tfrac{1}{3}\sqrt{12} = 2/\sqrt{3}$.

12.3.4.3 C. Going deeper

Exercise C1: Rank of a Gram matrix.

Let $(\mathbf{v}_1,\dots,\mathbf{v}_k)$ be a list in a finite-dimensional inner product space V over F, with Gram matrix $\mathbf{G}$.

(a) Prove that $\operatorname{rank}\mathbf{G} = \dim \mathrm{span}(\mathbf{v}_1,\dots,\mathbf{v}_k)$.

(b) Deduce Theorem 10.2.5 (c): $\mathbf{G}$ is invertible if and only if the list is independent.

Hint for (a): the coordinate matrix of the list in an orthonormal basis of the span.

Solution.

(a) Let $U = \mathrm{span}(\mathbf{v}_1,\dots,\mathbf{v}_k)$, $r = \dim U$, and let $(\mathbf{e}_1,\dots,\mathbf{e}_r)$ be an orthonormal basis

of U, which exists by Theorem 10.2.2. Let $\mathbf{A} \in M_{r\times k}(F)$ have as its j-th column the coordinate vector of $\mathbf{v}_j$. As computed in the proof of Theorem 10.2.5 (d), $\mathbf{G} = \mathbf{A}^*\mathbf{A}$. By Corollary 10.6.6 (b), $\operatorname{rank}\mathbf{G} = \operatorname{rank}(\mathbf{A}^*\mathbf{A}) = \operatorname{rank}\mathbf{A}$. Finally $\operatorname{rank}\mathbf{A} = r$: the columns of $\mathbf{A}$ span F^r, because the coordinate map $U \to F^r$ is an isomorphism carrying the spanning list $(\mathbf{v}_1, \dots, \mathbf{v}_k)$ of U to the columns of $\mathbf{A}$.

(b) $\mathbf{G}$ is a $k \times k$ matrix, so it is invertible if and only if $\operatorname{rank}\mathbf{G} = k$ (Theorem 6.5.3 (d)). By (a) that says $\dim \operatorname{span}(\mathbf{v}_1, \dots, \mathbf{v}_k) = k$, which holds exactly when the list is independent.

Exercise C2: Why the conjugate is not optional.

Over $\mathbb{C}$, one might try to build a table of inner products with the **bilinear** expression $\mathbf{v}_i^{\top}\mathbf{v}_j$, without any conjugate. Let $\mathbf{v} = (1, i) \in \mathbb{C}^2$.

(a) Compute $\mathbf{v}^{\top}\mathbf{v}$ and $\mathbf{v}^*\mathbf{v}$, and explain why only one of them is a legitimate squared length.

(b) The list $(\mathbf{v})$ is independent, yet the 1×1 "bilinear Gram matrix" $(\mathbf{v}^{\top}\mathbf{v})$ is singular. Which hypothesis of Theorem 12.3.1 is being violated, and which statement of Chapter 6 does this illustrate?

Solution.

(a) $\mathbf{v}^{\top}\mathbf{v} = 1^2 + i^2 = 0$, while $\mathbf{v}^*\mathbf{v} = |1|^2 + |i|^2 = 2$. A squared length must be ≥ 0 and must vanish only for the zero vector (Definition 10.1.1), and $\mathbf{v} \neq \mathbf{0}$; so $\mathbf{v}^{\top}\mathbf{v}$ cannot be one, and $\mathbf{v}^*\mathbf{v} = \|\mathbf{v}\|^2$ is the correct value.

(b) Theorem 12.3.1 is a statement about the Gram matrix of Definition 10.2.3, whose entries are $\langle \mathbf{v}_j, \mathbf{v}_i\rangle = \mathbf{v}_i^*\mathbf{v}_j$. The matrix $(\mathbf{v}^{\top}\mathbf{v}) = (0)$ is not that matrix, so the theorem simply does not apply; the genuine Gram matrix here is (2), which is positive definite, as it must be for an independent list. This is exactly the failure recorded after Corollary 6.7.3: over $\mathbb{C}$, $\mathbf{A} = \begin{pmatrix} 1 & i \end{pmatrix}$ has rank 1 while $\mathbf{A}\mathbf{A}^{\top} = (0)$, so the real equality case of that corollary has no complex analogue — unless the transpose is replaced by the conjugate transpose.

Exercise C3: Height and volume.

Let $(\mathbf{v}_1, \dots, \mathbf{v}_k)$ be an independent list in an inner product space over F. For each j, write U_j for the span of $\mathbf{v}_1, \dots, \mathbf{v}_j$.

(a) Prove that $\operatorname{vol}(\mathbf{v}_1, \dots, \mathbf{v}_k) \leq \|\mathbf{v}_1\|\|\mathbf{v}_2\| \cdots \|\mathbf{v}_k\|$, with equality if and only if the list is orthogonal.

(b) Deduce that $\det \mathbf{G}(\mathbf{v}_1, \dots, \mathbf{v}_k) \leq \|\mathbf{v}_1\|^2 \cdots \|\mathbf{v}_k\|^2$.

Hint for (a): compare each height with the corresponding length.

Solution.

(a) Fix $j \geq 2$ and write $\mathbf{v}_j = P_{U_{j-1}}\mathbf{v}_j + \mathbf{h}_j$ with $\mathbf{h}_j \in U_{j-1}^{\perp}$, as in Theorem 10.3.2 (a).

The two summands are orthogonal, so Theorem 10.1.3 gives

$$\|\mathbf{v}_j\|^2 = \|P_{U_{j-1}}\mathbf{v}_j\|^2 + \|\mathbf{h}_j\|^2 \;\geq\; \|\mathbf{h}_j\|^2 = d(\mathbf{v}_j, U_{j-1})^2,$$

with equality if and only if $P_{U_{j-1}}\mathbf{v}_j = \mathbf{0}$. Multiplying the k inequalities $d(\mathbf{v}_j, U_{j-1}) \leq \|\mathbf{v}_j\|$ (with $d(\mathbf{v}_1, U_0)$ read as $\|\mathbf{v}_1\|$) and using Definition 12.3.1 repeatedly gives

$$\mathrm{vol}(\mathbf{v}_1, \ldots, \mathbf{v}_k) \leq \|\mathbf{v}_1\| \cdots \|\mathbf{v}_k\|.$$

All factors are > 0, since the list is independent, so equality holds if and only if it holds in every factor, that is $P_{U_{j-1}}\mathbf{v}_j = \mathbf{0}$ for every $j \geq 2$. That says each $\mathbf{v}_j$ is orthogonal to U_{j-1}, hence to every earlier $\mathbf{v}_i$; and conversely an orthogonal list has $P_{U_{j-1}}\mathbf{v}_j = \mathbf{0}$ by Theorem 10.3.3 (a).

(b) Square (a) and apply Theorem 12.3.3.

12.4 Two Forms at Once

Chapter 11 asked when several operators can be diagonalized in one orthonormal basis, and answered: when they commute and each is normal (Theorem 11.7.1). That theorem is about **operators**, and its currency is the unitary similarity $\mathbf{U}^*T\mathbf{U}$. This section asks a question that looks similar and is not. Given two **forms** — two self-adjoint matrices, each thought of as the recipe $\mathbf{x} \mapsto \mathbf{x}^*\mathbf{A}\mathbf{x}$ — can one change of variable make both of them diagonal at once? No commuting is assumed, and in general the two matrices do not commute. The price is that the change of variable is no longer unitary, and the hypothesis is that one of the two forms is positive definite.

Throughout, $F = \mathbb{R}$ or $F = \mathbb{C}$, and "self-adjoint" means $\mathbf{A}^* = \mathbf{A}$ (over $\mathbb{R}$: symmetric).

12.4.1 Similarity is for operators, congruence is for forms

A matrix can play two roles, and the two roles come with different change-of-variable rules.

As an **operator**, $\mathbf{A}$ eats a vector and returns a vector. Rewriting $\mathbf{x} = \mathbf{S}\mathbf{y}$ in the equation $\mathbf{z} = \mathbf{A}\mathbf{x}$ turns it into $\mathbf{S}^{-1}\mathbf{z} = (\mathbf{S}^{-1}\mathbf{A}\mathbf{S})\mathbf{y}$: the new matrix is $\mathbf{S}^{-1}\mathbf{A}\mathbf{S}$, and the relation is **similarity**. Eigenvalues, trace, determinant and characteristic polynomial all survive it.

As a **form**, $\mathbf{A}$ eats a vector and returns the scalar $\mathbf{x}^*\mathbf{A}\mathbf{x}$. Rewriting $\mathbf{x} = \mathbf{S}\mathbf{y}$ turns that scalar into

$$(\mathbf{S}\mathbf{y})^*\mathbf{A}(\mathbf{S}\mathbf{y}) = \mathbf{y}^*(\mathbf{S}^*\mathbf{A}\mathbf{S})\mathbf{y},$$

so the new matrix is $\mathbf{S}^*\mathbf{A}\mathbf{S}$. Two matrices $\mathbf{A}$ and $\mathbf{S}^*\mathbf{A}\mathbf{S}$ with $\mathbf{S}$ invertible are called **congruent**; this is the operation of Proposition 12.1.2, where it was already shown to preserve the sign of a form. Congruence is the right relation here for the plain reason that it is the one the question is phrased in: "make both forms diagonal" means "make both $\mathbf{x}^*\mathbf{A}\mathbf{x}$ and $\mathbf{x}^*\mathbf{B}\mathbf{x}$ into sums of squares in the same new coordinates", and that is a statement about $\mathbf{S}^*\mathbf{A}\mathbf{S}$ and $\mathbf{S}^*\mathbf{B}\mathbf{S}$. Chapter 13 studies congruence in its own right, including what it does preserve; for now, note that it certainly does **not** preserve eigenvalues, since $\mathbf{S}^*\mathbf{I}\mathbf{S} = \mathbf{S}^*\mathbf{S}$ can be any positive definite matrix at all.

Congruence and similarity coincide in exactly one situation: when $\mathbf{S}$ is unitary, $\mathbf{S}^* = \mathbf{S}^{-1}$. That is the situation of Chapter 11, and it is what makes that chapter's theorems so strong and its hypotheses so restrictive.

Warning. **This is not Chapter 11's simultaneous diagonalization.** Theorem 11.7.1 needs the operators to **commute** and produces a **unitary** $\mathbf{U}$ with every $\mathbf{U}^*T\mathbf{U}$ diagonal; eigenvalues are preserved. The theorem below needs **no commuting** and one of the two matrices to be **positive definite**, and produces a merely invertible $\mathbf{S}$; the eigenvalues of $\mathbf{B}$ are destroyed, and even $\mathbf{A}$ comes out as $\mathbf{I}$. The two theorems have no common generalization: neither hypothesis implies the other. When the matrices both commute and one is positive definite, both theorems apply and give different factorizations.

12.4.2 Diagonalizing two forms at once

Theorem 12.4.1 — Diagonalizing Two Forms by Congruence

Let $\mathbf{A}, \mathbf{B} \in M_n(F)$ be self-adjoint with $\mathbf{A} \succ 0$. Then there is an invertible $\mathbf{S} \in M_n(F)$ with

$$\mathbf{S}^*\mathbf{A}\mathbf{S} = \mathbf{I}_n \qquad \text{and} \qquad \mathbf{S}^*\mathbf{B}\mathbf{S} = \mathbf{D}$$

for some **real** diagonal $\mathbf{D}$. Over $\mathbb{R}$, with $\mathbf{A}, \mathbf{B}$ symmetric, $\mathbf{S}$ may be taken real.

Idea. Two steps, and the first one is the whole idea. ① *Whiten.* The hypothesis $\mathbf{A} \succ 0$ gives an invertible positive definite square root $\mathbf{A}^{1/2}$, and the congruence by $\mathbf{A}^{-1/2}$ turns $\mathbf{A}$ into $\mathbf{I}$. That uses up the definiteness of $\mathbf{A}$ and nothing else. ② Now $\mathbf{I}$ is invariant under every **unitary** congruence, because a unitary congruence is a similarity; so we still have the whole spectral theorem available for the transformed $\mathbf{B}$, and it is self-adjoint. Diagonalize it and compose the two changes of variable.

Proof. Since $\mathbf{A} \succ 0$, Theorem 12.2.1 gives a unique $\mathbf{A}^{1/2} \succeq 0$ with $(\mathbf{A}^{1/2})^2 = \mathbf{A}$. Its eigenvalues are the non-negative square roots of the eigenvalues of $\mathbf{A}$, which are > 0 by Theorem 12.1.5; hence $\mathbf{A}^{1/2} \succ 0$ and in particular $\mathbf{A}^{1/2}$ is invertible. Write $\mathbf{A}^{-1/2} = (\mathbf{A}^{1/2})^{-1}$, which is again self-adjoint, since the inverse of an invertible self-adjoint matrix is self-adjoint.

Put $\mathbf{C} = \mathbf{A}^{-1/2}\mathbf{B}\mathbf{A}^{-1/2}$. Then $\mathbf{C}^* = \mathbf{A}^{-1/2}\mathbf{B}^*\mathbf{A}^{-1/2} = \mathbf{C}$, so $\mathbf{C}$ is self-adjoint. By the spectral theorem for matrices there is a unitary $\mathbf{U}$ and a real diagonal $\mathbf{D}$ with $\mathbf{C} = \mathbf{U}\mathbf{D}\mathbf{U}^*$ (Corollary 11.4.3 over $\mathbb{C}$; Corollary 11.5.2 over $\mathbb{R}$, with $\mathbf{U}$ orthogonal and real).

Set $\mathbf{S} = \mathbf{A}^{-1/2}\mathbf{U}$, a product of invertible matrices, hence invertible. Then

$$\mathbf{S}^*\mathbf{A}\mathbf{S} = \mathbf{U}^*\mathbf{A}^{-1/2}\mathbf{A}\mathbf{A}^{-1/2}\mathbf{U} = \mathbf{U}^*\mathbf{U} = \mathbf{I}_n,$$

where the middle equality uses $\mathbf{A}^{-1/2}\mathbf{A}\mathbf{A}^{-1/2} = \mathbf{A}^{-1/2}\mathbf{A}^{1/2}\mathbf{A}^{1/2}\mathbf{A}^{-1/2} = \mathbf{I}_n$. And

$$\mathbf{S}^*\mathbf{B}\mathbf{S} = \mathbf{U}^*\mathbf{A}^{-1/2}\mathbf{B}\mathbf{A}^{-1/2}\mathbf{U} = \mathbf{U}^*\mathbf{C}\mathbf{U} = \mathbf{D}.$$

Over $\mathbb{R}$ every matrix named here is real: $\mathbf{A}^{1/2}$ is real because it is a polynomial in $\mathbf{A}$

(Theorem 12.2.1), and $\mathbf{U}$ is real by Corollary 11.5.2. This proves the theorem.

■

The theorem says more than "both become diagonal": the definite one becomes the **identity**, which is the strongest normalization available, and it costs nothing extra. Note also which hypothesis did which job. Definiteness of $\mathbf{A}$ was used exactly once, to invert $\mathbf{A}^{1/2}$. Self-adjointness of $\mathbf{B}$ was used exactly once, to apply the spectral theorem to $\mathbf{C}$. Nothing at all was assumed about $\mathbf{AB}$ versus $\mathbf{BA}$.

Quick check. Why can $\mathbf{S}$ not be taken unitary in Theorem 12.4.1?

Solution. A unitary $\mathbf{S}$ has $\mathbf{S}^* = \mathbf{S}^{-1}$, so $\mathbf{S}^*\mathbf{AS} = \mathbf{I}$ would give $\mathbf{A} = \mathbf{SIS}^* = \mathbf{I}$. So a unitary $\mathbf{S}$ can only work when $\mathbf{A}$ is already the identity — and then the theorem is just the spectral theorem for $\mathbf{B}$.

12.4.3 The generalized eigenvalue problem

The matrix $\mathbf{S}$ of the theorem is not an abstract object: its columns solve an eigenvalue problem in which the identity has been replaced by $\mathbf{A}$.

Definition 12.4.1 — Generalized eigenvalue

Let $\mathbf{A}, \mathbf{B} \in M_n(F)$. A scalar $\lambda \in F$ is a **generalized eigenvalue** of the **pair** $(\mathbf{A}, \mathbf{B})$ if

$$\mathbf{Bx} = \lambda \mathbf{Ax} \qquad \text{for some } \mathbf{x} \neq \mathbf{0},$$

and such an $\mathbf{x}$ is a **generalized eigenvector** for λ. The family of matrices $\mathbf{B} - \lambda\mathbf{A}$ is called the **pencil** of the pair.

Taking $\mathbf{A} = \mathbf{I}$ recovers Definition 8.2.1, so the word "generalized" is honest. The condition $\mathbf{Bx} = \lambda\mathbf{Ax}$ with $\mathbf{x} \neq \mathbf{0}$ says that $\mathbf{B} - \lambda\mathbf{A}$ is singular, that is $\det(\mathbf{B} - \lambda\mathbf{A}) = 0$; so the generalized eigenvalues are the roots of the polynomial $\det(\mathbf{B} - \lambda\mathbf{A})$ in λ, the **characteristic polynomial of the pencil**. Its degree is at most n, and exactly n when $\mathbf{A}$ is invertible, since the λ^n-coefficient is $(-1)^n \det \mathbf{A}$. When $\mathbf{A}$ is singular the degree can drop, and the polynomial can even be a nonzero constant, in which case the pair has no generalized eigenvalues at all; exercise C3 below is such a pair. From here on $\mathbf{A} \succ 0$, so this does not arise.

Nothing so far forces those roots to be real: for $\mathbf{A} = \mathbf{I}$ they are just eigenvalues, and a general $\mathbf{B}$ has complex ones. Self-adjointness of $\mathbf{B}$ alone is not enough either, as the warning at the end of this section shows. It is definiteness of $\mathbf{A}$ that makes the problem behave.

Theorem 12.4.2 — The Definite Generalized Eigenvalue Problem

Let $\mathbf{A}, \mathbf{B} \in M_n(F)$ be self-adjoint with $\mathbf{A} \succ 0$, and let $\mathbf{S}$ and $\mathbf{D} = \operatorname{diag}(d_1, \dots, d_n)$ be as in Theorem 12.4.1, with columns $\mathbf{s}_1, \dots, \mathbf{s}_n$ of $\mathbf{S}$. Then:

(a) $\mathbf{Bs}_i = d_i \mathbf{As}_i$ for every i, and $\mathbf{s}_i^* \mathbf{As}_j = \delta_{ij}$: the columns of $\mathbf{S}$ are a basis of F^n of generalized eigenvectors, orthonormal for the inner product $\langle \mathbf{x}, \mathbf{y} \rangle_{\mathbf{A}} = \mathbf{y}^* \mathbf{Ax}$;

(b) the generalized eigenvalues of $(\mathbf{A}, \mathbf{B})$ are exactly $d_1, \dots, d_n$, all **real**, and

$$\det(\mathbf{B} - \lambda\mathbf{A}) = \frac{1}{|\det \mathbf{S}|^2} \prod_{i=1}^{n} (d_i - \lambda);$$

(c) $\mathbf{A}^{-1}\mathbf{B} = \mathbf{S}\mathbf{D}\mathbf{S}^{-1}$; in particular $\mathbf{A}^{-1}\mathbf{B}$ is diagonalizable with real eigenvalues $d_1, \dots, d_n$, although it need not be self-adjoint.

Idea. Everything is already in the two equations $\mathbf{S}^*\mathbf{A}\mathbf{S} = \mathbf{I}$ and $\mathbf{S}^*\mathbf{B}\mathbf{S} = \mathbf{D}$. Substituting the first into the second turns $\mathbf{D}$ into $\mathbf{S}^*\mathbf{A}\mathbf{S}\mathbf{D}$, and canceling the invertible $\mathbf{S}^*$ leaves $\mathbf{B}\mathbf{S} = \mathbf{A}\mathbf{S}\mathbf{D}$, which read column by column is (a). Then (b) and (c) are two ways of undoing the substitution.

Proof.

(a) From $\mathbf{S}^*\mathbf{A}\mathbf{S} = \mathbf{I}$ we get $\mathbf{D} = \mathbf{I}\mathbf{D} = \mathbf{S}^*\mathbf{A}\mathbf{S}\mathbf{D}$, and also $\mathbf{D} = \mathbf{S}^*\mathbf{B}\mathbf{S}$. Therefore $\mathbf{S}^*(\mathbf{B}\mathbf{S} - \mathbf{A}\mathbf{S}\mathbf{D}) = \mathbf{0}$, and $\mathbf{S}^*$ is invertible, so

$$\mathbf{B}\mathbf{S} = \mathbf{A}\mathbf{S}\mathbf{D}.$$

Column i of the left side is $\mathbf{B}\mathbf{s}_i$ and of the right side is $d_i\mathbf{A}\mathbf{s}_i$, since $\mathbf{D}$ is diagonal. Each $\mathbf{s}_i \neq \mathbf{0}$ because $\mathbf{S}$ is invertible, so each d_i is a generalized eigenvalue with eigenvector $\mathbf{s}_i$. The entry (i, j) of $\mathbf{S}^*\mathbf{A}\mathbf{S} = \mathbf{I}$ is $\mathbf{s}_i^*\mathbf{A}\mathbf{s}_j$, which is therefore δ_{ij}. Finally $\langle \mathbf{x}, \mathbf{y} \rangle_{\mathbf{A}} = \mathbf{y}^*\mathbf{A}\mathbf{x}$ is an inner product on F^n, exactly because $\mathbf{A} \succ 0$: it is sesquilinear, $\overline{\langle \mathbf{y}, \mathbf{x} \rangle_{\mathbf{A}}} = \overline{\mathbf{x}^*\mathbf{A}\mathbf{y}} = \mathbf{y}^*\mathbf{A}^*\mathbf{x} = \langle \mathbf{x}, \mathbf{y} \rangle_{\mathbf{A}}$, and $\langle \mathbf{x}, \mathbf{x} \rangle_{\mathbf{A}} = \mathbf{x}^*\mathbf{A}\mathbf{x} > 0$ for $\mathbf{x} \neq \mathbf{0}$.

(b) From $\mathbf{S}^*\mathbf{A}\mathbf{S} = \mathbf{I}$ and $\mathbf{S}^*\mathbf{B}\mathbf{S} = \mathbf{D}$ we get $\mathbf{A} = (\mathbf{S}^*)^{-1}\mathbf{S}^{-1}$ and $\mathbf{B} = (\mathbf{S}^*)^{-1}\mathbf{D}\mathbf{S}^{-1}$, hence

$$\mathbf{B} - \lambda\mathbf{A} = (\mathbf{S}^*)^{-1}(\mathbf{D} - \lambda\mathbf{I})\mathbf{S}^{-1}.$$

Taking determinants with Theorem 6.5.4, and using $\det(\mathbf{S}^*) = \overline{\det \mathbf{S}}$,

$$\det(\mathbf{B} - \lambda\mathbf{A}) = \frac{\det(\mathbf{D} - \lambda\mathbf{I})}{\overline{\det \mathbf{S}}\, \det \mathbf{S}} = \frac{1}{|\det \mathbf{S}|^2} \prod_{i} (d_i - \lambda),$$

the last step by Theorem 6.4.6. Since $|\det \mathbf{S}|^2 \neq 0$, the roots of $\det(\mathbf{B} - \lambda\mathbf{A})$ are exactly $d_1, \dots, d_n$; and λ is a generalized eigenvalue if and only if $\mathbf{B} - \lambda\mathbf{A}$ is singular, that is if and only if $\det(\mathbf{B} - \lambda\mathbf{A}) = 0$ (Theorem 2.4.4). The d_i are real because $\mathbf{D} = \mathbf{S}^*\mathbf{B}\mathbf{S}$ is self-adjoint, so its diagonal entries equal their own conjugates.

(c) Inverting $\mathbf{A} = (\mathbf{S}^*)^{-1}\mathbf{S}^{-1}$ gives $\mathbf{A}^{-1} = \mathbf{S}\mathbf{S}^*$, so

$$\mathbf{A}^{-1}\mathbf{B} = \mathbf{S}\mathbf{S}^*(\mathbf{S}^*)^{-1}\mathbf{D}\mathbf{S}^{-1} = \mathbf{S}\mathbf{D}\mathbf{S}^{-1}.$$

This proves the theorem. ∎

Part (c) explains the phenomenon. The matrix $\mathbf{A}^{-1}\mathbf{B}$ is what one would naively form to turn $\mathbf{B}\mathbf{x} = \lambda\mathbf{A}\mathbf{x}$ into an ordinary eigenvalue problem, and it is usually not self-adjoint, so there is no reason from Chapter 11 for its eigenvalues to be real. But it **is** self-adjoint with respect to the inner product $\langle \cdot, \cdot \rangle_{\mathbf{A}}$, and reality and the orthogonal eigenbasis come from that inner product rather than the standard one. The congruence $\mathbf{S}$ is exactly the change of variable that turns

$\langle \cdot, \cdot \rangle_{\mathbf{A}}$ into the standard inner product.

Example. (A pencil that does not commute)

Let

$$\mathbf{A} = \begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix}, \qquad \mathbf{B} = \begin{pmatrix} 0 & 3 \\ 3 & 6 \end{pmatrix}.$$

Check that $\mathbf{A} \succ 0$, that $\mathbf{AB} \neq \mathbf{BA}$, and that $\mathbf{B}$ is indefinite. Find the generalized eigenvalues and an $\mathbf{A}$-orthonormal basis of generalized eigenvectors, and write down $\mathbf{S}$.

Solution. Setting up. $\mathbf{A}$ is symmetric with leading principal minors $2 > 0$ and $4 - 1 = 3 > 0$, so $\mathbf{A} \succ 0$ by Theorem 12.1.5. Its own eigenvalues are 1 and 3. The products are

$$\mathbf{AB} = \begin{pmatrix} 3 & 12 \\ 6 & 15 \end{pmatrix}, \qquad \mathbf{BA} = \begin{pmatrix} 3 & 6 \\ 12 & 15 \end{pmatrix},$$

which differ, so Chapter 11's theorem does not apply. Also $\det \mathbf{B} = -9 < 0$, so $\mathbf{B}$ has one positive and one negative eigenvalue and is neither positive nor negative semidefinite.

The pencil.

$$\mathbf{B} - \lambda \mathbf{A} = \begin{pmatrix} -2\lambda & 3 - \lambda \\ 3 - \lambda & 6 - 2\lambda \end{pmatrix},$$

so

$$\begin{aligned} \det(\mathbf{B} - \lambda \mathbf{A}) &= -2\lambda(6 - 2\lambda) - (3 - \lambda)^2 \\ &= 4\lambda^2 - 12\lambda - 9 + 6\lambda - \lambda^2 \\ &= 3\lambda^2 - 6\lambda - 9 = 3(\lambda - 3)(\lambda + 1). \end{aligned}$$

The generalized eigenvalues are $\lambda = -1$ and $\lambda = 3$, both real, as Theorem 12.4.2 (b) promises.

Eigenvectors. For $\lambda = -1$, $\mathbf{B} + \mathbf{A} = \begin{pmatrix} 2 & 4 \\ 4 & 8 \end{pmatrix}$, whose kernel is spanned by $\mathbf{x}_1 = (2, -1)$. For $\lambda = 3$, $\mathbf{B} - 3\mathbf{A} = \begin{pmatrix} -6 & 0 \\ 0 & 0 \end{pmatrix}$, whose kernel is spanned by $\mathbf{x}_2 = (0, 1)$. Checking directly: $\mathbf{B}\mathbf{x}_1 = (-3, 0)$ and $\mathbf{A}\mathbf{x}_1 = (3, 0)$, so $\mathbf{B}\mathbf{x}_1 = -\mathbf{A}\mathbf{x}_1$; and $\mathbf{B}\mathbf{x}_2 = (3, 6) = 3(1, 2) = 3\mathbf{A}\mathbf{x}_2$.

Normalizing. $\mathbf{x}_1^{\top}\mathbf{A}\mathbf{x}_1 = (2, -1) \cdot (3, 0) = 6$ and $\mathbf{x}_2^{\top}\mathbf{A}\mathbf{x}_2 = (0, 1) \cdot (1, 2) = 2$, while $\mathbf{x}_1^{\top}\mathbf{A}\mathbf{x}_2 = (2, -1) \cdot (1, 2) = 0$: the two are already $\mathbf{A}$-orthogonal, as they must be, having different generalized eigenvalues. Scaling to $\mathbf{A}$-length 1,

$$\mathbf{S} = \begin{pmatrix} 2/\sqrt{6} & 0 \\ -1/\sqrt{6} & 1/\sqrt{2} \end{pmatrix}, \qquad \mathbf{S}^{\top}\mathbf{A}\mathbf{S} = \mathbf{I}_2, \qquad \mathbf{S}^{\top}\mathbf{B}\mathbf{S} = \begin{pmatrix} -1 & 0 \\ 0 & 3 \end{pmatrix}.$$

So in the coordinates $\mathbf{x} = \mathbf{S}\mathbf{y}$ the two forms read $\mathbf{x}^{\top}\mathbf{A}\mathbf{x} = y_1^2 + y_2^2$ and $\mathbf{x}^{\top}\mathbf{B}\mathbf{x} = -y_1^2 + 3y_2^2$. The signs $(-, +)$ match the signs of the eigenvalues of $\mathbf{B}$ itself, which are $3 \pm 3\sqrt{2}$; Chapter 13 shows that this is no coincidence.

The problem $\mathbf{B}\mathbf{x} = \lambda \mathbf{A}\mathbf{x}$ with $\mathbf{A} \succ 0$ is the one an engineer meets first: for a vibrating structure, $\mathbf{A}$ is the mass matrix and $\mathbf{B}$ the stiffness matrix, the generalized eigenvalues are the squared natural frequencies, and the $\mathbf{A}$-orthonormal eigenvectors are the normal modes, in which the motion decouples into independent one-dimensional oscillations.

12.4.4 When neither form is definite

Definiteness of one of the two matrices is not decoration.

Warning. **Two self-adjoint matrices, neither definite, need not be simultaneously diagonalizable by congruence.** Take the real symmetric pair

$$\mathbf{A} = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}, \qquad \mathbf{B} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}.$$

Suppose $\mathbf{S}^{\top}\mathbf{A}\mathbf{S}$ and $\mathbf{S}^{\top}\mathbf{B}\mathbf{S}$ were both diagonal for some invertible real $\mathbf{S}$, say $\mathbf{D}_{\mathbf{A}}$ and $\mathbf{D}_{\mathbf{B}}$. Since $\mathbf{A}$ is invertible, so is $\mathbf{D}_{\mathbf{A}}$, and from $\mathbf{A} = (\mathbf{S}^{\top})^{-1}\mathbf{D}_{\mathbf{A}}\mathbf{S}^{-1}$ and $\mathbf{B} = (\mathbf{S}^{\top})^{-1}\mathbf{D}_{\mathbf{B}}\mathbf{S}^{-1}$ we get

$$\mathbf{A}^{-1}\mathbf{B} = \mathbf{S}\mathbf{D}_{\mathbf{A}}^{-1}\mathbf{S}^{\top}(\mathbf{S}^{\top})^{-1}\mathbf{D}_{\mathbf{B}}\mathbf{S}^{-1} = \mathbf{S}\big(\mathbf{D}_{\mathbf{A}}^{-1}\mathbf{D}_{\mathbf{B}}\big)\mathbf{S}^{-1},$$

so $\mathbf{A}^{-1}\mathbf{B}$ would be similar to a real diagonal matrix and would have real eigenvalues. But $\mathbf{A}^{-1} = \mathbf{A}$ here, and

$$\mathbf{A}^{-1}\mathbf{B} = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}$$

has characteristic polynomial $\lambda^2 + 1$, with roots $\pm i$. So no such $\mathbf{S}$ exists — and the pencil has **no** generalized eigenvalues in $\mathbb{R}$ at all.

The obstruction in the warning is exactly the failure of part (c) of Theorem 12.4.2. That part is in fact the right way to test a pair: if $\mathbf{A}$ is invertible, a necessary condition for simultaneous diagonalization by congruence is that $\mathbf{A}^{-1}\mathbf{B}$ be diagonalizable with real eigenvalues, and the theorem says that $\mathbf{A} \succ 0$ is enough to guarantee it.

12.4.5 Exercises

12.4.5.1 A. Check your understanding

Exercise A1.

(a) Define what it means for two matrices to be **congruent**, and say which of similarity and congruence is the natural relation for a form.

(b) State Theorem 12.4.1, with all hypotheses.

(c) Name two differences between Theorem 12.4.1 and Theorem 11.7.1.

(d) Determine whether the following statement is correct, and justify your answer: the generalized eigenvalues of $(\mathbf{A}, \mathbf{B})$ are eigenvalues of $\mathbf{B}$.

(e) For $\mathbf{A} \succ 0$ and $\mathbf{B}$ self-adjoint, what inner product makes $\mathbf{A}^{-1}\mathbf{B}$ self-adjoint?

Solution.

(a) $\mathbf{A}$ and $\mathbf{C}$ are congruent if $\mathbf{C} = \mathbf{S}^{*}\mathbf{A}\mathbf{S}$ for some invertible $\mathbf{S}$. Congruence is the natural relation for a form, since the substitution $\mathbf{x} = \mathbf{S}\mathbf{y}$ turns $\mathbf{x}^{*}\mathbf{A}\mathbf{x}$ into $\mathbf{y}^{*}(\mathbf{S}^{*}\mathbf{A}\mathbf{S})\mathbf{y}$; similarity $\mathbf{S}^{-1}\mathbf{A}\mathbf{S}$ is the natural relation for an operator.

(b) If $\mathbf{A}, \mathbf{B} \in M_n(F)$ are self-adjoint and $\mathbf{A} \succ 0$, there is an invertible $\mathbf{S}$ with $\mathbf{S}^{*}\mathbf{A}\mathbf{S} = \mathbf{I}_n$ and $\mathbf{S}^{*}\mathbf{B}\mathbf{S}$ real diagonal.

(c) Chapter 11's theorem assumes the operators commute and are normal, and delivers a **unitary** change of basis preserving eigenvalues; this one assumes nothing about commuting but assumes one matrix is positive definite, and delivers a merely invertible $\mathbf{S}$ under which eigenvalues are not preserved.

(d) Incorrect. In Example (A pencil that does not commute) the generalized eigenvalues are -1 and 3, while the eigenvalues of $\mathbf{B}$ are $3 \pm 3\sqrt{2}$. They agree when $\mathbf{A} = \mathbf{I}$, and not in general.

(e) $\langle \mathbf{x}, \mathbf{y} \rangle_{\mathbf{A}} = \mathbf{y}^{*}\mathbf{A}\mathbf{x}$ (Theorem 12.4.2 (a)).

12.4.5.2 B. Practice

Exercise B1: A generalized eigenvalue problem.

Let

$$\mathbf{A} = \begin{pmatrix} 1 & 1 \\ 1 & 2 \end{pmatrix}, \qquad \mathbf{B} = \begin{pmatrix} 2 & 2 \\ 2 & 1 \end{pmatrix}.$$

(a) Verify that $\mathbf{A} \succ 0$ and find the generalized eigenvalues of $(\mathbf{A}, \mathbf{B})$.

(b) Find generalized eigenvectors and an invertible $\mathbf{S}$ with $\mathbf{S}^{\top}\mathbf{A}\mathbf{S} = \mathbf{I}_2$ and $\mathbf{S}^{\top}\mathbf{B}\mathbf{S}$ diagonal.

Solution.

(a) The leading principal minors of $\mathbf{A}$ are $1 > 0$ and $2 - 1 = 1 > 0$, so $\mathbf{A} \succ 0$ by Theorem 12.1.5. Then

$$\mathbf{B} - \lambda \mathbf{A} = \begin{pmatrix} 2 - \lambda & 2 - \lambda \\ 2 - \lambda & 1 - 2\lambda \end{pmatrix},$$

so

$$\begin{aligned} \det(\mathbf{B} - \lambda \mathbf{A}) &= (2 - \lambda)(1 - 2\lambda) - (2 - \lambda)^2 \\ &= (2 - \lambda)\big[(1 - 2\lambda) - (2 - \lambda)\big] \\ &= (2 - \lambda)(-1 - \lambda) = (\lambda - 2)(\lambda + 1). \end{aligned}$$

The generalized eigenvalues are 2 and -1.

(b) For $\lambda = 2$: $\mathbf{B} - 2\mathbf{A} = \begin{pmatrix} 0 & 0 \\ 0 & -3 \end{pmatrix}$, with kernel spanned by $\mathbf{x}_1 = (1, 0)$. For $\lambda = -1$: $\mathbf{B} + \mathbf{A} = \begin{pmatrix} 3 & 3 \\ 3 & 3 \end{pmatrix}$, with kernel spanned by $\mathbf{x}_2 = (1, -1)$. Check: $\mathbf{B}\mathbf{x}_1 = (2, 2) = 2\mathbf{A}\mathbf{x}_1$ since $\mathbf{A}\mathbf{x}_1 = (1, 1)$; and $\mathbf{B}\mathbf{x}_2 = (0, 1)$ while $\mathbf{A}\mathbf{x}_2 = (0, -1)$, so $\mathbf{B}\mathbf{x}_2 = -\mathbf{A}\mathbf{x}_2$.

Now $\mathbf{x}_1^{\top}\mathbf{A}\mathbf{x}_1 = (1, 0) \cdot (1, 1) = 1$ and $\mathbf{x}_2^{\top}\mathbf{A}\mathbf{x}_2 = (1, -1) \cdot (0, -1) = 1$, and $\mathbf{x}_1^{\top}\mathbf{A}\mathbf{x}_2 = (1, 0) \cdot (0, -1) = 0$. Both are already $\mathbf{A}$-unit vectors, so

$$\mathbf{S} = \begin{pmatrix} 1 & 1 \\ 0 & -1 \end{pmatrix}, \qquad \mathbf{S}^{\top}\mathbf{A}\mathbf{S} = \mathbf{I}_2, \qquad \mathbf{S}^{\top}\mathbf{B}\mathbf{S} = \begin{pmatrix} 2 & 0 \\ 0 & -1 \end{pmatrix}.$$

Exercise B2: Whitening by hand.

Let $\mathbf{A} = \operatorname{diag}(4, 9)$ and $\mathbf{B} = \begin{pmatrix} 4 & 6 \\ 6 & 9 \end{pmatrix}$. Follow the two steps of the proof of Theo-

rem 12.4.1: compute $\mathbf{A}^{-1/2}$, then $\mathbf{C} = \mathbf{A}^{-1/2}\mathbf{B}\mathbf{A}^{-1/2}$, diagonalize $\mathbf{C}$, and write down $\mathbf{S}$ and $\mathbf{S}^{\top}\mathbf{B}\mathbf{S}$.

Solution. $\mathbf{A}$ is diagonal with positive entries, so $\mathbf{A}^{1/2} = \operatorname{diag}(2,3)$ and $\mathbf{A}^{-1/2} = \operatorname{diag}(\tfrac{1}{2},\tfrac{1}{3})$. Then

$$\mathbf{C} = \begin{pmatrix} \tfrac{1}{2} & 0 \\ 0 & \tfrac{1}{3} \end{pmatrix} \begin{pmatrix} 4 & 6 \\ 6 & 9 \end{pmatrix} \begin{pmatrix} \tfrac{1}{2} & 0 \\ 0 & \tfrac{1}{3} \end{pmatrix} = \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix}.$$

Its eigenvalues are 2, with unit eigenvector $\tfrac{1}{\sqrt{2}}(1,1)$, and 0, with unit eigenvector $\tfrac{1}{\sqrt{2}}(1,-1)$. So $\mathbf{U} = \tfrac{1}{\sqrt{2}}\begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}$ and $\mathbf{D} = \operatorname{diag}(2,0)$, and

$$\mathbf{S} = \mathbf{A}^{-1/2}\mathbf{U} = \frac{1}{\sqrt{2}}\begin{pmatrix} \tfrac{1}{2} & \tfrac{1}{2} \\ \tfrac{1}{3} & -\tfrac{1}{3} \end{pmatrix}, \qquad \mathbf{S}^{\top}\mathbf{A}\mathbf{S} = \mathbf{I}_2, \qquad \mathbf{S}^{\top}\mathbf{B}\mathbf{S} = \begin{pmatrix} 2 & 0 \\ 0 & 0 \end{pmatrix}.$$

As a check, $\det(\mathbf{B} - \lambda\mathbf{A}) = (4-4\lambda)(9-9\lambda) - 36 = 36\lambda^2 - 72\lambda = 36\lambda(\lambda - 2)$, whose roots 0 and 2 are the diagonal entries of $\mathbf{S}^{\top}\mathbf{B}\mathbf{S}$.

Exercise B3: A pair that resists.

Let $\mathbf{A} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$ and $\mathbf{B} = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}$. Determine whether there is an invertible real $\mathbf{S}$ making $\mathbf{S}^{\top}\mathbf{A}\mathbf{S}$ and $\mathbf{S}^{\top}\mathbf{B}\mathbf{S}$ both diagonal. Justify your answer.

Solution. There is not. Both matrices are symmetric and $\mathbf{A}$ is invertible, with $\mathbf{A}^{-1} = \mathbf{A}$. If such an $\mathbf{S}$ existed, the computation in the warning above would give $\mathbf{A}^{-1}\mathbf{B} = \mathbf{S}(\mathbf{D}_{\mathbf{A}}^{-1}\mathbf{D}_{\mathbf{B}})\mathbf{S}^{-1}$, so $\mathbf{A}^{-1}\mathbf{B}$ would be diagonalizable. But

$$\mathbf{A}^{-1}\mathbf{B} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}\begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix},$$

which is non-zero with $(\mathbf{A}^{-1}\mathbf{B})^2 = \mathbf{0}$, hence has 0 as its only eigenvalue and is not diagonalizable (a diagonalizable matrix with only the eigenvalue 0 is $\mathbf{0}$). Here the generalized eigenvalues are both 0 and real, so reality of the spectrum is not the obstruction; diagonalizability is.

12.4.5.3 C. Going deeper

Exercise C1: The A-inner product.

Let $\mathbf{A} \succ 0$ and $\mathbf{B}$ be self-adjoint in $M_n(F)$, and write $\langle \mathbf{x}, \mathbf{y} \rangle_{\mathbf{A}} = \mathbf{y}^{*}\mathbf{A}\mathbf{x}$.

(a) Prove that $\langle \cdot, \cdot \rangle_{\mathbf{A}}$ is an inner product on F^n.

(b) Prove that $T = T_{\mathbf{A}^{-1}\mathbf{B}}$ is self-adjoint on $(F^n, \langle \cdot, \cdot \rangle_{\mathbf{A}})$.

(c) Deduce Theorem 12.4.2 (a) and (b) from the spectral theorem applied to T, without using Theorem 12.4.1.

Solution.

(a) Sesquilinearity in the first slot is clear from the formula. Conjugate symmetry:

$\overline{\langle \mathbf{y},\mathbf{x}\rangle_{\mathbf{A}}} = \overline{\mathbf{x}^*\mathbf{A}\mathbf{y}} = \mathbf{y}^*\mathbf{A}^*\mathbf{x} = \mathbf{y}^*\mathbf{A}\mathbf{x} = \langle \mathbf{x},\mathbf{y}\rangle_{\mathbf{A}}$, using $\mathbf{A}^* = \mathbf{A}$. Positive definiteness: $\langle \mathbf{x},\mathbf{x}\rangle_{\mathbf{A}} = \mathbf{x}^*\mathbf{A}\mathbf{x} > 0$ for $\mathbf{x} \neq \mathbf{0}$, which is Definition 12.1.1 for $\mathbf{A} \succ 0$.

(b) For all $\mathbf{x}, \mathbf{y}$,

$$\langle T\mathbf{x},\mathbf{y}\rangle_{\mathbf{A}} = \mathbf{y}^*\mathbf{A}\mathbf{A}^{-1}\mathbf{B}\mathbf{x} = \mathbf{y}^*\mathbf{B}\mathbf{x},$$

and

$$\langle \mathbf{x},T\mathbf{y}\rangle_{\mathbf{A}} = (\mathbf{A}^{-1}\mathbf{B}\mathbf{y})^*\mathbf{A}\mathbf{x} = \mathbf{y}^*\mathbf{B}^*\mathbf{A}^{-1}\mathbf{A}\mathbf{x} = \mathbf{y}^*\mathbf{B}\mathbf{x},$$

using $(\mathbf{A}^{-1})^* = \mathbf{A}^{-1}$ and $\mathbf{B}^* = \mathbf{B}$. The two agree, so T is self-adjoint for this inner product (Definition 10.6.1).

(c) By Theorem 11.5.1 (over $\mathbb{R}$) or Theorem 11.4.2 (over $\mathbb{C}$) applied to the self-adjoint T on the inner product space $(F^n, \langle\cdot,\cdot\rangle_{\mathbf{A}})$, there is a basis $\mathbf{s}_1, \dots, \mathbf{s}_n$ of F^n, orthonormal for $\langle\cdot,\cdot\rangle_{\mathbf{A}}$, with $T\mathbf{s}_i = d_i\mathbf{s}_i$ and $d_i \in \mathbb{R}$ (Theorem 11.2.1). The equation $\mathbf{A}^{-1}\mathbf{B}\mathbf{s}_i = d_i\mathbf{s}_i$ is $\mathbf{B}\mathbf{s}_i = d_i\mathbf{A}\mathbf{s}_i$, and $\mathbf{s}_i^*\mathbf{A}\mathbf{s}_j = \langle \mathbf{s}_j,\mathbf{s}_i\rangle_{\mathbf{A}} = \delta_{ij}$; this is (a). For (b), λ is a generalized eigenvalue exactly when $\mathbf{A}^{-1}\mathbf{B} - \lambda\mathbf{I}$ is singular, that is when λ is an eigenvalue of $\mathbf{A}^{-1}\mathbf{B}$, and those are $d_1, \dots, d_n$.

Exercise C2: Signs of the generalized eigenvalues.

Let $\mathbf{A} \succ 0$ and $\mathbf{B}$ be self-adjoint in $M_n(F)$, with generalized eigenvalues $d_1, \dots, d_n$.

(a) Prove that $\mathbf{B} \succeq 0$ if and only if every $d_i \geq 0$, and $\mathbf{B} \succ 0$ if and only if every $d_i > 0$.

(b) Deduce that if $\mathbf{A} \succ 0$ and $\mathbf{B} \succ 0$, then $\det\mathbf{B}/\det\mathbf{A} = \prod_i d_i > 0$.

Solution.

(a) Let $\mathbf{S}$ be as in Theorem 12.4.1, so $\mathbf{S}^*\mathbf{B}\mathbf{S} = \mathbf{D} = \operatorname{diag}(d_1, \dots, d_n)$. For $\mathbf{x} \in F^n$ put $\mathbf{y} = \mathbf{S}^{-1}\mathbf{x}$; as $\mathbf{x}$ runs over F^n so does $\mathbf{y}$, and $\mathbf{x} \neq \mathbf{0}$ exactly when $\mathbf{y} \neq \mathbf{0}$. Then

$$\mathbf{x}^*\mathbf{B}\mathbf{x} = \mathbf{y}^*\mathbf{S}^*\mathbf{B}\mathbf{S}\mathbf{y} = \mathbf{y}^*\mathbf{D}\mathbf{y} = \sum_i d_i|y_i|^2.$$

If every $d_i \geq 0$, this is ≥ 0 for all $\mathbf{y}$, so $\mathbf{B} \succeq 0$. Conversely, taking $\mathbf{y} = \mathbf{e}_i$ gives $d_i \geq 0$. The same argument with strict inequalities gives the second claim, using that $\sum_i d_i|y_i|^2 > 0$ for $\mathbf{y} \neq \mathbf{0}$ when every $d_i > 0$.

(b) Taking determinants in $\mathbf{S}^*\mathbf{B}\mathbf{S} = \mathbf{D}$ and $\mathbf{S}^*\mathbf{A}\mathbf{S} = \mathbf{I}$ gives $|\det\mathbf{S}|^2 \det\mathbf{B} = \prod_i d_i$ and $|\det\mathbf{S}|^2 \det\mathbf{A} = 1$. Dividing, $\det\mathbf{B}/\det\mathbf{A} = \prod_i d_i$, which is > 0 by (a).

Exercise C3: Dropping definiteness of A.

Let $\mathbf{A} = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}$ and $\mathbf{B} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$, so that $\mathbf{A} \succeq 0$ but $\mathbf{A} \not\succ 0$.

(a) Compute $\det(\mathbf{B} - \lambda\mathbf{A})$ and deduce that the pair has no generalized eigenvalues at all.

(b) Prove that no invertible $\mathbf{S} \in M_2(\mathbb{R})$ makes $\mathbf{S}^\top\mathbf{A}\mathbf{S}$ and $\mathbf{S}^\top\mathbf{B}\mathbf{S}$ both diagonal.

Hint for (b): compare the degree in λ of $\det(\mathbf{B} - \lambda\mathbf{A})$ on both sides.

Solution.

(a) $\mathbf{B}-\lambda\mathbf{A} = \begin{pmatrix} -\lambda & 1 \\ 1 & 0 \end{pmatrix}$, with determinant -1. This is never 0, so $\mathbf{B}-\lambda\mathbf{A}$ is invertible for every λ and there is no $\mathbf{x} \neq \mathbf{0}$ with $\mathbf{Bx} = \lambda\mathbf{Ax}$.

(b) Suppose $\mathbf{S}^{\top}\mathbf{AS} = \operatorname{diag}(a_1, a_2)$ and $\mathbf{S}^{\top}\mathbf{BS} = \operatorname{diag}(b_1, b_2)$. As in the proof of Theorem 12.4.2 (b),

$$\det(\mathbf{B} - \lambda\mathbf{A}) = \frac{1}{(\det \mathbf{S})^2}(b_1 - \lambda a_1)(b_2 - \lambda a_2).$$

By (a) the left side is the constant -1, so the right side is a non-zero constant. It is non-zero, so $b_1 b_2 \neq 0$ and hence $\det(\mathbf{S}^{\top}\mathbf{BS}) \neq 0$; it is constant in λ, so $a_1 = a_2 = 0$, which forces $\mathbf{S}^{\top}\mathbf{AS} = \mathbf{0}$ and therefore $\mathbf{A} = \mathbf{0}$. That is false, so no such $\mathbf{S}$ exists. (Alternatively: $\operatorname{rank}(\mathbf{S}^{\top}\mathbf{AS}) = \operatorname{rank}\mathbf{A} = 1$, so exactly one a_i is non-zero, and the right side then has degree 1 in λ, not 0.)

12.5 The Loewner Order

Every theorem so far in this chapter has compared a self-adjoint matrix with 0. Comparing it with 0 is only the first case of comparing it with something, and the analogy with real numbers suggests the general one: say that $\mathbf{A}$ is at least $\mathbf{B}$ when the difference is non-negative. That is a genuine order, and a surprising amount of ordinary arithmetic survives it. A little does not, and what fails is the point of the section: squaring both sides of an inequality between matrices is not allowed.

Throughout, $F = \mathbb{R}$ or $F = \mathbb{C}$, all matrices are in $M_n(F)$, and $\lambda_1(\mathbf{A}) \geq \cdots \geq \lambda_n(\mathbf{A})$ are the eigenvalues of a Hermitian $\mathbf{A}$ in decreasing order.

12.5.1 Comparing two self-adjoint matrices

The relation $\mathbf{A} \succeq 0$ already behaves like "≥ 0" for numbers: it is preserved by sums, by non-negative scalars and by congruence (Proposition 12.1.2). For real numbers, $a \geq b$ means nothing other than $a - b \geq 0$. Copying that sentence is the whole definition.

One self-adjoint matrix dominates another when their difference is positive semidefinite.

Definition 12.5.1 — The Loewner order

Let $\mathbf{A}, \mathbf{B} \in M_n(F)$ be Hermitian. Write

$$\mathbf{A} \succeq \mathbf{B} \quad \text{to mean} \quad \mathbf{A} - \mathbf{B} \succeq 0,$$

and $\mathbf{A} \succ \mathbf{B}$ to mean $\mathbf{A} - \mathbf{B} \succ 0$. This relation on the set of Hermitian matrices is the **Loewner order**.

In words: $\mathbf{A} \succeq \mathbf{B}$ says that $\langle \mathbf{Ax}, \mathbf{x}\rangle \geq \langle \mathbf{Bx}, \mathbf{x}\rangle$ for **every** $\mathbf{x} \in F^n$, since $\langle (\mathbf{A} - \mathbf{B})\mathbf{x}, \mathbf{x}\rangle = \langle \mathbf{Ax}, \mathbf{x}\rangle - \langle \mathbf{Bx}, \mathbf{x}\rangle$. So the order compares the two quadratic forms pointwise, and it is exactly as

strong as that comparison. Note also that the difference of two Hermitian matrices is Hermitian, so clause (P1) of Definition 12.1.1 is automatic here and only (P2) has to be checked. Taking $\mathbf{B} = \mathbf{0}$ recovers $\mathbf{A} \succeq 0$, so the notation is consistent.

Three examples, each of which will be used later.

- **Diagonal matrices.** $\operatorname{diag}(a_1, \dots, a_n) \succeq \operatorname{diag}(b_1, \dots, b_n)$ if and only if $a_i \geq b_i$ for every i, since the difference is diagonal and a diagonal Hermitian matrix is positive semidefinite exactly when its entries, which are its eigenvalues, are ≥ 0 (Theorem 12.1.4).
- **Eigenvalue bounds.** For Hermitian $\mathbf{A}$, $\lambda_1(\mathbf{A})\mathbf{I} \succeq \mathbf{A} \succeq \lambda_n(\mathbf{A})\mathbf{I}$. Indeed $\lambda_1(\mathbf{A})\mathbf{I} - \mathbf{A}$ is Hermitian with eigenvalues $\lambda_1(\mathbf{A}) - \lambda_i(\mathbf{A}) \geq 0$.
- **Projections.** If $\mathbf{P} \in M_n(F)$ is the matrix of an orthogonal projection onto a subspace of F^n, then $\mathbf{I} \succeq \mathbf{P} \succeq 0$: it is Hermitian, and its eigenvalues are 0 and 1.

A **non-example by minimal change**: replace $\operatorname{diag}(1, 1)$ by $\operatorname{diag}(1, -1)$ in the first item. Then $\operatorname{diag}(1, -1) \succeq \operatorname{diag}(0, 0)$ fails, and it fails only in the second coordinate — the test is coordinatewise for diagonal matrices, and one bad coordinate is enough.

Proposition 12.5.1 — The Loewner order is a partial order

On the set of Hermitian matrices in $M_n(F)$, the relation $\succeq$ is reflexive, transitive and antisymmetric: $\mathbf{A} \succeq \mathbf{A}$; if $\mathbf{A} \succeq \mathbf{B}$ and $\mathbf{B} \succeq \mathbf{C}$ then $\mathbf{A} \succeq \mathbf{C}$; and if $\mathbf{A} \succeq \mathbf{B}$ and $\mathbf{B} \succeq \mathbf{A}$ then $\mathbf{A} = \mathbf{B}$.

Proof. Reflexivity: $\mathbf{A} - \mathbf{A} = \mathbf{0}$, and $\langle \mathbf{0}\mathbf{x}, \mathbf{x} \rangle = 0 \geq 0$.

Transitivity: $\mathbf{A} - \mathbf{C} = (\mathbf{A} - \mathbf{B}) + (\mathbf{B} - \mathbf{C})$, and for every $\mathbf{x}$,

$$\langle (\mathbf{A} - \mathbf{C})\mathbf{x}, \mathbf{x} \rangle = \langle (\mathbf{A} - \mathbf{B})\mathbf{x}, \mathbf{x} \rangle + \langle (\mathbf{B} - \mathbf{C})\mathbf{x}, \mathbf{x} \rangle \;\geq\; 0,$$

both summands being ≥ 0 by hypothesis.

Antisymmetry: put $\mathbf{S} = \mathbf{A} - \mathbf{B}$, which is Hermitian. From $\mathbf{A} \succeq \mathbf{B}$ we get $\langle \mathbf{S}\mathbf{x}, \mathbf{x} \rangle \geq 0$ for every $\mathbf{x}$, and from $\mathbf{B} \succeq \mathbf{A}$ we get $\langle -\mathbf{S}\mathbf{x}, \mathbf{x} \rangle \geq 0$, that is $\langle \mathbf{S}\mathbf{x}, \mathbf{x} \rangle \leq 0$. Hence $\langle \mathbf{S}\mathbf{x}, \mathbf{x} \rangle = 0$ for every $\mathbf{x} \in F^n$, and $\mathbf{S}$ is self-adjoint, so $\mathbf{S} = \mathbf{0}$ by Theorem 11.2.5. Thus $\mathbf{A} = \mathbf{B}$. ∎

Antisymmetry is the clause that needed an argument, and the argument is the one the chapter keeps reusing: a self-adjoint matrix is determined by its quadratic form. Over $\mathbb{R}$ this is genuinely a theorem — the quarter turn of Definition 12.1.1's warning has vanishing quadratic form and is not $\mathbf{0}$ — and it is self-adjointness that rules that out.

Warning. **The Loewner order is partial, and it is not the entrywise order.** Two things go wrong if one forgets this. First, most pairs are incomparable: $\mathbf{A} = \operatorname{diag}(1, 0)$ and $\mathbf{B} = \operatorname{diag}(0, 1)$ satisfy neither $\mathbf{A} \succeq \mathbf{B}$ nor $\mathbf{B} \succeq \mathbf{A}$, so an argument that splits into "either $\mathbf{A} \succeq \mathbf{B}$ or $\mathbf{B} \succeq \mathbf{A}$" is not an argument. Second, $\mathbf{A} \succeq \mathbf{B}$ says nothing entrywise, in either direction:

$$\begin{pmatrix} 2 & 0 \\ 0 & 2 \end{pmatrix} \succeq \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix}, \qquad \text{yet the off-diagonal entries went down;}$$

the difference is $\left(\begin{smallmatrix} 1 & -1 \\ -1 & 1 \end{smallmatrix}\right)$, with eigenvalues 0 and 2. Conversely $\left(\begin{smallmatrix} 1 & 2 \\ 2 & 1 \end{smallmatrix}\right)$ has every entry

≥ 0 and is **not** $\succeq 0$, its eigenvalues being 3 and -1.

Quick check. Is the set of Hermitian $\mathbf{A}$ with $\mathbf{I} \succeq \mathbf{A} \succeq 0$ closed under multiplication?

Solution. No. Take $\mathbf{A} = \left(\begin{smallmatrix} 1 & 0 \\ 0 & 0 \end{smallmatrix}\right)$ and $\mathbf{B} = \frac{1}{2}\left(\begin{smallmatrix} 1 & 1 \\ 1 & 1 \end{smallmatrix}\right)$, both orthogonal projections, so both lie in the set. Then $\mathbf{AB} = \frac{1}{2}\left(\begin{smallmatrix} 1 & 1 \\ 0 & 0 \end{smallmatrix}\right)$, which is not even Hermitian, so it is not in the set and the order does not apply to it. The order lives on Hermitian matrices, and Hermitian matrices are not closed under multiplication (Exercise (C2: Sums and products)).

12.5.2 What survives

One small fact is needed first, and it is worth stating on its own because it is the elementary half of a theme Chapter 16 takes up in full: the largest and smallest eigenvalues of a Hermitian matrix are the largest and smallest values of its quadratic form on the unit sphere.

Lemma 12.5.2 — The extreme eigenvalues as extreme values

Let $\mathbf{A} \in M_n(F)$ be Hermitian. Then for every $\mathbf{x} \in F^n$ with $\|\mathbf{x}\| = 1$,

$$\lambda_n(\mathbf{A}) \;\leq\; \langle \mathbf{A}\mathbf{x}, \mathbf{x} \rangle \;\leq\; \lambda_1(\mathbf{A}),$$

and both bounds are attained, at unit eigenvectors for $\lambda_n(\mathbf{A})$ and $\lambda_1(\mathbf{A})$ respectively.

Proof. By Corollary 11.4.3 (over $\mathbb{C}$) or Corollary 11.5.2 (over $\mathbb{R}$), F^n has an orthonormal basis $(\mathbf{q}_1, \dots, \mathbf{q}_n)$ with $\mathbf{A}\mathbf{q}_i = \lambda_i(\mathbf{A})\mathbf{q}_i$. Write $\mathbf{x} = \sum_i c_i \mathbf{q}_i$; then $\sum_i |c_i|^2 = \|\mathbf{x}\|^2 = 1$ by Theorem 10.2.1, and

$$\langle \mathbf{A}\mathbf{x}, \mathbf{x} \rangle = \Big\langle \sum_i \lambda_i(\mathbf{A}) c_i \mathbf{q}_i, \sum_j c_j \mathbf{q}_j \Big\rangle = \sum_i \lambda_i(\mathbf{A}) |c_i|^2,$$

the cross terms vanishing by orthonormality. The right-hand side is a weighted average of the $\lambda_i(\mathbf{A})$ with non-negative weights summing to 1, hence lies between the smallest and the largest. Taking $\mathbf{x} = \mathbf{q}_1$ gives $\lambda_1(\mathbf{A})$ and $\mathbf{x} = \mathbf{q}_n$ gives $\lambda_n(\mathbf{A})$.

■

Theorem 12.5.3 — Basic Properties of the Loewner Order

Let $\mathbf{A}, \mathbf{B} \in M_n(F)$ be Hermitian with $\mathbf{A} \succeq \mathbf{B}$. Then:

(a) $\mathbf{S}^*\mathbf{A}\mathbf{S} \succeq \mathbf{S}^*\mathbf{B}\mathbf{S}$ for every $\mathbf{S} \in M_{n \times m}(F)$;
(b) $\lambda_1(\mathbf{A}) \geq \lambda_1(\mathbf{B})$ and $\lambda_n(\mathbf{A}) \geq \lambda_n(\mathbf{B})$;
(c) if moreover $\mathbf{B} \succeq 0$, then $\operatorname{tr}\mathbf{A} \geq \operatorname{tr}\mathbf{B}$ and $\det\mathbf{A} \geq \det\mathbf{B}$;
(d) if moreover $\mathbf{B} \succ 0$, then $\mathbf{A} \succ 0$ and $\mathbf{B}^{-1} \succeq \mathbf{A}^{-1}$.

Idea. Each clause has a one-line mechanism. (a) is the substitution $\mathbf{x} = \mathbf{S}\mathbf{y}$. (b) evaluates the quadratic form at the vector that is extremal for the *other* matrix. (c)

splits: the trace is a sum of eigenvalues, and for the determinant we whiten by $\mathbf{B}^{-1/2}$ so that the comparison becomes "$\succeq \mathbf{I}$", where the determinant is visibly ≥ 1. (d) is the same whitening, plus the observation that inverting reverses the order for *numbers* ≥ 1.

Proof.

(a) This is Proposition 12.1.2 (a) applied to the Hermitian matrix $\mathbf{A}-\mathbf{B} \succeq 0$, together with $\mathbf{S}^*\mathbf{A}\mathbf{S} - \mathbf{S}^*\mathbf{B}\mathbf{S} = \mathbf{S}^*(\mathbf{A}-\mathbf{B})\mathbf{S}$.

(b) Let $\mathbf{x}$ be a unit eigenvector of $\mathbf{B}$ for $\lambda_1(\mathbf{B})$. By Lemma 12.5.2 applied twice, and $\mathbf{A} \succeq \mathbf{B}$ in between,

$$\lambda_1(\mathbf{B}) = \langle \mathbf{B}\mathbf{x}, \mathbf{x}\rangle \leq \langle \mathbf{A}\mathbf{x}, \mathbf{x}\rangle \leq \lambda_1(\mathbf{A}).$$

Now let $\mathbf{y}$ be a unit eigenvector of $\mathbf{A}$ for $\lambda_n(\mathbf{A})$. Then

$$\lambda_n(\mathbf{A}) = \langle \mathbf{A}\mathbf{y}, \mathbf{y}\rangle \geq \langle \mathbf{B}\mathbf{y}, \mathbf{y}\rangle \geq \lambda_n(\mathbf{B}).$$

(c) The matrix $\mathbf{A}-\mathbf{B}$ is Hermitian and $\succeq 0$, so all its eigenvalues are ≥ 0 by Theorem 12.1.4, and $\operatorname{tr}(\mathbf{A}-\mathbf{B})$, being their sum (Theorem 8.3.3), is ≥ 0. Hence $\operatorname{tr}\mathbf{A} \geq \operatorname{tr}\mathbf{B}$.
For the determinant, first note $\mathbf{A} \succeq \mathbf{B} \succeq 0$ gives $\mathbf{A} \succeq 0$ by Proposition 12.5.1, so $\det\mathbf{A} \geq 0$ and $\det\mathbf{B} \geq 0$, both being products of non-negative eigenvalues. If $\mathbf{B}$ is singular then $\det\mathbf{B} = 0 \leq \det\mathbf{A}$ and we are done. Otherwise $\mathbf{B} \succeq 0$ with no zero eigenvalue means $\mathbf{B} \succ 0$ (Theorem 12.1.5), so $\mathbf{B}^{1/2} \succ 0$ is invertible and we may set $\mathbf{C} = \mathbf{B}^{-1/2}\mathbf{A}\mathbf{B}^{-1/2}$, where $\mathbf{B}^{-1/2} = (\mathbf{B}^{1/2})^{-1}$ is Hermitian. By (a) with $\mathbf{S} = \mathbf{B}^{-1/2}$,

$$\mathbf{C} = \mathbf{B}^{-1/2}\mathbf{A}\mathbf{B}^{-1/2} \succeq \mathbf{B}^{-1/2}\mathbf{B}\mathbf{B}^{-1/2} = \mathbf{I}_n,$$

so $\mathbf{C}-\mathbf{I} \succeq 0$ and every eigenvalue of $\mathbf{C}$ is ≥ 1. Hence $\det\mathbf{C} \geq 1$. Since $\mathbf{A} = \mathbf{B}^{1/2}\mathbf{C}\mathbf{B}^{1/2}$, Theorem 6.5.4 gives

$$\det\mathbf{A} = \det(\mathbf{B}^{1/2})^2 \det\mathbf{C} = \det\mathbf{B}\cdot\det\mathbf{C} \geq \det\mathbf{B}.$$

(d) Suppose $\mathbf{B} \succ 0$. For $\mathbf{x} \neq \mathbf{0}$, $\langle \mathbf{A}\mathbf{x}, \mathbf{x}\rangle \geq \langle \mathbf{B}\mathbf{x}, \mathbf{x}\rangle > 0$, so $\mathbf{A} \succ 0$ and in particular $\mathbf{A}$ is invertible (Theorem 12.1.5). Let $\mathbf{C} = \mathbf{B}^{-1/2}\mathbf{A}\mathbf{B}^{-1/2} \succeq \mathbf{I}$ as in (c). Then $\mathbf{C} \succ 0$, so $\mathbf{C}$ is invertible, and $\mathbf{C}^{-1}$ is Hermitian with eigenvalues the reciprocals of those of $\mathbf{C}$, all lying in $(0,1]$. Therefore $\mathbf{I}-\mathbf{C}^{-1}$ is Hermitian with non-negative eigenvalues, that is $\mathbf{I} \succeq \mathbf{C}^{-1}$ (Theorem 12.1.4). Applying (a) with $\mathbf{S} = \mathbf{B}^{-1/2}$ to this inequality,

$$\mathbf{B}^{-1} = \mathbf{B}^{-1/2}\mathbf{I}\mathbf{B}^{-1/2} \succeq \mathbf{B}^{-1/2}\mathbf{C}^{-1}\mathbf{B}^{-1/2} = \mathbf{B}^{-1/2}\mathbf{B}^{1/2}\mathbf{A}^{-1}\mathbf{B}^{1/2}\mathbf{B}^{-1/2} = \mathbf{A}^{-1},$$

using $\mathbf{C}^{-1} = (\mathbf{B}^{-1/2}\mathbf{A}\mathbf{B}^{-1/2})^{-1} = \mathbf{B}^{1/2}\mathbf{A}^{-1}\mathbf{B}^{1/2}$. This proves the theorem.

■

Clause (d) is the memorable one: **the order reverses under inversion**, exactly as $a \geq b > 0$ gives $1/b \geq 1/a$ for numbers. Clause (b) is the beginning of a longer story. The full statement is that $\lambda_i(\mathbf{A}) \geq \lambda_i(\mathbf{B})$ for **every** i, not only for $i = 1$ and $i = n$; but the intermediate eigenvalues have no description as a plain maximum over the whole unit sphere, and the min–max description that does the job is the Courant–Fischer theorem of Chapter 16. Nothing in this chapter uses the intermediate cases, so we prove the two extreme ones and leave the rest there.

Remark. Clause (c) does not extend to $\mathbf{A} \succeq \mathbf{B}$ without $\mathbf{B} \succeq 0$. Take $\mathbf{A} = \operatorname{diag}(1, -1)$ and $\mathbf{B} = \operatorname{diag}(0, -2)$: then $\mathbf{A} - \mathbf{B} = \operatorname{diag}(1, 1) \succeq 0$, so $\mathbf{A} \succeq \mathbf{B}$, yet $\det \mathbf{A} = -1 < 0 = \det \mathbf{B}$. The hypothesis $\mathbf{B} \succeq 0$ is what lets "bigger" be read off the eigenvalues one at a time, and so multiplied up into a determinant.

12.5.3 What fails: squaring

For positive numbers, $a \geq b \geq 0$ implies $a^2 \geq b^2$. The matrix version is false, and the smallest counterexample has integer entries.

Example. (Squaring does not preserve the Loewner order)

Let

$$\mathbf{A} = \begin{pmatrix} 2 & 1 \\ 1 & 1 \end{pmatrix}, \qquad \mathbf{B} = \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix}.$$

Show that $\mathbf{A} \succeq \mathbf{B} \succeq 0$ and that $\mathbf{A}^2 \succeq \mathbf{B}^2$ is false.

Solution. The hypotheses. Both matrices are real symmetric. $\mathbf{B} \succeq 0$: its leading principal minors are 1 and 0, and directly $\mathbf{x}^\top \mathbf{B}\mathbf{x} = (x_1 + x_2)^2 \geq 0$. Its eigenvalues are 0 and 2. Next,

$$\mathbf{A} - \mathbf{B} = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} \succeq 0,$$

so $\mathbf{A} \succeq \mathbf{B}$. (In fact $\mathbf{A} \succ 0$: $\det \mathbf{A} = 1 > 0$ and $a_{11} = 2 > 0$, so Sylvester's criterion applies, Theorem 12.1.5.)

The squares.

$$\mathbf{A}^2 = \begin{pmatrix} 5 & 3 \\ 3 & 2 \end{pmatrix}, \qquad \mathbf{B}^2 = \begin{pmatrix} 2 & 2 \\ 2 & 2 \end{pmatrix}, \qquad \mathbf{A}^2 - \mathbf{B}^2 = \begin{pmatrix} 3 & 1 \\ 1 & 0 \end{pmatrix}.$$

Its determinant is $0 - 1 = -1 < 0$, so its two eigenvalues have opposite signs and it is not positive semidefinite (Theorem 12.1.4). A witness is available without computing eigenvalues: with $\mathbf{x} = (1, -2)$,

$$\mathbf{x}^\top (\mathbf{A}^2 - \mathbf{B}^2)\mathbf{x} = 3 - 4 + 0 = -1 < 0.$$

So $\mathbf{A}^2 \not\succeq \mathbf{B}^2$.

Where does the argument for numbers break? It uses $a^2 - b^2 = (a - b)(a + b)$, a product of two non-negative numbers. For matrices, $(\mathbf{A} - \mathbf{B})(\mathbf{A} + \mathbf{B}) = \mathbf{A}^2 + \mathbf{A}\mathbf{B} - \mathbf{B}\mathbf{A} - \mathbf{B}^2$, which is $\mathbf{A}^2 - \mathbf{B}^2$ only when $\mathbf{A}$ and $\mathbf{B}$ commute — and in the example $\mathbf{A}\mathbf{B} = \left(\begin{smallmatrix} 3 & 3 \\ 2 & 2 \end{smallmatrix}\right)$ while $\mathbf{B}\mathbf{A} = \left(\begin{smallmatrix} 3 & 2 \\ 3 & 2 \end{smallmatrix}\right)$. Non-commutativity is the whole obstruction, and when it is removed the number argument goes through; that is exercise C1.

What *is* true is the same statement for the square **root**, and it is true with no commuting hypothesis at all.

Proposition 12.5.4 — The square root is order preserving

Let $\mathbf{A}, \mathbf{B} \in M_n(F)$ with $\mathbf{A} \succeq \mathbf{B} \succeq 0$. Then $\mathbf{A}^{1/2} \succeq \mathbf{B}^{1/2}$.

Idea. Suppose not. Then $\mathbf{X} - \mathbf{Y}$, with $\mathbf{X} = \mathbf{A}^{1/2}$ and $\mathbf{Y} = \mathbf{B}^{1/2}$, has a negative eigenvalue μ, with unit eigenvector $\mathbf{u}$. Two different consequences of $\mathbf{Xu} = \mathbf{Yu} + \mu\mathbf{u}$ then collide. Pairing with $\mathbf{u}$ says $\langle \mathbf{Yu}, \mathbf{u}\rangle \geq |\mu|$, because $\langle \mathbf{Xu}, \mathbf{u}\rangle \geq 0$. Taking norms and using $\|\mathbf{Xu}\|^2 \geq \|\mathbf{Yu}\|^2$, which is exactly the hypothesis $\mathbf{A} \succeq \mathbf{B}$, says $|\mu| \geq 2\langle \mathbf{Yu}, \mathbf{u}\rangle$. Together: $|\mu| \geq 2|\mu|$.

Proof. Write $\mathbf{X} = \mathbf{A}^{1/2}$ and $\mathbf{Y} = \mathbf{B}^{1/2}$, both Hermitian and $\succeq 0$ with $\mathbf{X}^2 = \mathbf{A}$ and $\mathbf{Y}^2 = \mathbf{B}$ (Theorem 12.2.1). Then $\mathbf{X} - \mathbf{Y}$ is Hermitian. Suppose, for a contradiction, that $\mathbf{X} - \mathbf{Y} \not\succeq 0$. By Theorem 12.1.4 it has a negative eigenvalue $\mu < 0$; choose a unit eigenvector $\mathbf{u}$, so that

$$\mathbf{Xu} = \mathbf{Yu} + \mu\mathbf{u}.$$

Pairing this with $\mathbf{u}$ and using $\|\mathbf{u}\| = 1$,

$$\langle \mathbf{Xu}, \mathbf{u}\rangle = \langle \mathbf{Yu}, \mathbf{u}\rangle + \mu.$$

All three numbers are real (Proposition 10.6.7), and $\langle \mathbf{Xu}, \mathbf{u}\rangle \geq 0$ because $\mathbf{X} \succeq 0$. Therefore

$$\langle \mathbf{Yu}, \mathbf{u}\rangle \;\geq\; -\mu = |\mu|. \tag{$*$}$$

Now take squared norms. Since $\mathbf{X}$ is Hermitian, $\|\mathbf{Xu}\|^2 = \langle \mathbf{X}^2\mathbf{u}, \mathbf{u}\rangle = \langle \mathbf{Au}, \mathbf{u}\rangle$, and likewise $\|\mathbf{Yu}\|^2 = \langle \mathbf{Bu}, \mathbf{u}\rangle$; so $\mathbf{A} \succeq \mathbf{B}$ gives $\|\mathbf{Xu}\|^2 \geq \|\mathbf{Yu}\|^2$. On the other hand, expanding $\mathbf{Xu} = \mathbf{Yu} + \mu\mathbf{u}$,

$$\|\mathbf{Xu}\|^2 = \|\mathbf{Yu}\|^2 + 2\mu\langle \mathbf{Yu}, \mathbf{u}\rangle + \mu^2,$$

where the cross term is $2\mu\langle \mathbf{Yu}, \mathbf{u}\rangle$ because μ and $\langle \mathbf{Yu}, \mathbf{u}\rangle$ are real. Comparing the two,

$$2\mu\langle \mathbf{Yu}, \mathbf{u}\rangle + \mu^2 \;\geq\; 0.$$

Substituting $\mu = -|\mu|$ turns this into $|\mu|^2 \geq 2|\mu|\langle \mathbf{Yu}, \mathbf{u}\rangle$, and dividing by $|\mu| > 0$ gives

$$|\mu| \;\geq\; 2\langle \mathbf{Yu}, \mathbf{u}\rangle. \tag{$**$}$$

Combining $(*)$ and $(**)$, $|\mu| \geq 2|\mu|$, so $|\mu| \leq 0$ and $\mu = 0$, contradicting $\mu < 0$. Hence $\mathbf{X} - \mathbf{Y} \succeq 0$, which is the assertion. ∎

So among the powers $t \mapsto t^s$, the exponent $s = 1/2$ preserves the Loewner order while $s = 2$ does not. The dividing line is at $s = 1$: the functions preserving the order are called **operator monotone**, and $t \mapsto t^s$ is operator monotone on $[0, \infty)$ exactly for $0 \leq s \leq 1$. Chapter 20 proves this, along with the companion fact that $t \mapsto \log t$ is operator monotone while $t \mapsto e^t$ is not.

12.5.4 Exercises

12.5.4.1 A. Check your understanding

Exercise A1.

(a) Define $\mathbf{A} \succeq \mathbf{B}$, and say on which set of matrices the relation is defined.

(b) Determine whether the following statement is correct, and justify your answer: for Hermitian $\mathbf{A}, \mathbf{B}$, either $\mathbf{A} \succeq \mathbf{B}$ or $\mathbf{B} \succeq \mathbf{A}$.

(c) Determine whether the following statement is correct, and justify your answer: $\mathbf{A} \succeq \mathbf{B}$ implies $a_{ij} \geq b_{ij}$ for all i, j.

(d) State what fails when both sides of $\mathbf{A} \succeq \mathbf{B} \succeq 0$ are squared, and what happens instead when both sides have their square roots taken.

(e) Which clause of Theorem 12.5.3 reverses an inequality, and what is the analogous fact about real numbers?

Solution.

(a) For Hermitian $\mathbf{A}, \mathbf{B} \in M_n(F)$, $\mathbf{A} \succeq \mathbf{B}$ means $\mathbf{A} - \mathbf{B} \succeq 0$, equivalently $\langle \mathbf{A}\mathbf{x}, \mathbf{x} \rangle \geq \langle \mathbf{B}\mathbf{x}, \mathbf{x} \rangle$ for every $\mathbf{x} \in F^n$ (Definition 12.5.1). It is defined on the Hermitian matrices of a fixed size.

(b) Incorrect: the order is partial. $\operatorname{diag}(1, 0)$ and $\operatorname{diag}(0, 1)$ are incomparable, since $\operatorname{diag}(1, -1)$ and $\operatorname{diag}(-1, 1)$ are both indefinite.

(c) Incorrect. $\operatorname{diag}(2, 2) \succeq \left(\begin{smallmatrix} 1 & 1 \\ 1 & 1 \end{smallmatrix}\right)$, because the difference $\left(\begin{smallmatrix} 1 & -1 \\ -1 & 1 \end{smallmatrix}\right)$ has eigenvalues 0 and 2; yet the $(1, 2)$-entries are 0 and 1.

(d) Squaring fails: $\mathbf{A} \succeq \mathbf{B} \succeq 0$ does not give $\mathbf{A}^2 \succeq \mathbf{B}^2$ (Example (Squaring does not preserve the Loewner order)). Taking square roots is legitimate: $\mathbf{A}^{1/2} \succeq \mathbf{B}^{1/2}$ (Proposition 12.5.4).

(e) Clause (d): $\mathbf{A} \succeq \mathbf{B} \succ 0$ gives $\mathbf{B}^{-1} \succeq \mathbf{A}^{-1}$. For real numbers, $a \geq b > 0$ gives $1/b \geq 1/a$.

12.5.4.2 B. Practice

Exercise B1: Decide the relation.

For each pair of real symmetric matrices, determine whether $\mathbf{A} \succeq \mathbf{B}$, whether $\mathbf{B} \succeq \mathbf{A}$, or neither. Justify your answer.

(i) $\mathbf{A} = \begin{pmatrix} 3 & 1 \\ 1 & 3 \end{pmatrix}$, $\mathbf{B} = \mathbf{I}_2$.

(ii) $\mathbf{A} = \begin{pmatrix} 2 & 0 \\ 0 & 1 \end{pmatrix}$, $\mathbf{B} = \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix}$.

(iii) $\mathbf{A} = \begin{pmatrix} 1 & 0 \\ 0 & 3 \end{pmatrix}$, $\mathbf{B} = \begin{pmatrix} 2 & 0 \\ 0 & 1 \end{pmatrix}$.

Solution.

(i) $\mathbf{A} - \mathbf{B} = \left(\begin{smallmatrix} 2 & 1 \\ 1 & 2 \end{smallmatrix}\right)$, with leading principal minors 2 and 3, both > 0, so $\mathbf{A} - \mathbf{B} \succ 0$

by Theorem 12.1.5 and $\mathbf{A} \succ \mathbf{B}$. Then $\mathbf{B} \succeq \mathbf{A}$ would force $\mathbf{A} = \mathbf{B}$ by Proposition 12.5.1, which is false, so $\mathbf{B} \not\succeq \mathbf{A}$.

(ii) $\mathbf{A} - \mathbf{B} = \left(\begin{smallmatrix} 1 & -1 \\ -1 & 0 \end{smallmatrix}\right)$, with determinant $-1 < 0$, so it is indefinite and $\mathbf{A} \not\succeq \mathbf{B}$. Also $\mathbf{B} - \mathbf{A}$ has determinant -1, so $\mathbf{B} \not\succeq \mathbf{A}$. Neither.

(iii) $\mathbf{A} - \mathbf{B} = \operatorname{diag}(-1, 2)$, indefinite; $\mathbf{B} - \mathbf{A} = \operatorname{diag}(1, -2)$, indefinite. Neither. (For diagonal matrices the comparison is entrywise, and the two entries disagree.)

Exercise B2: The order reverses.

Let $\mathbf{A} = \begin{pmatrix} 3 & 1 \\ 1 & 3 \end{pmatrix}$ and $\mathbf{B} = \begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix}$. Verify that $\mathbf{A} \succeq \mathbf{B} \succ 0$, compute $\mathbf{A}^{-1}$ and $\mathbf{B}^{-1}$, and check Theorem 12.5.3 (d) directly. Check the determinant clause as well.

Solution. $\mathbf{A} - \mathbf{B} = \mathbf{I}_2 \succ 0$, so $\mathbf{A} \succ \mathbf{B}$. And $\mathbf{B} \succ 0$, its leading principal minors being 2 and 3. Then $\det \mathbf{A} = 8$, $\det \mathbf{B} = 3$, so

$$\mathbf{A}^{-1} = \frac{1}{8}\begin{pmatrix} 3 & -1 \\ -1 & 3 \end{pmatrix}, \qquad \mathbf{B}^{-1} = \frac{1}{3}\begin{pmatrix} 2 & -1 \\ -1 & 2 \end{pmatrix},$$

and

$$\mathbf{B}^{-1} - \mathbf{A}^{-1} = \frac{1}{24}\begin{pmatrix} 16-9 & -8+3 \\ -8+3 & 16-9 \end{pmatrix} = \frac{1}{24}\begin{pmatrix} 7 & -5 \\ -5 & 7 \end{pmatrix}.$$

Its leading principal minors are $7/24 > 0$ and $(49 - 25)/576 = 1/24 > 0$, so $\mathbf{B}^{-1} \succ \mathbf{A}^{-1}$, as Theorem 12.5.3 (d) predicts. For the determinant clause, $\det \mathbf{A} = 8 \geq 3 = \det \mathbf{B}$; and for the trace, $6 \geq 4$.

Exercise B3: Another failure of squaring.

Let $\mathbf{A} = \begin{pmatrix} 3 & 1 \\ 1 & 1 \end{pmatrix}$ and $\mathbf{B} = \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix}$. Verify that $\mathbf{A} \succeq \mathbf{B} \succeq 0$, and exhibit a vector $\mathbf{x}$ with $\mathbf{x}^{\top}(\mathbf{A}^2 - \mathbf{B}^2)\mathbf{x} < 0$.

Solution. $\mathbf{A} - \mathbf{B} = \operatorname{diag}(2, 0) \succeq 0$, so $\mathbf{A} \succeq \mathbf{B}$; and $\mathbf{x}^{\top}\mathbf{B}\mathbf{x} = (x_1 + x_2)^2 \geq 0$, so $\mathbf{B} \succeq 0$. Squaring,

$$\mathbf{A}^2 = \begin{pmatrix} 10 & 4 \\ 4 & 2 \end{pmatrix}, \qquad \mathbf{B}^2 = \begin{pmatrix} 2 & 2 \\ 2 & 2 \end{pmatrix}, \qquad \mathbf{A}^2 - \mathbf{B}^2 = \begin{pmatrix} 8 & 2 \\ 2 & 0 \end{pmatrix},$$

whose determinant is $-4 < 0$. With $\mathbf{x} = (1, -3)$,

$$\mathbf{x}^{\top}(\mathbf{A}^2 - \mathbf{B}^2)\mathbf{x} = 8 - 12 + 0 = -4 < 0.$$

So $\mathbf{A}^2 \not\succeq \mathbf{B}^2$. (Any $\mathbf{x} = (1, t)$ with $t < -2$ works, since the value is $8 + 4t$.)

12.5.4.3 C. Going deeper

Exercise C1: When squaring does work.

Let $\mathbf{A}, \mathbf{B} \in M_n(F)$ with $\mathbf{A} \succeq \mathbf{B} \succeq 0$ and $\mathbf{AB} = \mathbf{BA}$.

(a) Prove that if $\mathbf{P}, \mathbf{Q} \succeq 0$ and $\mathbf{PQ} = \mathbf{QP}$, then $\mathbf{PQ} \succeq 0$.

(b) Deduce that $\mathbf{A}^2 \succeq \mathbf{B}^2$.

(c) Deduce that $\mathbf{A}^k \succeq \mathbf{B}^k$ for every integer $k \geq 1$.

Hint for (a): $\mathbf{P}^{1/2}$ *is a polynomial in* $\mathbf{P}$.

Solution.

(a) By Theorem 12.2.1, $\mathbf{P}^{1/2}$ is a polynomial in $\mathbf{P}$, so it commutes with every matrix that commutes with $\mathbf{P}$; in particular $\mathbf{P}^{1/2}\mathbf{Q} = \mathbf{Q}\mathbf{P}^{1/2}$. Hence

$$\mathbf{PQ} = \mathbf{P}^{1/2}\mathbf{P}^{1/2}\mathbf{Q} = \mathbf{P}^{1/2}\mathbf{Q}\mathbf{P}^{1/2} = (\mathbf{P}^{1/2})^{*}\mathbf{Q}\mathbf{P}^{1/2},$$

which is $\succeq 0$ by Proposition 12.1.2 (a), since $\mathbf{Q} \succeq 0$ and $\mathbf{P}^{1/2}$ is Hermitian.

(b) Put $\mathbf{P} = \mathbf{A} - \mathbf{B}$ and $\mathbf{Q} = \mathbf{A} + \mathbf{B}$. Both are $\succeq 0$: the first by hypothesis, the second as a sum of two matrices $\succeq 0$, using $\mathbf{A} \succeq \mathbf{B} \succeq 0$ and Proposition 12.5.1. They commute, because $\mathbf{AB} = \mathbf{BA}$ makes $\mathbf{PQ} = \mathbf{A}^2 + \mathbf{AB} - \mathbf{BA} - \mathbf{B}^2 = \mathbf{A}^2 - \mathbf{B}^2$ and $\mathbf{QP} = \mathbf{A}^2 - \mathbf{AB} + \mathbf{BA} - \mathbf{B}^2 = \mathbf{A}^2 - \mathbf{B}^2$ as well. By (a), $\mathbf{A}^2 - \mathbf{B}^2 = \mathbf{PQ} \succeq 0$.

(c) Induction on k. The case $k = 1$ is the hypothesis. Assume $\mathbf{A}^{k-1} \succeq \mathbf{B}^{k-1}$. Then

$$\mathbf{A}^k - \mathbf{B}^k = \mathbf{A}^{k-1}(\mathbf{A} - \mathbf{B}) + (\mathbf{A}^{k-1} - \mathbf{B}^{k-1})\mathbf{B},$$

and each term is $\succeq 0$ by (a). Indeed $\mathbf{A} \succeq 0$ is Hermitian with eigenvalues ≥ 0, so $\mathbf{A}^{k-1}$ is Hermitian with eigenvalues ≥ 0 and hence $\mathbf{A}^{k-1} \succeq 0$ (Theorem 12.1.4); it commutes with $\mathbf{A} - \mathbf{B}$, since $\mathbf{AB} = \mathbf{BA}$. Likewise $\mathbf{A}^{k-1} - \mathbf{B}^{k-1} \succeq 0$ by the induction hypothesis and it commutes with $\mathbf{B} \succeq 0$. Finally a sum of two matrices $\succeq 0$ is $\succeq 0$, directly from Definition 12.1.1.

Exercise C2: Kernels and ranks.

Let $\mathbf{A}, \mathbf{B} \in M_n(F)$ with $\mathbf{A} \succeq \mathbf{B} \succeq 0$.

(a) Prove that $\operatorname{nul}(\mathbf{A}) \subseteq \operatorname{nul}(\mathbf{B})$.

(b) Deduce that $\operatorname{rank}\mathbf{A} \geq \operatorname{rank}\mathbf{B}$.

(c) Give an example with $\mathbf{A} \succeq \mathbf{B} \succeq 0$ and $\operatorname{rank}\mathbf{A} = \operatorname{rank}\mathbf{B}$ but $\mathbf{A} \neq \mathbf{B}$.

Hint for (a): pair $\mathbf{Ax} = \mathbf{0}$ *with* $\mathbf{x}$*, then use* $\mathbf{B}^{1/2}$.

Solution.

(a) Let $\mathbf{x} \in \operatorname{nul}(\mathbf{A})$. Then $\langle \mathbf{Ax}, \mathbf{x}\rangle = 0$, and $0 \leq \langle \mathbf{Bx}, \mathbf{x}\rangle \leq \langle \mathbf{Ax}, \mathbf{x}\rangle = 0$, so $\langle \mathbf{Bx}, \mathbf{x}\rangle = 0$. Writing $\mathbf{B} = \mathbf{B}^{1/2}\mathbf{B}^{1/2}$ with $\mathbf{B}^{1/2}$ Hermitian (Theorem 12.2.1),

$$0 = \langle \mathbf{Bx}, \mathbf{x}\rangle = \langle \mathbf{B}^{1/2}\mathbf{x}, \mathbf{B}^{1/2}\mathbf{x}\rangle = \|\mathbf{B}^{1/2}\mathbf{x}\|^2,$$

so $\mathbf{B}^{1/2}\mathbf{x} = \mathbf{0}$ and hence $\mathbf{Bx} = \mathbf{B}^{1/2}(\mathbf{B}^{1/2}\mathbf{x}) = \mathbf{0}$.

(b) By (a), $\operatorname{nullity}\mathbf{A} \leq \operatorname{nullity}\mathbf{B}$, and by Rank–Nullity (Theorem 3.3.1) applied to both matrices on F^n, $\operatorname{rank}\mathbf{A} = n - \operatorname{nullity}\mathbf{A} \geq n - \operatorname{nullity}\mathbf{B} = \operatorname{rank}\mathbf{B}$.

(c) $\mathbf{A} = \operatorname{diag}(2, 2)$ and $\mathbf{B} = \operatorname{diag}(1, 1)$: both have rank 2, $\mathbf{A} - \mathbf{B} = \mathbf{I}_2 \succeq 0$, and $\mathbf{A} \neq \mathbf{B}$.

Exercise C3: Largest eigenvalue of a sum.

Let $\mathbf{A}, \mathbf{B} \in M_n(F)$ be Hermitian.

(a) Prove that $\lambda_1(\mathbf{A})\mathbf{I} \succeq \mathbf{A}$, and deduce $\lambda_1(\mathbf{A}+\mathbf{B}) \le \lambda_1(\mathbf{A}) + \lambda_1(\mathbf{B})$.

(b) Deduce that if $\mathbf{A} \succeq \mathbf{B}$, then $0 \le \lambda_1(\mathbf{A}) - \lambda_1(\mathbf{B}) \le \lambda_1(\mathbf{A}-\mathbf{B})$.

Solution.

(a) The matrix $\lambda_1(\mathbf{A})\mathbf{I} - \mathbf{A}$ is Hermitian with eigenvalues $\lambda_1(\mathbf{A}) - \lambda_i(\mathbf{A}) \ge 0$, so it is $\succeq 0$ by Theorem 12.1.4; that is $\lambda_1(\mathbf{A})\mathbf{I} \succeq \mathbf{A}$. Adding the same inequality for $\mathbf{B}$, and using that a sum of two matrices $\succeq 0$ is again $\succeq 0$ (Exercise (C2: The cone of positive matrices) (a)),

$$\big(\lambda_1(\mathbf{A}) + \lambda_1(\mathbf{B})\big)\mathbf{I} \;\succeq\; \mathbf{A} + \mathbf{B}.$$

By Theorem 12.5.3 (b) applied to this pair, $\lambda_1(\mathbf{A})+\lambda_1(\mathbf{B}) = \lambda_1\big((\lambda_1(\mathbf{A})+\lambda_1(\mathbf{B}))\mathbf{I}\big) \ge \lambda_1(\mathbf{A}+\mathbf{B})$.

(b) Write $\mathbf{A} = \mathbf{B} + (\mathbf{A}-\mathbf{B})$. Applying (a) to the pair $\mathbf{B}$ and $\mathbf{A}-\mathbf{B}$,

$$\lambda_1(\mathbf{A}) \le \lambda_1(\mathbf{B}) + \lambda_1(\mathbf{A}-\mathbf{B}),$$

so $\lambda_1(\mathbf{A}) - \lambda_1(\mathbf{B}) \le \lambda_1(\mathbf{A}-\mathbf{B})$. For the lower bound, $\mathbf{A} \succeq \mathbf{B}$ gives $\lambda_1(\mathbf{A}) \ge \lambda_1(\mathbf{B})$ by Theorem 12.5.3 (b). Note that (a) itself used no order hypothesis at all; only the lower bound needs $\mathbf{A} \succeq \mathbf{B}$.

12.6 Positive Matrices in Blocks

Chapter 7 cut a matrix into blocks, ran one step of elimination, and gave a name to what was left in the far corner: the Schur complement. Section 1 of this chapter met that same quantity as a single number, in the induction that proved Sylvester's criterion. This section puts the two together. For a Hermitian matrix split into blocks, positive definiteness can be decided one block at a time, and the deciding quantity is the Schur complement; two determinant inequalities, Fischer's and Hadamard's, then come almost for free.

Throughout, $F = \mathbb{R}$ or $F = \mathbb{C}$, and F^n carries the standard inner product.

12.6.1 What the blocks of a positive matrix must satisfy

A Hermitian matrix cut into blocks of sizes k and l has a shape forced on it. Suppose

$$\mathbf{M} = \begin{pmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{D} & \mathbf{C} \end{pmatrix} \in M_{k+l}(F),$$

with $\mathbf{A} \in M_k(F)$, $\mathbf{B} \in M_{k\times l}(F)$, $\mathbf{D} \in M_{l\times k}(F)$ and $\mathbf{C} \in M_l(F)$. Starring a block matrix

transposes the arrangement and stars each block, so $\mathbf{M}^* = \mathbf{M}$ says exactly three things: $\mathbf{A}^* = \mathbf{A}$, $\mathbf{C}^* = \mathbf{C}$, and $\mathbf{D} = \mathbf{B}^*$. A Hermitian $\mathbf{M}$ is therefore always of the form

$$\mathbf{M} = \begin{pmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{B}^* & \mathbf{C} \end{pmatrix}$$

with $\mathbf{A}$ and $\mathbf{C}$ Hermitian and $\mathbf{B}$ unrestricted, and we write it this way from now on.

Two necessary conditions for positivity are immediate. The vectors of F^{k+l} whose last l coordinates vanish form a copy of F^k, and on them the quadratic form of $\mathbf{M}$ is the quadratic form of $\mathbf{A}$:

$$\begin{pmatrix} \mathbf{x} \\ \mathbf{0} \end{pmatrix}^* \mathbf{M} \begin{pmatrix} \mathbf{x} \\ \mathbf{0} \end{pmatrix} = \mathbf{x}^* \mathbf{A} \mathbf{x}, \qquad \begin{pmatrix} \mathbf{0} \\ \mathbf{y} \end{pmatrix}^* \mathbf{M} \begin{pmatrix} \mathbf{0} \\ \mathbf{y} \end{pmatrix} = \mathbf{y}^* \mathbf{C} \mathbf{y}.$$

So $\mathbf{M} \succeq 0$ forces $\mathbf{A} \succeq 0$ and $\mathbf{C} \succeq 0$. This is the statement that a principal submatrix of a positive semidefinite matrix is positive semidefinite, used already in the proof of Theorem 12.1.4, here for the two index blocks $\{1, \dots, k\}$ and $\{k+1, \dots, k+l\}$.

The two conditions are not sufficient, and the smallest counterexample has $k = l = 1$:

$$\mathbf{M} = \begin{pmatrix} 0 & 1 \\ 1 & 1 \end{pmatrix}, \qquad \mathbf{A} = (0) \succeq 0, \quad \mathbf{C} = (1) \succ 0.$$

Here $\det \mathbf{M} = -1 < 0$, so $\mathbf{M} \not\succeq 0$ by Theorem 12.1.4 (e). Something must couple $\mathbf{B}$ to $\mathbf{A}$ and $\mathbf{C}$, and the 2×2 case already says what. For $\mathbf{M} = \left(\begin{smallmatrix} a & b \\ \bar{b} & c \end{smallmatrix}\right)$ Hermitian, Example (The 2×2 Test) gives $\mathbf{M} \succ 0$ if and only if $a > 0$ and $ac - |b|^2 > 0$. Divide the second condition by the positive number a:

$$c - \bar{b}\, a^{-1} b > 0.$$

Written with $\mathbf{B} = (b)$, so that $\mathbf{B}^* = (\bar{b})$, the left-hand side is the Schur complement $\mathbf{M}/\mathbf{A}$ of Definition 7.3.1. The general statement now writes itself: replace the scalars by blocks.

12.6.2 Testing one block at a time

Theorem 12.6.1 — Positive Definiteness Block by Block

Let $k, l \geq 1$ and let

$$\mathbf{M} = \begin{pmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{B}^* & \mathbf{C} \end{pmatrix} \in M_{k+l}(F)$$

be Hermitian, with $\mathbf{A} \in M_k(F)$, $\mathbf{B} \in M_{k \times l}(F)$ and $\mathbf{C} \in M_l(F)$.

(a) If $\mathbf{M} \succeq 0$, then $\mathbf{A} \succeq 0$ and $\mathbf{C} \succeq 0$. If $\mathbf{M} \succ 0$, then $\mathbf{A} \succ 0$ and $\mathbf{C} \succ 0$.

(b) Suppose $\mathbf{A} \succ 0$. Then $\mathbf{A}$ is invertible, the Schur complement

$$\mathbf{M}/\mathbf{A} = \mathbf{C} - \mathbf{B}^*\mathbf{A}^{-1}\mathbf{B} \in M_l(F)$$

is Hermitian, and

$$\mathbf{M} \succ 0 \iff \mathbf{M}/\mathbf{A} \succ 0, \qquad \mathbf{M} \succeq 0 \iff \mathbf{M}/\mathbf{A} \succeq 0.$$

Idea. Everything is one congruence. Chapter 7's block elimination clears $\mathbf{B}$ and $\mathbf{B}^*$ at once and leaves $\mathbf{A}$ and $\mathbf{M}/\mathbf{A}$ on the diagonal; for a Hermitian $\mathbf{M}$ the two outer factors of that elimination are adjoint to each other, because the row operation and the column operation are the same operation seen twice. So the elimination is a congruence $\mathbf{S}^*\mathbf{M}\mathbf{S}$, and Proposition 12.1.2 says that a congruence by an invertible matrix neither creates nor destroys positivity. All that remains is to read the verdict off a block **diagonal** matrix, where the quadratic form splits into two independent pieces. This is the step $(*)$ of Section 1's proof of Sylvester's criterion, with the last coordinate replaced by a block of l coordinates.

Proof.

(a) Let $\mathbf{x} \in F^k$ and put $\mathbf{v} = (\mathbf{x}, \mathbf{0}) \in F^{k+l}$. By Theorem 7.1.1, $\mathbf{M}\mathbf{v} = (\mathbf{A}\mathbf{x}, \mathbf{B}^*\mathbf{x})$, and hence $\mathbf{v}^*\mathbf{M}\mathbf{v} = \mathbf{x}^*\mathbf{A}\mathbf{x}$. If $\mathbf{M} \succeq 0$, the left side is ≥ 0 for every $\mathbf{x}$, so $\mathbf{A} \succeq 0$; if $\mathbf{M} \succ 0$, then $\mathbf{x} \neq \mathbf{0}$ forces $\mathbf{v} \neq \mathbf{0}$ and the left side is > 0, so $\mathbf{A} \succ 0$. The same argument with $\mathbf{v} = (\mathbf{0}, \mathbf{y})$ gives the statements for $\mathbf{C}$.

(b) Since $\mathbf{A} \succ 0$, every eigenvalue of $\mathbf{A}$ is positive (Theorem 12.1.5 (b)), so $0 \notin \operatorname{spec}(\mathbf{A})$ and $\mathbf{A}$ is invertible (Theorem 8.2.6). Also $(\mathbf{A}^{-1})^* = (\mathbf{A}^*)^{-1} = \mathbf{A}^{-1}$, so

$$(\mathbf{M}/\mathbf{A})^* = \mathbf{C}^* - \mathbf{B}^*(\mathbf{A}^{-1})^*\mathbf{B} = \mathbf{C} - \mathbf{B}^*\mathbf{A}^{-1}\mathbf{B} = \mathbf{M}/\mathbf{A},$$

and $\mathbf{M}/\mathbf{A}$ is Hermitian. Put

$$\mathbf{S} = \begin{pmatrix} \mathbf{I}_k & -\mathbf{A}^{-1}\mathbf{B} \\ 0 & \mathbf{I}_l \end{pmatrix}, \qquad \mathbf{S}^* = \begin{pmatrix} \mathbf{I}_k & 0 \\ -\mathbf{B}^*\mathbf{A}^{-1} & \mathbf{I}_l \end{pmatrix},$$

the second because $\mathbf{A}^{-1}$ is Hermitian. By Theorem 7.1.5, $\mathbf{S}$ is invertible. Two applications of Theorem 7.1.1 give

$$\begin{aligned} \mathbf{M}\mathbf{S} &= \begin{pmatrix} \mathbf{A} & \mathbf{B} - \mathbf{A}\mathbf{A}^{-1}\mathbf{B} \\ \mathbf{B}^* & \mathbf{C} - \mathbf{B}^*\mathbf{A}^{-1}\mathbf{B} \end{pmatrix} = \begin{pmatrix} \mathbf{A} & 0 \\ \mathbf{B}^* & \mathbf{M}/\mathbf{A} \end{pmatrix}, \\ \mathbf{S}^*(\mathbf{M}\mathbf{S}) &= \begin{pmatrix} \mathbf{A} & 0 \\ \mathbf{B}^* - \mathbf{B}^*\mathbf{A}^{-1}\mathbf{A} & \mathbf{M}/\mathbf{A} \end{pmatrix} = \begin{pmatrix} \mathbf{A} & 0 \\ 0 & \mathbf{M}/\mathbf{A} \end{pmatrix}. \end{aligned} \tag{$*$}$$

Write $\mathbf{N} = \mathbf{A} \oplus (\mathbf{M}/\mathbf{A})$ for that block diagonal matrix. For $\mathbf{y} = (\mathbf{y}_1, \mathbf{y}_2) \in F^k \times F^l$,

$$\mathbf{y}^*\mathbf{N}\mathbf{y} = \mathbf{y}_1^*\mathbf{A}\mathbf{y}_1 + \mathbf{y}_2^*(\mathbf{M}/\mathbf{A})\mathbf{y}_2. \tag{$\dagger$}$$

Claim. Given $\mathbf{A} \succ 0$: $\mathbf{N} \succ 0$ if and only if $\mathbf{M}/\mathbf{A} \succ 0$, and $\mathbf{N} \succeq 0$ if and only if $\mathbf{M}/\mathbf{A} \succeq 0$.

Proof. Taking $\mathbf{y}_1 = \mathbf{0}$ in (†) shows that positivity of $\mathbf{N}$, weak or strict, passes to $\mathbf{M}/\mathbf{A}$, since $\mathbf{y}_2 \neq \mathbf{0}$ forces $\mathbf{y} \neq \mathbf{0}$. Conversely, suppose $\mathbf{M}/\mathbf{A} \succeq 0$; then both terms of (†) are ≥ 0, so $\mathbf{N} \succeq 0$. If moreover $\mathbf{M}/\mathbf{A} \succ 0$, then for $\mathbf{y} \neq \mathbf{0}$ at least one of $\mathbf{y}_1$, $\mathbf{y}_2$ is non-zero, so at least one term of (†) is > 0 while the other is ≥ 0; hence $\mathbf{N} \succ 0$.

■

Finally $\mathbf{S}$ is invertible, so Proposition 12.1.2 (b) gives $\mathbf{M} \succ 0$ if and only if $\mathbf{S}^*\mathbf{M}\mathbf{S} = \mathbf{N} \succ 0$. For the weak version, Proposition 12.1.2 (a) applied to $\mathbf{S}$ turns $\mathbf{M} \succeq 0$ into $\mathbf{N} \succeq 0$, and applied to $\mathbf{S}^{-1}$, together with $(\mathbf{S}^{-1})^*\mathbf{N}\mathbf{S}^{-1} = \mathbf{M}$, turns $\mathbf{N} \succeq 0$ back into $\mathbf{M} \succeq 0$. Combining with the claim proves (b).

■

The identity (∗) is Theorem 7.3.1 (a) in disguise. That theorem factors $\mathbf{M} = Ł\,\mathbf{N}\,\mathbf{U}$ with Ł lower and $\mathbf{U}$ upper block triangular; here Ł and $\mathbf{U}$ are $(\mathbf{S}^{-1})^*$ and $\mathbf{S}^{-1}$, so the two outer factors are adjoint to each other and the factorization is a **congruence**, not merely an equivalence. Taking determinants in (∗) recovers Theorem 7.3.2,

$$\det \mathbf{M} = \det \mathbf{A} \cdot \det(\mathbf{M}/\mathbf{A}),$$

which is the form in which we use it below.

Chapter 7 closed its treatment of Schur complements by observing that when $\mathbf{M}$ is real symmetric the complement $\mathbf{M}/\mathbf{A}$ is symmetric again, and promising that "Chapter 12 uses Schur complements to test whether $\mathbf{M}$ is positive definite one block at a time". Theorem 12.6.1 is that test, and part (b) says exactly what the promise says: once the corner block $\mathbf{A}$ is known to be positive definite, the whole of $\mathbf{M}$ is positive definite precisely when the smaller matrix $\mathbf{M}/\mathbf{A}$ is. A question about $k + l$ coordinates has become a question about l of them.

It also finishes what Section 1 started. There, in the induction proving Sylvester's criterion, the matrix was split with $k = n - 1$ and $l = 1$; the shear $\mathbf{S}$ was the matrix above with the column $\mathbf{b}$ in place of $\mathbf{B}$; and the congruence came out as $\mathbf{S}^*\mathbf{A}\mathbf{S} = \mathbf{A}' \oplus (s)$ with the single number $s = d - \mathbf{b}^*\mathbf{A}'^{-1}\mathbf{b}$ in the corner. That section promised that Section 6 would replace the scalar by a block. The scalar has become $\mathbf{M}/\mathbf{A}$, and the argument is word for word the same one.

Example. (A 4×4 Tested in 2×2 Blocks)

Decide whether each of

$$\mathbf{M} = \left(\begin{array}{cc|cc} 2 & 1 & 1 & 0 \\ 1 & 1 & 1 & 1 \\ \hline 1 & 1 & 3 & 2 \\ 0 & 1 & 2 & 4 \end{array}\right), \qquad \mathbf{M}' = \left(\begin{array}{cc|cc} 2 & 1 & 1 & 0 \\ 1 & 1 & 1 & 1 \\ \hline 1 & 1 & 2 & 0 \\ 0 & 1 & 0 & 2 \end{array}\right)$$

is positive definite, using the displayed partition. For the one that is not, exhibit a vector on which the quadratic form is negative.

Solution. Both matrices are real symmetric with the same corner and border,

$$\mathbf{A} = \begin{pmatrix} 2 & 1 \\ 1 & 1 \end{pmatrix}, \qquad \mathbf{B} = \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix}.$$

Step 1: the corner. The leading principal minors of $\mathbf{A}$ are 2 and $2-1=1$, both positive, so $\mathbf{A} \succ 0$ by Sylvester's criterion (Theorem 12.1.5 (d)) and Theorem 12.6.1 (b) applies. Since $\det \mathbf{A} = 1$, Theorem 0.9.8 gives $\mathbf{A}^{-1} = \left(\begin{smallmatrix} 1 & -1 \\ -1 & 2 \end{smallmatrix}\right)$.

Step 2: the coupling term. It is the same for both matrices:

$$\mathbf{B}^\top \mathbf{A}^{-1} = \begin{pmatrix} 0 & 1 \\ -1 & 2 \end{pmatrix}, \qquad \mathbf{B}^\top \mathbf{A}^{-1} \mathbf{B} = \begin{pmatrix} 1 & 1 \\ 1 & 2 \end{pmatrix}.$$

Step 3: the complements. For $\mathbf{M}$, with $\mathbf{C} = \left(\begin{smallmatrix} 3 & 2 \\ 2 & 4 \end{smallmatrix}\right)$,

$$\mathbf{M}/\mathbf{A} = \begin{pmatrix} 3 & 2 \\ 2 & 4 \end{pmatrix} - \begin{pmatrix} 1 & 1 \\ 1 & 2 \end{pmatrix} = \begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix},$$

whose leading principal minors are 2 and 3. So $\mathbf{M}/\mathbf{A} \succ 0$, hence $\mathbf{M} \succ 0$. As a by-product, $\det \mathbf{M} = \det \mathbf{A} \cdot \det(\mathbf{M}/\mathbf{A}) = 1 \cdot 3 = 3$.

For $\mathbf{M}'$, with $\mathbf{C}' = \left(\begin{smallmatrix} 2 & 0 \\ 0 & 2 \end{smallmatrix}\right)$,

$$\mathbf{M}'/\mathbf{A} = \begin{pmatrix} 2 & 0 \\ 0 & 2 \end{pmatrix} - \begin{pmatrix} 1 & 1 \\ 1 & 2 \end{pmatrix} = \begin{pmatrix} 1 & -1 \\ -1 & 0 \end{pmatrix},$$

whose determinant is -1. So $\mathbf{M}'/\mathbf{A}$ is not even positive semidefinite, and $\mathbf{M}'$ is not positive definite.

Step 4: the witness. The congruence $(*)$ turns a bad vector for $\mathbf{M}'/\mathbf{A}$ into a bad vector for $\mathbf{M}'$. Here $\mathbf{y}_2 = (1,1)$ gives $\mathbf{y}_2^\top (\mathbf{M}'/\mathbf{A})\mathbf{y}_2 = 1-1-1+0 = -1$, so $\mathbf{y} = (0,0,1,1)$ satisfies $\mathbf{y}^\top(\mathbf{S}^\top \mathbf{M}' \mathbf{S})\mathbf{y} = -1$, and $\mathbf{x} = \mathbf{S}\mathbf{y}$ satisfies $\mathbf{x}^\top \mathbf{M}' \mathbf{x} = -1$. Since $-\mathbf{A}^{-1}\mathbf{B} = \left(\begin{smallmatrix} 0 & 1 \\ -1 & -2 \end{smallmatrix}\right)$, we get $\mathbf{x} = (1,-3,1,1)$. Checking directly, $\mathbf{M}'\mathbf{x} = (0,0,0,-1)$ and $\mathbf{x}^\top(\mathbf{M}'\mathbf{x}) = 0+0+0-1 = -1$.

One 2×2 inverse and one 2×2 product replaced four leading principal minors of a 4×4 matrix. And when the answer is "no", the congruence hands back an explicit vector, which a determinant test never does.

Quick check. Let $\mathbf{A} \succ 0$. What is $\mathbf{M}/\mathbf{A}$ when $\mathbf{B} = 0$, and what does Theorem 12.6.1 (b) say in that case?

Solution. When $\mathbf{B} = 0$ the Schur complement is $\mathbf{M}/\mathbf{A} = \mathbf{C} - 0 = \mathbf{C}$, so the criterion reads: $\mathbf{M} \succ 0$ if and only if $\mathbf{C} \succ 0$. That is the right answer, since $\mathbf{M} = \mathbf{A} \oplus \mathbf{C}$ is then block diagonal and (†) says its quadratic form is the sum of the two separate quadratic forms. The general case is this case after the change of variable $\mathbf{S}$.

Warning. **The corner must be definite, not merely semidefinite.** If $\mathbf{A}$ is singular, then $\mathbf{A}^{-1}$ does not exist, $\mathbf{M}/\mathbf{A}$ is undefined, and Theorem 12.6.1 (b) says nothing

whatsoever. This is a real obstruction, not a gap in the proof. The matrix $\left(\begin{smallmatrix} 0 & 1 \\ 1 & 1 \end{smallmatrix}\right)$ above has $\mathbf{A} \succeq 0$ and $\mathbf{C} \succ 0$ and is **not** positive semidefinite, while $\left(\begin{smallmatrix} 0 & 0 \\ 0 & 1 \end{smallmatrix}\right)$, with the same $\mathbf{A}$ and the same $\mathbf{C}$, **is**. The two differ only in $\mathbf{B}$, so no criterion that ignores $\mathbf{B}$ can separate them.

Remark. There is a criterion for the semidefinite case with a singular corner, and it has three clauses instead of one: for Hermitian $\mathbf{M}$, one has $\mathbf{M} \succeq 0$ exactly when $\mathbf{A} \succeq 0$, every column of $\mathbf{B}$ lies in the column space of $\mathbf{A}$, and $\mathbf{C} - \mathbf{B}^{*}\mathbf{A}^{+}\mathbf{B} \succeq 0$. The middle clause is what the warning's first matrix violates. The matrix $\mathbf{A}^{+}$ in the third clause is the Moore–Penrose pseudoinverse; it agrees with $\mathbf{A}^{-1}$ when $\mathbf{A}$ is invertible, and it is built from the singular values of $\mathbf{A}$ in Section 11 of this chapter. The statement and its proof belong there, with the tools they need. This section keeps the definite case, which is the one the rest of the chapter consumes.

12.6.3 Fischer's inequality

The congruence $(*)$ computes $\det \mathbf{M}$ as $\det \mathbf{A} \cdot \det(\mathbf{M}/\mathbf{A})$. If the Schur complement could be compared with $\mathbf{C}$, that would bound $\det \mathbf{M}$ by $\det \mathbf{A} \det \mathbf{C}$ — and it can be, because $\mathbf{C}$ is the Schur complement plus something positive:

$$\mathbf{C} = (\mathbf{M}/\mathbf{A}) + \mathbf{B}^{*}\mathbf{A}^{-1}\mathbf{B}.$$

So what is needed is that adding a positive semidefinite matrix never decreases a determinant. That is the next lemma, and it is where the square root of Section 2 earns its keep.

Lemma 12.6.2 — Adding a positive matrix does not decrease the determinant

Let $\mathbf{P}, \mathbf{Q} \in M_n(F)$ with $\mathbf{P} \succ 0$ and $\mathbf{Q} \succeq 0$. Then

$$\det(\mathbf{P} + \mathbf{Q}) \geq \det \mathbf{P} > 0,$$

with equality if and only if $\mathbf{Q} = 0$.

Idea. Whiten: divide the problem by $\mathbf{P}$ on both sides, using the inverse of $\mathbf{P}^{1/2}$. The sum $\mathbf{P} + \mathbf{Q}$ becomes $\mathbf{I} + \mathbf{K}$ with $\mathbf{K} \succeq 0$, and the determinant of $\mathbf{I} + \mathbf{K}$ is $\prod_i (1 + \mu_i)$ over the eigenvalues $\mu_i \geq 0$ of $\mathbf{K}$. A product of numbers ≥ 1 is ≥ 1, and it equals 1 only when every factor does.

Proof. By Theorem 12.2.1 the matrix $\mathbf{P}^{1/2} \succeq 0$ exists, and it is invertible because $\mathbf{P}$ is (Theorem 12.2.1 (c)). Write $\mathbf{R} = (\mathbf{P}^{1/2})^{-1}$, which is Hermitian, being the inverse of a Hermitian matrix. Since $\mathbf{P}^{1/2}\mathbf{R} = \mathbf{I}$ and $(\mathbf{P}^{1/2})^{2} = \mathbf{P}$,

$$\mathbf{P}^{1/2}\big(\mathbf{I} + \mathbf{R}\mathbf{Q}\mathbf{R}\big)\mathbf{P}^{1/2} = \mathbf{P} + \mathbf{Q}.$$

Put $\mathbf{K} = \mathbf{R}^{*}\mathbf{Q}\mathbf{R} = \mathbf{R}\mathbf{Q}\mathbf{R}$, so that $\mathbf{K} \succeq 0$ by Proposition 12.1.2 (a). Taking determinants

with Theorem 6.5.4, and using $(\det \mathbf{P}^{1/2})^2 = \det \mathbf{P}$,

$$\det(\mathbf{P}+\mathbf{Q}) = \det \mathbf{P} \cdot \det(\mathbf{I}+\mathbf{K}).$$

Now $\mathbf{K}$ is Hermitian, so $\mathbf{K} = \mathbf{U}\operatorname{diag}(\mu_1,\dots,\mu_n)\mathbf{U}^*$ with $\mathbf{U}$ unitary, by Corollary 11.4.3 over $\mathbb{C}$ and Corollary 11.5.2 over $\mathbb{R}$; and every $\mu_i \geq 0$ by Theorem 12.1.4 (b). Then $\mathbf{I}+\mathbf{K} = \mathbf{U}\operatorname{diag}(1+\mu_1,\dots,1+\mu_n)\mathbf{U}^*$, so

$$\det(\mathbf{I}+\mathbf{K}) = \prod_{i=1}^{n}(1+\mu_i) \geq 1,$$

each factor being ≥ 1. Also $\det \mathbf{P} > 0$, since the eigenvalues of $\mathbf{P}$ are positive (Theorem 12.1.5 (b)) and the determinant is their product. Hence $\det(\mathbf{P}+\mathbf{Q}) \geq \det \mathbf{P} > 0$.

For the equality case, the product equals 1 exactly when every $\mu_i = 0$, that is when $\mathbf{K} = \mathbf{U}\,0\,\mathbf{U}^* = 0$, and then $\mathbf{Q} = \mathbf{P}^{1/2}\mathbf{K}\mathbf{P}^{1/2} = 0$. Conversely $\mathbf{Q} = 0$ gives equality. This proves the lemma.

■

Remark. Section 5 states this in its natural generality: the determinant is monotone for the Loewner order, so $\mathbf{A} \succeq \mathbf{B} \succeq 0$ implies $\det \mathbf{A} \geq \det \mathbf{B}$. The special case proved here, in which the smaller of the two matrices is definite, is all this section and the next one need, and its proof is short enough to keep local.

Corollary 12.6.3 — Fischer's Inequality

Let $\mathbf{M} = \left(\begin{smallmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{B}^* & \mathbf{C} \end{smallmatrix}\right) \in M_{k+l}(F)$ with $\mathbf{M} \succeq 0$, where $\mathbf{A} \in M_k(F)$ and $\mathbf{C} \in M_l(F)$. Then

$$\det \mathbf{M} \leq \det \mathbf{A} \cdot \det \mathbf{C}.$$

If $\mathbf{M} \succ 0$, equality holds if and only if $\mathbf{B} = 0$.

Idea. Do the definite case first and reach the general case by a limit. For $\mathbf{M} \succ 0$ the Schur complement exists, the determinant splits as $\det \mathbf{A}\det(\mathbf{M}/\mathbf{A})$, and $\det \mathbf{C} \geq \det(\mathbf{M}/\mathbf{A})$ by Lemma 12.6.2 applied to $\mathbf{C} = (\mathbf{M}/\mathbf{A}) + \mathbf{B}^*\mathbf{A}^{-1}\mathbf{B}$. For $\mathbf{M} \succeq 0$, apply the definite case to $\mathbf{M}+t\mathbf{I}$ and let t shrink to 0: both sides are polynomials in t.

Proof. Case 1: $\mathbf{M} \succ 0$. By Theorem 12.6.1 (a), $\mathbf{A} \succ 0$, and by (b), $\mathbf{M}/\mathbf{A} \succ 0$. By Theorem 7.3.2,

$$\det \mathbf{M} = \det \mathbf{A} \cdot \det(\mathbf{M}/\mathbf{A}).$$

The matrix $\mathbf{A}^{-1}$ is positive definite. Indeed the eigenvalues of $\mathbf{A}$ are positive (Theorem 12.1.5 (b)), so $\mathbf{A}$ is invertible (Theorem 8.2.6); the identity $(\mathbf{A}^{-1})^* = (\mathbf{A}^*)^{-1} = \mathbf{A}^{-1}$ makes $\mathbf{A}^{-1}$ Hermitian; and Proposition 12.1.2 (b) with the invertible $\mathbf{S} = \mathbf{A}^{-1}$ turns $\mathbf{S}^*\mathbf{A}\mathbf{S} = \mathbf{A}^{-1}\mathbf{A}\mathbf{A}^{-1} = \mathbf{A}^{-1}$ into $\mathbf{A}^{-1} \succ 0$. (This is Exercise (B3: The inverse of a

positive definite matrix).) So $\mathbf{Q} := \mathbf{B}^*\mathbf{A}^{-1}\mathbf{B} \succeq 0$ by Proposition 12.1.2 (a) with $\mathbf{S} = \mathbf{B}$. Since $\mathbf{C} = (\mathbf{M}/\mathbf{A}) + \mathbf{Q}$, Lemma 12.6.2 with $\mathbf{P} = \mathbf{M}/\mathbf{A}$ gives $\det \mathbf{C} \geq \det(\mathbf{M}/\mathbf{A})$, with equality if and only if $\mathbf{Q} = 0$. Multiplying by $\det \mathbf{A} > 0$,

$$\det \mathbf{M} = \det \mathbf{A} \det(\mathbf{M}/\mathbf{A}) \leq \det \mathbf{A} \det \mathbf{C},$$

with equality if and only if $\mathbf{B}^*\mathbf{A}^{-1}\mathbf{B} = 0$.

It remains to see that $\mathbf{B}^*\mathbf{A}^{-1}\mathbf{B} = 0$ holds only for $\mathbf{B} = 0$. Let $\mathbf{R} = (\mathbf{A}^{1/2})^{-1}$, a Hermitian matrix with $\mathbf{R}^2 = \mathbf{A}^{-1}$, as in the proof of Lemma 12.6.2. Then $\mathbf{B}^*\mathbf{A}^{-1}\mathbf{B} = (\mathbf{RB})^*(\mathbf{RB})$, whose (j, j) entry is the squared norm of the j-th column of $\mathbf{RB}$. If the whole matrix is 0, every column of $\mathbf{RB}$ is $\mathbf{0}$, so $\mathbf{RB} = 0$ and $\mathbf{B} = \mathbf{A}^{1/2}(\mathbf{RB}) = 0$. The converse is clear.

Case 2: $\mathbf{M} \succeq 0$. For real $t > 0$ the matrix $\mathbf{M} + t\mathbf{I}_{k+l}$ is Hermitian with $\mathbf{v}^*(\mathbf{M} + t\mathbf{I})\mathbf{v} = \mathbf{v}^*\mathbf{M}\mathbf{v} + t\|\mathbf{v}\|^2 > 0$ for $\mathbf{v} \neq \mathbf{0}$, so $\mathbf{M} + t\mathbf{I} \succ 0$. Its blocks are $\mathbf{A} + t\mathbf{I}_k$, $\mathbf{B}$ and $\mathbf{C} + t\mathbf{I}_l$, so Case 1 gives

$$\det(\mathbf{M} + t\mathbf{I}) \leq \det(\mathbf{A} + t\mathbf{I}_k) \cdot \det(\mathbf{C} + t\mathbf{I}_l)$$

for every $t > 0$. A determinant is a polynomial in the entries (Theorem 6.4.3), and the entries here are polynomials in t, so both sides are polynomial, hence continuous, functions of t. Letting t decrease to 0 preserves the inequality, and at $t = 0$ it reads $\det \mathbf{M} \leq \det \mathbf{A} \det \mathbf{C}$. This proves the corollary.

■

The inequality says that for a positive matrix the off-diagonal blocks are a liability: they can only shrink the determinant, and they cost nothing only when they are absent. Applying it repeatedly, to finer and finer partitions, gives the classical case in which every block is 1×1. That is the next result.

12.6.4 Hadamard's inequality

Theorem 12.6.4 — Hadamard's Inequality (a) Let $\mathbf{A} \in M_n(F)$ with $\mathbf{A} \succeq 0$. Then

$$\det \mathbf{A} \leq a_{11}a_{22}\cdots a_{nn},$$

with equality if and only if $\mathbf{A}$ is diagonal or some $a_{ii} = 0$.

(b) Let $\mathbf{B} \in M_n(F)$ have columns $\mathbf{b}_1, \ldots, \mathbf{b}_n$. Then

$$|\det \mathbf{B}| \leq \|\mathbf{b}_1\|\,\|\mathbf{b}_2\|\cdots\|\mathbf{b}_n\|,$$

with equality if and only if the columns are pairwise orthogonal or some column is $\mathbf{0}$.

Idea. Part (a) is Fischer's inequality with $k = 1$, applied again and again: peel off the first row and column, bound $\det \mathbf{A}$ by $a_{11} \det \mathbf{A}'$, and induct on the size. Part (b) is part (a) for the Gram matrix $\mathbf{A} = \mathbf{B}^*\mathbf{B}$, whose diagonal entries are the squared lengths $\|\mathbf{b}_j\|^2$ and whose determinant is $|\det \mathbf{B}|^2$. The equality conditions transfer along the

same dictionary: $\mathbf{A}$ diagonal says the columns of $\mathbf{B}$ are orthogonal, and $a_{jj} = 0$ says $\mathbf{b}_j = \mathbf{0}$.

Proof.

(a) Induct on n. For $n = 1$ both sides are a_{11}.
Let $n \geq 2$ and split $\mathbf{A}$ with $k = 1$:

$$\mathbf{A} = \begin{pmatrix} a_{11} & \mathbf{b}^* \\ \mathbf{b} & \mathbf{A}' \end{pmatrix}, \qquad \mathbf{b} \in F^{n-1}, \quad \mathbf{A}' \in M_{n-1}(F),$$

so that $\mathbf{A}'$ is the submatrix on rows and columns $2, \dots, n$. By Theorem 12.6.1 (a), $\mathbf{A}' \succeq 0$, and by Corollary 12.6.3,

$$\det \mathbf{A} \leq a_{11} \det \mathbf{A}' \leq a_{11}\,(a_{22} \cdots a_{nn}),$$

the second step being the inductive hypothesis applied to $\mathbf{A}'$. This is the inequality. For equality, suppose first that some $a_{ii} = 0$. Fix $j \neq i$ and put $I = \{i, j\}$. By Theorem 12.1.4 ((a) $\Rightarrow$ (e)) the principal minor on the rows and columns I is ≥ 0, so

$$0 \leq \det \mathbf{A}_{I,I} = a_{ii}a_{jj} - |a_{ij}|^2 = -|a_{ij}|^2,$$

forcing $a_{ij} = 0$; and $a_{ji} = \overline{a_{ij}} = 0$ because $\mathbf{A}$ is Hermitian. As $j \neq i$ was arbitrary, row i and column i of $\mathbf{A}$ are zero (which is Exercise (C3: The largest entry sits on the diagonal) (b)) and $\det \mathbf{A} = 0$; the right-hand side is 0 too, so equality holds. If $\mathbf{A}$ is diagonal, both sides are the product of the diagonal entries. Conversely, suppose equality holds and every $a_{ii} > 0$. Then $\det \mathbf{A} = a_{11} \cdots a_{nn} > 0$, so $\mathbf{A}$ is invertible, and a positive semidefinite matrix with no zero eigenvalue is positive definite (Theorem 12.1.5 (b)). Both inequalities in the display are therefore equalities. The first is the equality case of Corollary 12.6.3 for the positive definite $\mathbf{A}$, so $\mathbf{b} = \mathbf{0}$: the first row and column vanish off the diagonal. The second is the equality case of the inductive hypothesis for $\mathbf{A}'$, whose diagonal entries are positive, so $\mathbf{A}'$ is diagonal. Hence $\mathbf{A}$ is diagonal, and the induction is complete.

(b) Put $\mathbf{A} = \mathbf{B}^*\mathbf{B}$, which is positive semidefinite by Theorem 12.1.4 (c). Its (j, j) entry is $\mathbf{b}_j^*\mathbf{b}_j = \|\mathbf{b}_j\|^2$. By Theorem 6.5.4, and because $\det(\mathbf{B}^*) = \overline{\det \mathbf{B}}$ — the star transposes, which does not change the determinant (Theorem 6.4.5), and conjugates every entry, which conjugates the determinant —

$$\det \mathbf{A} = \overline{\det \mathbf{B}} \det \mathbf{B} = |\det \mathbf{B}|^2.$$

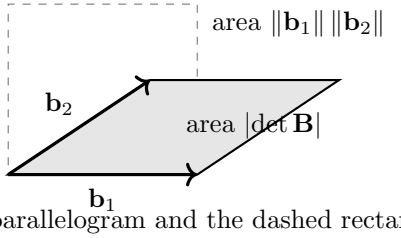
Part (a) now reads $|\det \mathbf{B}|^2 \leq \|\mathbf{b}_1\|^2 \cdots \|\mathbf{b}_n\|^2$, and taking non-negative square roots gives the inequality.

For equality, note that $a_{jj} = 0$ says $\mathbf{b}_j = \mathbf{0}$, and that $\mathbf{A}$ is diagonal exactly when $\langle \mathbf{b}_j, \mathbf{b}_i \rangle = a_{ij} = 0$ for all $i \neq j$, that is, exactly when the columns are pairwise orthogonal. So the equality condition of (a) translates into the stated one. This proves the theorem.

■

Remark. Part (b) has a geometric reading, and it is the reason the inequality is remembered. Over $\mathbb{R}$, $|\det \mathbf{B}|$ is the volume of the parallelepiped with edges $\mathbf{b}_1, \dots, \mathbf{b}_n$ (Definition 6.9.1), and the right-hand side is the volume of the box with the same edge

lengths. So among all parallelepipeds with prescribed edge lengths, the rectangular one has the largest volume, and up to degenerate cases it is the only one. Tilting an edge costs volume.



the shaded parallelogram and the dashed rectangle have the same two edge lengths

Example. (Two Determinant Bounds)

Bound $|\det \mathbf{B}|$ using Theorem 12.6.4 (b) for

$$\mathbf{B}_1 = \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}, \qquad \mathbf{B}_2 = \begin{pmatrix} 2 & 1 & 0 \\ 1 & 2 & 1 \\ 0 & 1 & 2 \end{pmatrix},$$

and compare each bound with the exact value.

Solution. For $\mathbf{B}_1$, both columns have norm $\sqrt{2}$, so the bound is 2. The determinant is $-1-1=-2$, so $|\det \mathbf{B}_1| = 2$ and the bound is attained. The equality case predicts this: $\langle (1,-1),(1,1)\rangle = 1-1=0$, so the columns are orthogonal.

For $\mathbf{B}_2$, the columns have norms $\sqrt{5}$, $\sqrt{6}$ and $\sqrt{5}$, so the bound is $5\sqrt{6} \approx 12.25$. Expanding along the first row, $\det \mathbf{B}_2 = 2(4-1) - 1(2-0) = 4$. The bound holds and is far from sharp, as it must be, since $\langle (1,2,1),(2,1,0)\rangle = 4 \neq 0$ means the columns are not orthogonal.

Warning. **Part (a) needs positivity; without it the inequality can fail in either direction.** The symmetric matrix

$$\mathbf{A} = \begin{pmatrix} 1 & 1 & 1 \\ 1 & -1 & 0 \\ 1 & 0 & -1 \end{pmatrix}$$

has $\det \mathbf{A} = 3$, while $a_{11}a_{22}a_{33} = 1 \cdot (-1) \cdot (-1) = 1$. So $\det \mathbf{A} > \prod_i a_{ii}$, and a diagonal entry of an indefinite matrix carries no information about the size of the determinant. Part (b), by contrast, has no hypothesis at all — but it bounds by **column** norms. For rows, apply the same result to $\mathbf{B}^\top$, whose determinant is unchanged (Theorem 6.4.5).

12.6.5 Exercises

12.6.5.1 A. Check your understanding

Exercise A1.

(a) Write down the general form of a Hermitian matrix in 2×2 block form, and say what each block must satisfy.

(b) State Theorem 12.6.1 (b) in full, including its hypothesis.

(c) True or false: if $\mathbf{M} = \left(\begin{smallmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{B}^* & \mathbf{C} \end{smallmatrix}\right)$ is Hermitian with $\mathbf{A} \succeq 0$ and $\mathbf{C} \succeq 0$, then $\mathbf{M} \succeq 0$. Justify your answer.

(d) State both forms of Hadamard's inequality, and say what hypothesis each one needs.

(e) In the proof of Fischer's inequality, which matrix plays the role of $\mathbf{Q}$ in Lemma 12.6.2, and which plays the role of $\mathbf{P}$?

Solution.

(a) $\mathbf{M} = \left(\begin{smallmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{B}^* & \mathbf{C} \end{smallmatrix}\right)$ with $\mathbf{A} \in M_k(F)$ and $\mathbf{C} \in M_l(F)$ Hermitian and $\mathbf{B} \in M_{k\times l}(F)$ arbitrary. The condition $\mathbf{M}^* = \mathbf{M}$ forces the lower-left block to be $\mathbf{B}^*$ and both diagonal blocks to be Hermitian.

(b) If $\mathbf{A} \succ 0$, then $\mathbf{A}$ is invertible, $\mathbf{M}/\mathbf{A} = \mathbf{C} - \mathbf{B}^*\mathbf{A}^{-1}\mathbf{B}$ is Hermitian, $\mathbf{M} \succ 0$ if and only if $\mathbf{M}/\mathbf{A} \succ 0$, and $\mathbf{M} \succeq 0$ if and only if $\mathbf{M}/\mathbf{A} \succeq 0$.

(c) False. Take $\mathbf{A} = (0)$, $\mathbf{B} = (1)$ and $\mathbf{C} = (1)$, so $\mathbf{M} = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 1 \end{smallmatrix}\right)$. Both diagonal blocks are positive semidefinite, but $\det \mathbf{M} = -1 < 0$, so $\mathbf{M} \not\succeq 0$ by Theorem 12.1.4 (e).

(d) By Theorem 12.6.4: for $\mathbf{A} \succeq 0$, $\det \mathbf{A} \le a_{11} \cdots a_{nn}$, and the hypothesis is positive semidefiniteness. For any square $\mathbf{B}$: $|\det \mathbf{B}| \le \|\mathbf{b}_1\| \cdots \|\mathbf{b}_n\|$ over the columns, with no hypothesis.

(e) In Corollary 12.6.3, $\mathbf{P} = \mathbf{M}/\mathbf{A}$ and $\mathbf{Q} = \mathbf{B}^*\mathbf{A}^{-1}\mathbf{B}$, so that $\mathbf{P} + \mathbf{Q} = \mathbf{C}$.

12.6.5.2 B. Practice

Exercise B1: Definiteness by blocks.

Each matrix below is real symmetric and is displayed with a $2, 2$ partition. Determine whether it is positive definite. Justify your answer, and for any that is not, give a vector $\mathbf{x}$ with $\mathbf{x}^\top \mathbf{M} \mathbf{x} < 0$.

(a)

$$\mathbf{M}_1 = \left(\begin{array}{cc|cc} 1 & 0 & 1 & 1 \\ 0 & 1 & 1 & -1 \\ \hline 1 & 1 & 3 & 0 \\ 1 & -1 & 0 & 3 \end{array}\right)$$

(b)

$$\mathbf{M}_2 = \left(\begin{array}{cc|cc} 1 & 0 & 1 & 1 \\ 0 & 1 & 1 & -1 \\ \hline 1 & 1 & 2 & 0 \\ 1 & -1 & 0 & 1 \end{array}\right)$$

Solution. In both cases $\mathbf{A} = \mathbf{I}_2 \succ 0$ and $\mathbf{B} = \left(\begin{smallmatrix} 1 & 1 \\ 1 & -1 \end{smallmatrix}\right)$, so Theorem 12.6.1 (b) applies with $\mathbf{A}^{-1} = \mathbf{I}_2$ and

$$\mathbf{B}^\top \mathbf{A}^{-1}\mathbf{B} = \mathbf{B}^\top \mathbf{B} = \begin{pmatrix} 2 & 0 \\ 0 & 2 \end{pmatrix}.$$

(a) $\mathbf{M}_1/\mathbf{A} = \left(\begin{smallmatrix} 3 & 0 \\ 0 & 3 \end{smallmatrix}\right) - \left(\begin{smallmatrix} 2 & 0 \\ 0 & 2 \end{smallmatrix}\right) = \mathbf{I}_2 \succ 0$. Hence $\mathbf{M}_1 \succ 0$, and $\det \mathbf{M}_1 = \det \mathbf{A} \det(\mathbf{M}_1/\mathbf{A}) = 1$.

(b) $\mathbf{M}_2/\mathbf{A} = \left(\begin{smallmatrix} 2 & 0 \\ 0 & 1 \end{smallmatrix}\right) - \left(\begin{smallmatrix} 2 & 0 \\ 0 & 2 \end{smallmatrix}\right) = \left(\begin{smallmatrix} 0 & 0 \\ 0 & -1 \end{smallmatrix}\right)$. This is the matrix of Section 1's warning: its leading principal minors are 0 and 0, and yet it is not positive semidefinite. So $\mathbf{M}_2$ is not positive definite, and not even positive semidefinite.

For the witness, $\mathbf{y}_2 = (0, 1)$ gives $\mathbf{y}_2^\top (\mathbf{M}_2/\mathbf{A})\mathbf{y}_2 = -1$. With $\mathbf{S} = \left(\begin{smallmatrix} \mathbf{I}_2 & -\mathbf{B} \\ 0 & \mathbf{I}_2 \end{smallmatrix}\right)$ and $\mathbf{y} = (0, 0, 0, 1)$, the vector $\mathbf{x} = \mathbf{S}\mathbf{y} = (-1, 1, 0, 1)$ satisfies $\mathbf{x}^\top \mathbf{M}_2 \mathbf{x} = -1$.

Exercise B2: A bordered matrix.

Let

$$\mathbf{M} = \begin{pmatrix} 2 & 1 & 1 \\ 1 & 2 & 0 \\ 1 & 0 & 2 \end{pmatrix}.$$

(a) Using the partition with $k = 1$, compute $\mathbf{M}/\mathbf{A}$ and decide whether $\mathbf{M} \succ 0$.

(b) Hence compute $\det \mathbf{M}$, and check Fischer's inequality for this partition.

Solution.

(a) Here $\mathbf{A} = (2) \succ 0$, $\mathbf{B} = \begin{pmatrix} 1 & 1 \end{pmatrix}$ and $\mathbf{C} = \left(\begin{smallmatrix} 2 & 0 \\ 0 & 2 \end{smallmatrix}\right)$. Then

$$\mathbf{B}^* \mathbf{A}^{-1} \mathbf{B} = \tfrac{1}{2} \begin{pmatrix} 1 \\ 1 \end{pmatrix} \begin{pmatrix} 1 & 1 \end{pmatrix} = \tfrac{1}{2} \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix}, \qquad \mathbf{M}/\mathbf{A} = \begin{pmatrix} 3/2 & -1/2 \\ -1/2 & 3/2 \end{pmatrix}.$$

The leading principal minors of $\mathbf{M}/\mathbf{A}$ are $3/2$ and $9/4 - 1/4 = 2$, both positive, so $\mathbf{M}/\mathbf{A} \succ 0$ and $\mathbf{M} \succ 0$ by Theorem 12.6.1 (b).

(b) By Theorem 7.3.2, $\det \mathbf{M} = 2 \cdot 2 = 4$. Fischer's inequality (Corollary 12.6.3) for this partition reads $\det \mathbf{M} \leq \det \mathbf{A} \det \mathbf{C} = 2 \cdot 4 = 8$, and indeed $4 \leq 8$. The inequality is strict, as it must be, since $\mathbf{B} \neq 0$.

Exercise B3: Hadamard bounds.

(a) Bound $|\det \mathbf{B}|$ for $\mathbf{B} = \left(\begin{smallmatrix} 1 & 2 \\ 3 & 4 \end{smallmatrix}\right)$, and compare with the exact value.

(b) Let

$$\mathbf{H} = \begin{pmatrix} 1 & 1 & 1 & 1 \\ 1 & 1 & -1 & -1 \\ 1 & -1 & 1 & -1 \\ 1 & -1 & -1 & 1 \end{pmatrix}.$$

Compute $\mathbf{H}^\top \mathbf{H}$, and deduce $|\det \mathbf{H}|$ without expanding the determinant.

Solution.

(a) The columns are $(1,3)$ and $(2,4)$, with norms $\sqrt{10}$ and $\sqrt{20}$, so the bound is $\sqrt{200} = 10\sqrt{2} \approx 14.14$. The determinant is $4-6=-2$, so $|\det \mathbf{B}| = 2$. The bound is true and very weak, because the columns are far from orthogonal.

(b) Every column of $\mathbf{H}$ has norm 2, and any two distinct columns are orthogonal: each of the six pairs agrees in two positions and disagrees in the other two, so the dot product is $1+1-1-1=0$. Hence $\mathbf{H}^{\top}\mathbf{H} = 4\mathbf{I}_4$. Taking determinants with Theorem 6.5.4 and Theorem 6.4.5, $(\det \mathbf{H})^2 = 4^4 = 256$, so $|\det \mathbf{H}| = 16$. This is exactly the Hadamard bound $\|\mathbf{h}_1\| \cdots \|\mathbf{h}_4\| = 2^4 = 16$, as the equality case of Theorem 12.6.4 (b) predicts for orthogonal columns.

12.6.5.3 C. Going deeper

Exercise C1: A zero corner kills its border.

(a) Prove that if $\mathbf{P} \succeq 0$ and $\mathbf{x}^*\mathbf{P}\mathbf{x} = 0$, then $\mathbf{P}\mathbf{x} = \mathbf{0}$.

(b) Deduce that if $\mathbf{M} = \left(\begin{smallmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{B}^* & \mathbf{C} \end{smallmatrix}\right) \succeq 0$ and $\mathbf{A} = 0$, then $\mathbf{B} = 0$.

(c) Deduce that if $\mathbf{M} \succeq 0$ and $\mathbf{A}$ is singular, then $\mathbf{M}$ is singular. What does Fischer's inequality say in that case?

Hint for (a): write $\mathbf{P} = \mathbf{N}^*\mathbf{N}$.

Solution.

(a) By Theorem 12.1.4 (c), $\mathbf{P} = \mathbf{N}^*\mathbf{N}$ for some $\mathbf{N}$. Then $0 = \mathbf{x}^*\mathbf{P}\mathbf{x} = \|\mathbf{N}\mathbf{x}\|^2$, so $\mathbf{N}\mathbf{x} = \mathbf{0}$ and $\mathbf{P}\mathbf{x} = \mathbf{N}^*(\mathbf{N}\mathbf{x}) = \mathbf{0}$.

(b) Let $\mathbf{x} \in F^k$ and put $\mathbf{v} = (\mathbf{x}, \mathbf{0})$. As computed in the proof of Theorem 12.6.1 (a), $\mathbf{v}^*\mathbf{M}\mathbf{v} = \mathbf{x}^*\mathbf{A}\mathbf{x} = 0$. By (a), $\mathbf{M}\mathbf{v} = \mathbf{0}$. But $\mathbf{M}\mathbf{v} = (\mathbf{A}\mathbf{x}, \mathbf{B}^*\mathbf{x}) = (\mathbf{0}, \mathbf{B}^*\mathbf{x})$, so $\mathbf{B}^*\mathbf{x} = \mathbf{0}$ for every $\mathbf{x} \in F^k$, that is $\mathbf{B}^* = 0$ and $\mathbf{B} = 0$.

(c) Choose $\mathbf{x} \neq \mathbf{0}$ with $\mathbf{A}\mathbf{x} = \mathbf{0}$, which is possible since $\mathbf{A}$ is singular (Theorem 2.4.4), and put $\mathbf{v} = (\mathbf{x}, \mathbf{0}) \neq \mathbf{0}$. Then $\mathbf{v}^*\mathbf{M}\mathbf{v} = \mathbf{x}^*\mathbf{A}\mathbf{x} = 0$, so $\mathbf{M}\mathbf{v} = \mathbf{0}$ by (a), and $\mathbf{M}$ is singular. Hence $\det \mathbf{M} = 0$, while $\det \mathbf{A} \det \mathbf{C} = 0$ as well, so Corollary 12.6.3 holds with both sides equal to 0. It is true, and it says nothing; the informative case is $\mathbf{A} \succ 0$.

Exercise C2: A Cauchy–Schwarz inequality for blocks.

Let $\mathbf{M} = \left(\begin{smallmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{B}^* & \mathbf{C} \end{smallmatrix}\right) \succeq 0$ with $\mathbf{A} \in M_k(F)$ and $\mathbf{C} \in M_l(F)$.

(a) Prove that for all $\mathbf{x} \in F^k$ and $\mathbf{y} \in F^l$,

$$|\mathbf{x}^*\mathbf{B}\mathbf{y}|^2 \leq (\mathbf{x}^*\mathbf{A}\mathbf{x})\,(\mathbf{y}^*\mathbf{C}\mathbf{y}).$$

(b) Deduce the Cauchy–Schwarz inequality $|\langle \mathbf{y}, \mathbf{x} \rangle| \leq \|\mathbf{x}\|\,\|\mathbf{y}\|$ in F^n.

Hint for (a): apply the definition of $\mathbf{M} \succeq 0$ *to the vector* $(\mathbf{x}, t\mathbf{y})$*, and choose the scalar* t *well.*

Solution.

(a) Write $p = \mathbf{x}^*\mathbf{A}\mathbf{x} \geq 0$, $q = \mathbf{y}^*\mathbf{C}\mathbf{y} \geq 0$ and $z = \mathbf{x}^*\mathbf{B}\mathbf{y}$. For a scalar $t \in F$, block multiplication (Theorem 7.1.1) gives, for $\mathbf{v} = (\mathbf{x}, t\mathbf{y})$,

$$\mathbf{v}^*\mathbf{M}\mathbf{v} = p + \overline{t}\,\overline{z} + tz + |t|^2 q = p + 2\,\mathrm{Re}(tz) + |t|^2 q \geq 0,$$

where the middle step uses $\overline{t}\,\overline{z} = \overline{tz}$ and $w + \overline{w} = 2\,\mathrm{Re}(w)$. Now take $t = r\omega$ with $r \geq 0$ real and ω a scalar of modulus 1 chosen so that $\omega z = -|z|$ (over $\mathbb{R}$, $\omega = \pm 1$). Then

$$p - 2r|z| + r^2 q \geq 0 \qquad \text{for every } r \geq 0. \tag{$*$}$$

If $q = 0$, then $(*)$ says $p \geq 2r|z|$ for all $r \geq 0$, which forces $|z| = 0$, and the claim reads $0 \leq 0$. If $q > 0$, take $r = |z|/q \geq 0$ in $(*)$:

$$p - \frac{2|z|^2}{q} + \frac{|z|^2}{q} = p - \frac{|z|^2}{q} \geq 0,$$

so $|z|^2 \leq pq$, as claimed.

(b) Take $k = l = n$ and $\mathbf{A} = \mathbf{B} = \mathbf{C} = \mathbf{I}_n$, so that $\mathbf{M} = \left(\begin{smallmatrix} \mathbf{I}_n & \mathbf{I}_n \\ \mathbf{I}_n & \mathbf{I}_n \end{smallmatrix}\right)$. This $\mathbf{M}$ is positive semidefinite, since $\mathbf{M} = \mathbf{W}^*\mathbf{W}$ for $\mathbf{W} = \left(\begin{smallmatrix} \mathbf{I}_n & \mathbf{I}_n \\ 0 & 0 \end{smallmatrix}\right)$ (Theorem 12.1.4 (c)). Part (a) then reads $|\mathbf{x}^*\mathbf{y}|^2 \leq \|\mathbf{x}\|^2\|\mathbf{y}\|^2$, and $\mathbf{x}^*\mathbf{y} = \langle \mathbf{y}, \mathbf{x}\rangle$ by the definition of the standard inner product. This is Theorem 10.1.5 for F^n.

Exercise C3: How large can a determinant be?.

(a) Let $\mathbf{B} \in M_n(F)$ have every entry of modulus at most 1. Prove that $|\det \mathbf{B}| \leq n^{n/2}$.

(b) Show that the bound is attained for $n = 1$, $n = 2$ and $n = 4$.

(c) Let $\mathbf{B} \in M_3(\mathbb{R})$ have every entry equal to 1 or -1. Prove that $\det \mathbf{B}$ is a multiple of 4, and deduce that $|\det \mathbf{B}| \leq 4$. Hence the bound of (a) is **not** attained for $n = 3$.

Hint for (c): normalize the first row and the first column, then subtract the first column from the other two.

Solution.

(a) Each column $\mathbf{b}_j$ has n entries of modulus ≤ 1, so $\|\mathbf{b}_j\|^2 = \sum_i |b_{ij}|^2 \leq n$ and $\|\mathbf{b}_j\| \leq \sqrt{n}$. By Theorem 12.6.4 (b), $|\det \mathbf{B}| \leq (\sqrt{n})^n = n^{n/2}$.

(b) For $n = 1$, $\mathbf{B} = (1)$ gives $1 = 1^{1/2}$. For $n = 2$, $\mathbf{B} = \left(\begin{smallmatrix} 1 & 1 \\ 1 & -1 \end{smallmatrix}\right)$ has $|\det \mathbf{B}| = 2 = 2^{2/2}$. For $n = 4$, the matrix $\mathbf{H}$ of Exercise (B3: Hadamard bounds) (b) has $|\det \mathbf{H}| = 16 = 4^{4/2}$. In each case all entries have modulus 1 and the columns are orthogonal, which is exactly what is needed for equality both in $\|\mathbf{b}_j\| \leq \sqrt{n}$ and in Theorem 12.6.4 (b).

(c) Multiplying a row or a column by -1 multiplies $\det \mathbf{B}$ by -1 (Theorem 6.5.1 (b) and (d)) and keeps all entries ± 1, so we may assume that the first row **and** the first column both consist of 1s: first scale the three columns to make the first row $(1, 1, 1)$, then scale rows 2 and 3 to make the first column $(1, 1, 1)$, which leaves the first row alone. Subtracting column 1 from columns 2 and 3 leaves the determinant unchanged (Theorem 6.5.1 (c) and (d)) and gives a matrix whose first

row is $(1,0,0)$ and whose remaining entries are $c_{ij} = b_{ij} - 1$ for $i,j \in \{2,3\}$; each lies in $\{0,-2\}$, since $b_{ij} \in \{1,-1\}$. Expanding along the first row (Theorem 6.6.1),

$$\det \mathbf{B} = c_{22}c_{33} - c_{23}c_{32}$$

with every $c_{ij} \in \{0,-2\}$. Each product lies in $\{0,4\}$, so $\det \mathbf{B} \in \{-4,0,4\}$ and in particular $|\det \mathbf{B}| \le 4$. Since $3^{3/2} = 3\sqrt{3} \approx 5.196 > 4$, the bound of (a) is not attained. The value 4 does occur, for instance for $\left(\begin{smallmatrix} 1 & 1 & 1 \\ 1 & -1 & 1 \\ 1 & 1 & -1 \end{smallmatrix}\right)$.

12.7 Products Entry by Entry

Matrix multiplication is not the only way to multiply two matrices of the same size. There is a much simpler product — multiply the entries in matching positions — which is useless for composing linear maps and extremely useful everywhere else. This section introduces it and proves the one theorem that makes it interesting: it preserves positivity. A determinant inequality follows, and it contains Hadamard's inequality of Section 6 as a special case.

Throughout, $F = \mathbb{R}$ or $F = \mathbb{C}$.

12.7.1 The entrywise product

Two matrices of the same shape can be multiplied the way two lists of numbers are: position by position. The operation has no interpretation in terms of linear maps, which is one reason it looks like a curiosity at first sight, and it is written with a small circle to keep it away from ordinary multiplication.

The Hadamard product multiplies matrices the way a spreadsheet would.

Definition 12.7.1 — Hadamard Product

Let $\mathbf{A}, \mathbf{B} \in M_{m\times n}(F)$. Their **Hadamard product**, or **entrywise product**, is the matrix $\mathbf{A} \circ \mathbf{B} \in M_{m\times n}(F)$ with

$$(\mathbf{A} \circ \mathbf{B})_{ij} = a_{ij}b_{ij} \qquad \text{for all } i,j.$$

Both factors must have **the same shape**, and the result has that shape too; there is no rule like "columns of the first match rows of the second". The operation is commutative and associative, and it is bilinear — $(\mathbf{A} + \mathbf{A}') \circ \mathbf{B} = \mathbf{A} \circ \mathbf{B} + \mathbf{A}' \circ \mathbf{B}$ and $(c\mathbf{A}) \circ \mathbf{B} = c(\mathbf{A} \circ \mathbf{B})$ — because each of these is a statement about numbers, checked one entry at a time. Its identity element is the all-ones matrix $\mathbf{J}$, not $\mathbf{I}$.

Examples.

- $\begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix} \circ \begin{pmatrix} 5 & 0 \\ -1 & 2 \end{pmatrix} = \begin{pmatrix} 5 & 0 \\ -3 & 8 \end{pmatrix}$.

- $\mathbf{A} \circ \mathbf{I} = \operatorname{diag}(a_{11}, \dots, a_{nn})$: multiplying entrywise by the identity **erases** everything off the diagonal, where ordinary multiplication by $\mathbf{I}$ changes nothing.
- $\mathbf{A} \circ \mathbf{J} = \mathbf{A}$, so $\mathbf{J}$ is the identity for $\circ$.
- For two diagonal matrices, $\mathbf{D} \circ \mathbf{D}' = \mathbf{D}\mathbf{D}'$: both products are $\operatorname{diag}(d_1 d_1', \dots, d_n d_n')$. For matrices in general the two have nothing to do with each other, though they can coincide by accident: $\left(\begin{smallmatrix} 1 & 1 \\ 0 & 0 \end{smallmatrix}\right)$ and $\left(\begin{smallmatrix} 1 & 0 \\ 0 & 0 \end{smallmatrix}\right)$ have equal Hadamard and matrix products without either being diagonal.
- For column vectors $\mathbf{u}, \mathbf{w} \in F^n$, regarded as $n \times 1$ matrices, $\mathbf{u} \circ \mathbf{w} = (u_1 w_1, \dots, u_n w_n)$.

Non-example by minimal change. Take $\mathbf{A} = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$ and $\mathbf{B} = \mathbf{A}$. Then $\mathbf{AB} = \mathbf{I}$, but $\mathbf{A} \circ \mathbf{B} = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right) \circ \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right) = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$. The two products differ, and they differ in the most basic way: $\mathbf{A}$ is its own inverse and its own Hadamard square.

> *Warning.* **$\mathbf{A} \circ \mathbf{B}$ is not $\mathbf{AB}$, and almost nothing carries over.** Two invertible matrices can have a singular entrywise product:
>
> $$\begin{pmatrix} 1 & 2 \\ 2 & 1 \end{pmatrix} \circ \begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix} = \begin{pmatrix} 2 & 2 \\ 2 & 2 \end{pmatrix},$$
>
> where the two factors have determinants -3 and 3 and the product has determinant 0. There is no formula for $\det(\mathbf{A} \circ \mathbf{B})$ in terms of $\det \mathbf{A}$ and $\det \mathbf{B}$, no relation between the eigenvalues, and no rule $(\mathbf{A} \circ \mathbf{B})^{-1} = \mathbf{A}^{-1} \circ \mathbf{B}^{-1}$. The one structural property that does survive is the subject of this section, and it is a genuine surprise.

The name is the same one that Section 6 attached to a determinant inequality. That is a coincidence of a busy mathematician, not of the mathematics: Hadamard's inequality and the Hadamard product are unrelated statements, and this section will nonetheless prove one from the other.

12.7.2 The Schur product theorem

Positivity is a statement about the quadratic form $\mathbf{x}^* \mathbf{A} \mathbf{x}$, and the quadratic form of $\mathbf{A} \circ \mathbf{B}$ has no visible relation to those of $\mathbf{A}$ and $\mathbf{B}$. So the following theorem cannot be proved by staring at the form. What works is to break both matrices into the simplest positive pieces there are — rank-one matrices $\mathbf{u}\mathbf{u}^*$ — and to notice that the entrywise product of two such pieces is again one.

Lemma 12.7.1 — Entrywise product of two rank-one positive matrices

Let $\mathbf{u}, \mathbf{w} \in F^n$. Then

$$(\mathbf{u}\mathbf{u}^*) \circ (\mathbf{w}\mathbf{w}^*) = (\mathbf{u} \circ \mathbf{w})(\mathbf{u} \circ \mathbf{w})^*.$$

Proof. Compare the (i, j) entries. The (i, j) entry of $\mathbf{u}\mathbf{u}^*$ is $u_i \overline{u_j}$ and that of $\mathbf{w}\mathbf{w}^*$ is $w_i \overline{w_j}$, so the left-hand side has (i, j) entry

$$u_i \overline{u_j}\, w_i \overline{w_j} = (u_i w_i)\, \overline{(u_j w_j)},$$

the rearrangement using commutativity of F and $\overline{u_j}\,\overline{w_j} = \overline{u_j w_j}$. The vector $\mathbf{u} \circ \mathbf{w}$ has i-th entry $u_i w_i$, so the right-hand side has (i,j) entry $(u_i w_i)\overline{(u_j w_j)}$ as well. The two matrices agree entry by entry.

■

That one line is the whole theorem; everything else is bookkeeping over the spectral decompositions.

Theorem 12.7.2 — Schur Product Theorem

Let $\mathbf{A}, \mathbf{B} \in M_n(F)$.

(a) If $\mathbf{A} \succeq 0$ and $\mathbf{B} \succeq 0$, then $\mathbf{A} \circ \mathbf{B} \succeq 0$.

(b) If $\mathbf{A} \succ 0$ and $\mathbf{B} \succ 0$, then $\mathbf{A} \circ \mathbf{B} \succ 0$.

Idea. For (a): the spectral theorem writes $\mathbf{A} = \sum_i \lambda_i \mathbf{u}_i \mathbf{u}_i^*$ and $\mathbf{B} = \sum_j \mu_j \mathbf{w}_j \mathbf{w}_j^*$ with all $\lambda_i, \mu_j \geq 0$. Expand $\mathbf{A} \circ \mathbf{B}$ by bilinearity into n^2 terms; by Lemma 12.7.1 each term is a non-negative multiple of a matrix $\mathbf{z}\mathbf{z}^*$, and those are positive semidefinite. A sum of positive semidefinite matrices is positive semidefinite, so we are done.

For (b), do not redo the argument with strict inequalities: the vectors $\mathbf{u}_i \circ \mathbf{w}_j$ need not span, and the bookkeeping becomes unpleasant. Instead peel a multiple of the identity off $\mathbf{B}$. If $\varepsilon > 0$ is the smallest eigenvalue of $\mathbf{B}$, then $\mathbf{B} = (\mathbf{B} - \varepsilon \mathbf{I}) + \varepsilon \mathbf{I}$ with $\mathbf{B} - \varepsilon \mathbf{I} \succeq 0$, so

$$\mathbf{A} \circ \mathbf{B} = \mathbf{A} \circ (\mathbf{B} - \varepsilon \mathbf{I}) + \varepsilon\, (\mathbf{A} \circ \mathbf{I}),$$

and $\mathbf{A} \circ \mathbf{I}$ is the diagonal matrix of the a_{ii}, which are strictly positive. Part (a) handles the first term, and a positive definite matrix plus a positive semidefinite one is positive definite.

Proof.

(a) Both $\mathbf{A}$ and $\mathbf{B}$ are Hermitian, so each has an orthonormal basis of eigenvectors. Let $(\mathbf{u}_1, \dots, \mathbf{u}_n)$ be one for $\mathbf{A}$, with $\mathbf{A}\mathbf{u}_i = \lambda_i \mathbf{u}_i$, and let $\mathbf{U}$ be the unitary matrix with these columns, so that $\mathbf{A} = \mathbf{U}\mathbf{D}\mathbf{U}^*$ with $\mathbf{D} = \operatorname{diag}(\lambda_1, \dots, \lambda_n)$ by Corollary 11.4.3 over $\mathbb{C}$ and Corollary 11.5.2 over $\mathbb{R}$. The columns of $\mathbf{U}\mathbf{D}$ are $\lambda_i \mathbf{u}_i$ and the rows of $\mathbf{U}^*$ are $\mathbf{u}_i^*$, so Corollary 7.1.3 gives

$$\mathbf{A} = \sum_{i=1}^{n} \lambda_i\, \mathbf{u}_i \mathbf{u}_i^*,$$

which over $\mathbb{R}$ is Corollary 11.5.4. In the same way $\mathbf{B} = \sum_j \mu_j \mathbf{w}_j \mathbf{w}_j^*$. Every $\lambda_i \geq 0$ and every $\mu_j \geq 0$, by Theorem 12.1.4 (b).
The Hadamard product is bilinear, so expanding both sums,

$$\mathbf{A} \circ \mathbf{B} = \sum_{i=1}^{n} \sum_{j=1}^{n} \lambda_i \mu_j \left[(\mathbf{u}_i \mathbf{u}_i^*) \circ (\mathbf{w}_j \mathbf{w}_j^*) \right] = \sum_{i,j} \lambda_i \mu_j\, \mathbf{z}_{ij} \mathbf{z}_{ij}^*,$$

where $\mathbf{z}_{ij} = \mathbf{u}_i \circ \mathbf{w}_j$ and the second equality is Lemma 12.7.1. Each $\mathbf{z}_{ij}\mathbf{z}_{ij}^*$ is positive semidefinite by Example (Five Positive Matrices) (b), and each coefficient $\lambda_i \mu_j$ is a non-negative real number. A non-negative combination of positive semidefinite

matrices is positive semidefinite (Exercise (C2: The cone of positive matrices) (a)): the combination is Hermitian, being a real combination of Hermitian matrices, and for every $\mathbf{x}$,

$$\langle\Big(\textstyle\sum_{i,j}\lambda_i\mu_j\mathbf{z}_{ij}\mathbf{z}_{ij}^*\Big)\mathbf{x},\mathbf{x}\rangle = \textstyle\sum_{i,j}\lambda_i\mu_j\langle\mathbf{z}_{ij}\mathbf{z}_{ij}^*\mathbf{x},\mathbf{x}\rangle \;\geq\; 0,$$

every term being a product of non-negative reals. So $\mathbf{A}\circ\mathbf{B}\succeq 0$.

(b) Let $\varepsilon>0$ be the smallest eigenvalue of $\mathbf{B}$, which is positive by Theorem 12.1.5 (b). The matrix $\mathbf{B}-\varepsilon\mathbf{I}$ is Hermitian with eigenvalues $\mu_j-\varepsilon\geq 0$, so $\mathbf{B}-\varepsilon\mathbf{I}\succeq 0$ by Theorem 12.1.4 (b). Since $\circ$ is bilinear and $\mathbf{A}\circ\mathbf{I}=\operatorname{diag}(a_{11},\dots,a_{nn})$,

$$\mathbf{A}\circ\mathbf{B}=\mathbf{A}\circ(\mathbf{B}-\varepsilon\mathbf{I})\;+\;\varepsilon\,\operatorname{diag}(a_{11},\dots,a_{nn}).$$

The first term is positive semidefinite by (a). In the second, $a_{ii}=\langle\mathbf{A}\mathbf{e}_i,\mathbf{e}_i\rangle>0$ because $\mathbf{A}\succ 0$ and $\mathbf{e}_i\neq\mathbf{0}$, so $\varepsilon\operatorname{diag}(a_{11},\dots,a_{nn})\succ 0$ by Example (Five Positive Matrices) (a). For $\mathbf{x}\neq\mathbf{0}$, the quadratic form of the sum is ≥ 0 plus >0, hence >0. So $\mathbf{A}\circ\mathbf{B}\succ 0$, and the theorem is proved.

■

The theorem is a genuine addition to the list of operations that preserve positivity. Sums and non-negative multiples were easy (Exercise (C2: The cone of positive matrices)), congruence was easy (Proposition 12.1.2), and the ordinary product is not on the list at all, since $\mathbf{AB}$ need not even be Hermitian. The entrywise product is on the list, and nothing in the definition of positivity suggests it should be.

Example. ($\mathbf{A}$ 3×3 Entrywise Product)

Let

$$\mathbf{A}=\begin{pmatrix}2&1&0\\1&2&1\\0&1&2\end{pmatrix},\qquad \mathbf{B}=\begin{pmatrix}1&-1&1\\-1&2&-1\\1&-1&3\end{pmatrix}.$$

Check that $\mathbf{A}\succ 0$ and $\mathbf{B}\succ 0$, compute $\mathbf{A}\circ\mathbf{B}$, and verify directly that it is positive definite.

Solution. The leading principal minors of $\mathbf{A}$ are 2, $4-1=3$ and, expanding along the first row, $2(4-1)-1(2-0)=4$. All are positive, so $\mathbf{A}\succ 0$ by Sylvester's criterion (Theorem 12.1.5 (d)).

Those of $\mathbf{B}$ are 1, $2-1=1$ and $1(6-1)+1(-3+1)+1(1-2)=5-2-1=2$. All positive, so $\mathbf{B}\succ 0$.

Entry by entry,

$$\mathbf{A}\circ\mathbf{B}=\begin{pmatrix}2&-1&0\\-1&4&-1\\0&-1&6\end{pmatrix},$$

whose leading principal minors are 2, $8-1=7$ and $2(24-1)+1(-6-0)=46-6=40$. All positive, so $\mathbf{A}\circ\mathbf{B}\succ 0$, as Theorem 12.7.2 (b) promised. Note that the eigenvalues of $\mathbf{A}\circ\mathbf{B}$ have nothing to do with those of $\mathbf{A}$ and $\mathbf{B}$, and that $\det(\mathbf{A}\circ\mathbf{B})=40$ is much larger than $\det\mathbf{A}\det\mathbf{B}=4\cdot 2=8$. The next theorem explains part of that: it forces $\det(\mathbf{A}\circ\mathbf{B})\geq\det\mathbf{A}\prod_i b_{ii}=24$. Getting down to the product $\det\mathbf{A}\det\mathbf{B}$ needs Hadamard's inequality (Theorem 12.6.4) as well, which is Exercise (C2: The product of the determinants).

Quick check. Let $\mathbf{A}=\left(\begin{smallmatrix}1&1\\1&1\end{smallmatrix}\right)$ and $\mathbf{B}=\left(\begin{smallmatrix}2&-1\\-1&2\end{smallmatrix}\right)$. Compute $\mathbf{A}\circ\mathbf{B}$ and decide whether it is positive definite. Does this contradict Theorem 12.7.2 (b)?

Solution. $\mathbf{A}\circ\mathbf{B}=\left(\begin{smallmatrix}2&-1\\-1&2\end{smallmatrix}\right)$, with leading principal minors 2 and 3, so it is positive definite. There is no contradiction: Theorem 12.7.2 (b) is an implication, not an equivalence. Here $\mathbf{A}$ is only positive semidefinite ($\mathbf{A}=\mathbf{1}\mathbf{1}^{\top}$, so $\det\mathbf{A}=0$), and the theorem's hypothesis fails — but the conclusion happens to hold anyway. Part (a) is what applies, and it correctly predicts $\mathbf{A}\circ\mathbf{B}\succeq 0$.

12.7.3 Oppenheim's inequality

Hadamard's inequality of Section 6 compared $\det\mathbf{A}$ with the product of the diagonal entries of $\mathbf{A}$. Oppenheim's inequality does the same for a Hadamard product, and it contains Hadamard's as the special case $\mathbf{B}=\mathbf{I}$.

Theorem 12.7.3 — Oppenheim's Inequality

Let $\mathbf{A},\mathbf{B}\in M_n(F)$ with $\mathbf{A}\succeq 0$ and $\mathbf{B}\succeq 0$. Then

$$\det(\mathbf{A}\circ\mathbf{B})\ \geq\ \det\mathbf{A}\cdot b_{11}b_{22}\cdots b_{nn}.$$

Idea. Induct on n, taking both matrices positive definite first. Split off the $(1,1)$ entry of each: the Schur complements $\mathbf{A}/\alpha$ and $\mathbf{B}/\beta$ are positive definite of size $n-1$, and a short computation, whose only real step is Lemma 12.7.1 again, shows that the Schur complement of the corner in $\mathbf{A}\circ\mathbf{B}$ is

$$(\mathbf{A}\circ\mathbf{B})/(\alpha\beta)=(\mathbf{A}/\alpha)\circ\mathbf{B}'+\tfrac{1}{\alpha}(\mathbf{a}\mathbf{a}^{*})\circ(\mathbf{B}/\beta),$$

a positive definite matrix plus a positive semidefinite one. So its determinant is at least that of the first term, by Lemma 12.6.2, and the inductive hypothesis handles that. The semidefinite case follows by replacing $\mathbf{A}$ and $\mathbf{B}$ with $\mathbf{A}+t\mathbf{I}$ and $\mathbf{B}+t\mathbf{I}$ and letting t shrink to 0.

Proof. Case 1: $\mathbf{A}\succ 0$ *and* $\mathbf{B}\succ 0$. Induct on n. For $n=1$ both sides are $a_{11}b_{11}$.

Let $n\geq 2$, and split both matrices with a $1\times(n-1)$ partition:

$$\mathbf{A} = \begin{pmatrix} \alpha & \mathbf{a}^* \\ \mathbf{a} & \mathbf{A}' \end{pmatrix}, \qquad \mathbf{B} = \begin{pmatrix} \beta & \mathbf{b}^* \\ \mathbf{b} & \mathbf{B}' \end{pmatrix},$$

with $\alpha = a_{11} > 0$, $\beta = b_{11} > 0$ and $\mathbf{a}, \mathbf{b} \in F^{n-1}$. The Schur complements are

$$\mathbf{A}/\alpha = \mathbf{A}' - \tfrac{1}{\alpha}\,\mathbf{a}\mathbf{a}^*, \qquad \mathbf{B}/\beta = \mathbf{B}' - \tfrac{1}{\beta}\,\mathbf{b}\mathbf{b}^*,$$

and both are positive definite by Theorem 12.6.1 (b). Since conjugation acts entrywise, $\mathbf{a}^* \circ \mathbf{b}^* = (\mathbf{a} \circ \mathbf{b})^*$, so

$$\mathbf{A} \circ \mathbf{B} = \begin{pmatrix} \alpha\beta & (\mathbf{a} \circ \mathbf{b})^* \\ \mathbf{a} \circ \mathbf{b} & \mathbf{A}' \circ \mathbf{B}' \end{pmatrix},$$

and $\alpha\beta > 0$, so this matrix too has a Schur complement at its corner:

$$(\mathbf{A} \circ \mathbf{B})/(\alpha\beta) = \mathbf{A}' \circ \mathbf{B}' - \tfrac{1}{\alpha\beta}\,(\mathbf{a} \circ \mathbf{b})(\mathbf{a} \circ \mathbf{b})^*.$$

By Lemma 12.7.1 the subtracted term is $\frac{1}{\alpha\beta}(\mathbf{a}\mathbf{a}^*) \circ (\mathbf{b}\mathbf{b}^*)$. Substituting $\mathbf{A}' = \mathbf{A}/\alpha + \frac{1}{\alpha}\mathbf{a}\mathbf{a}^*$ and expanding by bilinearity,

$$\begin{aligned} \mathbf{A}' \circ \mathbf{B}' &= (\mathbf{A}/\alpha) \circ \mathbf{B}' + \tfrac{1}{\alpha}\,(\mathbf{a}\mathbf{a}^*) \circ \mathbf{B}' \\ &= (\mathbf{A}/\alpha) \circ \mathbf{B}' + \tfrac{1}{\alpha}\,(\mathbf{a}\mathbf{a}^*) \circ \Big(\mathbf{B}/\beta + \tfrac{1}{\beta}\mathbf{b}\mathbf{b}^*\Big), \end{aligned}$$

and the last term of this is exactly $\frac{1}{\alpha\beta}(\mathbf{a}\mathbf{a}^*) \circ (\mathbf{b}\mathbf{b}^*)$. It therefore cancels, leaving

$$(\mathbf{A} \circ \mathbf{B})/(\alpha\beta) = \underbrace{(\mathbf{A}/\alpha) \circ \mathbf{B}'}_{\succ\, 0} + \underbrace{\tfrac{1}{\alpha}\,(\mathbf{a}\mathbf{a}^*) \circ (\mathbf{B}/\beta)}_{\succeq\, 0}. \tag{$*$}$$

The first term is positive definite by Theorem 12.7.2 (b), since $\mathbf{A}/\alpha \succ 0$ and $\mathbf{B}' \succ 0$ (the latter by Theorem 12.6.1 (a) applied to $\mathbf{B}$). The second is positive semidefinite by Theorem 12.7.2 (a), since $\mathbf{a}\mathbf{a}^* \succeq 0$ by Example (Five Positive Matrices) (b) and $\mathbf{B}/\beta \succ 0$, and $1/\alpha > 0$.

Now compute. By Theorem 7.3.2 applied to $\mathbf{A} \circ \mathbf{B}$, then $(*)$ with Lemma 12.6.2, then the inductive hypothesis applied to the pair $\mathbf{A}/\alpha$ and $\mathbf{B}'$:

$$\begin{aligned} \det(\mathbf{A} \circ \mathbf{B}) &= \alpha\beta \cdot \det\big[(\mathbf{A} \circ \mathbf{B})/(\alpha\beta)\big] \\ &\geq \alpha\beta \cdot \det\big[(\mathbf{A}/\alpha) \circ \mathbf{B}'\big] \\ &\geq \alpha\beta \cdot \det(\mathbf{A}/\alpha) \cdot b_{22} \cdots b_{nn}. \end{aligned}$$

By Theorem 7.3.2 again, now for $\mathbf{A}$, we have $\det(\mathbf{A}/\alpha) = \det \mathbf{A}/\alpha$. Substituting and canceling α,

$$\det(\mathbf{A} \circ \mathbf{B}) \;\geq\; \beta \det \mathbf{A} \cdot b_{22} \cdots b_{nn} = \det \mathbf{A} \cdot b_{11} b_{22} \cdots b_{nn},$$

which completes the induction.

Case 2: $\mathbf{A} \succeq 0$ *and* $\mathbf{B} \succeq 0$. For real $t > 0$, the matrices $\mathbf{A} + t\mathbf{I}$ and $\mathbf{B} + t\mathbf{I}$ are positive definite, as in the proof of Corollary 12.6.3. Case 1 gives

$$\det\big[(\mathbf{A} + t\mathbf{I}) \circ (\mathbf{B} + t\mathbf{I})\big] \;\geq\; \det(\mathbf{A} + t\mathbf{I}) \cdot \prod_{i=1}^{n} (b_{ii} + t).$$

Every entry of $(\mathbf{A} + t\mathbf{I}) \circ (\mathbf{B} + t\mathbf{I})$ is a polynomial in t, so both sides are polynomial, hence continuous, functions of t (Theorem 6.4.3). Letting t decrease to 0 preserves the inequality and gives the statement. This proves the theorem.

■

Remark. Taking $\mathbf{B} = \mathbf{I}$ recovers Hadamard's inequality. Indeed $\mathbf{A} \circ \mathbf{I} = \operatorname{diag}(a_{11}, \dots, a_{nn})$ and $\prod_i b_{ii} = 1$, so the conclusion reads $a_{11} \cdots a_{nn} \geq \det \mathbf{A}$, which is Theorem 12.6.4 (a). Swapping the roles of $\mathbf{A}$ and $\mathbf{B}$ gives the companion bound $\det(\mathbf{A} \circ \mathbf{B}) \geq \det \mathbf{B} \cdot \prod_i a_{ii}$, and combining either one with Hadamard's inequality gives $\det(\mathbf{A} \circ \mathbf{B}) \geq \det \mathbf{A} \det \mathbf{B}$; that last consequence is Exercise (C2: The product of the determinants).

12.7.4 Where this gets used

The natural home of the Hadamard product is data. A covariance matrix is a Gram matrix (Theorem 10.2.5), hence positive semidefinite, and rescaling each variable to unit variance turns it into a **correlation matrix**: positive semidefinite with every diagonal entry equal to 1. The Schur product theorem says that the entrywise product of two correlation matrices is another one — the diagonal entries stay $1 \cdot 1 = 1$ — so one can damp the correlations of one model by those of another and still have a legitimate covariance structure. Nothing in the definition of "positive semidefinite" makes that obvious, and it is the reason the theorem is quoted far outside linear algebra.

Warning. **Entrywise products preserve positivity; entrywise inverses do not.** Let $\mathbf{A} = \left(\begin{smallmatrix} 2 & 1 \\ 1 & 2 \end{smallmatrix}\right)$, which is positive definite, with leading principal minors 2 and 3. Replacing each entry by its reciprocal gives $\left(\begin{smallmatrix} 1/2 & 1 \\ 1 & 1/2 \end{smallmatrix}\right)$, whose determinant is $\frac{1}{4} - 1 = -\frac{3}{4} < 0$: not positive semidefinite. The entrywise reciprocal is not the Hadamard inverse of anything useful, and the matrix inverse $\mathbf{A}^{-1}$, which **is** positive definite (Exercise (B3: The inverse of a positive definite matrix)), has nothing to do with it.

12.7.5 Exercises

12.7.5.1 A. Check your understanding

Exercise A1.

(a) Define $\mathbf{A} \circ \mathbf{B}$, and say what shapes the two factors must have.

(b) What is $\mathbf{A} \circ \mathbf{I}$? What is $\mathbf{A} \circ \mathbf{J}$?

(c) State the Schur product theorem.

(d) True or false: if $\mathbf{A} \succ 0$, then the matrix with entries $1/a_{ij}$ (assuming no entry is 0) is positive definite. Justify your answer.

(e) What does Oppenheim's inequality say when $\mathbf{B} = \mathbf{I}$?

Solution.

(a) For $\mathbf{A}, \mathbf{B} \in M_{m\times n}(F)$ of the **same** shape, $(\mathbf{A} \circ \mathbf{B})_{ij} = a_{ij}b_{ij}$, and $\mathbf{A} \circ \mathbf{B}$ has that same shape (Definition 12.7.1).

(b) $\mathbf{A} \circ \mathbf{I} = \operatorname{diag}(a_{11}, \dots, a_{nn})$, and $\mathbf{A} \circ \mathbf{J} = \mathbf{A}$, since $\mathbf{J}$ has every entry 1.

(c) If $\mathbf{A} \succeq 0$ and $\mathbf{B} \succeq 0$, then $\mathbf{A} \circ \mathbf{B} \succeq 0$; if both are positive definite, so is $\mathbf{A} \circ \mathbf{B}$ (Theorem 12.7.2).

(d) False. For $\mathbf{A} = \left(\begin{smallmatrix} 2 & 1 \\ 1 & 2 \end{smallmatrix}\right) \succ 0$, the entrywise reciprocal is $\left(\begin{smallmatrix} 1/2 & 1 \\ 1 & 1/2 \end{smallmatrix}\right)$, with determinant $-3/4 < 0$.

(e) By Theorem 12.7.3 it says $\det(\mathbf{A} \circ \mathbf{I}) \geq \det \mathbf{A} \cdot 1$, that is $a_{11} \cdots a_{nn} \geq \det \mathbf{A}$: Hadamard's inequality, Theorem 12.6.4 (a).

12.7.5.2 B. Practice

Exercise B1: Compute and decide.

For each pair below, compute $\mathbf{A}\circ\mathbf{B}$ and determine whether it is positive definite, positive semidefinite but not definite, or neither. Say in each case whether Theorem 12.7.2 applies.

(a) $\mathbf{A} = \left(\begin{smallmatrix} 1 & 1 \\ 1 & 1 \end{smallmatrix}\right)$, $\mathbf{B} = \left(\begin{smallmatrix} 1 & 1 \\ 1 & 1 \end{smallmatrix}\right)$.

(b) $\mathbf{A} = \left(\begin{smallmatrix} 1 & 1 \\ 1 & 1 \end{smallmatrix}\right)$, $\mathbf{B} = \left(\begin{smallmatrix} 1 & 2 \\ 2 & 1 \end{smallmatrix}\right)$.

(c) $\mathbf{A} = \left(\begin{smallmatrix} 2 & 1 \\ 1 & 2 \end{smallmatrix}\right)$, $\mathbf{B} = \left(\begin{smallmatrix} 3 & -1 \\ -1 & 1 \end{smallmatrix}\right)$.

Solution.

(a) $\mathbf{A} \circ \mathbf{B} = \left(\begin{smallmatrix} 1 & 1 \\ 1 & 1 \end{smallmatrix}\right)$. Both factors are $\mathbf{1}\mathbf{1}^{\top} \succeq 0$ (Example (Five Positive Matrices) (b)), so Theorem 12.7.2 (a) applies and predicts $\succeq 0$. The product has determinant 0, so it is positive semidefinite but not definite.

(b) $\mathbf{A} \circ \mathbf{B} = \left(\begin{smallmatrix} 1 & 2 \\ 2 & 1 \end{smallmatrix}\right)$, whose determinant is $1 - 4 = -3 < 0$: neither. The theorem does not apply, since $\mathbf{B}$ is not positive semidefinite (its determinant is -3). This is what the hypothesis is for.

(c) $\mathbf{A} \succ 0$ (minors 2, 3) and $\mathbf{B} \succ 0$ (minors 3, 2), so Theorem 12.7.2 (b) applies. Indeed $\mathbf{A} \circ \mathbf{B} = \left(\begin{smallmatrix} 6 & -1 \\ -1 & 2 \end{smallmatrix}\right)$, with minors 6 and 11, is positive definite. Theorem 12.7.3 also checks out: $11 \geq \det \mathbf{A} \cdot b_{11}b_{22} = 3 \cdot 3 = 9$.

Exercise B2: Entrywise squares.

Let $\mathbf{A} = \left(\begin{smallmatrix} 1 & 1 & 1 \\ 1 & 2 & 2 \\ 1 & 2 & 3 \end{smallmatrix}\right)$.

(a) Show that $\mathbf{A} \succ 0$.

(b) Compute $\mathbf{A}\circ\mathbf{A}$, the matrix of squared entries, and verify that it is positive definite.

(c) Explain why (b) needed no computation.

Solution.

(a) The leading principal minors are 1, $2-1=1$ and, expanding along the first row, $1(6-4)-1(3-2)+1(2-2)=1$. All positive, so $\mathbf{A}\succ 0$ by Theorem 12.1.5 (d).

(b) $\mathbf{A}\circ\mathbf{A}=\begin{pmatrix}1&1&1\\1&4&4\\1&4&9\end{pmatrix}$, with leading principal minors 1, $4-1=3$ and $1(36-16)-1(9-4)+1(4-4)=20-5=15$. All positive, so it is positive definite.

(c) Theorem 12.7.2 (b) with $\mathbf{B}=\mathbf{A}$ gives $\mathbf{A}\circ\mathbf{A}\succ 0$ immediately.

12.7.5.3 C. Going deeper

Exercise C1: Polynomials applied entrywise.

Let $\mathbf{A}\in M_n(F)$ with $\mathbf{A}\succeq 0$.

(a) Prove that the entrywise power $\mathbf{A}^{\circ m}$, with (i,j) entry a_{ij}^m, is positive semidefinite for every integer $m\geq 1$.

(b) Let $p(x)=c_0+c_1x+\cdots+c_dx^d$ have **non-negative real** coefficients. Prove that the matrix $p^\circ(\mathbf{A})$ with (i,j) entry $p(a_{ij})$ is positive semidefinite.

(c) Give an example of $\mathbf{A}\succeq 0$ and a polynomial p with a negative coefficient for which $p^\circ(\mathbf{A})$ is not positive semidefinite.

Solution.

(a) Induct on m. For $m=1$ the claim is the hypothesis. If $\mathbf{A}^{\circ m}\succeq 0$, then $\mathbf{A}^{\circ(m+1)}=\mathbf{A}^{\circ m}\circ\mathbf{A}\succeq 0$ by Theorem 12.7.2 (a).

(b) By definition of the entries, $p^\circ(\mathbf{A})=c_0\mathbf{J}+c_1\mathbf{A}+c_2\mathbf{A}^{\circ 2}+\cdots+c_d\mathbf{A}^{\circ d}$, since each side has (i,j) entry $\sum_k c_k a_{ij}^k$ (with $a_{ij}^0=1$, which is the (i,j) entry of $\mathbf{J}$). Now $\mathbf{J}=\mathbf{1}\mathbf{1}^{\top}\succeq 0$ by Example (Five Positive Matrices) (b), each $\mathbf{A}^{\circ k}\succeq 0$ by (a), and each $c_k\geq 0$. A non-negative combination of positive semidefinite matrices is positive semidefinite (Exercise (C2: The cone of positive matrices) (a)).

(c) Take $\mathbf{A}=\mathbf{J}\in M_2(\mathbb{R})$, which is positive semidefinite, and $p(x)=x-2$. Then $p^\circ(\mathbf{A})$ has every entry -1, that is $p^\circ(\mathbf{A})=-\mathbf{J}$, and $\langle -\mathbf{J}\mathbf{e}_1,\mathbf{e}_1\rangle=-1<0$. So the hypothesis on the coefficients cannot be dropped.

Exercise C2: The product of the determinants.

Let $\mathbf{A},\mathbf{B}\in M_n(F)$ with $\mathbf{A}\succeq 0$ and $\mathbf{B}\succeq 0$. Prove that

$$\det(\mathbf{A}\circ\mathbf{B})\ \geq\ \det\mathbf{A}\cdot\det\mathbf{B}.$$

Is the inequality ever an equality with both matrices positive definite?

Solution. By Theorem 12.7.3, $\det(\mathbf{A}\circ\mathbf{B})\geq\det\mathbf{A}\cdot\prod_i b_{ii}$. By Theorem 12.6.4 (a) applied to $\mathbf{B}\succeq 0$, $\prod_i b_{ii}\geq\det\mathbf{B}$. Both $\det\mathbf{A}\geq 0$ and $\prod_i b_{ii}\geq 0$ (the diagonal entries of a positive semidefinite matrix are ≥ 0 by Exercise (C1: Zero trace forces zero) (a)),

so multiplying the second inequality by $\det \mathbf{A} \geq 0$ and chaining,

$$\det(\mathbf{A} \circ \mathbf{B}) \;\geq\; \det \mathbf{A} \prod_i b_{ii} \;\geq\; \det \mathbf{A} \det \mathbf{B}.$$

Yes, equality can occur: take $\mathbf{A} = \mathbf{B} = \mathbf{I}_n$, so that $\mathbf{A} \circ \mathbf{B} = \mathbf{I}_n$ and all three quantities are 1. More generally, take $\mathbf{A} \succ 0$ diagonal and $\mathbf{B} = \mathbf{I}_n$.

Exercise C3: The rank of an entrywise product.

Let $\mathbf{A}, \mathbf{B} \in M_n(F)$ with $\mathbf{A} \succeq 0$ and $\mathbf{B} \succeq 0$, of ranks r and s. Prove that

$$\operatorname{rank}(\mathbf{A} \circ \mathbf{B}) \leq rs.$$

Hint: how many terms in the proof of Theorem 12.7.2 (a) are actually non-zero?

Solution. Write $\mathbf{A} = \sum_i \lambda_i \mathbf{u}_i \mathbf{u}_i^*$ and $\mathbf{B} = \sum_j \mu_j \mathbf{w}_j \mathbf{w}_j^*$ as in the proof of Theorem 12.7.2 (a). The number of non-zero eigenvalues of $\mathbf{A}$ is $\operatorname{rank} \mathbf{A} = r$: diagonalizing, $\mathbf{A} = \mathbf{U}\mathbf{D}\mathbf{U}^*$ with $\mathbf{U}$ invertible, so $\operatorname{rank} \mathbf{A} = \operatorname{rank} \mathbf{D}$ by Theorem 2.5.9, and $\operatorname{rank} \mathbf{D}$ counts the non-zero λ_i. Likewise exactly s of the μ_j are non-zero. Dropping the vanishing terms,

$$\mathbf{A} \circ \mathbf{B} = \sum_{\lambda_i \neq 0} \sum_{\mu_j \neq 0} \lambda_i \mu_j \, \mathbf{z}_{ij} \mathbf{z}_{ij}^*, \qquad \mathbf{z}_{ij} = \mathbf{u}_i \circ \mathbf{w}_j,$$

a sum of rs matrices, each of rank at most 1, since every column of $\mathbf{z}_{ij}\mathbf{z}_{ij}^*$ lies in $\operatorname{span}(\mathbf{z}_{ij})$. The rank of a sum of two matrices is at most the sum of their ranks (Exercise (C1: Rank of a sum)); applying that repeatedly to the rs summands gives $\operatorname{rank}(\mathbf{A} \circ \mathbf{B}) \leq rs$.

12.8 The Singular Value Decomposition

Chapter 11 answered one question completely: an operator has an orthonormal basis of eigenvectors exactly when it is normal. That answer is useless for a 3×5 matrix, which has no eigenvalues at all — the equation $\mathbf{A}\mathbf{x} = \lambda \mathbf{x}$ is not even type-correct, because $\mathbf{A}\mathbf{x}$ and $\mathbf{x}$ live in different spaces. This section shows that every matrix, of every shape, still admits an orthonormal-to-orthogonal description, and that the numbers in it are the eigenvalues of a positive semidefinite matrix we already understand. It is the most-used factorization in applied linear algebra, and the whole of it comes from applying the spectral theorem to $\mathbf{A}^*\mathbf{A}$.

Throughout, F is $\mathbb{R}$ or $\mathbb{C}$, $\mathbf{A}^*$ is the conjugate transpose (the transpose when $F = \mathbb{R}$), and *unitary* means unitary over $\mathbb{C}$ and orthogonal over $\mathbb{R}$, as in Definition 10.7.2. Both F^m and F^n carry their standard inner products.

12.8.1 Where to look when there are no eigenvalues

Let $\mathbf{A} \in M_{m\times n}(F)$. There is exactly one square matrix that can be built from $\mathbf{A}$ at no cost, and Chapter 10 has already used it twice: the $n \times n$ matrix $\mathbf{A}^*\mathbf{A}$ of the normal equations. It is self-adjoint, since $(\mathbf{A}^*\mathbf{A})^* = \mathbf{A}^*\mathbf{A}^{**} = \mathbf{A}^*\mathbf{A}$, and it is positive semidefinite for the reason that makes every argument in this chapter work:

$$\langle \mathbf{A}^*\mathbf{A}\mathbf{x}, \mathbf{x}\rangle = \langle \mathbf{A}\mathbf{x}, \mathbf{A}\mathbf{x}\rangle = \|\mathbf{A}\mathbf{x}\|^2 \geq 0. \tag{12.8.1}$$

So $\mathbf{A}^*\mathbf{A} \succeq 0$, and Theorem 12.1.4 says its eigenvalues are non-negative real numbers, while the spectral theorem supplies an orthonormal basis of F^n consisting of its eigenvectors. Those eigenvalues are attached to $\mathbf{A}$, they exist for every shape of $\mathbf{A}$, and Eq. 12.8.1 says what they measure: how much $\mathbf{A}$ stretches.

A rectangular matrix has no eigenvalues of its own, but $\mathbf{A}^*\mathbf{A}$ does, and their square roots are the stretching factors of $\mathbf{A}$.

Definition 12.8.1 — Singular Values

Let $\mathbf{A} \in M_{m\times n}(F)$ and put $p = \min(m, n)$. Let

$$\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_n \geq 0$$

be the eigenvalues of $\mathbf{A}^*\mathbf{A} \in M_n(F)$, listed **with multiplicity** in decreasing order. The **singular values** of $\mathbf{A}$ are

$$\sigma_i(\mathbf{A}) := \sqrt{\lambda_i} \qquad (i = 1, \ldots, p),$$

so that $\sigma_1(\mathbf{A}) \geq \sigma_2(\mathbf{A}) \geq \cdots \geq \sigma_p(\mathbf{A}) \geq 0$. We write σ_i when $\mathbf{A}$ is clear.

Clause by clause. The list has exactly $p = \min(m, n)$ entries, not n: when $n > m$ the matrix $\mathbf{A}^*\mathbf{A}$ has rank $\operatorname{rank}\mathbf{A} \leq m < n$ by Corollary 10.6.6 (b), so $\lambda_{m+1} = \cdots = \lambda_n = 0$ and the discarded eigenvalues are all zero. The square root is the ordinary non-negative real square root, available because every $\lambda_i \geq 0$. The ordering is **decreasing**, matching the book's convention $\lambda_1(\mathbf{A}) \geq \cdots \geq \lambda_n(\mathbf{A})$ for the eigenvalues of a Hermitian matrix, and it is part of the definition: "the second singular value" means a definite number. Finally, the singular values are attached to $\mathbf{A}$ itself, with no choices made, because the eigenvalue list of $\mathbf{A}^*\mathbf{A}$ is.

Four examples, simplest first.

1. **The identity.** $\mathbf{A} = \mathbf{I}_n$ gives $\mathbf{A}^*\mathbf{A} = \mathbf{I}_n$, so every $\sigma_i = 1$. More generally a unitary $\mathbf{U} \in M_n(F)$ has $\mathbf{U}^*\mathbf{U} = \mathbf{I}$, so all its singular values are 1. A unitary matrix stretches nothing in any direction, and the list of singular values says exactly that.
2. **A rectangular diagonal matrix.** If $\mathbf{A} \in M_{m\times n}(F)$ has $a_{ii} = d_i$ for $i \leq p$ and all other entries 0, then $\mathbf{A}^*\mathbf{A} = \operatorname{diag}(|d_1|^2, \ldots)$ and the singular values are $|d_1|, \ldots, |d_p|$ **sorted downwards**. The absolute value matters: the singular values of $\operatorname{diag}(1, -2)$ are $2, 1$.
3. **A positive semidefinite matrix.** If $\mathbf{A} \succeq 0$ then $\mathbf{A}^*\mathbf{A} = \mathbf{A}^2$, whose eigenvalues are $\lambda_i(\mathbf{A})^2$ with $\lambda_i(\mathbf{A}) \geq 0$, so $\sigma_i(\mathbf{A}) = \lambda_i(\mathbf{A})$. For the matrices this chapter started with, singular values and eigenvalues coincide.

4. **A single row.** For $\mathbf{A} = \mathbf{a}^* \in M_{1\times n}(F)$ with $\mathbf{a} \neq \mathbf{0}$, $p = 1$ and $\mathbf{A}^*\mathbf{A} = \mathbf{a}\mathbf{a}^*$, whose non-zero eigenvalue is $\|\mathbf{a}\|^2$. So $\sigma_1 = \|\mathbf{a}\|$. The degenerate case $\mathbf{A} = \mathbf{0}$ has every $\sigma_i = 0$, and it matters: it is the only matrix with $\sigma_1 = 0$, since $\sigma_1 = 0$ forces $\mathbf{A}^*\mathbf{A} = \mathbf{0}$ and then $\|\mathbf{A}\mathbf{x}\|^2 = 0$ for every $\mathbf{x}$ by Eq. 12.8.1.

Now the non-example, by minimal change. Replace "square roots of the eigenvalues of $\mathbf{A}^*\mathbf{A}$" by "absolute values of the eigenvalues of $\mathbf{A}$". For $\mathbf{A} \succeq 0$, and more generally for any normal $\mathbf{A}$, the two agree (Exercise (C3: Singular values equal to eigenvalue moduli)). But the second recipe is undefined for a non-square matrix, and for

$$\mathbf{N} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$$

it returns $0, 0$, while $\mathbf{N}^*\mathbf{N} = \operatorname{diag}(0, 1)$ gives the singular values $1, 0$. The clause that fails is the one that does all the work: $\mathbf{A}^*\mathbf{A}$ is positive semidefinite for **every** $\mathbf{A}$, whereas $\mathbf{A}$ itself may have no useful spectrum.

Warning. **Singular values are not eigenvalues.** The matrix $\mathbf{N}$ above has both eigenvalues equal to 0 and largest singular value 1: it annihilates $\mathbf{e}_1$ but sends $\mathbf{e}_2$ to a unit vector, so calling it "small" because its spectrum is $\{0\}$ is wrong. Singular values are always real and non-negative; eigenvalues need not be either. The two lists agree, after taking absolute values, exactly for normal matrices — this is Exercise (C3: Singular values equal to eigenvalue moduli), and Chapter 11's Schur inequality is what makes the converse true.

Quick check. What are the singular values of an orthogonal projection $\mathbf{P} \in M_n(F)$ onto an r-dimensional subspace?

Solution. $\mathbf{P}^*\mathbf{P} = \mathbf{P}^2 = \mathbf{P}$, because an orthogonal projection is self-adjoint and idempotent. So the eigenvalues of $\mathbf{P}^*\mathbf{P}$ are those of $\mathbf{P}$, namely 1 with multiplicity r and 0 with multiplicity $n - r$. Sorted downwards, the singular values are $\sigma_1 = \cdots = \sigma_r = 1$ and $\sigma_{r+1} = \cdots = \sigma_n = 0$. This is also Example 3 above, since $\mathbf{P} \succeq 0$.

12.8.2 The theorem

Here is the payoff. The eigenvectors of $\mathbf{A}^*\mathbf{A}$ are an orthonormal basis of the domain; the claim is that $\mathbf{A}$ carries them to an **orthogonal** list in the codomain, whose lengths are the singular values.

Theorem 12.8.1 — Singular Value Decomposition

Let $\mathbf{A} \in M_{m\times n}(F)$, let $p = \min(m, n)$ and let $\sigma_1 \geq \cdots \geq \sigma_p \geq 0$ be its singular values. Then there are unitary matrices $\mathbf{U} \in M_m(F)$ and $\mathbf{V} \in M_n(F)$ such that

$$\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^*,$$

where $\mathbf{\Sigma} \in M_{m\times n}(\mathbb{R})$ has $(\mathbf{\Sigma})_{ii} = \sigma_i$ for $i = 1, \ldots, p$ and every other entry 0. Moreover the number of non-zero σ_i equals $\operatorname{rank} \mathbf{A}$.

Idea. Picture the 2×2 real case. A matrix carries the unit circle to an ellipse, and an ellipse has two perpendicular axes; the theorem says that the two unit vectors sent to the ends of those axes are themselves perpendicular. That is exactly what Chapter 11's principal axis theorem (Theorem 11.5.5) said about the level curves of a quadratic form, and the link is that $\|\mathbf{Ax}\|^2 = \mathbf{x}^*(\mathbf{A}^*\mathbf{A})\mathbf{x}$ **is** a quadratic form, with matrix $\mathbf{A}^*\mathbf{A}$. So the plan is: ① diagonalize $\mathbf{A}^*\mathbf{A}$ by the spectral theorem, getting an orthonormal basis $\mathbf{v}_1, \dots, \mathbf{v}_n$ with $\mathbf{A}^*\mathbf{A}\mathbf{v}_i = \sigma_i^2 \mathbf{v}_i$; ② compute $\langle \mathbf{A}\mathbf{v}_i, \mathbf{A}\mathbf{v}_j \rangle$ and watch the eigenvalue equation force it to be $\sigma_i^2 \delta_{ij}$, so the images are already orthogonal; ③ normalize the non-zero ones to unit vectors $\mathbf{u}_i$, and, if there are fewer than m of them, pad the list out to an orthonormal basis of F^m; ④ read $\mathbf{AV} = \mathbf{U\Sigma}$ off column by column.

Proof. **Step 1: diagonalize $\mathbf{A}^*\mathbf{A}$.** The matrix $\mathbf{A}^*\mathbf{A} \in M_n(F)$ is self-adjoint, and Eq. 12.8.1 makes it positive semidefinite in the sense of Definition 12.1.1. By the spectral theorem in matrix form — Corollary 11.5.2 when $F = \mathbb{R}$, Corollary 11.4.3 when $F = \mathbb{C}$, each of which allows the eigenvalues to be listed in a prescribed order — there is a unitary $\mathbf{V} \in M_n(F)$ with columns $\mathbf{v}_1, \dots, \mathbf{v}_n$ such that

$$\mathbf{A}^*\mathbf{A}\,\mathbf{v}_i = \lambda_i \mathbf{v}_i, \qquad \lambda_1 \geq \cdots \geq \lambda_n \geq 0,$$

the eigenvalues being non-negative by Theorem 12.1.4. Set $\sigma_i = \sqrt{\lambda_i}$ for all $i \leq n$; for $i \leq p$ these are the singular values of Definition 12.8.1.

Step 2: the images are orthogonal. For all i, j, using $\langle \mathbf{x}, \mathbf{y} \rangle = \mathbf{y}^*\mathbf{x}$ and the eigenvalue equation,

$$\langle \mathbf{A}\mathbf{v}_i, \mathbf{A}\mathbf{v}_j \rangle = \langle \mathbf{A}^*\mathbf{A}\mathbf{v}_i, \mathbf{v}_j \rangle = \lambda_i \langle \mathbf{v}_i, \mathbf{v}_j \rangle = \lambda_i \delta_{ij},$$

the first equality by Definition 10.6.1 and the last because $\mathbf{V}$ is unitary, so its columns are orthonormal (Theorem 10.7.3 (f)). In particular $\|\mathbf{A}\mathbf{v}_i\|^2 = \lambda_i = \sigma_i^2$, so

$$\mathbf{A}\mathbf{v}_i = \mathbf{0} \iff \sigma_i = 0. \tag{12.8.2}$$

Step 3: normalize, and count. Let r be the number of indices with $\sigma_i > 0$; since the σ_i decrease, these are $i = 1, \dots, r$. For $i \leq r$ put

$$\mathbf{u}_i \coloneqq \frac{1}{\sigma_i} \mathbf{A}\mathbf{v}_i,$$

which is legitimate because $\sigma_i \neq 0$. By Step 2, $\langle \mathbf{u}_i, \mathbf{u}_j \rangle = \lambda_i \delta_{ij} / (\sigma_i \sigma_j) = \delta_{ij}$ for $i, j \leq r$, so $(\mathbf{u}_1, \dots, \mathbf{u}_r)$ is an orthonormal list in F^m.

We claim $r = \operatorname{rank} \mathbf{A}$. Any $\mathbf{x} \in F^n$ is $\mathbf{x} = \sum_i c_i \mathbf{v}_i$ since $(\mathbf{v}_1, \dots, \mathbf{v}_n)$ is a basis, and then $\mathbf{Ax} = \sum_{i \leq r} c_i \sigma_i \mathbf{u}_i$ by Eq. 12.8.2. Hence $\operatorname{im} \mathbf{A} = \operatorname{span}(\mathbf{u}_1, \dots, \mathbf{u}_r)$, and the $\mathbf{u}_i$ are orthonormal, hence independent (Theorem 10.1.4), so $\operatorname{rank} \mathbf{A} = r$. In particular $r \leq \min(m, n) = p$, so every index i with $\sigma_i > 0$ satisfies $i \leq p$, and the non-zero singular values are exactly $\sigma_1, \dots, \sigma_r$.

Step 4: pad the list. If $r = m$ the list $(\mathbf{u}_1, \dots, \mathbf{u}_r)$ is already an orthonormal basis of F^m, and we set $\mathbf{U} = (\mathbf{u}_1 \mid \cdots \mid \mathbf{u}_m)$. If $r < m$, apply Corollary 10.2.3 to the orthonormal list $(\mathbf{u}_1, \dots, \mathbf{u}_r)$ in F^m: there are $\mathbf{u}_{r+1}, \dots, \mathbf{u}_m$ making $(\mathbf{u}_1, \dots, \mathbf{u}_m)$ an orthonormal basis of F^m. Either way let $\mathbf{U} \in M_m(F)$ have these columns; it is unitary because its columns are orthonormal (Theorem 10.7.3 (f)). Note that the padding vectors are **not** determined by $\mathbf{A}$, and nothing below uses any property of them beyond orthonormality.

Step 5: read off the columns. Let $\mathbf{\Sigma} \in M_{m\times n}(\mathbb{R})$ be as in the statement. Column i of $\mathbf{U\Sigma}$ is $\mathbf{U}$ times column i of $\mathbf{\Sigma}$, which is $\sigma_i \mathbf{e}_i$ for $i \le p$ and $\mathbf{0}$ for $i > p$; so column i of $\mathbf{U\Sigma}$ is $\sigma_i \mathbf{u}_i$ for $i \le p$ and $\mathbf{0}$ for $i > p$. Column i of $\mathbf{AV}$ is $\mathbf{A}\mathbf{v}_i$. Compare:

- for $i \le r$, $\mathbf{A}\mathbf{v}_i = \sigma_i \mathbf{u}_i$ by the definition of $\mathbf{u}_i$;
- for $r < i \le p$, $\sigma_i = 0$, so both columns are $\mathbf{0}$ by Eq. 12.8.2;
- for $i > p$ (possible only when $n > m$), we have $i > p \ge r$, so $\sigma_i = 0$ and $\mathbf{A}\mathbf{v}_i = \mathbf{0}$, and both columns are $\mathbf{0}$.

Hence $\mathbf{AV} = \mathbf{U\Sigma}$. Since $\mathbf{V}$ is unitary, $\mathbf{V}^{-1} = \mathbf{V}^*$, so $\mathbf{A} = \mathbf{U\Sigma V}^*$. This proves the theorem.

■

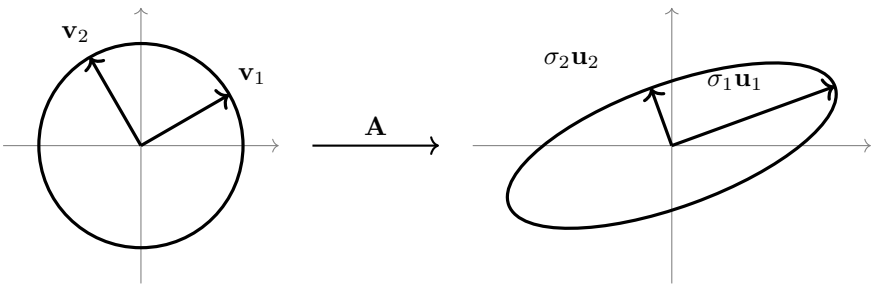
A factorization $\mathbf{A} = \mathbf{U\Sigma V}^*$ as in the theorem is called **a singular value decomposition** of $\mathbf{A}$, the columns $\mathbf{u}_i$ of $\mathbf{U}$ are **left singular vectors** and the columns $\mathbf{v}_i$ of $\mathbf{V}$ are **right singular vectors**. The two equations to keep in mind are the ones the proof produced,

$$\mathbf{A}\mathbf{v}_i = \sigma_i \mathbf{u}_i, \qquad \mathbf{A}^*\mathbf{u}_i = \sigma_i \mathbf{v}_i \qquad (i \le r), \tag{12.8.3}$$

the second obtained by applying $\mathbf{A}^*$ to the first and using $\mathbf{A}^*\mathbf{A}\mathbf{v}_i = \sigma_i^2 \mathbf{v}_i$. In words: $\mathbf{A}$ matches up two orthonormal bases, one in each space, stretching the i-th direction by σ_i, and $\mathbf{A}^*$ runs the same correspondence backwards with the same factors.

Remark. **The last item on the invertibility list.** For a square $\mathbf{A} \in M_n(F)$, the count at the end of the theorem says that all n singular values are non-zero exactly when $\operatorname{rank}\mathbf{A} = n$, which is invertibility (Theorem 6.5.3 (d)). This is the item Chapter 2 promised when it began the list (Theorem 2.4.4), later grown in Theorem 6.5.3, Theorem 8.2.6 and Theorem 12.1.6, and it is the last one the book adds.

Here is the picture the Idea described, in the real 2×2 case.



the unit circle — its image, an ellipse

A carries a pair of perpendicular unit vectors to the semi-axes of an ellipse; their lengths are σ_1 and σ_2

Compare the principal axes figure of Chapter 11 §05. There the ellipse was a level curve $\mathbf{x}^\top\mathbf{A}\mathbf{x} = 1$ of a quadratic form and the axes lay along the eigenvectors of a symmetric $\mathbf{A}$; here the ellipse is the *image* of the unit circle under an arbitrary $\mathbf{A}$. The two pictures are the same picture, because $\|\mathbf{A}\mathbf{x}\|^2 = \mathbf{x}^*(\mathbf{A}^*\mathbf{A})\mathbf{x}$ is a quadratic form with matrix $\mathbf{A}^*\mathbf{A}$, and the right singular vectors of $\mathbf{A}$ are its principal axes. A large σ_i now means a **long** semi-axis, whereas in Theorem 11.5.5 a

large λ_i meant a short one; the reason is that the two pictures are related by taking reciprocals of square roots.

12.8.3 What is unique and what is not

The singular values were defined before the theorem, so they cannot depend on any choice. What needs saying is the converse: any factorization of the stated shape recovers them.

Theorem 12.8.2 — The Singular Values Are Determined

Let $\mathbf{A} \in M_{m\times n}(F)$ and suppose $\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^*$ with $\mathbf{U}, \mathbf{V}$ unitary and $\mathbf{\Sigma} \in M_{m\times n}(\mathbb{R})$ of the shape in Theorem 12.8.1, with diagonal entries $s_1 \geq \cdots \geq s_p \geq 0$. Then $s_i = \sigma_i(\mathbf{A})$ for every i. Moreover:

(a) the columns of $\mathbf{V}$ are forced to be an orthonormal basis of F^n consisting of eigenvectors of $\mathbf{A}^*\mathbf{A}$, with $\mathbf{A}^*\mathbf{A}\mathbf{v}_i = \sigma_i^2\mathbf{v}_i$ for every $i \leq n$, where $\sigma_i := 0$ for $p < i \leq n$; and any such basis occurs;

(b) once $\mathbf{V}$ is chosen, $\mathbf{u}_i = \mathbf{A}\mathbf{v}_i/\sigma_i$ is forced for every $i \leq r = \operatorname{rank}\mathbf{A}$, while $\mathbf{u}_{r+1}, \ldots, \mathbf{u}_m$ may be any orthonormal basis of $(\operatorname{im}\mathbf{A})^\perp$.

Proof. From $\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^*$ and $\mathbf{U}^*\mathbf{U} = \mathbf{I}_m$,

$$\mathbf{A}^*\mathbf{A} = \mathbf{V}\mathbf{\Sigma}^*\mathbf{U}^*\mathbf{U}\mathbf{\Sigma}\mathbf{V}^* = \mathbf{V}(\mathbf{\Sigma}^*\mathbf{\Sigma})\mathbf{V}^*,$$

and $\mathbf{\Sigma}^*\mathbf{\Sigma} \in M_n(\mathbb{R})$ is the diagonal matrix with entries $s_1^2, \ldots, s_p^2$ followed by zeros. So $\mathbf{A}^*\mathbf{A}$ is unitarily diagonalized with this diagonal, and its eigenvalue list in decreasing order is therefore $s_1^2 \geq \cdots \geq s_p^2 \geq 0 \geq \ldots$ — already sorted, since the s_i are. Comparing with Definition 12.8.1 gives $s_i^2 = \sigma_i(\mathbf{A})^2$, hence $s_i = \sigma_i(\mathbf{A})$ because both are nonnegative.

(a) The displayed equation says the i-th column of $\mathbf{V}$ satisfies $\mathbf{A}^*\mathbf{A}\mathbf{v}_i = \sigma_i^2\mathbf{v}_i$, and the columns of a unitary matrix are orthonormal. Conversely, given any orthonormal basis of eigenvectors of $\mathbf{A}^*\mathbf{A}$ ordered by decreasing eigenvalue, Steps 2–5 of the proof of Theorem 12.8.1 build a factorization from it.

(b) For $i \leq r$ we have $\sigma_i \neq 0$, and comparing column i of $\mathbf{A}\mathbf{V} = \mathbf{U}\mathbf{\Sigma}$ gives $\mathbf{A}\mathbf{v}_i = \sigma_i\mathbf{u}_i$, so $\mathbf{u}_i = \mathbf{A}\mathbf{v}_i/\sigma_i$. For $i > r$ the corresponding column of $\mathbf{\Sigma}$ is zero, so $\mathbf{u}_i$ is unconstrained by the equation $\mathbf{A}\mathbf{V} = \mathbf{U}\mathbf{\Sigma}$; the only constraint left is that $(\mathbf{u}_1, \ldots, \mathbf{u}_m)$ be orthonormal, which says exactly that $(\mathbf{u}_{r+1}, \ldots, \mathbf{u}_m)$ is an orthonormal basis of $\operatorname{span}(\mathbf{u}_1, \ldots, \mathbf{u}_r)^\perp = (\operatorname{im}\mathbf{A})^\perp$.

∎

So $\mathbf{\Sigma}$ is unique and $\mathbf{U}, \mathbf{V}$ are not. The freedom is of two kinds, and both are visible in small cases. If $\mathbf{A}^*\mathbf{A}$ has a repeated eigenvalue, any orthonormal basis of that eigenspace may be used: $\mathbf{A} = \mathbf{I}_2$ has $\mathbf{\Sigma} = \mathbf{I}_2$ and $\mathbf{I}_2 = \mathbf{U}\mathbf{I}_2\mathbf{U}^*$ for **every** unitary $\mathbf{U}$, with $\mathbf{V} = \mathbf{U}$. If the eigenvalues are distinct, each $\mathbf{v}_i$ is still free up to a scalar of modulus 1, and replacing $\mathbf{v}_i$ by $c\mathbf{v}_i$ replaces $\mathbf{u}_i$ by $c\mathbf{u}_i$, leaving $\sigma_i\mathbf{u}_i\mathbf{v}_i^*$ unchanged because $c\bar{c} = 1$.

Remark. That last observation is why the factorization is worth having even though it is not unique: the *products* $\sigma_i \mathbf{u}_i \mathbf{v}_i^*$ are what later sections use, and those are unchanged by the phase freedom. Section 11 will define the pseudoinverse through a singular value decomposition and will have to check exactly this.

12.8.4 The compact form, and the four subspaces

Steps 3 and 5 of the proof produced more than the statement recorded: they located $\operatorname{im} \mathbf{A}$ and $\ker \mathbf{A}$ inside the two bases. Writing the factorization so that only the non-zero singular values appear makes this visible.

Theorem 12.8.3 — Compact Singular Value Decomposition

Let $\mathbf{A} \in M_{m\times n}(F)$ have rank r and let $\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^*$ be as in Theorem 12.8.1, with columns $\mathbf{u}_1, \dots, \mathbf{u}_m$ and $\mathbf{v}_1, \dots, \mathbf{v}_n$. Then

$$\mathbf{A} = \sum_{i=1}^{r} \sigma_i \, \mathbf{u}_i \mathbf{v}_i^*,$$

a sum of r matrices of rank 1. Equivalently $\mathbf{A} = \mathbf{U}_r \mathbf{\Sigma}_r \mathbf{V}_r^*$, where $\mathbf{U}_r \in M_{m\times r}(F)$ and $\mathbf{V}_r \in M_{n\times r}(F)$ hold the first r columns of $\mathbf{U}$ and $\mathbf{V}$, and $\mathbf{\Sigma}_r = \operatorname{diag}(\sigma_1, \dots, \sigma_r)$ is square and **invertible**.

Proof. Write $\mathbf{A} = (\mathbf{U}\mathbf{\Sigma})\mathbf{V}^*$. The columns of $\mathbf{U}\mathbf{\Sigma}$ are $\sigma_1\mathbf{u}_1, \dots, \sigma_p\mathbf{u}_p$ followed by zero columns, as computed in Step 5 of Theorem 12.8.1, and the rows of $\mathbf{V}^*$ are $\mathbf{v}_1^*, \dots, \mathbf{v}_n^*$. By the outer product expansion of a matrix product (Corollary 7.1.3),

$$\mathbf{A} = \sum_{i=1}^{p} (\sigma_i \mathbf{u}_i)\mathbf{v}_i^* = \sum_{i=1}^{r} \sigma_i \, \mathbf{u}_i \mathbf{v}_i^*,$$

the terms with $i > r$ vanishing because $\sigma_i = 0$ there. Each $\mathbf{u}_i\mathbf{v}_i^*$ is non-zero with all columns multiples of $\mathbf{u}_i$, hence of rank 1. The same computation with the truncated matrices gives $\mathbf{U}_r\mathbf{\Sigma}_r\mathbf{V}_r^* = \sum_{i\le r} \sigma_i \mathbf{u}_i \mathbf{v}_i^*$, and $\mathbf{\Sigma}_r$ is invertible because its diagonal entries $\sigma_1, \dots, \sigma_r$ are non-zero.

■

Corollary 12.8.4 — The Four Fundamental Subspaces from the Compact Form

With the notation of Theorem 12.8.3:

(a) $(\mathbf{u}_1, \dots, \mathbf{u}_r)$ is an orthonormal basis of $\operatorname{im} \mathbf{A} = \operatorname{col}(\mathbf{A})$;
(b) $(\mathbf{u}_{r+1}, \dots, \mathbf{u}_m)$ is an orthonormal basis of $\ker \mathbf{A}^*$;
(c) $(\mathbf{v}_1, \dots, \mathbf{v}_r)$ is an orthonormal basis of $\operatorname{im} \mathbf{A}^*$;
(d) $(\mathbf{v}_{r+1}, \dots, \mathbf{v}_n)$ is an orthonormal basis of $\ker \mathbf{A}$.

Idea. Two of the four were proved on the way to Theorem 12.8.1. The other two come for free by applying the same statements to $\mathbf{A}^*$, whose singular value decomposition is $\mathbf{A}^* = \mathbf{V}\mathbf{\Sigma}^*\mathbf{U}^*$ — the roles of $\mathbf{u}$ and $\mathbf{v}$ simply swap.

Proof. Part (a). Step 3 of Theorem 12.8.1 showed $\operatorname{im}\mathbf{A} = \operatorname{span}(\mathbf{u}_1, \dots, \mathbf{u}_r)$, and these r vectors are orthonormal.

Part (d). By Eq. 12.8.2, $\mathbf{A}\mathbf{v}_i = \mathbf{0}$ exactly for $i > r$, and for $\mathbf{x} = \sum_i c_i\mathbf{v}_i$ we computed $\mathbf{A}\mathbf{x} = \sum_{i\le r} c_i\sigma_i\mathbf{u}_i$. Since the $\mathbf{u}_i$ are independent and the σ_i non-zero for $i \le r$, $\mathbf{A}\mathbf{x} = \mathbf{0}$ if and only if $c_1 = \cdots = c_r = 0$, that is, $\mathbf{x} \in \operatorname{span}(\mathbf{v}_{r+1}, \dots, \mathbf{v}_n)$.

Parts (b) and (c). Taking conjugate transposes, $\mathbf{A}^* = \mathbf{V}\mathbf{\Sigma}^*\mathbf{U}^*$, and $\mathbf{\Sigma}^* \in M_{n\times m}(\mathbb{R})$ has the same diagonal $\sigma_1, \dots, \sigma_p$. So this is a singular value decomposition of $\mathbf{A}^*$, with the columns of $\mathbf{V}$ as left singular vectors and those of $\mathbf{U}$ as right singular vectors, and $\operatorname{rank}\mathbf{A}^* = \operatorname{rank}\mathbf{A} = r$ by Corollary 10.6.6 (a). Now the two parts just proved, applied to $\mathbf{A}^*$ instead of $\mathbf{A}$, give exactly (c) and (b).

■

This is the cleanest possible form of Theorem 10.6.5. That theorem said the four subspaces come in two orthogonal pairs, $F^n = \ker\mathbf{A} \oplus \operatorname{im}\mathbf{A}^*$ and $F^m = \operatorname{im}\mathbf{A} \oplus \ker\mathbf{A}^*$. The corollary hands over **orthonormal bases of all four at once**, out of two matrices, and adds the missing piece of information: how $\mathbf{A}$ maps one pair to the other. Restricted to $\operatorname{im}\mathbf{A}^*$, the map $\mathbf{A}$ is a bijection onto $\operatorname{im}\mathbf{A}$, and in the bases $(\mathbf{v}_1, \dots, \mathbf{v}_r)$ and $(\mathbf{u}_1, \dots, \mathbf{u}_r)$ its matrix is the diagonal $\mathbf{\Sigma}_r$. Every matrix, after an orthonormal change of basis on each side, is a positive diagonal matrix padded with zeros.

Quick check. Let $\mathbf{A} \in M_{m\times n}(F)$ have rank r. Using Corollary 12.8.4, what is $\dim\ker\mathbf{A}^*$, and why does the answer not depend on which singular value decomposition was used?

Solution. The list $(\mathbf{u}_{r+1}, \dots, \mathbf{u}_m)$ has $m - r$ members, so $\dim\ker\mathbf{A}^* = m - r$. It cannot depend on the factorization because $r = \operatorname{rank}\mathbf{A}$ is determined by $\mathbf{A}$ (Theorem 12.8.2), and in any case the answer agrees with $\dim(\operatorname{im}\mathbf{A})^\perp = m - \operatorname{rank}\mathbf{A}$ from Theorem 10.6.5 and Theorem 10.3.2.

12.8.5 Two computations and one comparison

The Frobenius norm. From $\|\mathbf{A}\|_F^2 = \operatorname{tr}(\mathbf{A}^*\mathbf{A})$ and $\mathbf{A}^*\mathbf{A} = \mathbf{V}(\mathbf{\Sigma}^*\mathbf{\Sigma})\mathbf{V}^*$, or directly from Lemma 11.11.1,

$$\|\mathbf{A}\|_F^2 = \|\mathbf{U}\mathbf{\Sigma}\mathbf{V}^*\|_F^2 = \|\mathbf{\Sigma}\|_F^2 = \sum_{i=1}^{p}\sigma_i^2.$$

So the Frobenius norm is the Euclidean length of the singular value list. Section 10 turns this one identity into the best low-rank approximation theorem.

The largest stretch. Let $\mathbf{x} = \sum_i c_i\mathbf{v}_i$ be a unit vector, so $\sum_i|c_i|^2 = 1$ by Theorem 10.9.2. Then $\mathbf{A}\mathbf{x} = \sum_{i\le r} c_i\sigma_i\mathbf{u}_i$, and since the $\mathbf{u}_i$ are orthonormal, Pythagoras (Theorem 10.1.3) gives

$$\|\mathbf{A}\mathbf{x}\|^2 = \sum_{i\le r}\sigma_i^2|c_i|^2 \le \sigma_1^2\sum_i|c_i|^2 = \sigma_1^2,$$

with equality at $\mathbf{x} = \mathbf{v}_1$. So $\sigma_1 = \max\{\|\mathbf{A}\mathbf{x}\| : \|\mathbf{x}\| = 1\}$: the largest singular value is the largest

factor by which $\mathbf{A}$ can lengthen a vector. Chapter 15 gives that quantity a name, the operator norm $\|\mathbf{A}\|_2$, and this computation is why $\|\mathbf{A}\|_2 = \sigma_1$.

Against the eigenvalues. For a normal $\mathbf{A} \in M_n(\mathbb{C})$, write $\mathbf{A} = \mathbf{U}\mathbf{D}\mathbf{U}^*$ with $\mathbf{D} = \operatorname{diag}(\lambda_1, \dots, \lambda_n)$ by Corollary 11.4.3. Then

$$\mathbf{A}^*\mathbf{A} = \mathbf{U}\mathbf{D}^*\mathbf{D}\mathbf{U}^* = \mathbf{U}\operatorname{diag}\big(|\lambda_1|^2, \dots, |\lambda_n|^2\big)\mathbf{U}^*,$$

so the singular values of $\mathbf{A}$ are the moduli $|\lambda_i|$, sorted downwards. For a general matrix there is no relation at all in one direction — $\mathbf{N} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$ has spectrum $\{0\}$ and $\sigma_1 = 1$ — and only the crude bound $|\lambda| \le \sigma_1$ in the other, since $\mathbf{A}\mathbf{x} = \lambda\mathbf{x}$ with $\|\mathbf{x}\| = 1$ gives $|\lambda| = \|\mathbf{A}\mathbf{x}\| \le \sigma_1$.

Example. (A singular value decomposition of a 2 by 3 matrix)

Find a singular value decomposition of

$$\mathbf{A} = \begin{pmatrix} 1 & 0 & 1 \\ 0 & 1 & -1 \end{pmatrix} \in M_{2\times 3}(\mathbb{R}),$$

and read off orthonormal bases of its four fundamental subspaces.

Solution. Here $m = 2$, $n = 3$, $p = 2$. The proof asks for the eigenvectors of the 3×3 matrix $\mathbf{A}^\top\mathbf{A}$, but there is a shortcut worth taking whenever $m < n$: run the proof on $\mathbf{A}^\top$ instead. It produces $\mathbf{A}^\top = \mathbf{V}\mathbf{\Sigma}^\top\mathbf{U}^\top$, and transposing that equation gives $\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^\top$, which is what we want. The eigenvalue computation then lives in the smaller matrix

$$\mathbf{A}\mathbf{A}^\top = \begin{pmatrix} 2 & -1 \\ -1 & 2 \end{pmatrix}.$$

Step 1. The characteristic polynomial of $\mathbf{A}\mathbf{A}^\top$ is $x^2 - 4x + 3 = (x-1)(x-3)$, so the eigenvalues are 3 and 1 and the singular values are $\sigma_1 = \sqrt{3}$, $\sigma_2 = 1$. For $\lambda = 3$, $\mathbf{A}\mathbf{A}^\top - 3\mathbf{I} = \begin{pmatrix} -1 & -1 \\ -1 & -1 \end{pmatrix}$ gives $x_1 = -x_2$, and for $\lambda = 1$ we get $x_1 = x_2$. Normalizing,

$$\mathbf{u}_1 = \tfrac{1}{\sqrt{2}}(1, -1), \qquad \mathbf{u}_2 = \tfrac{1}{\sqrt{2}}(1, 1).$$

Both singular values are non-zero, so $r = \operatorname{rank}\mathbf{A} = 2$.

Steps 2–4. The roles of $\mathbf{u}$ and $\mathbf{v}$ are swapped along with the roles of $\mathbf{A}$ and $\mathbf{A}^\top$, so here $\mathbf{v}_i = \mathbf{A}^\top\mathbf{u}_i/\sigma_i$:

$$\mathbf{v}_1 = \tfrac{\mathbf{A}^\top(1,-1)}{\sqrt{2}\sqrt{3}} = \tfrac{1}{\sqrt{6}}(1, -1, 2), \qquad \mathbf{v}_2 = \tfrac{\mathbf{A}^\top(1,1)}{\sqrt{2}} = \tfrac{1}{\sqrt{2}}(1, 1, 0).$$

This time the padding step is needed, since $r = 2 < 3$: a unit vector orthogonal to both is

$$\mathbf{v}_3 = \tfrac{1}{\sqrt{3}}(-1, 1, 1).$$

Step 5. Assembling,

$$\mathbf{U} = \tfrac{1}{\sqrt{2}}\begin{pmatrix} 1 & 1 \\ -1 & 1 \end{pmatrix}, \qquad \mathbf{\Sigma} = \begin{pmatrix} \sqrt{3} & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix},$$

$$\mathbf{V} = \begin{pmatrix} \frac{1}{\sqrt{6}} & \frac{1}{\sqrt{2}} & -\frac{1}{\sqrt{3}} \\ -\frac{1}{\sqrt{6}} & \frac{1}{\sqrt{2}} & \frac{1}{\sqrt{3}} \\ \frac{2}{\sqrt{6}} & 0 & \frac{1}{\sqrt{3}} \end{pmatrix}, \qquad \mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^{\top}.$$

As a check, $\|\mathbf{A}\|_F^2 = 1+0+1+0+1+1 = 4$ and $\sigma_1^2 + \sigma_2^2 = 3+1 = 4$.

The four subspaces (Corollary 12.8.4), with $r = 2$: $\operatorname{col}(\mathbf{A})$ has the orthonormal basis $\mathbf{u}_1, \mathbf{u}_2$, which is all of $\mathbb{R}^2$, so $\operatorname{nul}(\mathbf{A}^{\top}) = \{\mathbf{0}\}$; $\operatorname{row}(\mathbf{A}) = \operatorname{col}(\mathbf{A}^{\top})$ has the orthonormal basis $\mathbf{v}_1, \mathbf{v}_2$; and $\operatorname{nul}(\mathbf{A}) = \operatorname{span}(\mathbf{v}_3)$ is the line through $(-1,1,1)$. The last is easy to verify directly: $\mathbf{A}(-1,1,1) = (-1+1, 1-1) = \mathbf{0}$.

12.8.6 Exercises

12.8.6.1 A. Check your understanding

Exercise A1.

(a) Define the singular values of a matrix $\mathbf{A} \in M_{m\times n}(F)$. How many are there?

(b) State the singular value decomposition, with the size and the defining property of each factor.

(c) True or false: the singular values of $\mathbf{A}$ are the absolute values of its eigenvalues. Justify your answer.

(d) How many non-zero singular values does $\mathbf{A}$ have, and why?

(e) Given a compact singular value decomposition $\mathbf{A} = \sum_{i\le r} \sigma_i \mathbf{u}_i \mathbf{v}_i^*$, write down orthonormal bases of all four fundamental subspaces of $\mathbf{A}$.

(f) True or false: in $\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^*$ the three factors are determined by $\mathbf{A}$. Justify your answer.

Solution.

(a) They are $\sigma_i = \sqrt{\lambda_i}$ for $i = 1, \dots, \min(m,n)$, where $\lambda_1 \ge \cdots \ge \lambda_n \ge 0$ are the eigenvalues of $\mathbf{A}^*\mathbf{A}$ with multiplicity (Definition 12.8.1). There are $\min(m,n)$ of them.

(b) Theorem 12.8.1: $\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^*$ with $\mathbf{U} \in M_m(F)$ unitary, $\mathbf{V} \in M_n(F)$ unitary and $\mathbf{\Sigma} \in M_{m\times n}(\mathbb{R})$ having $\sigma_1 \ge \cdots \ge \sigma_p \ge 0$ in positions (i,i) and zeros elsewhere.

(c) False. $\mathbf{N} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$ has both eigenvalues 0 and singular values $1, 0$. The statement is true for normal matrices (Exercise (C3: Singular values equal to eigenvalue moduli)), and for a non-square matrix it does not even make sense.

(d) Exactly $\operatorname{rank}\mathbf{A}$, by Theorem 12.8.1. The reason is that $\mathbf{A}\mathbf{v}_i = \mathbf{0}$ precisely when $\sigma_i = 0$, so the $\mathbf{v}_i$ with $\sigma_i = 0$ span $\ker\mathbf{A}$.

(e) $(\mathbf{u}_1, \dots, \mathbf{u}_r)$ for $\operatorname{im}\mathbf{A}$; $(\mathbf{u}_{r+1}, \dots, \mathbf{u}_m)$ for $\ker\mathbf{A}^*$; $(\mathbf{v}_1, \dots, \mathbf{v}_r)$ for $\operatorname{im}\mathbf{A}^*$; $(\mathbf{v}_{r+1}, \dots, \mathbf{v}_n)$ for $\ker\mathbf{A}$ (Corollary 12.8.4).

(f) False for $\mathbf{U}$ and $\mathbf{V}$, true for $\mathbf{\Sigma}$ (Theorem 12.8.2). For instance $\mathbf{I}_2 = \mathbf{U}\mathbf{I}_2\mathbf{U}^*$ for every unitary $\mathbf{U}$. The freedom is: any orthonormal eigenbasis of $\mathbf{A}^*\mathbf{A}$ may be used for $\mathbf{V}$, and the last $m-r$ columns of $\mathbf{U}$ may be any orthonormal basis of $(\operatorname{im}\mathbf{A})^{\perp}$.

12.8.6.2 B. Practice

Exercise B1: A 2 by 2 decomposition.

Find a singular value decomposition $\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^\top$ of

$$\mathbf{A} = \begin{pmatrix} 3 & 0 \\ 4 & 5 \end{pmatrix} \in M_2(\mathbb{R}),$$

and compare the singular values with the eigenvalues of $\mathbf{A}$.

Solution. $\mathbf{A}^\top\mathbf{A} = \begin{pmatrix} 25 & 20 \\ 20 & 25 \end{pmatrix}$, with characteristic polynomial $x^2 - 50x + (625 - 400) = x^2 - 50x + 225$, whose roots are 45 and 5. So $\sigma_1 = 3\sqrt{5}$ and $\sigma_2 = \sqrt{5}$.

For $\lambda = 45$ the equation $-20x_1 + 20x_2 = 0$ gives $\mathbf{v}_1 = \frac{1}{\sqrt{2}}(1, 1)$; for $\lambda = 5$, $\mathbf{v}_2 = \frac{1}{\sqrt{2}}(1, -1)$. Then

$$\mathbf{u}_1 = \frac{\mathbf{A}\mathbf{v}_1}{3\sqrt{5}} = \frac{(3, 9)}{3\sqrt{10}} = \frac{1}{\sqrt{10}}(1, 3), \qquad \mathbf{u}_2 = \frac{\mathbf{A}\mathbf{v}_2}{\sqrt{5}} = \frac{(3, -1)}{\sqrt{10}}.$$

Hence

$$\mathbf{U} = \frac{1}{\sqrt{10}}\begin{pmatrix} 1 & 3 \\ 3 & -1 \end{pmatrix}, \quad \mathbf{\Sigma} = \begin{pmatrix} 3\sqrt{5} & 0 \\ 0 & \sqrt{5} \end{pmatrix}, \quad \mathbf{V} = \frac{1}{\sqrt{2}}\begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix},$$

and $\mathbf{U}\mathbf{\Sigma}\mathbf{V}^\top = \mathbf{A}$. Check: $\sigma_1^2 + \sigma_2^2 = 45 + 5 = 50 = 9 + 16 + 25 = \|\mathbf{A}\|_F^2$.

The eigenvalues of $\mathbf{A}$ are 3 and 5, the diagonal entries of a triangular matrix. They are not the singular values, not even after reordering: $\mathbf{A}$ is not normal, since $\mathbf{A}^\top\mathbf{A} \neq \mathbf{A}\mathbf{A}^\top = \begin{pmatrix} 9 & 12 \\ 12 & 41 \end{pmatrix}$. Note, however, that $\sigma_1\sigma_2 = 15 = |\det \mathbf{A}|$, as Exercise (C2: The adjoint and the determinant) explains.

Exercise B2: When the left singular vectors must be padded.

Find a singular value decomposition of

$$\mathbf{A} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \\ 1 & 0 \end{pmatrix} \in M_{3\times 2}(\mathbb{R}),$$

saying explicitly where the padding step of Theorem 12.8.1 is used.

Solution. $\mathbf{A}^\top\mathbf{A} = \operatorname{diag}(2, 1)$, already diagonal with decreasing diagonal, so $\mathbf{V} = \mathbf{I}_2$, $\mathbf{v}_1 = \mathbf{e}_1$, $\mathbf{v}_2 = \mathbf{e}_2$, and $\sigma_1 = \sqrt{2}$, $\sigma_2 = 1$. Both are non-zero, so $r = 2$. Then

$$\mathbf{u}_1 = \frac{1}{\sqrt{2}}\mathbf{A}\mathbf{e}_1 = \frac{1}{\sqrt{2}}(1, 0, 1), \qquad \mathbf{u}_2 = \mathbf{A}\mathbf{e}_2 = (0, 1, 0).$$

Here $r = 2 < 3 = m$, so Step 4 of Theorem 12.8.1 applies: extend $(\mathbf{u}_1, \mathbf{u}_2)$ to an orthonormal basis of $\mathbb{R}^3$. A vector orthogonal to both is $(1, 0, -1)$, so take $\mathbf{u}_3 = \frac{1}{\sqrt{2}}(1, 0, -1)$. Then

$$\mathbf{U} = \begin{pmatrix} \frac{1}{\sqrt{2}} & 0 & \frac{1}{\sqrt{2}} \\ 0 & 1 & 0 \\ \frac{1}{\sqrt{2}} & 0 & -\frac{1}{\sqrt{2}} \end{pmatrix}, \qquad \mathbf{\Sigma} = \begin{pmatrix} \sqrt{2} & 0 \\ 0 & 1 \\ 0 & 0 \end{pmatrix}, \qquad \mathbf{V} = \mathbf{I}_2,$$

and $\mathbf{U\Sigma V}^\top = \mathbf{U\Sigma} = \mathbf{A}$. The vector $\mathbf{u}_3$ is not determined by $\mathbf{A}$ beyond its line: $-\mathbf{u}_3$ would do just as well. By Corollary 12.8.4, $\text{nul}(\mathbf{A}^\top) = \text{span}(\mathbf{u}_3)$, which is confirmed by $\mathbf{A}^\top(1,0,-1) = (1-1,0) = \mathbf{0}$.

Exercise B3: Compact form and the four subspaces.

For

$$\mathbf{A} = \begin{pmatrix} 2 & 2 \\ 1 & 1 \\ 2 & 2 \end{pmatrix} \in M_{3\times 2}(\mathbb{R}),$$

find the compact singular value decomposition $\mathbf{A} = \sum_{i\le r} \sigma_i \mathbf{u}_i \mathbf{v}_i^\top$, and hence orthonormal bases of all four fundamental subspaces.

Solution. $\mathbf{A}^\top\mathbf{A} = \begin{pmatrix} 9 & 9 \\ 9 & 9 \end{pmatrix}$, with eigenvalues 18 and 0, so $\sigma_1 = 3\sqrt{2}$, $\sigma_2 = 0$ and $r = 1$. An eigenvector for 18 is $\mathbf{v}_1 = \frac{1}{\sqrt{2}}(1,1)$, and for 0 it is $\mathbf{v}_2 = \frac{1}{\sqrt{2}}(1,-1)$. Then

$$\mathbf{u}_1 = \frac{\mathbf{A}\mathbf{v}_1}{3\sqrt{2}} = \frac{(4,2,4)}{\sqrt{2}\cdot 3\sqrt{2}} = \tfrac{1}{3}(2,1,2),$$

a unit vector since $4+1+4=9$. The compact form is $\mathbf{A} = 3\sqrt{2}\,\mathbf{u}_1\mathbf{v}_1^\top$, and multiplying out gives back $\mathbf{A}$.

Four subspaces: $\text{col}(\mathbf{A}) = \text{span}\big(\frac{1}{3}(2,1,2)\big)$ and $\text{row}(\mathbf{A}) = \text{span}\big(\frac{1}{\sqrt{2}}(1,1)\big)$, both one-dimensional; $\text{nul}(\mathbf{A}) = \text{span}\big(\frac{1}{\sqrt{2}}(1,-1)\big)$; and $\text{nul}(\mathbf{A}^\top)$ is the plane $\{\mathbf{y} : 2y_1 + y_2 + 2y_3 = 0\}$, for which an orthonormal basis is $\frac{1}{\sqrt{2}}(1,0,-1)$ and $\frac{1}{3\sqrt{2}}(1,-4,1)$. (Any orthonormal basis of that plane is a legitimate $(\mathbf{u}_2,\mathbf{u}_3)$, which is the freedom described in Theorem 12.8.2 (b).)

Exercise B4: Determine whether.

Determine which of the following statements are correct. For those that are correct, prove them; for those that are not, give a counterexample.

(a) If every eigenvalue of $\mathbf{A} \in M_n(\mathbb{C})$ is 0, then every singular value of $\mathbf{A}$ is 0.
(b) $\sigma_i(c\mathbf{A}) = |c|\,\sigma_i(\mathbf{A})$ for every scalar c.
(c) $\sigma_i(\mathbf{A}^2) = \sigma_i(\mathbf{A})^2$ for every square $\mathbf{A}$.
(d) $\mathbf{A}$ is invertible if and only if $n = m$ and every singular value of $\mathbf{A}$ is non-zero.

Solution.

(a) Incorrect. $\mathbf{N} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$ has spectrum $\{0\}$, while $\mathbf{N}^*\mathbf{N} = \text{diag}(0,1)$ gives $\sigma_1 = 1$.

(b) Correct. $(c\mathbf{A})^*(c\mathbf{A}) = \overline{c}c\,\mathbf{A}^*\mathbf{A} = |c|^2\mathbf{A}^*\mathbf{A}$, whose eigenvalues are $|c|^2\lambda_i$; taking square roots and noting that multiplying by $|c|^2 \ge 0$ preserves the decreasing order gives the claim.

(c) Incorrect, with the same $\mathbf{N}$: $\mathbf{N}^2 = \mathbf{0}$ has both singular values 0, while $\sigma_1(\mathbf{N})^2 = 1$. (It is correct for $\mathbf{A} \succeq 0$, and more generally for normal $\mathbf{A}$, because then the singular

values are the moduli of the eigenvalues and $\mathbf{A}^2$ has eigenvalues λ_i^2.)

(d) Correct. If $\mathbf{A} \in M_n(F)$ then, by Theorem 12.8.1, the number of non-zero singular values is $\operatorname{rank}\mathbf{A}$, and $\mathbf{A}$ is invertible exactly when $\operatorname{rank}\mathbf{A} = n$ (Theorem 6.5.3 (d)). A non-square matrix is never invertible.

12.8.6.3 C. Going deeper

Exercise C1: The Frobenius norm and the largest singular value.

Let $\mathbf{A} \in M_{m\times n}(F)$ with singular values $\sigma_1 \geq \cdots \geq \sigma_p$.

(a) The text obtained $\|\mathbf{A}\|_F^2 = \sum_{i=1}^{p} \sigma_i^2$ from unitary invariance. Prove it a second way, directly from $\|\mathbf{A}\|_F^2 = \operatorname{tr}(\mathbf{A}^*\mathbf{A})$ and the eigenvalues of $\mathbf{A}^*\mathbf{A}$, without invoking Lemma 11.11.1.

(b) Deduce that $\sigma_1 \leq \|\mathbf{A}\|_F$, and determine exactly when equality holds.

Solution.

(a) Take a singular value decomposition $\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^*$ (Theorem 12.8.1). By Lemma 11.11.1, applied once on each side, $\|\mathbf{A}\|_F = \|\mathbf{U}\mathbf{\Sigma}\mathbf{V}^*\|_F = \|\mathbf{\Sigma}\|_F$. The only non-zero entries of $\mathbf{\Sigma}$ are $\sigma_1, \ldots, \sigma_p$ on the diagonal, so $\|\mathbf{\Sigma}\|_F^2 = \sum_i \sigma_i^2$.

(b) Every term of $\sum_i \sigma_i^2$ is non-negative, so $\sigma_1^2 \leq \sum_i \sigma_i^2 = \|\mathbf{A}\|_F^2$, and taking non-negative square roots gives $\sigma_1 \leq \|\mathbf{A}\|_F$. Equality holds if and only if $\sigma_2 = \cdots = \sigma_p = 0$, that is, if and only if $\operatorname{rank}\mathbf{A} \leq 1$ (Theorem 12.8.1).

Exercise C2: The adjoint and the determinant.

Let $\mathbf{A} \in M_{m\times n}(F)$.

(a) Prove that $\mathbf{A}$ and $\mathbf{A}^*$ have the same non-zero singular values, with the same multiplicities.

(b) Suppose $m = n$. Prove that $|\det\mathbf{A}| = \sigma_1\sigma_2\cdots\sigma_n$.

(c) Hence give a formula for $|\det\mathbf{A}|$ in terms of $\mathbf{A}^*\mathbf{A}$ only, and check it on $\mathbf{A} = \begin{pmatrix} 3 & 0 \\ 4 & 5 \end{pmatrix}$.

Solution.

(a) If $\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^*$ is a singular value decomposition, then $\mathbf{A}^* = \mathbf{V}\mathbf{\Sigma}^*\mathbf{U}^*$ with $\mathbf{V}, \mathbf{U}$ unitary and $\mathbf{\Sigma}^* \in M_{n\times m}(\mathbb{R})$ carrying the same diagonal entries $\sigma_1, \ldots, \sigma_p$. By Theorem 12.8.2 this is a singular value decomposition of $\mathbf{A}^*$, so the singular value list of $\mathbf{A}^*$ is $\sigma_1, \ldots, \sigma_p$ as well. (The two lists have the same length $p = \min(m, n)$, so they are in fact equal, not merely equal in their non-zero parts.)

(b) Take determinants in $\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^*$. By Theorem 6.5.4, $\det\mathbf{A} = \det\mathbf{U} \cdot \det\mathbf{\Sigma} \cdot \det\mathbf{V}^*$. A unitary $\mathbf{U}$ has $|\det\mathbf{U}| = 1$, since $\det(\mathbf{U}^*)\det(\mathbf{U}) = \det(\mathbf{I}) = 1$ and $\det(\mathbf{U}^*) = \overline{\det\mathbf{U}}$, so $|\det\mathbf{U}|^2 = 1$. The same holds for $\mathbf{V}^*$. And $\det\mathbf{\Sigma} = \sigma_1\cdots\sigma_n$ by Theorem 6.4.6. Taking absolute values gives $|\det\mathbf{A}| = \sigma_1\cdots\sigma_n$.

(c) Squaring, $|\det\mathbf{A}|^2 = \prod_i \sigma_i^2 = \det(\mathbf{A}^*\mathbf{A})$, so $|\det\mathbf{A}| = \sqrt{\det(\mathbf{A}^*\mathbf{A})}$. For the given

$\mathbf{A}$, $\det \mathbf{A} = 15$ and $\det(\mathbf{A}^\top \mathbf{A}) = 625 - 400 = 225 = 15^2$.

Exercise C3: Singular values equal to eigenvalue moduli.

Let $\mathbf{A} \in M_n(\mathbb{C})$ have eigenvalues $\lambda_1, \dots, \lambda_n$ listed with algebraic multiplicity and ordered so that $|\lambda_1| \geq \cdots \geq |\lambda_n|$.

(a) Prove that if $\mathbf{A}$ is normal, then $\sigma_i(\mathbf{A}) = |\lambda_i|$ for every i.

(b) Prove the converse: if $\sigma_i(\mathbf{A}) = |\lambda_i|$ for every i, then $\mathbf{A}$ is normal.

Hint for (b): compare two expressions for $\|\mathbf{A}\|_F^2$.

Solution.

(a) Suppose $\mathbf{A}$ is normal. By Corollary 11.4.3, $\mathbf{A} = \mathbf{U}\mathbf{D}\mathbf{U}^*$ with $\mathbf{U}$ unitary and $\mathbf{D} = \operatorname{diag}(\lambda_1, \dots, \lambda_n)$. Then

$$\mathbf{A}^*\mathbf{A} = \mathbf{U}\mathbf{D}^*\mathbf{U}^*\mathbf{U}\mathbf{D}\mathbf{U}^* = \mathbf{U}\operatorname{diag}\big(|\lambda_i|^2\big)\mathbf{U}^*,$$

so the eigenvalues of $\mathbf{A}^*\mathbf{A}$ are $|\lambda_1|^2, \dots, |\lambda_n|^2$ with multiplicity. These are already in decreasing order by hypothesis, so $\sigma_i(\mathbf{A}) = |\lambda_i|$ for every i by Definition 12.8.1.

(b) Suppose $\sigma_i(\mathbf{A}) = |\lambda_i|$ for every i. By Exercise (C1: The Frobenius norm and the largest singular value) (a),

$$\sum_{i=1}^{n} |\lambda_i|^2 = \sum_{i=1}^{n} \sigma_i^2 = \|\mathbf{A}\|_F^2.$$

Schur's inequality (Theorem 11.11.2) says $\sum_i |\lambda_i|^2 \leq \|\mathbf{A}\|_F^2$ with equality **if and only if** $\mathbf{A}$ is normal. We have equality, so $\mathbf{A}$ is normal.

12.9 Polar Decomposition and Takagi's Factorization

Every non-zero complex number is a rotation times a stretch, $z = e^{i\theta} r$ with $r = |z| > 0$. Section 8 has put the matrix version within reach: if $\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^*$, then inserting $\mathbf{V}^*\mathbf{V} = \mathbf{I}$ in the middle splits the factorization into a unitary part and a positive semidefinite part. This section carries that out, proves that the unitary part is the closest unitary matrix to $\mathbf{A}$, and then treats a factorization that looks like the singular value decomposition but is not: Takagi's, for complex **symmetric** matrices.

The field is $\mathbb{C}$ unless stated otherwise, and $|\mathbf{A}| = (\mathbf{A}^*\mathbf{A})^{1/2}$ is the matrix absolute value of Definition 12.2.1.

12.9.1 Rotation times stretch

Theorem 12.9.1 — Polar Decomposition

Let $\mathbf{A} \in M_n(\mathbb{C})$. Then there is a unitary $\mathbf{W} \in M_n(\mathbb{C})$ with

$$\mathbf{A} = \mathbf{W}|\mathbf{A}|.$$

The positive semidefinite factor $|\mathbf{A}|$ is determined by $\mathbf{A}$. The unitary factor $\mathbf{W}$ is determined by $\mathbf{A}$ if and only if $\mathbf{A}$ is invertible, and then $\mathbf{W} = \mathbf{A}|\mathbf{A}|^{-1}$. Moreover the same $\mathbf{W}$ satisfies the right-handed identity

$$\mathbf{A} = |\mathbf{A}^*|\,\mathbf{W}, \qquad |\mathbf{A}^*| = \mathbf{W}|\mathbf{A}|\mathbf{W}^*.$$

Idea. The singular value decomposition already separates the two kinds of behavior: $\mathbf{U}$ and $\mathbf{V}^*$ rotate, and $\mathbf{\Sigma}$ stretches along the axes. Writing $\mathbf{U\Sigma V}^* = (\mathbf{UV}^*)(\mathbf{V\Sigma V}^*)$ puts all the rotating in the first bracket and all the stretching in the second, and the second bracket is a positive semidefinite matrix whose square is $\mathbf{A}^*\mathbf{A}$. Uniqueness of the positive semidefinite square root does the rest. For the uniqueness of $\mathbf{W}$, notice that $\mathbf{W}$ is pinned down only where $|\mathbf{A}|$ is invertible; when $\mathbf{A} = \mathbf{0}$, every unitary works.

Proof. **Existence.** By Theorem 12.8.1 write $\mathbf{A} = \mathbf{U\Sigma V}^*$ with $\mathbf{U}, \mathbf{V} \in M_n(\mathbb{C})$ unitary and $\mathbf{\Sigma} = \operatorname{diag}(\sigma_1, \ldots, \sigma_n)$ with $\sigma_i \geq 0$. Put

$$\mathbf{W} := \mathbf{UV}^*, \qquad \mathbf{P} := \mathbf{V\Sigma V}^*.$$

Then $\mathbf{W}$ is unitary, being a product of unitary matrices, and

$$\mathbf{WP} = \mathbf{UV}^*\mathbf{V\Sigma V}^* = \mathbf{U\Sigma V}^* = \mathbf{A}.$$

The matrix $\mathbf{P}$ is self-adjoint, since $\mathbf{P}^* = \mathbf{V\Sigma}^*\mathbf{V}^* = \mathbf{P}$, and positive semidefinite: its eigenvalues are the $\sigma_i \geq 0$ because $\mathbf{V}^*\mathbf{PV} = \mathbf{\Sigma}$, so Theorem 12.1.4 applies. Finally

$$\mathbf{P}^2 = \mathbf{V\Sigma V}^*\mathbf{V\Sigma V}^* = \mathbf{V\Sigma}^2\mathbf{V}^* = \mathbf{A}^*\mathbf{A},$$

the last equality because $\mathbf{A}^*\mathbf{A} = \mathbf{V\Sigma U}^*\mathbf{U\Sigma V}^* = \mathbf{V\Sigma}^2\mathbf{V}^*$. A positive semidefinite matrix has exactly one positive semidefinite square root (Theorem 12.2.1), so $\mathbf{P} = (\mathbf{A}^*\mathbf{A})^{1/2} = |\mathbf{A}|$, and $\mathbf{A} = \mathbf{W}|\mathbf{A}|$.

The factor $|\mathbf{A}|$ is determined, since $\mathbf{A}^*\mathbf{A}$ is and the square root is unique.

Uniqueness of W. ($\Rightarrow$) Suppose $\mathbf{A}$ is invertible. Then $|\mathbf{A}|^2 = \mathbf{A}^*\mathbf{A}$ is invertible, so $|\mathbf{A}|$ is, and any $\mathbf{W}$ with $\mathbf{A} = \mathbf{W}|\mathbf{A}|$ satisfies $\mathbf{W} = \mathbf{A}|\mathbf{A}|^{-1}$: there is only one. ($\Leftarrow$) Suppose $\mathbf{A}$ is not invertible, so there is a non-zero $\mathbf{z} \in \ker \mathbf{A}$. Let $\mathbf{H} = \mathbf{H}_\mathbf{z}$ be the Householder reflection of Definition 10.8.1, which is unitary with $\mathbf{Hz} = -\mathbf{z}$ and $\mathbf{Hv} = \mathbf{v}$ for every $\mathbf{v} \perp \mathbf{z}$ (Proposition 10.8.2 (c), (d)). By Proposition 12.2.2, $\operatorname{nul}|\mathbf{A}| = \operatorname{nul} \mathbf{A}$, and $|\mathbf{A}|$ is self-adjoint, so

$$\operatorname{col}|\mathbf{A}| = \operatorname{col}\big(|\mathbf{A}|^*\big) = \big(\operatorname{nul}|\mathbf{A}|\big)^\perp = (\operatorname{nul} \mathbf{A})^\perp \subseteq \mathbf{z}^\perp$$

by Theorem 10.6.5 (b). Hence $\mathbf{H}$ fixes every vector of $\operatorname{col}|\mathbf{A}|$, that is, $\mathbf{H}|\mathbf{A}| = |\mathbf{A}|$, and therefore $(\mathbf{WH})|\mathbf{A}| = \mathbf{A}$ as well, with $\mathbf{WH}$ unitary and $\mathbf{WH} \neq \mathbf{W}$ because $\mathbf{H} \neq \mathbf{I}$ and $\mathbf{W}$ is invertible. So $\mathbf{W}$ is not determined.

The right-handed form. Set $\mathbf{Q} := \mathbf{W}|\mathbf{A}|\mathbf{W}^*$. It is self-adjoint and positive semidefinite, being a unitary congruence of a positive semidefinite matrix: $\mathbf{x}^*\mathbf{Qx} = (\mathbf{W}^*\mathbf{x})^*|\mathbf{A}|(\mathbf{W}^*\mathbf{x}) \geq$

0. And

$$\mathbf{Q}^2 = \mathbf{W}|\mathbf{A}|^2\mathbf{W}^* = \mathbf{W}\mathbf{A}^*\mathbf{A}\mathbf{W}^* = \mathbf{A}\mathbf{A}^*,$$

using $\mathbf{A} = \mathbf{W}|\mathbf{A}|$, so $\mathbf{A}^* = |\mathbf{A}|\mathbf{W}^*$ and $\mathbf{A}\mathbf{A}^* = \mathbf{W}|\mathbf{A}|^2\mathbf{W}^*$. By uniqueness of the square root again, $\mathbf{Q} = (\mathbf{A}\mathbf{A}^*)^{1/2} = |\mathbf{A}^*|$. Therefore $|\mathbf{A}^*|\mathbf{W} = \mathbf{W}|\mathbf{A}|\mathbf{W}^*\mathbf{W} = \mathbf{W}|\mathbf{A}| = \mathbf{A}$. This proves the theorem.

■

Remark. There is a second route to existence, the one Proposition 12.2.2 was pointing at: the identity $\||\mathbf{A}|\mathbf{x}\| = \|\mathbf{A}\mathbf{x}\|$ says that $|\mathbf{A}|\mathbf{x} \mapsto \mathbf{A}\mathbf{x}$ is a well-defined isometry from $\operatorname{col}|\mathbf{A}|$ onto $\operatorname{col}\mathbf{A}$, and extending it by any isometry between the orthogonal complements produces $\mathbf{W}$ directly. That proof shows more clearly *where* the freedom in $\mathbf{W}$ lives, but it needs the extension step written out; the route above borrows all of that from Theorem 12.8.1.

For $n = 1$ the theorem is exactly $z = e^{i\theta}|z|$: a 1×1 unitary matrix is a complex number of modulus 1, and $|\mathbf{A}|$ is the modulus. The non-uniqueness for singular $\mathbf{A}$ is the matrix version of the fact that θ is undefined when $z = 0$.

Example. (A polar decomposition)

Find the left and right polar decompositions of $\mathbf{A} = \begin{pmatrix} 3 & 0 \\ 4 & 5 \end{pmatrix}$.

Solution. Exercise (B1: A 2 by 2 decomposition) gives the singular value decomposition

$$\mathbf{U} = \tfrac{1}{\sqrt{10}}\begin{pmatrix} 1 & 3 \\ 3 & -1 \end{pmatrix}, \quad \mathbf{\Sigma} = \sqrt{5}\begin{pmatrix} 3 & 0 \\ 0 & 1 \end{pmatrix}, \quad \mathbf{V} = \tfrac{1}{\sqrt{2}}\begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}.$$

Hence

$$\mathbf{W} = \mathbf{U}\mathbf{V}^\top = \tfrac{1}{\sqrt{20}}\begin{pmatrix} 1 & 3 \\ 3 & -1 \end{pmatrix}\begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix} = \tfrac{1}{\sqrt{5}}\begin{pmatrix} 2 & -1 \\ 1 & 2 \end{pmatrix},$$

$$|\mathbf{A}| = \mathbf{V}\mathbf{\Sigma}\mathbf{V}^\top = \sqrt{5}\begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix}.$$

Check: $|\mathbf{A}|^2 = 5\begin{pmatrix} 5 & 4 \\ 4 & 5 \end{pmatrix} = \begin{pmatrix} 25 & 20 \\ 20 & 25 \end{pmatrix} = \mathbf{A}^\top\mathbf{A}$, the columns of $\mathbf{W}$ are orthonormal, and $\mathbf{W}|\mathbf{A}| = \mathbf{A}$. Here $\mathbf{W}$ is a rotation, since $\det\mathbf{W} = (4+1)/5 = 1$.

For the right-handed form, $\mathbf{A}\mathbf{A}^\top = \begin{pmatrix} 9 & 12 \\ 12 & 41 \end{pmatrix}$ and

$$|\mathbf{A}^*| = \mathbf{W}|\mathbf{A}|\mathbf{W}^\top = \tfrac{\sqrt{5}}{5}\begin{pmatrix} 6 & 3 \\ 3 & 14 \end{pmatrix},$$

whose square is indeed $\frac{1}{5}\begin{pmatrix} 45 & 60 \\ 60 & 205 \end{pmatrix} = \mathbf{A}\mathbf{A}^\top$. The two absolute values differ, and that is not an accident.

Remark. $|\mathbf{A}| = |\mathbf{A}^*|$ exactly when $\mathbf{A}$ is normal. Indeed $\mathbf{A}^*\mathbf{A} = \mathbf{A}\mathbf{A}^*$ if and only if the two positive semidefinite square roots agree, by uniqueness. So for a normal matrix —

and only then — the stretching looks the same before and after the rotation, and $\mathbf{W}$ commutes with $|\mathbf{A}|$ by the identity $|\mathbf{A}^*| = \mathbf{W}|\mathbf{A}|\mathbf{W}^*$.

Quick check. What is the polar decomposition of a unitary matrix? Of a positive semidefinite matrix?

Solution. If $\mathbf{A}$ is unitary then $\mathbf{A}^*\mathbf{A} = \mathbf{I}$, so $|\mathbf{A}| = \mathbf{I}$ and $\mathbf{W} = \mathbf{A}$: all rotation, no stretch. If $\mathbf{A} \succeq 0$ then $\mathbf{A}^*\mathbf{A} = \mathbf{A}^2$ and $\mathbf{A}$ is itself a positive semidefinite square root of $\mathbf{A}^2$, so $|\mathbf{A}| = \mathbf{A}$ by uniqueness (Theorem 12.2.1) and $\mathbf{W} = \mathbf{I}$ whenever $\mathbf{A}$ is invertible: all stretch, no rotation.

12.9.2 The nearest unitary matrix

The polar factor is not merely *a* unitary matrix attached to $\mathbf{A}$. It is the one closest to $\mathbf{A}$, measured in the Frobenius norm of Chapter 11 §11. This is the reason the polar decomposition is used in practice: given a matrix that ought to be unitary but has drifted, $\mathbf{W}$ is how to put it back.

Corollary 12.9.2 — The Polar Factor Is the Nearest Unitary Matrix

Let $\mathbf{A} \in M_n(\mathbb{C})$ with polar decomposition $\mathbf{A} = \mathbf{W}|\mathbf{A}|$. Then

$$\|\mathbf{A} - \mathbf{W}\|_F \le \|\mathbf{A} - \mathbf{Q}\|_F \qquad \text{for every unitary } \mathbf{Q} \in M_n(\mathbb{C}),$$

and the minimum value is $\left(\|\mathbf{A}\|_F^2 + n - 2\sum_i \sigma_i\right)^{1/2}$. If $\mathbf{A}$ is invertible, $\mathbf{W}$ is the **only** unitary matrix attaining the minimum.

Idea. Two moves. First, the Frobenius norm does not see unitary factors (Lemma 11.11.1), so sandwiching by $\mathbf{U}^*$ and $\mathbf{V}$ turns the problem into: among unitary $\mathbf{Z}$, which is closest to the diagonal matrix $\mathbf{\Sigma}$? Second, expanding $\|\mathbf{\Sigma} - \mathbf{Z}\|_F^2$ leaves only the diagonal entries of $\mathbf{Z}$ to be chosen, and each of them has modulus at most 1 because it sits in a unit column. So the best possible $\mathbf{Z}$ is $\mathbf{I}$, and translating back gives $\mathbf{Q} = \mathbf{U}\mathbf{V}^* = \mathbf{W}$.

Proof. Fix a singular value decomposition $\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^*$ as in Theorem 12.8.1, so that $\mathbf{W} = \mathbf{U}\mathbf{V}^*$ as in the proof of Theorem 12.9.1. Let $\mathbf{Q}$ be unitary and put $\mathbf{Z} := \mathbf{U}^*\mathbf{Q}\mathbf{V}$, which is unitary; as $\mathbf{Q}$ runs over all unitary matrices so does $\mathbf{Z}$, since $\mathbf{Q} = \mathbf{U}\mathbf{Z}\mathbf{V}^*$. By Lemma 11.11.1, applied with the unitary factors $\mathbf{U}^*$ on the left and $\mathbf{V}$ on the right,

$$\|\mathbf{A} - \mathbf{Q}\|_F = \|\mathbf{U}^*(\mathbf{A} - \mathbf{Q})\mathbf{V}\|_F = \|\mathbf{\Sigma} - \mathbf{Z}\|_F.$$

Expanding the square in the Frobenius inner product $\langle \mathbf{X}, \mathbf{Y} \rangle = \operatorname{tr}(\mathbf{Y}^*\mathbf{X})$ of Chapter 10 §01,

$$\begin{aligned} \|\mathbf{\Sigma} - \mathbf{Z}\|_F^2 &= \|\mathbf{\Sigma}\|_F^2 + \|\mathbf{Z}\|_F^2 - 2\operatorname{Re}\operatorname{tr}(\mathbf{Z}^*\mathbf{\Sigma}) \\ &= \sum_{i=1}^{n} \sigma_i^2 + n - 2\sum_{i=1}^{n} \sigma_i \operatorname{Re} z_{ii}, \end{aligned} \tag{12.9.1}$$

where $\|\mathbf{Z}\|_F^2 = \operatorname{tr}(\mathbf{Z}^*\mathbf{Z}) = \operatorname{tr}\mathbf{I}_n = n$, and $\operatorname{tr}(\mathbf{Z}^*\mathbf{\Sigma}) = \sum_i (\mathbf{Z}^*)_{ii}\sigma_i = \sum_i \overline{z_{ii}}\sigma_i$, whose real

part is $\sum_i \sigma_i \operatorname{Re} z_{ii}$.

Column i of $\mathbf{Z}$ is a unit vector, so $|z_{ii}| \le 1$ and hence $\operatorname{Re} z_{ii} \le 1$. Since every $\sigma_i \ge 0$,

$$\sum_{i=1}^{n} \sigma_i \operatorname{Re} z_{ii} \le \sum_{i=1}^{n} \sigma_i,$$

so Eq. 12.9.1 gives $\|\mathbf{A}-\mathbf{Q}\|_F^2 \ge \sum_i \sigma_i^2 + n - 2\sum_i \sigma_i$ for every unitary $\mathbf{Q}$. Taking $\mathbf{Q} = \mathbf{W} = \mathbf{U}\mathbf{V}^*$ makes $\mathbf{Z} = \mathbf{U}^*\mathbf{U}\mathbf{V}^*\mathbf{V} = \mathbf{I}_n$, for which $\operatorname{Re} z_{ii} = 1$ for every i and the bound is attained. Finally $\|\mathbf{A}\|_F = \|\mathbf{U}\mathbf{\Sigma}\mathbf{V}^*\|_F = \|\mathbf{\Sigma}\|_F$ by Lemma 11.11.1, applied once on each side, and the only non-zero entries of $\mathbf{\Sigma}$ are $\sigma_1, \dots, \sigma_n$ on its diagonal, so $\|\mathbf{A}\|_F^2 = \sum_i \sigma_i^2$ (Exercise (C1: The Frobenius norm and the largest singular value)). The minimum value is therefore as stated.

Now suppose $\mathbf{A}$ is invertible, so $\sigma_i > 0$ for every i, and suppose $\mathbf{Q}$ attains the minimum. Then $\sum_i \sigma_i(1 - \operatorname{Re} z_{ii}) = 0$ is a sum of non-negative terms, so $\operatorname{Re} z_{ii} = 1$ for every i; with $|z_{ii}| \le 1$ this forces $z_{ii} = 1$. Column i of $\mathbf{Z}$ then has a coordinate equal to 1 and total squared length 1, so all its other coordinates vanish and the column is $\mathbf{e}_i$. Hence $\mathbf{Z} = \mathbf{I}_n$ and $\mathbf{Q} = \mathbf{U}\mathbf{Z}\mathbf{V}^* = \mathbf{W}$. This proves the corollary.

■

For $\mathbf{A} = \begin{pmatrix} 3 & 0 \\ 4 & 5 \end{pmatrix}$ of Example (A polar decomposition), with $\sigma_1 = 3\sqrt{5}$, $\sigma_2 = \sqrt{5}$ and $\|\mathbf{A}\|_F^2 = 50$, the nearest unitary matrix is $\mathbf{W} = \frac{1}{\sqrt{5}}\begin{pmatrix} 2 & -1 \\ 1 & 2 \end{pmatrix}$ and the distance to the unitary group is $\sqrt{52 - 8\sqrt{5}}$, about 5.84.

Warning. The corollary is a statement about the **Frobenius** norm. A different way of measuring distance can have a different minimizer, and "nearest" always needs its yardstick named. It is true, though not proved here, that $\mathbf{W}$ also minimizes the distance in every unitarily invariant norm; Chapter 20 takes up that family of norms.

12.9.3 Takagi's factorization

A complex matrix can be symmetric, $\mathbf{A}^\top = \mathbf{A}$, without being Hermitian, $\mathbf{A}^* = \mathbf{A}$. Over $\mathbb{R}$ the two coincide and Chapter 11 handled them; over $\mathbb{C}$ they are genuinely different conditions, and symmetry is much the weaker one. It does not imply normality, it does not imply diagonalizability, and it says nothing about the eigenvalues. Here is the standing example:

$$\mathbf{N} = \begin{pmatrix} 1 & i \\ i & -1 \end{pmatrix}, \qquad \mathbf{N}^\top = \mathbf{N}, \qquad \mathbf{N}^2 = \mathbf{0}.$$

A non-zero matrix with $\mathbf{N}^2 = \mathbf{0}$ has minimal polynomial x^2 and is therefore not diagonalizable, so no version of the spectral theorem can apply to $\mathbf{N}$. Nevertheless something survives, and it is a statement about singular values rather than eigenvalues.

Theorem 12.9.3 — Takagi's Factorization

Let $\mathbf{A} \in M_n(\mathbb{C})$ be **symmetric**, $\mathbf{A}^\top = \mathbf{A}$, with singular values $\sigma_1 \ge \cdots \ge \sigma_n \ge 0$.

Then there is a unitary $\mathbf{U} \in M_n(\mathbb{C})$ with

$$\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{U}^{\top}, \qquad \mathbf{\Sigma} = \operatorname{diag}(\sigma_1, \dots, \sigma_n).$$

Read the statement against the two theorems it resembles.

- **Against the singular value decomposition.** Theorem 12.8.1 gives $\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^*$ with two unrelated unitary matrices. Since $\mathbf{U}^{\top} = (\overline{\mathbf{U}})^*$, Takagi's identity says $\mathbf{A} = \mathbf{U}\mathbf{\Sigma}(\overline{\mathbf{U}})^*$: it is a singular value decomposition in which the right factor is forced to be $\mathbf{V} = \overline{\mathbf{U}}$. So the content is not a new diagonal matrix but a relation between $\mathbf{U}$ and $\mathbf{V}$.
- **Against the spectral theorem.** Corollary 11.4.3 writes a normal $\mathbf{A}$ as $\mathbf{U}\mathbf{D}\mathbf{U}^*$, a *similarity*, with the eigenvalues of $\mathbf{A}$ on the diagonal. Takagi writes a symmetric $\mathbf{A}$ as $\mathbf{U}\mathbf{\Sigma}\mathbf{U}^{\top}$, which is a *congruence* $\mathbf{X} \mapsto \mathbf{U}\mathbf{X}\mathbf{U}^{\top}$, with the singular values on the diagonal. The hypotheses are different (symmetric, not normal), the diagonal holds different numbers, and the transpose is not the conjugate transpose.

The difference is visible even for a real matrix. Take $\mathbf{A} = \begin{pmatrix} 3 & 4 \\ 4 & -3 \end{pmatrix}$, which is real symmetric with eigenvalues 5 and -5. Corollary 11.5.2 gives $\mathbf{A} = \mathbf{Q}\operatorname{diag}(5, -5)\mathbf{Q}^{\top}$ with $\mathbf{Q}$ real orthogonal. Takagi insists on the **non-negative** diagonal $\operatorname{diag}(5, 5)$, and no real $\mathbf{U}$ can achieve that, since $\mathbf{U}\operatorname{diag}(5, 5)\mathbf{U}^{\top} = 5\mathbf{U}\mathbf{U}^{\top} = 5\mathbf{I}$ for real orthogonal $\mathbf{U}$. A genuinely complex $\mathbf{U}$ is needed, and Example (Takagi for a real symmetric matrix) finds one.

Idea. Four steps, and the first two are the polar decomposition doing the work. ① Symmetry makes $\mathbf{A}$ intertwine $\mathbf{A}^*\mathbf{A}$ with its conjugate: $\mathbf{A}(\mathbf{A}^*\mathbf{A}) = \overline{(\mathbf{A}^*\mathbf{A})}\mathbf{A}$. Because the positive square root is a polynomial in the matrix, the same relation passes to $|\mathbf{A}|$. ② That relation, combined with $\mathbf{A}^{\top} = \mathbf{A}$, forces the polar factor $\mathbf{W}$ to be a **symmetric** unitary matrix. ③ A symmetric unitary matrix factors as $\mathbf{V}\mathbf{V}^{\top}$: split it into real and imaginary parts, which turn out to be commuting real symmetric matrices, and use Chapter 11's simultaneous diagonalization (Corollary 11.7.3). ④ Conjugating $\mathbf{A}$ by that $\mathbf{V}$ in the right way produces a matrix that is both symmetric and Hermitian, hence **real** symmetric, and the real spectral theorem in matrix form (Corollary 11.5.2) finishes the job. We prove all of this for invertible $\mathbf{A}$, where the polar factor is unique and $|\mathbf{A}|^{-1}$ exists.

Proof. We prove the theorem for **invertible** $\mathbf{A}$. Throughout, $\mathbf{A}^{\top} = \mathbf{A}$, so $\mathbf{A}^* = \overline{\mathbf{A}^{\top}} = \overline{\mathbf{A}}$. Write $\mathbf{M} \coloneqq \mathbf{A}^*\mathbf{A} = \overline{\mathbf{A}}\mathbf{A}$ and $\mathbf{P} \coloneqq |\mathbf{A}| = \mathbf{M}^{1/2}$. Since $\mathbf{A}$ is invertible, so are $\mathbf{M}$ and $\mathbf{P}$, and $\mathbf{M} \succ 0$.

Step 1: $\mathbf{A}\mathbf{M} = \overline{\mathbf{M}}\mathbf{A}$ and $\mathbf{A}\mathbf{P} = \overline{\mathbf{P}}\mathbf{A}$. For the first, $\overline{\mathbf{M}} = \overline{\overline{\mathbf{A}}\mathbf{A}} = \mathbf{A}\overline{\mathbf{A}}$, so

$$\mathbf{A}\mathbf{M} = \mathbf{A}\overline{\mathbf{A}}\mathbf{A} = \overline{\mathbf{M}}\mathbf{A}.$$

For the second we need a polynomial.

Claim. There is a polynomial p with **real** coefficients such that $p(\mathbf{M}) = \mathbf{P}$ and $p(\overline{\mathbf{M}}) = \overline{\mathbf{P}}$.

Proof. By Theorem 12.2.1 (a) there is a polynomial p with real coefficients such that $p(\mathbf{M}) = \mathbf{M}^{1/2} = \mathbf{P}$. Conjugating every entry of the identity $\mathbf{P} = p(\mathbf{M})$, and using that the coefficients of p are real so that conjugation passes through them, gives $\overline{\mathbf{P}} = p(\overline{\mathbf{M}})$.

■

Iterating Step 1's first identity gives $\mathbf{A}\mathbf{M}^j = \overline{\mathbf{M}}^j\mathbf{A}$ for every $j \geq 0$, hence $\mathbf{A}\,p(\mathbf{M}) = p(\overline{\mathbf{M}})\,\mathbf{A}$ for every polynomial p, and with the claim's p this reads

$$\mathbf{A}\mathbf{P} = \overline{\mathbf{P}}\mathbf{A}. \tag{12.9.2}$$

Step 2: the polar factor is symmetric. By Theorem 12.9.1, $\mathbf{A} = \mathbf{W}\mathbf{P}$ with $\mathbf{W} = \mathbf{A}\mathbf{P}^{-1}$ unitary. Substituting $\mathbf{A} = \mathbf{W}\mathbf{P}$ into Eq. 12.9.2 gives $\mathbf{W}\mathbf{P}^2 = \overline{\mathbf{P}}\mathbf{W}\mathbf{P}$, and canceling the invertible $\mathbf{P}$ on the right,

$$\mathbf{W}\mathbf{P} = \overline{\mathbf{P}}\,\mathbf{W}.$$

On the other hand $\mathbf{P}$ is Hermitian, so $\mathbf{P}^\top = \overline{\mathbf{P}}$, and transposing $\mathbf{A} = \mathbf{W}\mathbf{P}$ while using $\mathbf{A}^\top = \mathbf{A}$ gives

$$\mathbf{W}\mathbf{P} = \mathbf{A} = \mathbf{A}^\top = \mathbf{P}^\top\mathbf{W}^\top = \overline{\mathbf{P}}\,\mathbf{W}^\top.$$

Comparing the two displays, $\overline{\mathbf{P}}\mathbf{W} = \overline{\mathbf{P}}\mathbf{W}^\top$, and $\overline{\mathbf{P}}$ is invertible, so $\mathbf{W}^\top = \mathbf{W}$.

Step 3: a symmetric unitary matrix is $\mathbf{V}\mathbf{V}^\top$.

Claim. Let $\mathbf{W} \in M_n(\mathbb{C})$ be unitary with $\mathbf{W}^\top = \mathbf{W}$. Then $\mathbf{W} = \mathbf{V}\mathbf{V}^\top$ for some unitary $\mathbf{V}$.

Proof. From $\mathbf{W}^{-1} = \mathbf{W}^* = \overline{\mathbf{W}^\top} = \overline{\mathbf{W}}$ we get $\overline{\mathbf{W}}\mathbf{W} = \mathbf{I}$. Write $\mathbf{W} = \mathbf{X} + i\mathbf{Y}$ with $\mathbf{X} = \frac{1}{2}(\mathbf{W} + \overline{\mathbf{W}})$ and $\mathbf{Y} = \frac{1}{2i}(\mathbf{W} - \overline{\mathbf{W}})$, both **real** matrices, and both symmetric because $\mathbf{W}$ and $\overline{\mathbf{W}}$ are. Then

$$\mathbf{I} = \overline{\mathbf{W}}\mathbf{W} = (\mathbf{X} - i\mathbf{Y})(\mathbf{X} + i\mathbf{Y}) = \mathbf{X}^2 + \mathbf{Y}^2 + i(\mathbf{X}\mathbf{Y} - \mathbf{Y}\mathbf{X}),$$

and since $\mathbf{X}^2+\mathbf{Y}^2$ and $\mathbf{X}\mathbf{Y}-\mathbf{Y}\mathbf{X}$ are real matrices, comparing real and imaginary parts gives

$$\mathbf{X}^2 + \mathbf{Y}^2 = \mathbf{I}, \qquad \mathbf{X}\mathbf{Y} = \mathbf{Y}\mathbf{X}.$$

So $\mathbf{X}$ and $\mathbf{Y}$ are commuting real symmetric matrices, and Corollary 11.7.3 supplies $\mathbf{Q} \in \mathrm{O}(n)$ with $\mathbf{Q}^\top\mathbf{X}\mathbf{Q} = \mathrm{diag}(x_1, \ldots, x_n)$ and $\mathbf{Q}^\top\mathbf{Y}\mathbf{Q} = \mathrm{diag}(y_1, \ldots, y_n)$. Hence $\mathbf{Q}^\top\mathbf{W}\mathbf{Q} = \mathrm{diag}(x_1 + iy_1, \ldots, x_n + iy_n)$, and $x_j^2 + y_j^2 = 1$ for every j by the first relation. Each $x_j + iy_j$ therefore has modulus 1. The polynomial $x^2 - (x_j + iy_j)$ has a root $c_j \in \mathbb{C}$ by Theorem 5.5.1, and $|c_j|^2 = |c_j^2| = 1$, so $|c_j| = 1$. Put $\mathbf{C} = \mathrm{diag}(c_1, \ldots, c_n)$ and $\mathbf{V} := \mathbf{Q}\mathbf{C}$, which is unitary as a product of unitary matrices. Since $\mathbf{Q}$ is real orthogonal, $\mathbf{Q}^\top = \mathbf{Q}^{-1}$, and $\mathbf{C}^\top = \mathbf{C}$, so

$$\mathbf{V}\mathbf{V}^\top = \mathbf{Q}\mathbf{C}\mathbf{C}^\top\mathbf{Q}^\top = \mathbf{Q}\mathbf{C}^2\mathbf{Q}^\top = \mathbf{Q}\,\mathrm{diag}(x_j + iy_j)\,\mathbf{Q}^\top = \mathbf{W}.$$

This proves the claim.

■

Step 4: conjugate to a real matrix. Take $\mathbf{V}$ from Step 3, so $\mathbf{W} = \mathbf{V}\mathbf{V}^{\top}$, and set

$$\mathbf{B} \coloneqq \mathbf{V}^{*}\mathbf{A}\overline{\mathbf{V}}.$$

Three observations. First, $\mathbf{B}^{\top} = \mathbf{B}$: using $(\overline{\mathbf{V}})^{\top} = \mathbf{V}^{*}$, $(\mathbf{V}^{*})^{\top} = \overline{\mathbf{V}}$ and $\mathbf{A}^{\top} = \mathbf{A}$,

$$\mathbf{B}^{\top} = (\overline{\mathbf{V}})^{\top}\,\mathbf{A}^{\top}\,(\mathbf{V}^{*})^{\top} = \mathbf{V}^{*}\mathbf{A}\overline{\mathbf{V}} = \mathbf{B}.$$

Second, $\mathbf{B} \succ 0$: since $\mathbf{A} = \mathbf{W}\mathbf{P} = \mathbf{V}\mathbf{V}^{\top}\mathbf{P}$ and $\mathbf{V}^{*}\mathbf{V} = \mathbf{I}$,

$$\mathbf{B} = \mathbf{V}^{*}\mathbf{V}\mathbf{V}^{\top}\mathbf{P}\overline{\mathbf{V}} = \mathbf{V}^{\top}\mathbf{P}\overline{\mathbf{V}} = (\overline{\mathbf{V}})^{*}\,\mathbf{P}\,(\overline{\mathbf{V}}),$$

a unitary congruence of the positive definite $\mathbf{P}$, so $\mathbf{x}^{*}\mathbf{B}\mathbf{x} = (\overline{\mathbf{V}}\mathbf{x})^{*}\mathbf{P}(\overline{\mathbf{V}}\mathbf{x}) > 0$ for $\mathbf{x} \neq \mathbf{0}$; in particular $\mathbf{B}^{*} = \mathbf{B}$. Third, $\mathbf{B}$ is **real**, because

$$\overline{\mathbf{B}} = \overline{\mathbf{B}^{\top}} = \mathbf{B}^{*} = \mathbf{B},$$

the first equality using $\mathbf{B}^{\top} = \mathbf{B}$, the second the definition of the conjugate transpose, and the third Hermitian symmetry.

So $\mathbf{B}$ is a real symmetric positive definite matrix. By Corollary 11.5.2 there is $\mathbf{Q}_0 \in \mathrm{O}(n)$ with $\mathbf{B} = \mathbf{Q}_0\mathbf{\Sigma}\mathbf{Q}_0^{\top}$, where $\mathbf{\Sigma}$ is the diagonal matrix of eigenvalues of $\mathbf{B}$, which we list in decreasing order. Finally, using $\mathbf{V}\mathbf{V}^{*} = \mathbf{I}$ and its conjugate $\overline{\mathbf{V}}\mathbf{V}^{\top} = \mathbf{I}$,

$$\mathbf{V}\mathbf{B}\mathbf{V}^{\top} = \mathbf{V}\mathbf{V}^{*}\mathbf{A}\overline{\mathbf{V}}\mathbf{V}^{\top} = \mathbf{A},$$

so with $\mathbf{U} \coloneqq \mathbf{V}\mathbf{Q}_0$, which is unitary,

$$\mathbf{A} = \mathbf{V}\mathbf{Q}_0\mathbf{\Sigma}\mathbf{Q}_0^{\top}\mathbf{V}^{\top} = \mathbf{U}\mathbf{\Sigma}\mathbf{U}^{\top}.$$

It remains to identify the diagonal. Conjugate-transposing, $\mathbf{A}^{*} = \overline{\mathbf{U}}\mathbf{\Sigma}\mathbf{U}^{*}$, so

$$\mathbf{A}^{*}\mathbf{A} = \overline{\mathbf{U}}\mathbf{\Sigma}\mathbf{U}^{*}\mathbf{U}\mathbf{\Sigma}\mathbf{U}^{\top} = \overline{\mathbf{U}}\,\mathbf{\Sigma}^{2}\,(\overline{\mathbf{U}})^{*}.$$

This exhibits $\mathbf{\Sigma}^{2}$ as the eigenvalue list of $\mathbf{A}^{*}\mathbf{A}$ in decreasing order, so $\mathbf{\Sigma} = \operatorname{diag}(\sigma_1, \dots, \sigma_n)$ by Definition 12.8.1. This proves the theorem for invertible $\mathbf{A}$.

■

Remark. **What is left out.** The theorem as stated is true for every complex symmetric $\mathbf{A}$, singular ones included, and the example below exhibits a singular case. Our proof used invertibility twice: to know that $\mathbf{P}$ is invertible, so that $\mathbf{W} = \mathbf{A}\mathbf{P}^{-1}$ is determined and the cancellations of Step 2 are legal. One way to remove the hypothesis is to apply the proved case to $\mathbf{A} + t\mathbf{I}$, which is symmetric and invertible for all but finitely many t, and let $t \to 0$ along a sequence for which the unitary factors converge — a step that needs the compactness of the unitary group, which is analysis this book has not set up. We state the general theorem and prove the invertible case.

Example. (Takagi for a real symmetric matrix)

Find a Takagi factorization of $\mathbf{A} = \begin{pmatrix} 3 & 4 \\ 4 & -3 \end{pmatrix}$.

Solution. First the singular values: $\mathbf{A}^*\mathbf{A} = \mathbf{A}^\top\mathbf{A} = \mathbf{A}^2 = 25\mathbf{I}$, so $\sigma_1 = \sigma_2 = 5$ and $\mathbf{\Sigma} = 5\mathbf{I}$. We therefore need a unitary $\mathbf{U}$ with

$$\mathbf{A} = 5\,\mathbf{U}\mathbf{U}^\top, \qquad \text{that is} \qquad \mathbf{U}\mathbf{U}^\top = \tfrac{1}{5}\mathbf{A}.$$

The matrix $\frac{1}{5}\mathbf{A}$ is real symmetric and orthogonal, with eigenvalues 1 and -1. Its eigenvectors: $(\mathbf{A} - 5\mathbf{I})\mathbf{x} = \mathbf{0}$ reads $-2x_1 + 4x_2 = 0$, giving $\mathbf{q}_1 = \frac{1}{\sqrt{5}}(2,1)$, and orthogonally $\mathbf{q}_2 = \frac{1}{\sqrt{5}}(1,-2)$. So with $\mathbf{Q} = \frac{1}{\sqrt{5}}\begin{pmatrix} 2 & 1 \\ 1 & -2 \end{pmatrix} \in \mathrm{O}(2)$ we have $\frac{1}{5}\mathbf{A} = \mathbf{Q}\,\mathrm{diag}(1,-1)\mathbf{Q}^\top$. The diagonal entries 1 and -1 have square roots 1 and i, so, following Step 3 of Theorem 12.9.3, set

$$\mathbf{U} = \mathbf{Q}\,\mathrm{diag}(1,i) = \tfrac{1}{\sqrt{5}}\begin{pmatrix} 2 & i \\ 1 & -2i \end{pmatrix}.$$

Then $\mathbf{U}$ is unitary — its columns $\frac{1}{\sqrt{5}}(2,1)$ and $\frac{i}{\sqrt{5}}(1,-2)$ are orthonormal, since multiplying a real orthonormal pair by unit scalars keeps it orthonormal — and

$$\mathbf{U}\mathbf{\Sigma}\mathbf{U}^\top = 5\,\mathbf{U}\mathbf{U}^\top = \mathbf{Q}\,\mathrm{diag}(5,-5)\mathbf{Q}^\top = \mathbf{A}.$$

Note where the complex entries were needed: $\mathrm{diag}(1,i)$ converted the eigenvalue -5 of $\mathbf{A}$ into the singular value $+5$.

For a singular example, return to $\mathbf{N} = \begin{pmatrix} 1 & i \\ i & -1 \end{pmatrix}$. Here $\mathbf{N}^*\mathbf{N} = \begin{pmatrix} 2 & 2i \\ -2i & 2 \end{pmatrix}$, with eigenvalues 4 and 0, so $\sigma_1 = 2$ and $\sigma_2 = 0$. With $\mathbf{U} = \frac{1}{\sqrt{2}}\begin{pmatrix} 1 & i \\ i & 1 \end{pmatrix}$, which is unitary, one checks $\mathbf{U}\,\mathrm{diag}(2,0)\mathbf{U}^\top = 2\,\mathbf{u}_1\mathbf{u}_1^\top = \mathbf{N}$, where $\mathbf{u}_1 = \frac{1}{\sqrt{2}}(1,i)$ is the first column of $\mathbf{U}$. The theorem holds here even though our proof did not reach it, and even though $\mathbf{N}$ has no eigenbasis at all.

Warning. **Symmetric is not Hermitian, and $\mathbf{U}^\top$ is not $\mathbf{U}^*$.** Takagi's hypothesis is $\mathbf{A}^\top = \mathbf{A}$ with no conjugation, which over $\mathbb{C}$ is a different and weaker condition than $\mathbf{A}^* = \mathbf{A}$; the matrix $\mathbf{N}$ above is symmetric, is not Hermitian, is not normal and is not diagonalizable. The conclusion likewise carries $\mathbf{U}^\top$, not $\mathbf{U}^*$: writing $\mathbf{U}\mathbf{\Sigma}\mathbf{U}^*$ by mistake would assert that $\mathbf{A}$ is positive semidefinite, which $\mathbf{N}$ certainly is not.

12.9.4 Exercises

12.9.4.1 A. Check your understanding

Exercise A1.

(a) State the polar decomposition, and say which factor is unique and when.

(b) What is $|\mathbf{A}|$, and what identity relates $\||\mathbf{A}|\mathbf{x}\|$ to $\|\mathbf{A}\mathbf{x}\|$?

(c) What does the polar decomposition say when $n = 1$?

(d) True or false: $|\mathbf{A}| = |\mathbf{A}^*|$ for every square $\mathbf{A}$. Justify your answer.

(e) State Takagi's factorization, and name two ways in which it differs from the singular value decomposition and from the complex spectral theorem.

(f) True or false: a complex symmetric matrix is diagonalizable. Justify your answer.

Solution.

(a) Every $\mathbf{A} \in M_n(\mathbb{C})$ is $\mathbf{A} = \mathbf{W}|\mathbf{A}|$ with $\mathbf{W}$ unitary (Theorem 12.9.1). The positive semidefinite factor $|\mathbf{A}|$ is always unique; $\mathbf{W}$ is unique exactly when $\mathbf{A}$ is invertible, and then $\mathbf{W} = \mathbf{A}|\mathbf{A}|^{-1}$.

(b) $|\mathbf{A}| = (\mathbf{A}^*\mathbf{A})^{1/2}$, the unique positive semidefinite square root of $\mathbf{A}^*\mathbf{A}$ (Definition 12.2.1), and $\||\mathbf{A}|\mathbf{x}\| = \|\mathbf{A}\mathbf{x}\|$ for every $\mathbf{x}$.

(c) It says $z = e^{i\theta}|z|$: a complex number is a number of modulus 1 times its modulus, with θ undetermined exactly when $z = 0$.

(d) False in general, true exactly for normal $\mathbf{A}$. For $\mathbf{A} = \begin{pmatrix} 3 & 0 \\ 4 & 5 \end{pmatrix}$, $\mathbf{A}^\top\mathbf{A} = \begin{pmatrix} 25 & 20 \\ 20 & 25 \end{pmatrix} \neq \begin{pmatrix} 9 & 12 \\ 12 & 41 \end{pmatrix} = \mathbf{A}\mathbf{A}^\top$, so the two square roots differ.

(e) Theorem 12.9.3: a symmetric $\mathbf{A} \in M_n(\mathbb{C})$ is $\mathbf{U}\mathbf{\Sigma}\mathbf{U}^\top$ with $\mathbf{U}$ unitary and $\mathbf{\Sigma}$ the diagonal matrix of singular values. Against the singular value decomposition: the right factor is not free but forced to be $\overline{\mathbf{U}}$. Against the spectral theorem: the hypothesis is symmetry rather than normality, the operation is the congruence $\mathbf{X} \mapsto \mathbf{U}\mathbf{X}\mathbf{U}^\top$ rather than a similarity, and the diagonal carries singular values rather than eigenvalues.

(f) False. $\mathbf{N} = \begin{pmatrix} 1 & i \\ i & -1 \end{pmatrix}$ is symmetric and non-zero with $\mathbf{N}^2 = \mathbf{0}$, so its minimal polynomial is x^2, which has a repeated root; it is not diagonalizable.

12.9.4.2 B. Practice

Exercise B1: A polar decomposition by hand.

Find both polar decompositions $\mathbf{A} = \mathbf{W}|\mathbf{A}| = |\mathbf{A}^*|\mathbf{W}$ of

$$\mathbf{A} = \begin{pmatrix} 0 & -2 \\ 3 & 0 \end{pmatrix},$$

and say what $\mathbf{W}$ is geometrically.

Solution. $\mathbf{A}^\top\mathbf{A} = \begin{pmatrix} 9 & 0 \\ 0 & 4 \end{pmatrix}$, which is diagonal with non-negative entries, so $|\mathbf{A}| = \operatorname{diag}(3, 2)$: this is positive semidefinite and squares to $\mathbf{A}^\top\mathbf{A}$, which by Theorem 12.2.1 identifies it. Since $\mathbf{A}$ is invertible,

$$\mathbf{W} = \mathbf{A}|\mathbf{A}|^{-1} = \begin{pmatrix} 0 & -2 \\ 3 & 0 \end{pmatrix}\begin{pmatrix} \frac{1}{3} & 0 \\ 0 & \frac{1}{2} \end{pmatrix} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix},$$

the quarter turn of $\mathbb{R}^2$. Check: $\mathbf{W}^\top\mathbf{W} = \mathbf{I}$ and $\mathbf{W}|\mathbf{A}| = \mathbf{A}$.

For the right-handed form, $\mathbf{A}\mathbf{A}^\top = \operatorname{diag}(4, 9)$, so $|\mathbf{A}^*| = \operatorname{diag}(2, 3)$, and indeed

$$|\mathbf{A}^*|\mathbf{W} = \begin{pmatrix} 2 & 0 \\ 0 & 3 \end{pmatrix}\begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} = \begin{pmatrix} 0 & -2 \\ 3 & 0 \end{pmatrix} = \mathbf{A}.$$

The two absolute values are different, which is consistent with $\mathbf{A}$ not being normal. In

words: $\mathbf{A}$ stretches by 3 horizontally and 2 vertically, then rotates by a quarter turn; equivalently it rotates first and then stretches by 2 horizontally and 3 vertically.

Exercise B2: The nearest unitary matrix.

Let $\mathbf{A} = \operatorname{diag}(2, -3) \in M_2(\mathbb{R})$. Find the unitary matrix nearest to $\mathbf{A}$ in the Frobenius norm, compute the distance, and verify the value against the formula of Corollary 12.9.2.

Solution. $\mathbf{A}^*\mathbf{A} = \operatorname{diag}(4, 9)$, so $|\mathbf{A}| = \operatorname{diag}(2, 3)$ and $\mathbf{W} = \mathbf{A}|\mathbf{A}|^{-1} = \operatorname{diag}(1, -1)$, which is unitary. By Corollary 12.9.2, $\mathbf{W}$ is the nearest unitary matrix, and it is the only one since $\mathbf{A}$ is invertible. Directly,

$$\mathbf{A} - \mathbf{W} = \operatorname{diag}(1, -2), \qquad \|\mathbf{A} - \mathbf{W}\|_F^2 = 1 + 4 = 5.$$

The formula gives $\|\mathbf{A}\|_F^2 + n - 2(\sigma_1 + \sigma_2) = 13 + 2 - 2(3 + 2) = 5$, the same. So the distance is $\sqrt{5}$.

Exercise B3: A Takagi factorization.

Find a Takagi factorization of $\mathbf{A} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$, and explain why no **real** $\mathbf{U}$ can work.

Solution. $\mathbf{A}$ is symmetric and $\mathbf{A}^*\mathbf{A} = \mathbf{A}^2 = \mathbf{I}$, so $\sigma_1 = \sigma_2 = 1$ and $\mathbf{\Sigma} = \mathbf{I}$. We need a unitary $\mathbf{U}$ with $\mathbf{U}\mathbf{U}^\top = \mathbf{A}$.

Diagonalize $\mathbf{A}$ over $\mathbb{R}$: its eigenvalues are 1 and -1, with unit eigenvectors $\frac{1}{\sqrt{2}}(1, 1)$ and $\frac{1}{\sqrt{2}}(1, -1)$, so $\mathbf{A} = \mathbf{Q}\operatorname{diag}(1, -1)\mathbf{Q}^\top$ with $\mathbf{Q} = \frac{1}{\sqrt{2}}\begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}$. Following Step 3 of Theorem 12.9.3, take square roots 1 and i of the diagonal entries:

$$\mathbf{U} = \mathbf{Q}\operatorname{diag}(1, i) = \frac{1}{\sqrt{2}}\begin{pmatrix} 1 & i \\ 1 & -i \end{pmatrix}, \qquad \mathbf{U}\mathbf{U}^\top = \mathbf{Q}\operatorname{diag}(1, -1)\mathbf{Q}^\top = \mathbf{A}.$$

$\mathbf{U}$ is unitary, and $\mathbf{U}\mathbf{\Sigma}\mathbf{U}^\top = \mathbf{U}\mathbf{U}^\top = \mathbf{A}$.

No real $\mathbf{U}$ works: a real $\mathbf{U}$ with $\mathbf{U}^*\mathbf{U} = \mathbf{I}$ is orthogonal, and then $\mathbf{U}\mathbf{\Sigma}\mathbf{U}^\top = \mathbf{U}\mathbf{U}^\top = \mathbf{I} \neq \mathbf{A}$.

12.9.4.3 C. Going deeper

Exercise C1: The positive factor is forced.

Let $\mathbf{A} \in M_n(\mathbb{C})$.

(a) Suppose $\mathbf{A} = \mathbf{Q}\mathbf{P}$ with $\mathbf{Q}$ unitary and $\mathbf{P} \succeq 0$. Prove that $\mathbf{P} = |\mathbf{A}|$. (Invertibility is **not** assumed.)

(b) Deduce that $\mathbf{A}$ is unitary if and only if $|\mathbf{A}| = \mathbf{I}$.

Solution.

(a) From $\mathbf{A} = \mathbf{QP}$ we get $\mathbf{A}^*\mathbf{A} = \mathbf{P}^*\mathbf{Q}^*\mathbf{QP} = \mathbf{P}^*\mathbf{P} = \mathbf{P}^2$, using $\mathbf{Q}^*\mathbf{Q} = \mathbf{I}$ and $\mathbf{P}^* = \mathbf{P}$. So $\mathbf{P}$ is a positive semidefinite square root of $\mathbf{A}^*\mathbf{A}$. Such a square root is unique (Theorem 12.2.1), and $|\mathbf{A}|$ is one by definition (Definition 12.2.1). Hence $\mathbf{P} = |\mathbf{A}|$.

(b) ($\Rightarrow$) If $\mathbf{A}$ is unitary then $\mathbf{A}^*\mathbf{A} = \mathbf{I}$, and $\mathbf{I} \succeq 0$ with $\mathbf{I}^2 = \mathbf{I}$, so $|\mathbf{A}| = \mathbf{I}$ by uniqueness. ($\Leftarrow$) If $|\mathbf{A}| = \mathbf{I}$ then $\mathbf{A}^*\mathbf{A} = |\mathbf{A}|^2 = \mathbf{I}$, which for a square matrix says $\mathbf{A}$ is unitary (Definition 10.7.2).

Exercise C2: Normality through the polar factors.

Let $\mathbf{A} \in M_n(\mathbb{C})$ be invertible with polar decomposition $\mathbf{A} = \mathbf{W}|\mathbf{A}|$. Prove that the following are equivalent.

(a) $\mathbf{A}$ is normal.

(b) $|\mathbf{A}| = |\mathbf{A}^*|$.

(c) $\mathbf{W}|\mathbf{A}| = |\mathbf{A}|\mathbf{W}$.

Solution.

(a) $\Rightarrow$ (b). If $\mathbf{A}^*\mathbf{A} = \mathbf{AA}^*$, then $|\mathbf{A}|$ and $|\mathbf{A}^*|$ are positive semidefinite square roots of the same matrix, hence equal by Theorem 12.2.1.

(b) $\Rightarrow$ (c). By Theorem 12.9.1, $|\mathbf{A}^*| = \mathbf{W}|\mathbf{A}|\mathbf{W}^*$. If this equals $|\mathbf{A}|$, multiply on the right by $\mathbf{W}$ to get $|\mathbf{A}|\mathbf{W} = \mathbf{W}|\mathbf{A}|$.

(c) $\Rightarrow$ (a). Write $\mathbf{P} = |\mathbf{A}|$, so $\mathbf{A} = \mathbf{WP} = \mathbf{PW}$. Then

$$\mathbf{AA}^* = \mathbf{WPP}^*\mathbf{W}^* = \mathbf{WP}^2\mathbf{W}^* = \mathbf{P}^2\mathbf{WW}^* = \mathbf{P}^2,$$

using $\mathbf{P}^* = \mathbf{P}$, then $\mathbf{WP}^2 = \mathbf{P}^2\mathbf{W}$ (which follows from $\mathbf{WP} = \mathbf{PW}$), then $\mathbf{WW}^* = \mathbf{I}$. And $\mathbf{A}^*\mathbf{A} = \mathbf{P}^*\mathbf{W}^*\mathbf{WP} = \mathbf{P}^2$. So $\mathbf{AA}^* = \mathbf{A}^*\mathbf{A}$.

Exercise C3: Complex symmetric matrices are transposed squares.

Let $\mathbf{A} \in M_n(\mathbb{C})$ be symmetric and invertible.

(a) Using Theorem 12.9.3, prove that $\mathbf{A} = \mathbf{B}^\top\mathbf{B}$ for some invertible $\mathbf{B} \in M_n(\mathbb{C})$.

(b) Show that over $\mathbb{R}$ the analogous statement is false unless $\mathbf{A}$ is positive definite, and give a 1×1 witness.

(c) Explain in one sentence why (a) and (b) do not contradict each other.

Solution.

(a) By Theorem 12.9.3, $\mathbf{A} = \mathbf{U\Sigma U}^\top$ with $\mathbf{U}$ unitary and $\mathbf{\Sigma} = \operatorname{diag}(\sigma_1, \dots, \sigma_n)$, where every $\sigma_i > 0$ because $\mathbf{A}$ is invertible (Theorem 12.8.1). Let $\mathbf{\Sigma}^{1/2} = \operatorname{diag}(\sqrt{\sigma_1}, \dots, \sqrt{\sigma_n})$ and put $\mathbf{B} \coloneqq \mathbf{\Sigma}^{1/2}\mathbf{U}^\top$, which is invertible as a product of invertible matrices. Then

$$\mathbf{B}^\top\mathbf{B} = \mathbf{U}\,\mathbf{\Sigma}^{1/2}\mathbf{\Sigma}^{1/2}\,\mathbf{U}^\top = \mathbf{U\Sigma U}^\top = \mathbf{A},$$

using $(\mathbf{\Sigma}^{1/2})^\top = \mathbf{\Sigma}^{1/2}$ and $(\mathbf{U}^\top)^\top = \mathbf{U}$.

(b) Over $\mathbb{R}$, if $\mathbf{A} = \mathbf{B}^\top\mathbf{B}$ with $\mathbf{B} \in M_n(\mathbb{R})$ then $\mathbf{x}^\top\mathbf{Ax} = \|\mathbf{Bx}\|^2 \geq 0$ for every $\mathbf{x}$, so

$\mathbf{A} \succeq 0$, and $\mathbf{A} \succ 0$ when $\mathbf{B}$ is invertible. So no real $\mathbf{A}$ with a negative eigenvalue is of this form: for $n = 1$, $\mathbf{A} = (-1)$ is symmetric and invertible but $b^2 = -1$ has no real solution.

(c) The factor $\mathbf{B}$ produced in (a) is complex, and over $\mathbb{C}$ the quantity $\mathbf{x}^{\top}\mathbf{A}\mathbf{x}$ is not a sum of squared lengths — the transpose carries no conjugation, so $\mathbf{B}^{\top}\mathbf{B}$ says nothing about positivity. Indeed $b = i$ solves $b^2 = -1$.

12.10 Low-Rank Approximation

The compact singular value decomposition writes a matrix as a sum of rank-one pieces arranged in decreasing order of size. A sum can be cut short. This section shows that cutting it short after k terms produces the **best** approximation to $\mathbf{A}$ by a matrix of rank k, measured in the Frobenius norm, and that the error it leaves is a quantity we can write down before doing any work. One theorem answers three questions at once: how to compress a matrix, which k-dimensional subspace best fits a cloud of data, and how far a given matrix is from being singular.

Throughout, $F = \mathbb{R}$ or $F = \mathbb{C}$, $\mathbf{A} \in M_{m\times n}(F)$, $p = \min(m, n)$, $r = \operatorname{rank}\mathbf{A}$, and

$$\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_p \geq 0$$

are the singular values of $\mathbf{A}$ (Definition 12.8.1), so that $\sigma_i > 0$ exactly for $i \leq r$. We fix a singular value decomposition $\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^{*}$ (Theorem 12.8.1) and write $\mathbf{u}_1, \ldots, \mathbf{u}_m$ for the columns of $\mathbf{U}$ and $\mathbf{v}_1, \ldots, \mathbf{v}_n$ for the columns of $\mathbf{V}$.

12.10.1 Cutting the sum short

Multiplying out $\mathbf{U}\mathbf{\Sigma}\mathbf{V}^{*}$ column by column gives the rank-one expansion

$$\mathbf{A} = \sum_{i=1}^{p} \sigma_i \mathbf{u}_i \mathbf{v}_i^{*} = \sum_{i=1}^{r} \sigma_i \mathbf{u}_i \mathbf{v}_i^{*},$$

the second equality because the terms with $i > r$ have $\sigma_i = 0$; this is the compact form Theorem 12.8.3. Each summand is a matrix of rank one, and the coefficients decrease. The natural thing to do with such a sum is to keep the large terms and discard the small ones.

Keep the first k rank-one pieces and throw the rest away.

Definition 12.10.1 — Truncated singular value decomposition

For $0 \leq k \leq p$, the **rank-k truncation** of $\mathbf{A}$ relative to the chosen singular value decomposition $\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^{*}$ (Theorem 12.8.1) is

$$\mathbf{A}_k := \sum_{i=1}^{k} \sigma_i \mathbf{u}_i \mathbf{v}_i^{*},$$

with $\mathbf{A}_0 = \mathbf{0}$; for $k \geq p$ we set $\mathbf{A}_k = \mathbf{A}$.

Two clauses need comment. The subscript counts **terms kept**, not rows and columns: $\mathbf{A}_k$ is the same size as $\mathbf{A}$, not a submatrix of it. (Section 1 used $\mathbf{A}_k$ for the top-left $k \times k$ corner; that meaning is gone for the rest of this section.) And the definition says "relative to the chosen decomposition", because Theorem 12.8.2 leaves the unitary factors some freedom, and different choices can give different truncations. Everything proved below holds for **every** choice; the warning at the end of the section shows that the dependence is real.

The rank of $\mathbf{A}_k$ is exactly $\min(k, r)$: the vectors $\mathbf{u}_1, \dots, \mathbf{u}_k$ are orthonormal, hence independent, so the columns of $\mathbf{A}_k$ span $\operatorname{span}(\mathbf{u}_1, \dots, \mathbf{u}_{\min(k,r)})$ once the vanishing terms are dropped.

Example. (Truncating a diagonal matrix)

Let $\mathbf{A} = \operatorname{diag}(5, 3, 1) \in M_3(\mathbb{R})$. Write down $\mathbf{A}_1$ and $\mathbf{A}_2$.

Solution. A diagonal matrix with positive decreasing entries is already in the form $\mathbf{U}\mathbf{\Sigma}\mathbf{V}^*$ with $\mathbf{U} = \mathbf{V} = \mathbf{I}_3$, so $\sigma_i = 5, 3, 1$ and $\mathbf{u}_i = \mathbf{v}_i = \mathbf{e}_i$. Hence

$$\mathbf{A}_1 = 5\mathbf{e}_1\mathbf{e}_1^* = \operatorname{diag}(5, 0, 0), \qquad \mathbf{A}_2 = \operatorname{diag}(5, 3, 0).$$

Truncation of a diagonal matrix is just deleting its smallest diagonal entries. Everything in this section is this statement, conjugated by two unitary matrices.

The first thing to compute is how much was thrown away.

Lemma 12.10.1 — The Frobenius norm counts singular values

Let $\mathbf{A} \in M_{m\times n}(F)$ have singular values $\sigma_1 \geq \cdots \geq \sigma_p$. Then (the first identity is the one Section 8 already obtained, recorded here with a label because the proof of the main theorem uses it repeatedly)

$$\|\mathbf{A}\|_F^2 = \sum_{i=1}^{p} \sigma_i^2, \qquad \|\mathbf{A} - \mathbf{A}_k\|_F^2 = \sum_{i>k} \sigma_i^2$$

for every $0 \leq k \leq p$.

Proof. The Frobenius norm does not see unitary factors (Lemma 11.11.1), so from $\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^*$,

$$\|\mathbf{A}\|_F = \|\mathbf{\Sigma}\mathbf{V}^*\|_F = \|\mathbf{\Sigma}\|_F.$$

The only non-zero entries of $\mathbf{\Sigma}$ are $\sigma_1, \dots, \sigma_p$ on the diagonal, so $\|\mathbf{\Sigma}\|_F^2 = \sum_i \sigma_i^2$.

For the second identity, subtract the first k terms of the rank-one expansion:

$$\mathbf{A} - \mathbf{A}_k = \sum_{i>k} \sigma_i \mathbf{u}_i \mathbf{v}_i^* = \mathbf{U}\mathbf{\Sigma}^{(k)}\mathbf{V}^*,$$

where $\mathbf{\Sigma}^{(k)}$ is $\mathbf{\Sigma}$ with its first k diagonal entries replaced by 0. Applying the first identity to this matrix — the display is a singular value decomposition of it in the sense of Theorem 12.8.1, up to reordering the diagonal — gives $\|\mathbf{A} - \mathbf{A}_k\|_F^2 = \sum_{i>k} \sigma_i^2$.

■

So the truncation error is decided in advance by the singular values, and it is small exactly when the discarded σ_i are small. The content of the section is that no other matrix of rank k does better.

Quick check. A matrix has singular values $5, 4, 3$. What is the smallest k for which the relative error $\|\mathbf{A} - \mathbf{A}_k\|_F / \|\mathbf{A}\|_F$ is at most $\frac{1}{2}$?

Solution. By Lemma 12.10.1, $\|\mathbf{A}\|_F^2 = 25 + 16 + 9 = 50$. For $k = 1$ the error squared is $16 + 9 = 25$, so the relative error is $\sqrt{25/50} = 1/\sqrt{2} \approx 0.71$, too big. For $k = 2$ the error squared is 9, and $\sqrt{9/50} \approx 0.42 \le \frac{1}{2}$. So $k = 2$. Note that the test is on the *squares*: halving the error means keeping three quarters of $\sum \sigma_i^2$.

12.10.2 How much a subspace can hold

The proof of the theorem needs one inequality, and it is the only place where any work happens. The question it answers is: if we are allowed to keep only an s-dimensional subspace of F^m, how much of $\mathbf{A}$ can we capture? The answer is $\sigma_1^2 + \cdots + \sigma_s^2$, and the best subspace is the span of the leading left singular vectors.

Lemma 12.10.2 — An orthonormal list captures at most the leading singular values

Let $\mathbf{A} \in M_{m \times n}(F)$ with singular values $\sigma_1 \ge \cdots \ge \sigma_p$, extended by $\sigma_i = 0$ for $p < i \le m$. Let $\mathbf{q}_1, \dots, \mathbf{q}_s$ be an orthonormal list in F^m, so that $s \le m$. Then

$$\sum_{j=1}^{s} \|\mathbf{A}^* \mathbf{q}_j\|^2 \;\le\; \sum_{i=1}^{s} \sigma_i^2 .$$

Idea. Write each $\mathbf{q}_j$ in the orthonormal basis $(\mathbf{u}_1, \dots, \mathbf{u}_m)$. The quantity $\|\mathbf{A}^* \mathbf{q}_j\|^2$ then becomes $\sum_i \sigma_i^2 |c_{ji}|^2$, so the total is $\sum_i \sigma_i^2 t_i$ with weights $t_i = \sum_j |c_{ji}|^2$. Two facts pin the weights down: each $t_i \le 1$, because the $\mathbf{q}_j$ are orthonormal and Bessel's inequality applies to $\mathbf{u}_i$; and $\sum_i t_i = s$, because each $\mathbf{q}_j$ is a unit vector. A weighted sum of a decreasing sequence with weights in $[0, 1]$ that sum to s is largest when the first s weights are 1 — which is the last display of the proof.

Proof. If $s = 0$ both sides are empty sums, so assume $s \ge 1$. Fix j and put $c_{ji} = \langle \mathbf{q}_j, \mathbf{u}_i \rangle$ for $1 \le i \le m$, so that the i-th entry of $\mathbf{U}^* \mathbf{q}_j$ is c_{ji}. Since $\mathbf{A}^* = \mathbf{V} \mathbf{\Sigma}^* \mathbf{U}^*$ and $\mathbf{V}$ is unitary, hence an isometry (Definition 10.7.2, Theorem 10.7.3),

$$\|\mathbf{A}^* \mathbf{q}_j\|^2 = \|\mathbf{\Sigma}^* \mathbf{U}^* \mathbf{q}_j\|^2 = \sum_{i=1}^{m} \sigma_i^2 |c_{ji}|^2 ,$$

because $\mathbf{\Sigma}^*$ multiplies the i-th entry by σ_i and discards the entries beyond the p-th, which is the same as using $\sigma_i = 0$ there. Summing over j and exchanging the two finite sums,

$$\sum_{j=1}^{s} \|\mathbf{A}^* \mathbf{q}_j\|^2 = \sum_{i=1}^{m} \sigma_i^2 t_i , \qquad t_i := \sum_{j=1}^{s} |c_{ji}|^2 .$$

Now bound the weights. Since $|c_{ji}| = |\langle \mathbf{u}_i, \mathbf{q}_j \rangle|$ and $(\mathbf{q}_1, \dots, \mathbf{q}_s)$ is an orthonormal list, Bessel's inequality (Theorem 10.9.1) applied to the vector $\mathbf{u}_i$ gives

$$t_i = \sum_{j=1}^{s} |\langle \mathbf{u}_i, \mathbf{q}_j \rangle|^2 \;\le\; \|\mathbf{u}_i\|^2 = 1.$$

Since $(\mathbf{u}_1, \dots, \mathbf{u}_m)$ is an orthonormal **basis** of F^m, Parseval's identity (Theorem 10.9.2) gives $\sum_{i=1}^{m} |c_{ji}|^2 = \|\mathbf{q}_j\|^2 = 1$ for each j, and therefore

$$\sum_{i=1}^{m} t_i = \sum_{j=1}^{s} \sum_{i=1}^{m} |c_{ji}|^2 = s.$$

Finally, using $\sigma_i^2 \ge \sigma_s^2$ together with $t_i - 1 \le 0$ for $i \le s$, and $\sigma_i^2 \le \sigma_s^2$ together with $t_i \ge 0$ for $i > s$,

$$\begin{aligned} \sum_{i=1}^{m} \sigma_i^2 t_i - \sum_{i=1}^{s} \sigma_i^2 &= \sum_{i \le s} \sigma_i^2 (t_i - 1) + \sum_{i > s} \sigma_i^2 t_i \\ &\le \sigma_s^2 \Big(\sum_{i \le s} (t_i - 1) + \sum_{i > s} t_i \Big) \\ &= \sigma_s^2 \Big(\sum_{i=1}^{m} t_i - s \Big) = 0. \end{aligned}$$

This is the stated inequality.

■

Equality is attainable: take $\mathbf{q}_j = \mathbf{u}_j$ for $j \le s$. Then $\mathbf{A}^* \mathbf{u}_j = \sigma_j \mathbf{v}_j$ by the rank-one expansion, so $\|\mathbf{A}^* \mathbf{u}_j\|^2 = \sigma_j^2$ and the two sides agree. The lemma is the extreme case of a family of statements about sums of the largest eigenvalues of a Hermitian matrix; Chapter 16 develops the family through the Courant–Fischer min–max theorem, of which the inequality above is the crudest and most useful consequence.

12.10.3 The Eckart–Young theorem

Now the theorem. Read it as a statement about a minimization problem: over the set of matrices of rank at most k — which is not a subspace, so no earlier optimization theorem applies to it directly — the minimum of $\|\mathbf{A} - \mathbf{B}\|_F$ exists, is attained at a matrix we can write down, and has a value we already computed.

Theorem 12.10.3 — Eckart–Young Theorem, Frobenius case

Let $\mathbf{A} \in M_{m \times n}(F)$ with singular values $\sigma_1 \ge \cdots \ge \sigma_p$, and let $0 \le k \le p$. Then for **every** $\mathbf{B} \in M_{m \times n}(F)$ with $\operatorname{rank} \mathbf{B} \le k$,

$$\|\mathbf{A} - \mathbf{B}\|_F \;\ge\; \Big(\sum_{i > k} \sigma_i^2 \Big)^{1/2},$$

and equality holds for $\mathbf{B} = \mathbf{A}_k$. In words: the truncation $\mathbf{A}_k$ minimizes $\|\mathbf{A} - \mathbf{B}\|_F$ over all matrices of rank at most k, and the minimum value is $\left(\sum_{i>k} \sigma_i^2\right)^{1/2}$.

Idea. The difficulty is that $\mathbf{B}$ is an arbitrary matrix of rank $\leq k$, and there is no formula for such a thing. The rescue is to stop looking at $\mathbf{B}$ and look only at its column space S, a subspace of dimension $s \leq k$. ① Every column of $\mathbf{B}$ lies in S, so column by column the Best Approximation Theorem says $\mathbf{B}$ cannot beat $P_S\mathbf{A}$, the matrix obtained by projecting every column of $\mathbf{A}$ onto S. So it suffices to minimize over subspaces. ② For a subspace, Pythagoras splits the error into "all of $\mathbf{A}$" minus "the part S captures", and the captured part is exactly the quantity Lemma 12.10.2 bounds. ③ The bound is $\sigma_1^2 + \cdots + \sigma_k^2$, and subtracting it from $\|\mathbf{A}\|_F^2 = \sum_i \sigma_i^2$ leaves $\sum_{i>k} \sigma_i^2$, which Lemma 12.10.1 says is exactly what $\mathbf{A}_k$ achieves.

Proof. **Step 1: reduce to a projection.** Let $\mathbf{B}$ have rank $\leq k$ and put $S = \operatorname{col}(\mathbf{B})$, so $s := \dim S = \operatorname{rank} \mathbf{B} \leq k$. Write $\mathbf{a}_1, \ldots, \mathbf{a}_n$ and $\mathbf{b}_1, \ldots, \mathbf{b}_n$ for the columns of $\mathbf{A}$ and of $\mathbf{B}$. By the definition of the Frobenius norm, summing squares of entries column by column,

$$\|\mathbf{A} - \mathbf{B}\|_F^2 = \sum_{j=1}^{n} \|\mathbf{a}_j - \mathbf{b}_j\|^2.$$

Each $\mathbf{b}_j$ lies in S, so Theorem 10.3.5 gives $\|\mathbf{a}_j - \mathbf{b}_j\| \geq \|\mathbf{a}_j - P_S\mathbf{a}_j\|$ for every j, where P_S is the orthogonal projection onto S (Definition 10.3.2), identified throughout with its matrix in the standard basis of F^m. Hence

$$\|\mathbf{A} - \mathbf{B}\|_F^2 \;\geq\; \sum_{j=1}^{n} \|\mathbf{a}_j - P_S\mathbf{a}_j\|^2 = \|\mathbf{A} - P_S\mathbf{A}\|_F^2,$$

the last equality because the j-th column of $P_S\mathbf{A}$ is $P_S\mathbf{a}_j$.

Step 2: what a subspace captures. Choose an orthonormal basis $(\mathbf{q}_1, \ldots, \mathbf{q}_s)$ of S. For each j, the vectors $\mathbf{a}_j - P_S\mathbf{a}_j$ and $P_S\mathbf{a}_j$ are orthogonal, so Theorem 10.1.3 gives $\|\mathbf{a}_j - P_S\mathbf{a}_j\|^2 = \|\mathbf{a}_j\|^2 - \|P_S\mathbf{a}_j\|^2$, and summing over j,

$$\|\mathbf{A} - P_S\mathbf{A}\|_F^2 = \|\mathbf{A}\|_F^2 - \|P_S\mathbf{A}\|_F^2.$$

By Theorem 10.3.3 (a), $P_S\mathbf{a}_j = \sum_{l \leq s} \langle \mathbf{a}_j, \mathbf{q}_l \rangle \mathbf{q}_l$, whose summands are pairwise orthogonal, so Theorem 10.1.3 gives $\|P_S\mathbf{a}_j\|^2 = \sum_{l=1}^{s} |\langle \mathbf{a}_j, \mathbf{q}_l \rangle|^2$. Exchanging the sums,

$$\|P_S\mathbf{A}\|_F^2 = \sum_{l=1}^{s} \sum_{j=1}^{n} |\langle \mathbf{a}_j, \mathbf{q}_l \rangle|^2 = \sum_{l=1}^{s} \|\mathbf{A}^* \mathbf{q}_l\|^2,$$

where the last equality holds because $\langle \mathbf{a}_j, \mathbf{q}_l \rangle = \mathbf{q}_l^* \mathbf{a}_j$ is the j-th entry of the row vector $\mathbf{q}_l^* \mathbf{A}$, whose entries are the conjugates of those of $\mathbf{A}^* \mathbf{q}_l$.

Step 3: apply the bound. By Lemma 12.10.2 and $s \leq k$, and since all $\sigma_i^2 \geq 0$,

$$\|P_S\mathbf{A}\|_F^2 \;\leq\; \sum_{i=1}^{s} \sigma_i^2 \;\leq\; \sum_{i=1}^{k} \sigma_i^2.$$

Combining the three steps with $\|\mathbf{A}\|_F^2 = \sum_i \sigma_i^2$ (Lemma 12.10.1),

$$\|\mathbf{A} - \mathbf{B}\|_F^2 \;\geq\; \|\mathbf{A}\|_F^2 - \sum_{i=1}^{k} \sigma_i^2 = \sum_{i>k} \sigma_i^2.$$

Equality. The matrix $\mathbf{A}_k$ has rank $\min(k, r) \leq k$, and $\|\mathbf{A} - \mathbf{A}_k\|_F^2 = \sum_{i>k} \sigma_i^2$ by Lemma 12.10.1. So the lower bound is attained, and it is the minimum. This proves the theorem.

■

Three remarks are worth extracting. First, the theorem is a genuine minimum, not an infimum: the minimizing matrix is exhibited. Second, the minimum value depends on $\mathbf{A}$ only through its singular values, so it is unchanged if $\mathbf{A}$ is replaced by $\mathbf{U}'\mathbf{A}\mathbf{V}'$ with $\mathbf{U}', \mathbf{V}'$ unitary. Third, the case $k = r - 1$ reads: the Frobenius distance from $\mathbf{A}$ to the matrices of rank $< r$ is σ_r, the smallest non-zero singular value. Exercise C1 turns that into a statement about how far an invertible matrix is from being singular.

Remark. The same matrix $\mathbf{A}_k$ is also optimal in the **spectral norm** $\|\cdot\|_2$, where the minimum value is σ_{k+1} rather than $\left(\sum_{i>k} \sigma_i^2\right)^{1/2}$. We cannot state that here, because the spectral norm is defined only in Chapter 15. In fact both statements are instances of one theorem: $\mathbf{A}_k$ is a best rank-k approximation in **every** unitarily invariant norm. Chapter 20 proves that, and the proof is genuinely different from the one above — it needs inequalities between the singular values of $\mathbf{A}$ and of $\mathbf{A} - \mathbf{B}$, not a projection argument.

12.10.4 A worked example

Example. (The best rank-one approximation of a 3 × 2 matrix)

Let

$$\mathbf{A} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \\ 1 & 1 \end{pmatrix} \in M_{3\times 2}(\mathbb{R}).$$

Find the best rank-one approximation of $\mathbf{A}$ in the Frobenius norm, and compute the error in two ways.

Solution. Singular values and vectors. Since $\mathbf{A}$ has more rows than columns, work with the 2×2 matrix

$$\mathbf{A}^\top \mathbf{A} = \begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix},$$

whose eigenvalues are 3 and 1 with orthonormal eigenvectors

$$\mathbf{v}_1 = \tfrac{1}{\sqrt{2}}(1, 1), \qquad \mathbf{v}_2 = \tfrac{1}{\sqrt{2}}(1, -1).$$

Hence $\sigma_1 = \sqrt{3}$ and $\sigma_2 = 1$, and the left singular vectors are $\mathbf{u}_i = \mathbf{A}\mathbf{v}_i/\sigma_i$:

$$\mathbf{u}_1 = \tfrac{1}{\sqrt{6}}(1, 1, 2), \qquad \mathbf{u}_2 = \tfrac{1}{\sqrt{2}}(1, -1, 0).$$

(Both are unit vectors, as they must be: $1+1+4=6$ and $1+1=2$.)

The approximation. By Theorem 12.10.3 the answer is $\mathbf{A}_1 = \sigma_1 \mathbf{u}_1 \mathbf{v}_1^{\top}$. The scalar in front is $\sqrt{3}/(\sqrt{6}\sqrt{2}) = \sqrt{3}/\sqrt{12} = \frac{1}{2}$, so

$$\mathbf{A}_1 = \frac{1}{2}\begin{pmatrix} 1 & 1 \\ 1 & 1 \\ 2 & 2 \end{pmatrix}.$$

It has rank one, its two columns being equal and non-zero.

The error, twice. Directly,

$$\mathbf{A} - \mathbf{A}_1 = \frac{1}{2}\begin{pmatrix} 1 & -1 \\ -1 & 1 \\ 0 & 0 \end{pmatrix}, \qquad \|\mathbf{A} - \mathbf{A}_1\|_F^2 = 4 \cdot \tfrac{1}{4} = 1.$$

From the theorem, the error squared is $\sigma_2^2 = 1$. The two agree. As a further check, $\|\mathbf{A}\|_F^2 = 1+1+1+1 = 4$ and $\sigma_1^2 + \sigma_2^2 = 3+1 = 4$, as Lemma 12.10.1 requires; the relative error of the rank-one approximation is $\sqrt{1/4} = \frac{1}{2}$.

12.10.5 Best-fitting subspaces

Step 1 of the proof did more than its job. It showed that the optimal $\mathbf{B}$ may be taken of the form $P_S\mathbf{A}$, and Steps 2 and 3 identified the best S. That identification is a theorem in its own right, and it is the statement people mean when they speak of fitting a low-dimensional structure to data.

Corollary 12.10.4 — The best-fitting subspace

Let $\mathbf{a}_1, \dots, \mathbf{a}_n \in F^m$ be the columns of $\mathbf{A}$, and let $1 \le k \le p$. Among all subspaces $S \subseteq F^m$ with $\dim S \le k$, the total squared distance

$$D(S) := \sum_{j=1}^{n} d(\mathbf{a}_j, S)^2$$

is smallest for $S = \operatorname{span}(\mathbf{u}_1, \dots, \mathbf{u}_k)$, and its smallest value is $\sum_{i>k} \sigma_i^2$.

Proof. By Definition 10.3.3, $d(\mathbf{a}_j, S) = \|\mathbf{a}_j - P_S\mathbf{a}_j\|$, so $D(S) = \|\mathbf{A} - P_S\mathbf{A}\|_F^2$ as in Step 1 of Theorem 12.10.3. Since $\operatorname{rank}(P_S\mathbf{A}) \le \dim S \le k$, the theorem gives $D(S) \ge \sum_{i>k} \sigma_i^2$. For $S_0 = \operatorname{span}(\mathbf{u}_1, \dots, \mathbf{u}_k)$ the columns $\mathbf{u}_1, \dots, \mathbf{u}_k$ are orthonormal, so Theorem 10.3.3 (a) gives

$$P_{S_0}\mathbf{A} = \sum_{i=1}^{k} \mathbf{u}_i \mathbf{u}_i^* \mathbf{A} = \sum_{i=1}^{k} \sigma_i \mathbf{u}_i \mathbf{v}_i^* = \mathbf{A}_k,$$

using $\mathbf{u}_i^*\mathbf{A} = \sigma_i \mathbf{v}_i^*$, which is the rank-one expansion read one row at a time. Hence $D(S_0) = \|\mathbf{A} - \mathbf{A}_k\|_F^2 = \sum_{i>k} \sigma_i^2$.

■

What this is used for, honestly. Two applications are within reach of what we have proved, and a third is not.

The first is **compression**. Storing $\mathbf{A}$ costs mn numbers; storing $\mathbf{A}_k$ as the list $\sigma_1, \mathbf{u}_1, \mathbf{v}_1, \dots, \sigma_k, \mathbf{u}_k, \mathbf{v}_k$ costs $k(m+n+1)$. When k is much smaller than m and n that is a large saving, and Theorem 12.10.3 says no other rank-k object stored the same way is closer to $\mathbf{A}$ in the Frobenius norm. The relative error is $\left(\sum_{i>k}\sigma_i^2 / \sum_i \sigma_i^2\right)^{1/2}$, computable before choosing k. Whether that error is acceptable is not a mathematical question.

The second is **principal components**. Take n data points in $\mathbb{R}^m$ and place them as the columns of $\mathbf{A}$. Then Corollary 12.10.4 says: the k-dimensional subspace through the origin that minimizes the total squared distance to the data is spanned by $\mathbf{u}_1, \dots, \mathbf{u}_k$, the leading left singular vectors. These directions are the **principal components** of the data, and the numbers σ_i^2 measure how much of $\sum_j \|\mathbf{a}_j\|^2$ each one accounts for. That is a theorem of linear algebra, and it is the whole of what this book has proved.

What is *not* proved here is the statistics. The usual procedure subtracts the mean of the data first, so that $\frac{1}{n}\mathbf{A}\mathbf{A}^\top$ becomes a sample covariance matrix, and then interprets $\sigma_i^2/\sum_l \sigma_l^2$ as a fraction of variance explained. Those steps need a probabilistic model, a reason to prefer squared error, and an argument that the sample answer says something about a larger population. Chapter 23 §10 supplies the first two — the model for the finite population of the data themselves, where expectation is an average and no measure theory is needed, and three reasons to prefer squared error — and says plainly that the third belongs to probability and statistics, which this book does not develop. It also says why a singular value decomposition is never computed by forming $\mathbf{A}^*\mathbf{A}$ and finding its eigenvalues, the route taken in every hand computation in this chapter; the algorithm that replaces it is assembled nowhere in this book.

Warning. **The truncation is optimal for this norm, and low rank does not mean small.** Two mistakes to avoid.

Other measures of error give other answers. Let $\mathbf{A} = \operatorname{diag}(2,1)$, so $\sigma_1 = 2$, $\sigma_2 = 1$, and $\mathbf{A}_1 = \operatorname{diag}(2,0)$, whose error matrix $\operatorname{diag}(0,1)$ has a largest entry of modulus 1. The rank-one matrix

$$\mathbf{B} = \frac{1}{2}\begin{pmatrix} 3 & \sqrt{3} \\ \sqrt{3} & 1 \end{pmatrix}, \qquad \mathbf{A}-\mathbf{B} = \frac{1}{2}\begin{pmatrix} 1 & -\sqrt{3} \\ -\sqrt{3} & 1 \end{pmatrix},$$

has $\det \mathbf{B} = \frac{3}{4} - \frac{3}{4} = 0$, so $\operatorname{rank}\mathbf{B} = 1$, and every entry of $\mathbf{A}-\mathbf{B}$ has modulus at most $\sqrt{3}/2 \approx 0.87 < 1$. So $\mathbf{B}$ beats $\mathbf{A}_1$ if the error is measured entrywise. It loses in the Frobenius norm, as it must: $\|\mathbf{A}-\mathbf{B}\|_F^2 = 2 > 1 = \|\mathbf{A}-\mathbf{A}_1\|_F^2$.

Small rank and small size are unrelated. The $n \times n$ all-ones matrix $\mathbf{J}$ has rank 1 and $\|\mathbf{J}\|_F = n$, while $\varepsilon\mathbf{I}_n$ has rank n and $\|\varepsilon\mathbf{I}_n\|_F = \varepsilon\sqrt{n}$, as small as we like. "Approximating by a matrix of low rank" is a statement about structure, never about magnitude.

12.10.6 Exercises

12.10.6.1 A. Check your understanding

Exercise A1.

(a) State the Eckart–Young Theorem, including the value of the minimum.

(b) Express $\|\mathbf{A}\|_F$ in terms of the singular values of $\mathbf{A}$.

(c) Let $\operatorname{rank}\mathbf{A} = r$. What is $\mathbf{A}_k$ for $k \geq r$, and what is the minimum of $\|\mathbf{A} - \mathbf{B}\|_F$ over $\operatorname{rank}\mathbf{B} \leq k$ in that case?

(d) True or false: the truncation $\mathbf{A}_k$ is the *unique* matrix of rank at most k nearest to $\mathbf{A}$ in the Frobenius norm. Justify your answer.

(e) A matrix of rank 1 is close to $\mathbf{0}$ in the Frobenius norm. True or false? Justify your answer.

Solution.

(a) For $\mathbf{A} \in M_{m\times n}(F)$ with singular values $\sigma_1 \geq \cdots \geq \sigma_p$ and $0 \leq k \leq p$: every $\mathbf{B}$ with $\operatorname{rank}\mathbf{B} \leq k$ satisfies $\|\mathbf{A} - \mathbf{B}\|_F \geq \left(\sum_{i>k} \sigma_i^2\right)^{1/2}$, with equality for $\mathbf{B} = \mathbf{A}_k = \sum_{i\leq k} \sigma_i \mathbf{u}_i \mathbf{v}_i^*$.

(b) $\|\mathbf{A}\|_F = \left(\sum_{i=1}^{p} \sigma_i^2\right)^{1/2}$ (Lemma 12.10.1).

(c) $\mathbf{A}_k = \mathbf{A}$, since the terms with $i > r$ are zero; the minimum is 0, attained at $\mathbf{B} = \mathbf{A}$ itself, which has rank $r \leq k$.

(d) False in general. Take $\mathbf{A} = \mathbf{I}_2$, so $\sigma_1 = \sigma_2 = 1$. Both $\mathbf{B}_1 = \operatorname{diag}(1, 0)$ and $\mathbf{B}_2 = \frac{1}{2}\left(\begin{smallmatrix} 1 & 1 \\ 1 & 1 \end{smallmatrix}\right)$ have rank 1, and $\|\mathbf{I}_2 - \mathbf{B}_1\|_F^2 = 1 = \|\mathbf{I}_2 - \mathbf{B}_2\|_F^2$, which is the minimum σ_2^2. (Both are truncations of $\mathbf{I}_2$, for two different singular value decompositions.)

(e) False. Rank is unrelated to size: the all-ones matrix $\mathbf{J} \in M_n(\mathbb{R})$ has rank 1 and $\|\mathbf{J}\|_F = n$.

12.10.6.2 B. Practice

Exercise B1: Errors from the singular values alone.

A matrix $\mathbf{A}$ has singular values $6, 3, 2, 1$.

(a) Compute $\|\mathbf{A}\|_F$ and the minimum of $\|\mathbf{A} - \mathbf{B}\|_F$ over matrices $\mathbf{B}$ of rank at most k, for $k = 1, 2, 3$.

(b) Find the smallest k for which the relative error $\|\mathbf{A} - \mathbf{A}_k\|_F / \|\mathbf{A}\|_F$ is at most 0.3.

Solution.

(a) $\|\mathbf{A}\|_F^2 = 36 + 9 + 4 + 1 = 50$, so $\|\mathbf{A}\|_F = \sqrt{50} = 5\sqrt{2}$. By Theorem 12.10.3 the minima are

$$\sqrt{9 + 4 + 1} = \sqrt{14}, \qquad \sqrt{4 + 1} = \sqrt{5}, \qquad \sqrt{1} = 1$$

for $k = 1, 2, 3$.

(b) The condition is $\sum_{i>k} \sigma_i^2 \leq 0.09 \cdot 50 = 4.5$. For $k = 2$ the left side is $5 > 4.5$; for $k = 3$ it is $1 \leq 4.5$. So $k = 3$.

Exercise B2: A best rank-one approximation.

Let $\mathbf{A} = \begin{pmatrix} 3 & 1 \\ 1 & 3 \end{pmatrix} \in M_2(\mathbb{R})$. Find the singular values of $\mathbf{A}$, the best rank-one approximation $\mathbf{A}_1$ in the Frobenius norm, and the error, computed both directly and from the theorem.

Solution. $\mathbf{A}$ is symmetric with eigenvalues 4 and 2 (trace 6, determinant 8) and orthonormal eigenvectors $\mathbf{q}_1 = \frac{1}{\sqrt{2}}(1,1)$, $\mathbf{q}_2 = \frac{1}{\sqrt{2}}(1,-1)$. Both eigenvalues are positive, so $\mathbf{A} \succ 0$, and $\mathbf{A}^\top\mathbf{A} = \mathbf{A}^2$ has eigenvalues 16 and 4; hence $\sigma_1 = 4$, $\sigma_2 = 2$, with $\mathbf{u}_i = \mathbf{v}_i = \mathbf{q}_i$.

Therefore

$$\mathbf{A}_1 = 4\mathbf{q}_1\mathbf{q}_1^\top = 4 \cdot \frac{1}{2}\begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix} = \begin{pmatrix} 2 & 2 \\ 2 & 2 \end{pmatrix},$$

which has rank one. Directly,

$$\mathbf{A} - \mathbf{A}_1 = \begin{pmatrix} 1 & -1 \\ -1 & 1 \end{pmatrix}, \qquad \|\mathbf{A} - \mathbf{A}_1\|_F^2 = 4.$$

From Theorem 12.10.3 the error squared is $\sigma_2^2 = 4$. The two agree, and $\|\mathbf{A}\|_F^2 = 9 + 1 + 1 + 9 = 20 = 16 + 4$ checks Lemma 12.10.1.

Exercise B3: Pythagoras for the truncation.

Let $\mathbf{A} \in M_{m\times n}(F)$ and $0 \le k \le p$. Prove that

$$\|\mathbf{A}\|_F^2 = \|\mathbf{A}_k\|_F^2 + \|\mathbf{A} - \mathbf{A}_k\|_F^2,$$

and deduce that $k \mapsto \|\mathbf{A} - \mathbf{A}_k\|_F$ is non-increasing.

Solution. By Lemma 12.10.1 applied to $\mathbf{A}$ and to $\mathbf{A} - \mathbf{A}_k$, and by the same lemma applied to $\mathbf{A}_k$, whose singular values are $\sigma_1, \dots, \sigma_k$ followed by zeros (it equals $\mathbf{U}\mathbf{\Sigma}'\mathbf{V}^*$ with $\mathbf{\Sigma}'$ the matrix keeping only the first k diagonal entries of $\mathbf{\Sigma}$),

$$\|\mathbf{A}_k\|_F^2 + \|\mathbf{A} - \mathbf{A}_k\|_F^2 = \sum_{i \le k} \sigma_i^2 + \sum_{i > k} \sigma_i^2 = \|\mathbf{A}\|_F^2.$$

Since $\|\mathbf{A} - \mathbf{A}_k\|_F^2 = \sum_{i>k} \sigma_i^2$ and the σ_i^2 are non-negative, increasing k by one removes a non-negative term, so the sequence is non-increasing. This proves both claims.

12.10.6.3 C. Going deeper

Exercise C1: How far is a matrix from being singular?.

Let $\mathbf{A} \in M_n(F)$ be invertible, with singular values $\sigma_1 \ge \cdots \ge \sigma_n > 0$.

(a) Prove that $\|\mathbf{A} - \mathbf{B}\|_F \ge \sigma_n$ for every singular $\mathbf{B} \in M_n(F)$.

(b) Exhibit a singular $\mathbf{B}$ with $\|\mathbf{A} - \mathbf{B}\|_F = \sigma_n$.

(c) Deduce that the distance from $\mathbf{A}$ to the set of singular matrices, measured in the Frobenius norm, is exactly σ_n, and illustrate this with $\mathbf{A} = \begin{pmatrix} 3 & 1 \\ 1 & 3 \end{pmatrix}$.

Solution.

(a) A singular $\mathbf{B} \in M_n(F)$ has $\operatorname{rank}\mathbf{B} \le n - 1$ (Theorem 6.5.3 (d)). By Theo-

rem 12.10.3 with $k = n-1$,

$$\|\mathbf{A}-\mathbf{B}\|_F \;\geq\; \Big(\sum_{i>n-1}\sigma_i^2\Big)^{1/2} = \sigma_n.$$

(b) Take $\mathbf{B} = \mathbf{A}_{n-1} = \sum_{i\leq n-1}\sigma_i\mathbf{u}_i\mathbf{v}_i^*$. Its rank is $n-1 < n$, so it is singular, and $\|\mathbf{A}-\mathbf{B}\|_F = \sigma_n$ by Lemma 12.10.1.

(c) By (a) the distance is at least σ_n and by (b) it is at most σ_n, so it equals σ_n; in particular the minimum is attained. For the given $\mathbf{A}$, Exercise B2 found $\sigma_2 = 2$ and $\mathbf{A}_1 = \left(\begin{smallmatrix}2&2\\2&2\end{smallmatrix}\right)$, which is singular and at Frobenius distance 2. So no singular matrix is closer to $\mathbf{A}$ than 2. The smallest singular value is therefore a quantitative version of invertibility: $\mathbf{A}$ is invertible exactly when $\sigma_n > 0$, and it is *far* from singular exactly when σ_n is large.

Exercise C2: The best line through a cloud of points.

The four points $(1,1),(2,2),(1,-1)$ and $(0,0)$ of $\mathbb{R}^2$ are to be fitted by a line through the origin, minimizing the total squared distance from the points to the line.

(a) Write the points as the columns of a matrix $\mathbf{A}$ and compute $\mathbf{A}\mathbf{A}^\top$ and the singular values of $\mathbf{A}$.

(b) Use Corollary 12.10.4 to find the best line and the minimum total squared distance.

(c) Verify the answer by computing the four distances directly.

Solution.

(a) With the points as columns,

$$\mathbf{A} = \begin{pmatrix}1&2&1&0\\1&2&-1&0\end{pmatrix}, \qquad \mathbf{A}\mathbf{A}^\top = \begin{pmatrix}6&4\\4&6\end{pmatrix}.$$

The eigenvalues of $\mathbf{A}\mathbf{A}^\top$ are 10 and 2 (trace 12, determinant 20), with orthonormal eigenvectors $\mathbf{u}_1 = \frac{1}{\sqrt{2}}(1,1)$ and $\mathbf{u}_2 = \frac{1}{\sqrt{2}}(1,-1)$. The eigenvalues of $\mathbf{A}\mathbf{A}^\top$ are the squares of the singular values, since $\mathbf{A}\mathbf{A}^\top = \mathbf{U}\mathbf{\Sigma}\mathbf{\Sigma}^*\mathbf{U}^*$; hence $\sigma_1 = \sqrt{10}$ and $\sigma_2 = \sqrt{2}$.

(b) By Corollary 12.10.4 with $k=1$, the best line is $S_0 = \operatorname{span}(\mathbf{u}_1)$, the line $y = x$, and the minimum total squared distance is $\sigma_2^2 = 2$.

(c) The points $(1,1),(2,2)$ and $(0,0)$ lie on $y=x$, contributing 0. For $(1,-1)$, the projection onto $\operatorname{span}\big((1,1)\big)$ is $\frac{1-1}{2}(1,1) = (0,0)$, so the distance squared is $1+1 = 2$. The total is 2, as predicted. (The point $(0,0)$ contributes nothing to any subspace through the origin; it is there as a reminder that the corollary counts all columns, including zero ones.)

Exercise C3: Truncation respects unitaries but not sums.

Let $\mathbf{A} \in M_{m\times n}(F)$, and let $\mathbf{Q} \in M_m(F)$ and $\mathbf{R} \in M_n(F)$ be unitary (orthogonal, when $F = \mathbb{R}$).

(a) Prove that $\mathbf{Q}\mathbf{A}_k\mathbf{R}^*$ is a best rank-k approximation of $\mathbf{Q}\mathbf{A}\mathbf{R}^*$ in the Frobenius

norm.

(b) Deduce that the function $\mathbf{A} \mapsto \min\{\|\mathbf{A}-\mathbf{B}\|_F : \operatorname{rank}\mathbf{B} \le k\}$ is unchanged by $\mathbf{A} \mapsto \mathbf{QAR}^*$.

(c) Give $\mathbf{A}, \mathbf{B} \in M_2(\mathbb{R})$ with $(\mathbf{A}+\mathbf{B})_1 \neq \mathbf{A}_1 + \mathbf{B}_1$ for every choice of the truncations involved. *Hint: two rank-one matrices whose sum is a multiple of the identity.*

Solution.

(a) If $\mathbf{A} = \mathbf{U\Sigma V}^*$ is a singular value decomposition (Theorem 12.8.1), then

$$\mathbf{QAR}^* = (\mathbf{QU})\mathbf{\Sigma}(\mathbf{RV})^*$$

is one as well, since a product of unitary matrices is unitary (Proposition 10.7.4 (a)) and $\mathbf{\Sigma}$ is unchanged. Its left and right singular vectors are $\mathbf{Qu}_i$ and $\mathbf{Rv}_i$, so its rank-k truncation for this decomposition is

$$\sum_{i\le k} \sigma_i (\mathbf{Qu}_i)(\mathbf{Rv}_i)^* = \mathbf{Q}\Big(\sum_{i\le k} \sigma_i \mathbf{u}_i \mathbf{v}_i^*\Big)\mathbf{R}^* = \mathbf{QA}_k\mathbf{R}^*.$$

By Theorem 12.10.3 applied to $\mathbf{QAR}^*$, this is a best rank-k approximation.

(b) The two matrices have the same singular values, so by Theorem 12.10.3 both minima equal $\left(\sum_{i>k}\sigma_i^2\right)^{1/2}$.

(c) Take $\mathbf{A} = \operatorname{diag}(1,0)$ and $\mathbf{B} = \operatorname{diag}(0,1)$. Each has rank one, so $\mathbf{A}_1 = \mathbf{A}$ and $\mathbf{B}_1 = \mathbf{B}$ for every singular value decomposition, and $\mathbf{A}_1+\mathbf{B}_1 = \mathbf{I}_2$. But $\mathbf{A}+\mathbf{B} = \mathbf{I}_2$, whose rank-one truncations all have rank one, hence are never $\mathbf{I}_2$. So $(\mathbf{A}+\mathbf{B})_1 \neq \mathbf{A}_1+\mathbf{B}_1$. Truncation is not a linear operation, which is why "keep the biggest pieces" cannot be analyzed one summand at a time.

12.11 The Moore–Penrose Pseudoinverse

Chapter 10 solved $\mathbf{Ax} = \mathbf{b}$ twice over: when there is no solution it produced a least-squares solution, and when there are too many it produced the shortest one. It then left an IOU. The two answers "are usually wanted together: given any $\mathbf{A}$ and $\mathbf{b}$, first minimize $\|\mathbf{Ax}-\mathbf{b}\|$, then among the minimizers take the shortest. Chapter 12 packages the combined answer as a single matrix, the **pseudoinverse** $\mathbf{A}^+$, with $\mathbf{x} = \mathbf{A}^+\mathbf{b}$ in all cases at once." This section builds that matrix and pays the debt.

Throughout, $F = \mathbb{R}$ or $F = \mathbb{C}$, $\mathbf{A} \in M_{m\times n}(F)$, $p = \min(m,n)$ and $r = \operatorname{rank}\mathbf{A}$, with singular values $\sigma_1 \ge \cdots \ge \sigma_p \ge 0$ (Definition 12.8.1), so $\sigma_i > 0$ exactly for $i \le r$.

12.11.1 One matrix instead of three formulas

Here is the state of play at the end of Chapter 10. To answer "what is the best $\mathbf{x}$?" we had three different recipes, and choosing between them required knowing something about $\mathbf{A}$ first.

- If $\mathbf{A}$ is square and invertible, $\mathbf{x} = \mathbf{A}^{-1}\mathbf{b}$.
- If the columns of $\mathbf{A}$ are independent, $\mathbf{x} = (\mathbf{A}^*\mathbf{A})^{-1}\mathbf{A}^*\mathbf{b}$ (Corollary 10.4.4).

- If $\mathbf{Ax} = \mathbf{b}$ is consistent but $\mathbf{A}$ has a kernel, $\mathbf{x} = \mathbf{x}_{\min}$, the unique solution orthogonal to $\mathrm{nul}(\mathbf{A})$ (Theorem 10.4.5).

Three recipes, three hypotheses, and a gap: when $\mathbf{A}$ has both a kernel *and* a column space missing $\mathbf{b}$, none of them applies. That is not an exotic case. It is what happens whenever a large table of measurements has both redundant columns and noise.

The goal, stated before we know how to reach it, is a single matrix $\mathbf{A}^+$, depending on $\mathbf{A}$ alone, for which $\mathbf{x} = \mathbf{A}^+\mathbf{b}$ is the right answer in every case. Reading the goal backwards tells us what $\mathbf{A}^+$ must do, and the singular value decomposition tells us how to build it.

12.11.2 Inverting what can be inverted

Why is there no inverse in general? Two obstructions, and they are the two halves of Theorem 10.6.5. The map $\mathbf{x} \mapsto \mathbf{Ax}$ may fail to be injective, because $\mathrm{nul}(\mathbf{A}) \neq \{\mathbf{0}\}$; and it may fail to be surjective, because $\mathrm{col}(\mathbf{A}) \neq F^m$. Neither obstruction is fatal if we are willing to sacrifice part of the domain and part of the codomain.

Restrict the map to $\mathrm{col}(\mathbf{A}^*) = \mathrm{nul}(\mathbf{A})^\perp$, which throws away the kernel. What is left is a bijection onto $\mathrm{col}(\mathbf{A})$, and a bijection has an inverse. Extend that inverse to all of F^m by declaring it $\mathbf{0}$ on $\mathrm{col}(\mathbf{A})^\perp$, where nothing in the image can tell us anything. That is the whole construction, and it is the same trick that turns sin into arcsin: shrink the domain until the function is injective, shrink the codomain until it is surjective, invert, and say clearly what was given up.

Invert what can be inverted, and send the rest to zero.

The singular value decomposition performs all three operations at once, because it presents $\mathbf{A}$ as a diagonal matrix in orthonormal coordinates, and a diagonal matrix is inverted one entry at a time.

Definition 12.11.1 — Moore–Penrose pseudoinverse

Let $\mathbf{A} \in M_{m\times n}(F)$ and let $\mathbf{A} = \mathbf{U\Sigma V}^*$ be a singular value decomposition (Theorem 12.8.1), so that $\mathbf{U} \in M_m(F)$ and $\mathbf{V} \in M_n(F)$ are unitary and $\mathbf{\Sigma} \in M_{m\times n}(F)$ has the singular values $\sigma_1, \dots, \sigma_p$ on its diagonal and zeros elsewhere. Let $\mathbf{\Sigma}^+ \in M_{n\times m}(F)$ be the matrix with

$$(\mathbf{\Sigma}^+)_{ii} = \begin{cases} \sigma_i^{-1}, & \sigma_i > 0, \\ 0, & \sigma_i = 0, \end{cases}$$

for $1 \le i \le p$, and all other entries 0. The **Moore–Penrose pseudoinverse** of $\mathbf{A}$ is

$$\mathbf{A}^+ \coloneqq \mathbf{V\Sigma}^+\mathbf{U}^* \in M_{n\times m}(F).$$

Clause by clause. The matrix $\mathbf{\Sigma}^+$ is **$\mathbf{\Sigma}$ transposed and then inverted where inversion is legal**: the shape flips from $m \times n$ to $n \times m$, each non-zero diagonal entry is replaced by its reciprocal, and each zero diagonal entry is left alone — **not** replaced by anything, since 0^{-1} does not exist. The outer factors are exchanged and starred, exactly as they would be in $(\mathbf{U\Sigma V}^*)^{-1} = \mathbf{V\Sigma}^{-1}\mathbf{U}^*$ if $\mathbf{\Sigma}$ were invertible. And the result is $n \times m$, the shape an inverse of $\mathbf{A}$ would have to be.

Well-definedness is a real question here, not a formality. The singular *values* are determined by $\mathbf{A}$, but the unitary factors are not (Theorem 12.8.2), so the recipe above is

applied to a choice, and nothing so far says that two choices give the same answer. They do.

Proposition 12.11.1 — The pseudoinverse does not depend on the decomposition

Let $\mathbf{A} \in M_{m\times n}(F)$ and let $\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^*$ be any singular value decomposition (Theorem 12.8.1). Then $\mathbf{X} = \mathbf{V}\mathbf{\Sigma}^+\mathbf{U}^*$ is the unique matrix in $M_{n\times m}(F)$ such that

(i) for every $\mathbf{y} \in \operatorname{col}(\mathbf{A})$, $\mathbf{X}\mathbf{y}$ is the unique vector of $\operatorname{col}(\mathbf{A}^*)$ that $\mathbf{A}$ sends to $\mathbf{y}$;
(ii) $\mathbf{X}\mathbf{y} = \mathbf{0}$ for every $\mathbf{y} \in \operatorname{col}(\mathbf{A})^\perp$.

In particular $\mathbf{A}^+$ depends on $\mathbf{A}$ alone.

Idea. Conditions (i) and (ii) mention only $\mathbf{A}$, so if one matrix satisfies them, that matrix is determined by $\mathbf{A}$. The work is to check that they can be satisfied at all — which is the "restrict, invert, extend" story of the previous page written out — and that the matrix built from an arbitrary decomposition is the one that satisfies them. For the second part, the singular vectors are orthonormal bases of the subspaces involved, so both conditions can be checked on basis vectors.

Proof. **The conditions determine at most one matrix.** First, $\mathbf{A}$ maps $\operatorname{col}(\mathbf{A}^*)$ bijectively onto $\operatorname{col}(\mathbf{A})$. Injectivity: if $\mathbf{x} \in \operatorname{col}(\mathbf{A}^*)$ and $\mathbf{A}\mathbf{x} = \mathbf{0}$, then $\mathbf{x} \in \operatorname{nul}(\mathbf{A}) \cap \operatorname{nul}(\mathbf{A})^\perp = \{\mathbf{0}\}$, since $\operatorname{col}(\mathbf{A}^*) = \operatorname{nul}(\mathbf{A})^\perp$ by Theorem 10.6.5 (b). Surjectivity: the image is contained in $\operatorname{col}(\mathbf{A})$, and by injectivity it has dimension $\dim\operatorname{col}(\mathbf{A}^*) = \operatorname{rank}\mathbf{A}^* = \operatorname{rank}\mathbf{A} = \dim\operatorname{col}(\mathbf{A})$, the middle equality by Corollary 10.6.6 (a) applied to $\mathbf{x} \mapsto \mathbf{A}\mathbf{x}$. So (i) prescribes $\mathbf{X}$ on $\operatorname{col}(\mathbf{A})$ and (ii) prescribes it on $\operatorname{col}(\mathbf{A})^\perp$; since $F^m = \operatorname{col}(\mathbf{A}) \oplus \operatorname{col}(\mathbf{A})^\perp$ by Theorem 10.3.2 (a), a linear map is determined by the two prescriptions.

The matrix $\mathbf{X} = \mathbf{V}\mathbf{\Sigma}^+\mathbf{U}^*$ satisfies them. Write $\mathbf{u}_1, \dots, \mathbf{u}_m$ and $\mathbf{v}_1, \dots, \mathbf{v}_n$ for the columns of $\mathbf{U}$ and $\mathbf{V}$. Since rank is unchanged by invertible factors (Theorem 2.5.9), $r = \operatorname{rank}\mathbf{A} = \operatorname{rank}\mathbf{\Sigma}$ is the number of non-zero σ_i. By Corollary 12.8.4, $(\mathbf{u}_1, \dots, \mathbf{u}_r)$ is an orthonormal basis of $\operatorname{col}(\mathbf{A})$, the remaining $\mathbf{u}_j$ are an orthonormal basis of $\operatorname{col}(\mathbf{A})^\perp$, and $(\mathbf{v}_1, \dots, \mathbf{v}_r)$ is an orthonormal basis of $\operatorname{col}(\mathbf{A}^*)$. Multiplying out the definition,

$$\mathbf{X} = \sum_{i=1}^{r} \sigma_i^{-1}\mathbf{v}_i\mathbf{u}_i^*,$$

so $\mathbf{X}\mathbf{u}_i = \sigma_i^{-1}\mathbf{v}_i$ for $i \le r$ and $\mathbf{X}\mathbf{u}_j = \mathbf{0}$ for $j > r$. The second statement gives (ii) by linearity.

For (i), let $\mathbf{y} = \sum_{i\le r} c_i\mathbf{u}_i \in \operatorname{col}(\mathbf{A})$. Then $\mathbf{X}\mathbf{y} = \sum_{i\le r} c_i\sigma_i^{-1}\mathbf{v}_i \in \operatorname{col}(\mathbf{A}^*)$, and since $\mathbf{A}\mathbf{v}_i = \sigma_i\mathbf{u}_i$ (the rank-one expansion of Theorem 12.8.3 read one column at a time),

$$\mathbf{A}(\mathbf{X}\mathbf{y}) = \sum_{i\le r} c_i\sigma_i^{-1}\sigma_i\mathbf{u}_i = \mathbf{y}.$$

By the injectivity proved above, $\mathbf{X}\mathbf{y}$ is the *unique* vector of $\operatorname{col}(\mathbf{A}^*)$ with this property. This proves (i), and with it the proposition.

■

So $\mathbf{A}^+$ is an honest function of $\mathbf{A}$. Five examples, simplest first.

Example. (Five pseudoinverses)

(a) **$\mathbf{A}$ invertible.** Then $m = n = r$, $\mathbf{\Sigma}$ is invertible and $\mathbf{\Sigma}^+ = \mathbf{\Sigma}^{-1}$, so $\mathbf{A}^+ = \mathbf{V}\mathbf{\Sigma}^{-1}\mathbf{U}^* = (\mathbf{U}\mathbf{\Sigma}\mathbf{V}^*)^{-1} = \mathbf{A}^{-1}$. The pseudoinverse extends the inverse, which is the first thing it had to do.

(b) **$\mathbf{A} = \mathbf{0} \in M_{m\times n}(F)$.** Every singular value is 0, so $\mathbf{\Sigma}^+ = \mathbf{0}$ and $\mathbf{A}^+ = \mathbf{0} \in M_{n\times m}(F)$. The degenerate case is worth keeping in mind: the pseudoinverse of the worst possible matrix is not undefined, it is zero, which is what "invert nothing, kill everything" means.

(c) **Diagonal.** $\operatorname{diag}(2,0,5)^+ = \operatorname{diag}\left(\frac{1}{2}, 0, \frac{1}{5}\right)$. The zero is left where it is.

(d) **A single non-zero column $\mathbf{a} \in M_{n\times 1}(F)$.** Here $\sigma_1 = \|\mathbf{a}\|$, $\mathbf{u}_1 = \mathbf{a}/\|\mathbf{a}\|$ and $\mathbf{v}_1 = 1$, so $\mathbf{a}^+ = \mathbf{a}^*/\|\mathbf{a}\|^2$, a row vector. Then $\mathbf{a}^+\mathbf{a} = 1$ but $\mathbf{a}\mathbf{a}^+ = \mathbf{a}\mathbf{a}^*/\|\mathbf{a}\|^2$ is the orthogonal projection onto $\operatorname{span}(\mathbf{a})$.

(e) $\mathbf{A} = \left(\begin{smallmatrix}1&1\\1&1\end{smallmatrix}\right)$**.** This is $\sigma_1\mathbf{u}_1\mathbf{v}_1^*$ with $\sigma_1 = 2$ and $\mathbf{u}_1 = \mathbf{v}_1 = \frac{1}{\sqrt{2}}(1,1)$, since $2\mathbf{u}_1\mathbf{v}_1^* = 2\cdot\frac{1}{2}\left(\begin{smallmatrix}1&1\\1&1\end{smallmatrix}\right) = \mathbf{A}$. Hence

$$\mathbf{A}^+ = \tfrac{1}{2}\mathbf{v}_1\mathbf{u}_1^* = \frac{1}{4}\begin{pmatrix}1&1\\1&1\end{pmatrix}.$$

A **non-example by minimal change.** Item (a) of the list is often written $\mathbf{A}^+ = (\mathbf{A}^*\mathbf{A})^{-1}\mathbf{A}^*$, and Theorem 12.11.3 below confirms that formula whenever the columns of $\mathbf{A}$ are independent. Change one column of a 3×2 matrix into a multiple of the other, and the formula stops existing: $\mathbf{A}^*\mathbf{A}$ is then singular (Lemma 10.4.3), so $(\mathbf{A}^*\mathbf{A})^{-1}$ is not a matrix at all. The pseudoinverse survives the change; the formula does not. That is the difference between a definition and a recipe.

Why this definition. It is forced. Any reasonable "inverse" must undo $\mathbf{A}$ where $\mathbf{A}$ can be undone; there is exactly one subspace on which $\mathbf{A}$ is a bijection and which meets $\operatorname{nul}(\mathbf{A})$ only in $\mathbf{0}$ while being determined by $\mathbf{A}$ alone, namely $\operatorname{nul}(\mathbf{A})^\perp$; and setting the answer to $\mathbf{0}$ on $\operatorname{col}(\mathbf{A})^\perp$ is the only choice that keeps the map linear without inventing information. The names are those of the two people who published the idea, thirty-five years apart: Moore in 1920 through a projection formula, Penrose in 1955 through the four conditions of the next theorem.

Warning. **$\mathbf{A}^+\mathbf{A}$ is not the identity, and $\mathbf{A}^+$ is $n\times m$.** Two habits from the invertible case have to go. First the shape: if $\mathbf{A}$ is 3×5 then $\mathbf{A}^+$ is 5×3, so $\mathbf{A}\mathbf{A}^+$ is 3×3 and $\mathbf{A}^+\mathbf{A}$ is 5×5 — they are not even the same size, let alone both $\mathbf{I}$. Second the identity: for $\mathbf{A} = \left(\begin{smallmatrix}1&1\\1&1\end{smallmatrix}\right)$ of Example (Five pseudoinverses) (e),

$$\mathbf{A}^+\mathbf{A} = \frac{1}{4}\begin{pmatrix}1&1\\1&1\end{pmatrix}\begin{pmatrix}1&1\\1&1\end{pmatrix} = \frac{1}{2}\begin{pmatrix}1&1\\1&1\end{pmatrix} \neq \mathbf{I}_2.$$

The right question is not "is it the identity?" but "the identity on *what*?", and Theorem 12.11.3 answers it: $\mathbf{A}^+\mathbf{A}$ is the identity on $\operatorname{col}(\mathbf{A}^*)$ and zero on $\operatorname{nul}(\mathbf{A})$.

Quick check. Let $\mathbf{A} = \left(\begin{smallmatrix}1&1\\0&0\end{smallmatrix}\right)$. Find $\mathbf{A}^+$, then compute $\mathbf{A}\mathbf{A}^+$ and $\mathbf{A}^+\mathbf{A}$ and identify each as a projection.

Solution. Here $\mathbf{A} = \mathbf{e}_1(1,1)$ has rank one, so $\sigma_1 = \|\mathbf{e}_1\|\,\|(1,1)\| = \sqrt{2}$ with $\mathbf{u}_1 = \mathbf{e}_1$ and

$\mathbf{v}_1 = \frac{1}{\sqrt{2}}(1,1)$, and

$$\mathbf{A}^+ = \sigma_1^{-1}\mathbf{v}_1\mathbf{u}_1^* = \frac{1}{2}\begin{pmatrix}1 & 0\\ 1 & 0\end{pmatrix}.$$

Therefore

$$\mathbf{A}\mathbf{A}^+ = \begin{pmatrix}1 & 0\\ 0 & 0\end{pmatrix}, \qquad \mathbf{A}^+\mathbf{A} = \frac{1}{2}\begin{pmatrix}1 & 1\\ 1 & 1\end{pmatrix}.$$

Neither is $\mathbf{I}_2$. The first is the orthogonal projection onto $\operatorname{span}(\mathbf{e}_1) = \operatorname{col}(\mathbf{A})$; the second is the orthogonal projection onto $\operatorname{span}\big((1,1)\big) = \operatorname{col}(\mathbf{A}^\top)$, the row space. Each is the identity exactly on the subspace named, and zero on its orthogonal complement — which is what "as close to the identity as the shapes allow" means.

12.11.3 The four Penrose conditions

The definition builds $\mathbf{A}^+$ out of a decomposition. The following theorem characterizes it by four equations that mention nothing but $\mathbf{A}$, $\mathbf{X}$ and the star. It is the second, and better, answer to the well-definedness question, and it is how one *verifies* a candidate pseudoinverse in practice: guess, then check four identities.

Theorem 12.11.2 — The Penrose Conditions

Let $\mathbf{A} \in M_{m\times n}(F)$. Then $\mathbf{X} = \mathbf{A}^+$ is the **unique** matrix in $M_{n\times m}(F)$ satisfying all four of

(P1) $\mathbf{A}\mathbf{X}\mathbf{A} = \mathbf{A}$;
(P2) $\mathbf{X}\mathbf{A}\mathbf{X} = \mathbf{X}$;
(P3) $(\mathbf{A}\mathbf{X})^* = \mathbf{A}\mathbf{X}$;
(P4) $(\mathbf{X}\mathbf{A})^* = \mathbf{X}\mathbf{A}$.

Idea. Existence is a computation with $\mathbf{\Sigma}$: each condition collapses to an identity between $\mathbf{\Sigma}$, $\mathbf{\Sigma}^+$ and the diagonal matrix of r ones. Uniqueness is a puzzle. Given two solutions $\mathbf{X}_1$ and $\mathbf{X}_2$, the goal is a chain of equalities starting at $\mathbf{X}_1$ and ending at $\mathbf{X}_2$, so the plan is to walk to a symmetric midpoint: get $\mathbf{X}_1 = \mathbf{X}_1\mathbf{A}\mathbf{X}_2$ by pushing $\mathbf{X}_2$ in from the right, then run the mirror image of the same argument with $\mathbf{X}_2$ as the subject. Two preliminary identities make the walk possible, and both come from starring one of the conditions — the move that manufactures an $\mathbf{A}^*$ when the hypotheses offer only $\mathbf{A}$.

Proof. **Existence.** Let $\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^*$ and $\mathbf{X} = \mathbf{V}\mathbf{\Sigma}^+\mathbf{U}^*$. Using $\mathbf{V}^*\mathbf{V} = \mathbf{I}_n$ and $\mathbf{U}^*\mathbf{U} = \mathbf{I}_m$,

$$\mathbf{A}\mathbf{X} = \mathbf{U}\mathbf{\Sigma}\mathbf{\Sigma}^+\mathbf{U}^*, \qquad \mathbf{X}\mathbf{A} = \mathbf{V}\mathbf{\Sigma}^+\mathbf{\Sigma}\mathbf{V}^*.$$

Now $\mathbf{\Sigma}\mathbf{\Sigma}^+ \in M_m(F)$ is diagonal with $\sigma_i\sigma_i^{-1} = 1$ in the first r diagonal places and 0 elsewhere, and $\mathbf{\Sigma}^+\mathbf{\Sigma} \in M_n(F)$ is diagonal with the same pattern. Both are real diagonal, hence Hermitian, so $\mathbf{A}\mathbf{X}$ and $\mathbf{X}\mathbf{A}$ are Hermitian, which is (P3) and (P4). Moreover $\mathbf{\Sigma}\mathbf{\Sigma}^+\mathbf{\Sigma} = \mathbf{\Sigma}$ and $\mathbf{\Sigma}^+\mathbf{\Sigma}\mathbf{\Sigma}^+ = \mathbf{\Sigma}^+$, because multiplying a diagonal matrix by a diagonal matrix of ones and zeros keeps exactly the entries in the positions marked 1, and those are the positions where $\mathbf{\Sigma}$ and $\mathbf{\Sigma}^+$ are non-zero anyway. Hence

$$\mathbf{A}\mathbf{X}\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{\Sigma}^+\mathbf{\Sigma}\mathbf{V}^* = \mathbf{A}, \qquad \mathbf{X}\mathbf{A}\mathbf{X} = \mathbf{V}\mathbf{\Sigma}^+\mathbf{\Sigma}\mathbf{\Sigma}^+\mathbf{U}^* = \mathbf{X},$$

which is (P1) and (P2).

Uniqueness. Suppose $\mathbf{X}$ satisfies (P1)–(P4). Two consequences:

$$\mathbf{X}\mathbf{X}^*\mathbf{A}^* = \mathbf{X}, \qquad \mathbf{A}\mathbf{A}^*\mathbf{X}^* = \mathbf{A}. \tag{$*$}$$

For the first, $\mathbf{X} = \mathbf{X}\mathbf{A}\mathbf{X}$ by (P2), and $\mathbf{A}\mathbf{X} = (\mathbf{A}\mathbf{X})^* = \mathbf{X}^*\mathbf{A}^*$ by (P3), so $\mathbf{X} = \mathbf{X}(\mathbf{A}\mathbf{X}) = \mathbf{X}\mathbf{X}^*\mathbf{A}^*$. For the second, $\mathbf{A} = \mathbf{A}\mathbf{X}\mathbf{A}$ by (P1), and $\mathbf{X}\mathbf{A} = (\mathbf{X}\mathbf{A})^* = \mathbf{A}^*\mathbf{X}^*$ by (P4), so $\mathbf{A} = \mathbf{A}(\mathbf{X}\mathbf{A}) = \mathbf{A}\mathbf{A}^*\mathbf{X}^*$. Starring the second identity of $(*)$ gives the form we also need,

$$\mathbf{X}\mathbf{A}\mathbf{A}^* = \mathbf{A}^*. \tag{$**$}$$

Now let $\mathbf{X}_1$ and $\mathbf{X}_2$ both satisfy (P1)–(P4). Starting from $\mathbf{X}_1$ and working towards a term containing $\mathbf{X}_2$,

$$\begin{aligned}\mathbf{X}_1 &= \mathbf{X}_1\mathbf{X}_1^*\mathbf{A}^* = \mathbf{X}_1\mathbf{X}_1^*(\mathbf{A}\mathbf{X}_2\mathbf{A})^* \\ &= \mathbf{X}_1\mathbf{X}_1^*\mathbf{A}^*(\mathbf{A}\mathbf{X}_2)^* = \mathbf{X}_1\mathbf{X}_1^*\mathbf{A}^*\mathbf{A}\mathbf{X}_2 \\ &= \mathbf{X}_1\mathbf{A}\mathbf{X}_2.\end{aligned}$$

The first equality is $(*)$ for $\mathbf{X}_1$; the second replaces $\mathbf{A}$ by $\mathbf{A}\mathbf{X}_2\mathbf{A}$, which is (P1) for $\mathbf{X}_2$; the third reverses the product under the star; the fourth is (P3) for $\mathbf{X}_2$; and the last is $(*)$ for $\mathbf{X}_1$ again, applied to the first three factors.

Now the mirror argument, with $\mathbf{X}_2$ as the subject:

$$\begin{aligned}\mathbf{X}_1\mathbf{A}\mathbf{X}_2 &= \mathbf{X}_1\mathbf{A}\mathbf{A}^*\mathbf{X}_2^*\mathbf{X}_2 = \mathbf{A}^*\mathbf{X}_2^*\mathbf{X}_2 \\ &= (\mathbf{X}_2\mathbf{A})^*\mathbf{X}_2 = \mathbf{X}_2\mathbf{A}\mathbf{X}_2 = \mathbf{X}_2.\end{aligned}$$

Here the first equality replaces $\mathbf{A}$ by $\mathbf{A}\mathbf{A}^*\mathbf{X}_2^*$, which is $(*)$ for $\mathbf{X}_2$; the second is $(**)$ for $\mathbf{X}_1$; the fourth is (P4) for $\mathbf{X}_2$; and the last is (P2) for $\mathbf{X}_2$.

Hence $\mathbf{X}_1 = \mathbf{X}_2$. Since $\mathbf{A}^+$ satisfies the four conditions, every matrix satisfying them equals $\mathbf{A}^+$. This proves the theorem.

■

Both halves of the argument are the same two moves: star a condition to trade $\mathbf{A}$ for $\mathbf{A}^*$, then use $(*)$ to collapse a triple product. The conditions are also exactly what one should check when an explicit candidate is on the table, and several of the proofs below do nothing else.

Remark. The four conditions are not independent decoration. Dropping (P2) leaves the **generalized inverses**, matrices with $\mathbf{A}\mathbf{X}\mathbf{A} = \mathbf{A}$, of which there are many when $\mathbf{A}$ is singular; dropping (P3) and (P4) leaves more still. Each condition removes freedom, and only all four together remove all of it. Exercise C3 identifies the matrices for which $\mathbf{A}^*$ itself already satisfies them.

12.11.4 What the pseudoinverse does

Theorem 12.11.3 — Properties of the pseudoinverse

Let $\mathbf{A} \in M_{m\times n}(F)$. Then:

(a) $\mathbf{A}\mathbf{A}^+ = P_{\mathrm{col}(\mathbf{A})}$ and $\mathbf{A}^+\mathbf{A} = P_{\mathrm{col}(\mathbf{A}^*)}$, the orthogonal projections onto the column space of $\mathbf{A}$ in F^m and onto the column space of $\mathbf{A}^*$ in F^n;

(b) $(\mathbf{A}^+)^+ = \mathbf{A}$;

(c) $(\mathbf{A}^+)^* = (\mathbf{A}^*)^+$;

(d) $\operatorname{rank}\mathbf{A}^+ = \operatorname{rank}\mathbf{A}$;

(e) $\mathbf{A}^+ = \mathbf{A}^{-1}$ if $\mathbf{A}$ is invertible; $\mathbf{A}^+ = (\mathbf{A}^*\mathbf{A})^{-1}\mathbf{A}^*$ if $\operatorname{rank}\mathbf{A} = n$; and $\mathbf{A}^+ = \mathbf{A}^*(\mathbf{A}\mathbf{A}^*)^{-1}$ if $\operatorname{rank}\mathbf{A} = m$.

Idea. Clause (a) is the computation already done in the existence half of Theorem 12.11.2, read through Theorem 10.3.3. Clauses (b) and (c) are one line each, because the Penrose conditions are almost symmetric in $\mathbf{A}$ and $\mathbf{X}$, and starring all four of them produces the four conditions for $\mathbf{A}^*$. Clause (e) is three checks of the same kind: write down the candidate and confirm (P1)–(P4).

Proof.

(a) With $\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^*$ and the notation of Proposition 12.11.1, the existence computation gave $\mathbf{A}\mathbf{A}^+ = \mathbf{U}\mathbf{\Sigma}\mathbf{\Sigma}^+\mathbf{U}^*$, where $\mathbf{\Sigma}\mathbf{\Sigma}^+$ is diagonal with r ones followed by zeros. Multiplying out,

$$\mathbf{A}\mathbf{A}^+ = \sum_{i=1}^{r} \mathbf{u}_i\mathbf{u}_i^*.$$

For $\mathbf{y} \in F^m$ this sends $\mathbf{y}$ to $\sum_{i\le r}\langle \mathbf{y}, \mathbf{u}_i\rangle \mathbf{u}_i$, which by Theorem 10.3.3 (a) is the orthogonal projection of $\mathbf{y}$ onto $\operatorname{span}(\mathbf{u}_1,\dots,\mathbf{u}_r) = \operatorname{col}(\mathbf{A})$ (Corollary 12.8.4). The same computation with $\mathbf{\Sigma}^+\mathbf{\Sigma}$ gives $\mathbf{A}^+\mathbf{A} = \sum_{i\le r}\mathbf{v}_i\mathbf{v}_i^* = P_{\mathrm{col}(\mathbf{A}^*)}$.

(b) The four Penrose conditions for the pair $(\mathbf{A}, \mathbf{X})$ become, when the roles of $\mathbf{A}$ and $\mathbf{X}$ are exchanged, the list (P2), (P1), (P4), (P3) — the same four conditions. So $\mathbf{A}$ satisfies the Penrose conditions for $\mathbf{A}^+$, and Theorem 12.11.2 gives $(\mathbf{A}^+)^+ = \mathbf{A}$.

(c) Put $\mathbf{X} = (\mathbf{A}^+)^*$ and check the four conditions for $\mathbf{A}^*$. Using $(\mathbf{B}\mathbf{C})^* = \mathbf{C}^*\mathbf{B}^*$ throughout,

$$\mathbf{A}^*\mathbf{X}\mathbf{A}^* = (\mathbf{A}\mathbf{A}^+\mathbf{A})^* = \mathbf{A}^*, \qquad \mathbf{X}\mathbf{A}^*\mathbf{X} = (\mathbf{A}^+\mathbf{A}\mathbf{A}^+)^* = \mathbf{X},$$

which are (P1) and (P2). Next, $\mathbf{A}^*\mathbf{X} = (\mathbf{A}^+\mathbf{A})^* = \mathbf{A}^+\mathbf{A}$ by (P4) for $\mathbf{A}$, and $\mathbf{A}^+\mathbf{A}$ is Hermitian, so (P3) holds; and $\mathbf{X}\mathbf{A}^* = (\mathbf{A}\mathbf{A}^+)^* = \mathbf{A}\mathbf{A}^+$ by (P3) for $\mathbf{A}$, which is Hermitian, so (P4) holds. By uniqueness, $\mathbf{X} = (\mathbf{A}^*)^+$.

(d) $\mathbf{A}^+ = \mathbf{V}\mathbf{\Sigma}^+\mathbf{U}^*$ with $\mathbf{U}, \mathbf{V}$ invertible, so $\operatorname{rank}\mathbf{A}^+ = \operatorname{rank}\mathbf{\Sigma}^+ = r$ by Theorem 2.5.9, the last equality because $\mathbf{\Sigma}^+$ has exactly r non-zero entries, all in distinct rows and columns.

(e) The invertible case is Example (Five pseudoinverses) (a). Suppose $\operatorname{rank}\mathbf{A} = n$. Then $\mathbf{A}^*\mathbf{A}$ is invertible (Corollary 10.4.4), so $\mathbf{X} = (\mathbf{A}^*\mathbf{A})^{-1}\mathbf{A}^*$ is defined, and $((\mathbf{A}^*\mathbf{A})^{-1})^* = (\mathbf{A}^*\mathbf{A})^{-1}$ since $\mathbf{A}^*\mathbf{A}$ is Hermitian. Then

$$\mathbf{X}\mathbf{A} = (\mathbf{A}^*\mathbf{A})^{-1}\mathbf{A}^*\mathbf{A} = \mathbf{I}_n,$$

which is Hermitian, giving (P4); and (P1), (P2) follow at once, since $\mathbf{A}\mathbf{X}\mathbf{A} = \mathbf{A}\mathbf{I}_n = \mathbf{A}$ and $\mathbf{X}\mathbf{A}\mathbf{X} = \mathbf{I}_n\mathbf{X} = \mathbf{X}$. For (P3), $\mathbf{A}\mathbf{X} = \mathbf{A}(\mathbf{A}^*\mathbf{A})^{-1}\mathbf{A}^*$, whose conjugate transpose is itself. So $\mathbf{X} = \mathbf{A}^+$.

For the last formula, suppose $\operatorname{rank}\mathbf{A} = m$. Then $\operatorname{rank}\mathbf{A}^* = m$ is the number of columns

of $\mathbf{A}^*$, so the case just proved applies to $\mathbf{A}^*$ and gives $(\mathbf{A}^*)^+ = (\mathbf{A}\mathbf{A}^*)^{-1}\mathbf{A}$. By (c),

$$\mathbf{A}^+ = \big((\mathbf{A}^*)^+\big)^* = \big((\mathbf{A}\mathbf{A}^*)^{-1}\mathbf{A}\big)^* = \mathbf{A}^*(\mathbf{A}\mathbf{A}^*)^{-1},$$

using that $\mathbf{A}\mathbf{A}^*$ is Hermitian, hence so is its inverse. This proves the theorem.

■

Clause (a) is the one to remember, and it answers the question the warning raised. The products $\mathbf{A}\mathbf{A}^+$ and $\mathbf{A}^+\mathbf{A}$ are not identities; they are the identity **restricted to the subspaces where $\mathbf{A}$ is invertible**, and zero on the complements. Clause (e) shows that the three recipes of Chapter 10 were all the pseudoinverse in disguise, each written in the notation that its hypothesis made available.

Warning. **$(\mathbf{AB})^+ \neq \mathbf{B}^+\mathbf{A}^+$ in general.** The rule $(\mathbf{AB})^{-1} = \mathbf{B}^{-1}\mathbf{A}^{-1}$ does not survive. Take

$$\mathbf{A} = \begin{pmatrix} 1 & 1 \\ 0 & 0 \end{pmatrix}, \qquad \mathbf{B} = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}.$$

The Quick check above found $\mathbf{A}^+ = \frac{1}{2}\left(\begin{smallmatrix} 1 & 0 \\ 1 & 0 \end{smallmatrix}\right)$, and one may confirm it against Theorem 12.11.2: the two products computed there are Hermitian, and $\mathbf{A}\mathbf{A}^+\mathbf{A} = \mathbf{A}$, $\mathbf{A}^+\mathbf{A}\mathbf{A}^+ = \mathbf{A}^+$. Meanwhile $\mathbf{B}$ is Hermitian and idempotent, so $\mathbf{X} = \mathbf{B}$ satisfies (P1)–(P4) and $\mathbf{B}^+ = \mathbf{B}$. Now $\mathbf{AB} = \left(\begin{smallmatrix} 1 & 0 \\ 0 & 0 \end{smallmatrix}\right) = \mathbf{B}$, so

$$(\mathbf{AB})^+ = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}, \qquad \mathbf{B}^+\mathbf{A}^+ = \frac{1}{2}\begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}.$$

The two differ by a factor of 2. The reversal rule does hold under extra hypotheses — for instance when $\mathbf{A}$ has independent columns and $\mathbf{B}$ has independent rows, which is Exercise C2 — but never assume it.

12.11.5 Least squares and minimum norm, in one matrix

Everything is now in place to pay Chapter 10's debt.

Theorem 12.11.4 — The pseudoinverse solves both problems at once

Let $\mathbf{A} \in M_{m\times n}(F)$ and $\mathbf{b} \in F^m$, and put $\mathbf{x}^+ = \mathbf{A}^+\mathbf{b}$. Then:

(a) $\mathbf{x}^+$ is a least-squares solution of $\mathbf{A}\mathbf{x} = \mathbf{b}$, that is, $\|\mathbf{A}\mathbf{x}^+ - \mathbf{b}\| \le \|\mathbf{A}\mathbf{z} - \mathbf{b}\|$ for every $\mathbf{z} \in F^n$;

(b) $\|\mathbf{x}^+\| < \|\mathbf{x}\|$ for every other least-squares solution $\mathbf{x}$;

(c) if $\mathbf{A}\mathbf{x} = \mathbf{b}$ is consistent, $\mathbf{x}^+$ is its minimum-norm solution in the sense of Theorem 10.4.5; if $\mathbf{A}$ is invertible, $\mathbf{x}^+ = \mathbf{A}^{-1}\mathbf{b}$.

Idea. Both halves are already proved; the pseudoinverse only has to be recognized inside them. For (a), $\mathbf{A}\mathbf{x}^+ = \mathbf{A}\mathbf{A}^+\mathbf{b}$ is the projection of $\mathbf{b}$ onto $\operatorname{col}(\mathbf{A})$, which is precisely condition (b) of the Least Squares Theorem. For (b), the least-squares solutions are the

solutions of one consistent system, so the Minimum-Norm Solution Theorem applies to that system and singles out the solution lying in $\text{nul}(\mathbf{A})^{\perp}$; and $\mathbf{A}^{+}\mathbf{b}$ lies there, because every column of $\mathbf{A}^{+}$ does.

Proof.

(a) By Theorem 12.11.3 (a), $\mathbf{A}\mathbf{x}^{+} = \mathbf{A}\mathbf{A}^{+}\mathbf{b} = P_U\mathbf{b}$ with $U = \text{col}(\mathbf{A})$. This is condition (b) of Theorem 10.4.2, so $\mathbf{x}^{+}$ is a least-squares solution.

(b) By Theorem 10.4.2, the least-squares solutions of $\mathbf{A}\mathbf{x} = \mathbf{b}$ are exactly the solutions of the system $\mathbf{A}\mathbf{x} = P_U\mathbf{b}$, which is consistent because $P_U\mathbf{b} \in U = \text{col}(\mathbf{A})$. Apply Theorem 10.4.5 to that system: exactly one of its solutions lies in $\text{nul}(\mathbf{A})^{\perp}$, and it is strictly shorter than all the others.
It remains to see that $\mathbf{x}^{+}$ is that one. By (P2), $\mathbf{A}^{+} = \mathbf{A}^{+}\mathbf{A}\mathbf{A}^{+} = P_{\text{col}(\mathbf{A}^{*})}\mathbf{A}^{+}$ using Theorem 12.11.3 (a), so every column of $\mathbf{A}^{+}$, and hence every vector $\mathbf{A}^{+}\mathbf{b}$, lies in $\text{col}(\mathbf{A}^{*})$. By Theorem 10.6.5 (b), $\text{col}(\mathbf{A}^{*}) = \text{nul}(\mathbf{A})^{\perp}$. So $\mathbf{x}^{+}$ is the minimum-norm solution of $\mathbf{A}\mathbf{x} = P_U\mathbf{b}$, which by the previous paragraph is what (b) asserts.

(c) If $\mathbf{A}\mathbf{x} = \mathbf{b}$ is consistent then $\mathbf{b} \in \text{col}(\mathbf{A})$, so $P_U\mathbf{b} = \mathbf{b}$ and the least-squares solutions are the actual solutions; (b) then says $\mathbf{x}^{+}$ is the shortest of them, which is Theorem 10.4.5's $\mathbf{x}_{\text{min}}$. If $\mathbf{A}$ is invertible, $\mathbf{A}^{+} = \mathbf{A}^{-1}$ by Theorem 12.11.3 (e). This proves the theorem.

■

The promise, discharged. Section 4 of Chapter 10 said that the two answers are usually wanted together — first minimize $\|\mathbf{A}\mathbf{x} - \mathbf{b}\|$, then among the minimizers take the shortest — and that Chapter 12 would package the combined answer as a single matrix $\mathbf{A}^{+}$, with $\mathbf{x} = \mathbf{A}^{+}\mathbf{b}$ in all cases at once. That is Theorem 12.11.4, word for word: clause (a) does the minimizing, clause (b) takes the shortest, and clause (c) plus Theorem 12.11.3 (e) checks that the three special recipes of Chapter 10 are recovered as special cases. There is no hypothesis on $\mathbf{A}$ anywhere in the statement.

The notation, settled. Chapter 10 wrote $\mathbf{x}_{\text{min}}$ for the minimum-norm solution of a *consistent* system and left the symbol without a formula. From now on it has one, and its meaning extends to every system:

$$\mathbf{x}_{\text{min}} = \mathbf{A}^{+}\mathbf{b},$$

the minimum-norm least-squares solution of $\mathbf{A}\mathbf{x} = \mathbf{b}$. For a consistent system this agrees with Chapter 10's $\mathbf{x}_{\text{min}}$, by Theorem 12.11.4 (c); for an inconsistent one it is the shortest of the minimizers of $\|\mathbf{A}\mathbf{x} - \mathbf{b}\|$, by clauses (a) and (b). One symbol, one formula, no case distinction.

Example. (Chapter 10's minimum-norm solution, recomputed)

In Chapter 10 the system

$$x_1 + x_2 + x_3 = 3, \qquad x_1 + 2x_2 + 3x_3 = 7$$

was solved for its shortest solution by intersecting the solution line with $\text{nul}(\mathbf{A})^{\perp}$, as Theorem 10.4.5 prescribes. Recompute $\mathbf{x}_{\text{min}}$ as $\mathbf{A}^{+}\mathbf{b}$.

Solution. Here

$$\mathbf{A} = \begin{pmatrix} 1 & 1 & 1 \\ 1 & 2 & 3 \end{pmatrix}, \qquad \mathbf{b} = (3, 7).$$

The two rows are independent, so $\operatorname{rank}\mathbf{A} = 2 = m$ and Theorem 12.11.3 (e) gives $\mathbf{A}^{+} = \mathbf{A}^{\top}(\mathbf{A}\mathbf{A}^{\top})^{-1}$. Now

$$\mathbf{A}\mathbf{A}^{\top} = \begin{pmatrix} 3 & 6 \\ 6 & 14 \end{pmatrix}, \qquad (\mathbf{A}\mathbf{A}^{\top})^{-1} = \frac{1}{6}\begin{pmatrix} 14 & -6 \\ -6 & 3 \end{pmatrix},$$

since the determinant is $42 - 36 = 6$. Therefore

$$\mathbf{A}^{+} = \frac{1}{6}\begin{pmatrix} 1 & 1 \\ 1 & 2 \\ 1 & 3 \end{pmatrix}\begin{pmatrix} 14 & -6 \\ -6 & 3 \end{pmatrix} = \frac{1}{6}\begin{pmatrix} 8 & -3 \\ 2 & 0 \\ -4 & 3 \end{pmatrix},$$

and

$$\mathbf{x}_{\min} = \mathbf{A}^{+}\mathbf{b} = \frac{1}{6}\begin{pmatrix} 24 - 21 \\ 6 + 0 \\ -12 + 21 \end{pmatrix} = \left(\tfrac{1}{2}, 1, \tfrac{3}{2}\right).$$

This is exactly the answer Chapter 10 obtained by hand, and $\|\mathbf{x}_{\min}\|^2 = \frac{1}{4} + 1 + \frac{9}{4} = \frac{7}{2}$ as before. The system is consistent — $\frac{1}{2} + 1 + \frac{3}{2} = 3$ and $\frac{1}{2} + 2 + \frac{9}{2} = 7$ — so no projection was needed; what the pseudoinverse did was replace a geometric argument by one matrix product.

The next example is the case no formula of Chapter 10 reaches: the system is inconsistent **and** underdetermined at the same time.

Example. (Inconsistent and underdetermined at once)

Find $\mathbf{x}_{\min}$ for

$$\mathbf{A} = \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix}, \qquad \mathbf{b} = (1, 3),$$

and verify directly that it minimizes the residual and is the shortest minimizer.

Solution. The system reads $x_1 + x_2 = 1$ and $x_1 + x_2 = 3$, so it is inconsistent; and $\operatorname{nul}(\mathbf{A}) = \operatorname{span}\big((1, -1)\big) \neq \{\mathbf{0}\}$, so the columns are dependent. Neither $\mathbf{A}^{-1}$ nor $(\mathbf{A}^{*}\mathbf{A})^{-1}\mathbf{A}^{*}$ exists. From Example (Five pseudoinverses) (e), $\mathbf{A}^{+} = \frac{1}{4}\left(\begin{smallmatrix} 1 & 1 \\ 1 & 1 \end{smallmatrix}\right)$, so

$$\mathbf{x}_{\min} = \mathbf{A}^{+}\mathbf{b} = \frac{1}{4}(1 + 3, 1 + 3) = (1, 1).$$

Check. $\operatorname{col}(\mathbf{A}) = \operatorname{span}\big((1, 1)\big)$, and the projection of $\mathbf{b} = (1, 3)$ onto it is $\frac{1+3}{2}(1, 1) = (2, 2)$. Indeed $\mathbf{A}(1, 1) = (2, 2)$, so the residual is $\mathbf{b} - (2, 2) = (-1, 1)$, of squared length 2 — the smallest possible. The least-squares solutions are all $\mathbf{x}$ with $x_1 + x_2 = 2$, that is $(1, 1) + t(1, -1)$, and

$$\|(1, 1) + t(1, -1)\|^2 = 2 + 2t^2,$$

which is smallest exactly at $t = 0$. So $(1, 1)$ is the shortest least-squares solution, as Theorem 12.11.4 (b) predicts.

12.11.6 The block criterion, finished

Section 6 tested a block matrix for positive definiteness one block at a time, and had to assume the corner block invertible: the Schur complement $\mathbf{M}/\mathbf{A} = \mathbf{C} - \mathbf{B}^*\mathbf{A}^{-1}\mathbf{B}$ is meaningless otherwise. The pseudoinverse removes that hypothesis, and the promise Section 6 made is paid here.

Proposition 12.11.5 — The Semidefinite Block Criterion

Let $\mathbf{A} \in M_k(F)$ and $\mathbf{C} \in M_l(F)$ be self-adjoint and put

$$\mathbf{M} = \begin{pmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{B}^* & \mathbf{C} \end{pmatrix} \in M_{k+l}(F).$$

Then $\mathbf{M} \succeq 0$ if and only if $\mathbf{A} \succeq 0$, every column of $\mathbf{B}$ lies in $\operatorname{col}(\mathbf{A})$, and $\mathbf{C} - \mathbf{B}^*\mathbf{A}^{+}\mathbf{B} \succeq 0$.

Idea. Section 6 cleared the corner with the shear $\left(\begin{smallmatrix} \mathbf{I} & -\mathbf{A}^{-1}\mathbf{B} \\ \mathbf{0} & \mathbf{I} \end{smallmatrix}\right)$. Write $\mathbf{A}^{+}$ in place of $\mathbf{A}^{-1}$ and the same shear still clears it — but only because $\mathbf{A}\mathbf{A}^{+}$ is the projection onto $\operatorname{col}(\mathbf{A})$, so $\mathbf{A}\mathbf{A}^{+}\mathbf{B} = \mathbf{B}$ exactly when the columns of $\mathbf{B}$ are already in $\operatorname{col}(\mathbf{A})$. That condition is not a technicality: it is what the two-sided test forces.

Proof. Suppose first that $\mathbf{M} \succeq 0$. Taking $\mathbf{v} = (\mathbf{x}, \mathbf{0})$ gives $\langle \mathbf{A}\mathbf{x}, \mathbf{x}\rangle \geq 0$, so $\mathbf{A} \succeq 0$. For the column condition, let $\mathbf{x} \in \operatorname{nul}(\mathbf{A})$ and $\mathbf{y} \in F^l$, and put $\mathbf{v}_t = (t\mathbf{x}, \mathbf{y})$ for $t \in \mathbb{R}$. Then

$$\langle \mathbf{M}\mathbf{v}_t, \mathbf{v}_t\rangle = t^2\langle \mathbf{A}\mathbf{x}, \mathbf{x}\rangle + 2t\,\Re\langle \mathbf{B}\mathbf{y}, \mathbf{x}\rangle + \langle \mathbf{C}\mathbf{y}, \mathbf{y}\rangle = 2t\,\Re\langle \mathbf{B}\mathbf{y}, \mathbf{x}\rangle + \langle \mathbf{C}\mathbf{y}, \mathbf{y}\rangle,$$

using $\mathbf{A}\mathbf{x} = \mathbf{0}$. A real affine function of t that is non-negative for every t has zero slope, so $\Re\langle \mathbf{B}\mathbf{y}, \mathbf{x}\rangle = 0$ for all $\mathbf{y}$; replacing $\mathbf{y}$ by $i\mathbf{y}$ over $\mathbb{C}$ kills the imaginary part too. Hence $\langle \mathbf{B}\mathbf{y}, \mathbf{x}\rangle = 0$ for every $\mathbf{y}$, that is $\mathbf{B}^*\mathbf{x} = \mathbf{0}$. So $\operatorname{nul}(\mathbf{A}) \subseteq \operatorname{nul}(\mathbf{B}^*)$, and taking orthogonal complements with Theorem 10.6.5 gives $\operatorname{col}(\mathbf{B}) \subseteq \operatorname{col}(\mathbf{A})$, since $\mathbf{A}$ is self-adjoint.

Now assume $\mathbf{A} \succeq 0$ and $\operatorname{col}(\mathbf{B}) \subseteq \operatorname{col}(\mathbf{A})$; we show $\mathbf{M} \succeq 0$ is equivalent to $\mathbf{C} - \mathbf{B}^*\mathbf{A}^{+}\mathbf{B} \succeq 0$, which finishes both directions. By Theorem 12.11.3 (a), $\mathbf{A}\mathbf{A}^{+} = P_{\operatorname{col}(\mathbf{A})}$, so $\mathbf{A}\mathbf{A}^{+}\mathbf{B} = \mathbf{B}$; taking adjoints, and using that $\mathbf{A}$ and $\mathbf{A}^{+}$ are self-adjoint (Theorem 12.11.3 (c)), also $\mathbf{B}^*\mathbf{A}^{+}\mathbf{A} = \mathbf{B}^*$. Put

$$\mathbf{S} = \begin{pmatrix} \mathbf{I}_k & -\mathbf{A}^{+}\mathbf{B} \\ \mathbf{0} & \mathbf{I}_l \end{pmatrix},$$

which is invertible. Multiplying out and canceling with the two identities just recorded,

$$\mathbf{S}^*\mathbf{M}\mathbf{S} = \begin{pmatrix} \mathbf{A} & \mathbf{0} \\ \mathbf{0} & \mathbf{C} - \mathbf{B}^*\mathbf{A}^{+}\mathbf{B} \end{pmatrix}.$$

Since $\mathbf{S}$ is invertible, Proposition 12.1.2 (a) applied to $\mathbf{S}$ and then to $\mathbf{S}^{-1}$ shows that $\mathbf{M} \succeq 0$ if and only if $\mathbf{S}^*\mathbf{M}\mathbf{S} \succeq 0$, and a block diagonal matrix is positive semidefinite exactly when both blocks are. This shows the three conditions together are equivalent to $\mathbf{M} \succeq 0$.

■

The column condition cannot be dropped. With

$$\mathbf{A} = \begin{pmatrix} 2 & 0 \\ 0 & 0 \end{pmatrix}, \qquad \mathbf{C} = (1),$$

the choice $\mathbf{B} = (1, 0)^{\top}$ has its column in $\operatorname{col}(\mathbf{A})$ and gives $\mathbf{C} - \mathbf{B}^{*}\mathbf{A}^{+}\mathbf{B} = (\tfrac{1}{2}) \succeq 0$, so $\mathbf{M} \succeq 0$. The choice $\mathbf{B} = (0, 1)^{\top}$ does not, and there $\mathbf{M}$ is not positive semidefinite even though $\mathbf{A} \succeq 0$, $\mathbf{C} \succeq 0$ and $\mathbf{B}^{*}\mathbf{A}^{+}\mathbf{B} = \mathbf{0}$ makes the third condition hold trivially.

12.11.7 Exercises

12.11.7.1 A. Check your understanding

Exercise A1.

(a) Define $\mathbf{A}^{+}$ in terms of a singular value decomposition of $\mathbf{A}$ (Theorem 12.8.1), and say what size it is.

(b) State the four Penrose conditions, and say what Theorem 12.11.2 asserts about them.

(c) What are $\mathbf{A}\mathbf{A}^{+}$ and $\mathbf{A}^{+}\mathbf{A}$? Under what condition on $\mathbf{A}$ is the second of them $\mathbf{I}_n$?

(d) Write down $\mathbf{0}^{+}$ for the zero matrix $\mathbf{0} \in M_{m\times n}(F)$, and $\mathbf{A}^{+}$ for an invertible $\mathbf{A}$.

(e) True or false: $(\mathbf{A}\mathbf{B})^{+} = \mathbf{B}^{+}\mathbf{A}^{+}$ whenever the product $\mathbf{A}\mathbf{B}$ is defined. Justify your answer.

Solution.

(a) If $\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^{*}$, then $\mathbf{A}^{+} = \mathbf{V}\mathbf{\Sigma}^{+}\mathbf{U}^{*}$, where $\mathbf{\Sigma}^{+} \in M_{n\times m}(F)$ has σ_i^{-1} in the (i,i) place for each $\sigma_i > 0$ and zeros elsewhere. It is $n \times m$, the transpose of the shape of $\mathbf{A}$.

(b) $\mathbf{A}\mathbf{X}\mathbf{A} = \mathbf{A}$, $\mathbf{X}\mathbf{A}\mathbf{X} = \mathbf{X}$, $(\mathbf{A}\mathbf{X})^{*} = \mathbf{A}\mathbf{X}$, $(\mathbf{X}\mathbf{A})^{*} = \mathbf{X}\mathbf{A}$. The theorem says $\mathbf{A}^{+}$ satisfies all four and is the only matrix that does; so the four conditions may be used as a definition, and checking them is enough to identify a candidate.

(c) $\mathbf{A}\mathbf{A}^{+} = P_{\operatorname{col}(\mathbf{A})}$ and $\mathbf{A}^{+}\mathbf{A} = P_{\operatorname{col}(\mathbf{A}^{*})}$ (Theorem 12.11.3 (a)). The second is $\mathbf{I}_n$ exactly when $\operatorname{col}(\mathbf{A}^{*}) = F^{n}$, that is when $\operatorname{rank}\mathbf{A} = n$, that is when the columns of $\mathbf{A}$ are independent.

(d) $\mathbf{0}^{+} = \mathbf{0} \in M_{n\times m}(F)$; $\mathbf{A}^{+} = \mathbf{A}^{-1}$ when $\mathbf{A}$ is invertible.

(e) False. With $\mathbf{A} = \left(\begin{smallmatrix} 1 & 1 \\ 0 & 0 \end{smallmatrix}\right)$ and $\mathbf{B} = \left(\begin{smallmatrix} 1 & 0 \\ 0 & 0 \end{smallmatrix}\right)$ the two sides are $\left(\begin{smallmatrix} 1 & 0 \\ 0 & 0 \end{smallmatrix}\right)$ and $\frac{1}{2}\left(\begin{smallmatrix} 1 & 0 \\ 0 & 0 \end{smallmatrix}\right)$, as computed in the warning above.

12.11.7.2 B. Practice

Exercise B1: Four pseudoinverses.

Compute $\mathbf{A}^{+}$ for each of the following, stating which method you used.

(a) $\mathbf{A} = \operatorname{diag}(3, 0, 0, 4) \in M_4(\mathbb{R})$;

(b) $\mathbf{A} = (1, 2, 2)^{\top} \in M_{3\times 1}(\mathbb{R})$;

(c) $\mathbf{A} = \begin{pmatrix} 1 & 2 \\ 2 & 4 \end{pmatrix} \in M_2(\mathbb{R})$;

(d) $\mathbf{A} = \begin{pmatrix} 1 & 0 & 1 \\ 0 & 1 & 1 \end{pmatrix} \in M_{2\times 3}(\mathbb{R})$.

Solution.

(a) A diagonal matrix is its own singular value decomposition (Theorem 12.8.1) up to ordering, so invert the non-zero entries in place: $\mathbf{A}^+ = \operatorname{diag}\left(\tfrac{1}{3}, 0, 0, \tfrac{1}{4}\right)$.

(b) A single non-zero column, so Example (Five pseudoinverses) (d) applies with $\|\mathbf{A}\|^2 = 1 + 4 + 4 = 9$:

$$\mathbf{A}^+ = \tfrac{1}{9}(1, 2, 2) \in M_{1\times 3}(\mathbb{R}).$$

(c) Rank one: $\mathbf{A} = \mathbf{u}\mathbf{v}^\top$ with $\mathbf{u} = (1, 2)$ and $\mathbf{v} = (1, 2)$. Then $\sigma_1 = \|\mathbf{u}\|\,\|\mathbf{v}\| = 5$ with $\mathbf{u}_1 = \mathbf{u}/\sqrt{5}$ and $\mathbf{v}_1 = \mathbf{v}/\sqrt{5}$, so

$$\mathbf{A}^+ = \tfrac{1}{5}\mathbf{v}_1\mathbf{u}_1^\top = \tfrac{1}{25}\begin{pmatrix} 1 & 2 \\ 2 & 4 \end{pmatrix}.$$

(Check: $\mathbf{A}\mathbf{A}^+ = \frac{1}{25}\left(\begin{smallmatrix} 5 & 10 \\ 10 & 20 \end{smallmatrix}\right)$ is Hermitian and idempotent, and $\mathbf{A}\mathbf{A}^+\mathbf{A} = \mathbf{A}$.)

(d) The rows are independent, so $\operatorname{rank}\mathbf{A} = 2 = m$ and Theorem 12.11.3 (e) gives $\mathbf{A}^+ = \mathbf{A}^\top(\mathbf{A}\mathbf{A}^\top)^{-1}$. Here $\mathbf{A}\mathbf{A}^\top = \left(\begin{smallmatrix} 2 & 1 \\ 1 & 2 \end{smallmatrix}\right)$ with inverse $\frac{1}{3}\left(\begin{smallmatrix} 2 & -1 \\ -1 & 2 \end{smallmatrix}\right)$, so

$$\mathbf{A}^+ = \frac{1}{3}\begin{pmatrix} 1 & 0 \\ 0 & 1 \\ 1 & 1 \end{pmatrix}\begin{pmatrix} 2 & -1 \\ -1 & 2 \end{pmatrix} = \frac{1}{3}\begin{pmatrix} 2 & -1 \\ -1 & 2 \\ 1 & 1 \end{pmatrix}.$$

Exercise B2: A system that is both inconsistent and underdetermined.

Let

$$\mathbf{A} = \begin{pmatrix} 1 & 2 \\ 2 & 4 \\ 1 & 2 \end{pmatrix}, \qquad \mathbf{b} = (1, 4, 1).$$

Compute $\mathbf{A}^+$ and $\mathbf{x}_{\min} = \mathbf{A}^+\mathbf{b}$. Verify that $\mathbf{A}\mathbf{x}_{\min}$ is the orthogonal projection of $\mathbf{b}$ onto $\operatorname{col}(\mathbf{A})$, and compare $\|\mathbf{x}_{\min}\|$ with the norm of one other least-squares solution.

Solution. Both columns are multiples of $\mathbf{u} = (1, 2, 1)$, so $\mathbf{A} = \mathbf{u}\mathbf{v}^\top$ with $\mathbf{v} = (1, 2)$, and $\operatorname{rank}\mathbf{A} = 1$. Then $\|\mathbf{u}\|^2 = 6$, $\|\mathbf{v}\|^2 = 5$ and $\sigma_1 = \sqrt{30}$, with $\mathbf{u}_1 = \mathbf{u}/\sqrt{6}$ and $\mathbf{v}_1 = \mathbf{v}/\sqrt{5}$. Hence

$$\mathbf{A}^+ = \sigma_1^{-1}\mathbf{v}_1\mathbf{u}_1^\top = \frac{1}{30}\mathbf{v}\mathbf{u}^\top = \frac{1}{30}\begin{pmatrix} 1 & 2 & 1 \\ 2 & 4 & 2 \end{pmatrix}.$$

Therefore

$$\mathbf{x}_{\min} = \mathbf{A}^+\mathbf{b} = \frac{1}{30}(1 + 8 + 1,\ 2 + 16 + 2) = \left(\tfrac{1}{3}, \tfrac{2}{3}\right).$$

Projection. $\operatorname{col}(\mathbf{A}) = \operatorname{span}(\mathbf{u})$ and $\langle \mathbf{b}, \mathbf{u}\rangle = 1+8+1 = 10$, so $P_{\operatorname{col}(\mathbf{A})}\mathbf{b} = \frac{10}{6}\mathbf{u} = \frac{5}{3}(1, 2, 1)$. And $\mathbf{A}\mathbf{x}_{\min} = \mathbf{u}\left(\mathbf{v}^\top\mathbf{x}_{\min}\right) = \mathbf{u}\left(\frac{1}{3} + \frac{4}{3}\right) = \frac{5}{3}\mathbf{u}$. They agree.

Shortest. The least-squares solutions are the $\mathbf{x}$ with $\mathbf{v}^\top\mathbf{x} = x_1 + 2x_2 = \frac{5}{3}$. Another one is $\left(\frac{5}{3}, 0\right)$, of squared norm $\frac{25}{9}$, against $\|\mathbf{x}_{\min}\|^2 = \frac{1}{9} + \frac{4}{9} = \frac{5}{9}$. The pseudoinverse solution

is shorter, as Theorem 12.11.4 (b) requires.

Exercise B3: Checking a candidate.

Let $\mathbf{A} = \begin{pmatrix} 1 & 0 \\ 1 & 1 \\ 0 & 1 \end{pmatrix}$ and $\mathbf{X} = \frac{1}{3}\begin{pmatrix} 2 & 1 & -1 \\ -1 & 1 & 2 \end{pmatrix}$. Verify the four Penrose conditions for $\mathbf{X}$, and hence find the minimum-norm least-squares solution of $\mathbf{A}\mathbf{x} = (1, 2, 3)$.

Solution. Compute the two products first:

$$\mathbf{X}\mathbf{A} = \frac{1}{3}\begin{pmatrix} 3 & 0 \\ 0 & 3 \end{pmatrix} = \mathbf{I}_2, \qquad \mathbf{A}\mathbf{X} = \frac{1}{3}\begin{pmatrix} 2 & 1 & -1 \\ 1 & 2 & 1 \\ -1 & 1 & 2 \end{pmatrix}.$$

(P4): $\mathbf{X}\mathbf{A} = \mathbf{I}_2$ is Hermitian. (P3): $\mathbf{A}\mathbf{X}$ is visibly symmetric. (P1): $\mathbf{A}\mathbf{X}\mathbf{A} = \mathbf{A}(\mathbf{X}\mathbf{A}) = \mathbf{A}\mathbf{I}_2 = \mathbf{A}$. (P2): $\mathbf{X}\mathbf{A}\mathbf{X} = \mathbf{I}_2\mathbf{X} = \mathbf{X}$. All four hold, so $\mathbf{X} = \mathbf{A}^+$ by Theorem 12.11.2.

Then

$$\mathbf{x}_{\min} = \mathbf{X}(1, 2, 3) = \frac{1}{3}(2 + 2 - 3,\ -1 + 2 + 6) = \left(\tfrac{1}{3}, \tfrac{7}{3}\right).$$

(The columns of $\mathbf{A}$ are independent, so this is also $(\mathbf{A}^\top\mathbf{A})^{-1}\mathbf{A}^\top\mathbf{b}$, and it is the unique least-squares solution; the normal equations $\left(\begin{smallmatrix} 2 & 1 \\ 1 & 2 \end{smallmatrix}\right)\mathbf{x} = (3, 5)$ confirm it.)

12.11.7.3 C. Going deeper

Exercise C1: Pseudoinverses of $\mathbf{A}^*\mathbf{A}$.

Let $\mathbf{A} \in M_{m\times n}(F)$.

(a) Prove that $(\mathbf{A}^*\mathbf{A})^+ = \mathbf{A}^+(\mathbf{A}^+)^*$.

(b) Deduce that $\mathbf{A}^+ = (\mathbf{A}^*\mathbf{A})^+\mathbf{A}^*$, the formula $(\mathbf{A}^*\mathbf{A})^{-1}\mathbf{A}^*$ with the inverse replaced by the pseudoinverse.

Hint: use a singular value decomposition and reduce each identity to an identity between diagonal matrices.

Solution. Write $\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^*$.

(a) Then $\mathbf{A}^*\mathbf{A} = \mathbf{V}\mathbf{\Sigma}^*\mathbf{\Sigma}\mathbf{V}^*$, and $\mathbf{\Sigma}^*\mathbf{\Sigma} \in M_n(F)$ is diagonal with entries $\sigma_1^2, \dots, \sigma_p^2$ followed by zeros. That display is a singular value decomposition of $\mathbf{A}^*\mathbf{A}$ in the sense of Theorem 12.8.1 (both outer factors are $\mathbf{V}$, which is unitary, and the middle factor is diagonal with non-negative entries), so

$$(\mathbf{A}^*\mathbf{A})^+ = \mathbf{V}(\mathbf{\Sigma}^*\mathbf{\Sigma})^+\mathbf{V}^*,$$

where $(\mathbf{\Sigma}^*\mathbf{\Sigma})^+$ is diagonal with entries σ_i^{-2} for $i \le r$ and 0 elsewhere. On the other side, $(\mathbf{A}^+)^* = (\mathbf{V}\mathbf{\Sigma}^+\mathbf{U}^*)^* = \mathbf{U}(\mathbf{\Sigma}^+)^*\mathbf{V}^*$, so

$$\mathbf{A}^+(\mathbf{A}^+)^* = \mathbf{V}\mathbf{\Sigma}^+\mathbf{U}^*\mathbf{U}(\mathbf{\Sigma}^+)^*\mathbf{V}^* = \mathbf{V}\mathbf{\Sigma}^+(\mathbf{\Sigma}^+)^*\mathbf{V}^*.$$

The middle factor $\mathbf{\Sigma}^+(\mathbf{\Sigma}^+)^*$ is diagonal with entries $\sigma_i^{-1}\sigma_i^{-1} = \sigma_i^{-2}$ for $i \le r$ and 0 elsewhere, which is $(\mathbf{\Sigma}^*\mathbf{\Sigma})^+$. Hence the two sides agree.

(b) Using (a) and $\mathbf{A}^* = \mathbf{V}\mathbf{\Sigma}^*\mathbf{U}^*$,

$$(\mathbf{A}^*\mathbf{A})^+\mathbf{A}^* = \mathbf{V}\mathbf{\Sigma}^+(\mathbf{\Sigma}^+)^*\mathbf{\Sigma}^*\mathbf{U}^*.$$

Now $(\mathbf{\Sigma}^+)^*\mathbf{\Sigma}^* = (\mathbf{\Sigma}\mathbf{\Sigma}^+)^* = \mathbf{\Sigma}\mathbf{\Sigma}^+$, which is the $m \times m$ diagonal matrix with r ones and then zeros; and $\mathbf{\Sigma}^+$ multiplied by it on the right is $\mathbf{\Sigma}^+$, since $\mathbf{\Sigma}^+$ has non-zero entries only in the first r columns. So the right-hand side is $\mathbf{V}\mathbf{\Sigma}^+\mathbf{U}^* = \mathbf{A}^+$.

Exercise C2: When the reversal rule does hold.

Let $\mathbf{A} \in M_{m\times n}(F)$ with $\operatorname{rank}\mathbf{A} = n$ and $\mathbf{B} \in M_{n\times q}(F)$ with $\operatorname{rank}\mathbf{B} = n$. Prove that

$$(\mathbf{AB})^+ = \mathbf{B}^+\mathbf{A}^+.$$

Hint: write both pseudoinverses with the formulas of Theorem 12.11.3 (e) and verify the Penrose conditions for the product.

Solution. By Theorem 12.11.3 (e), $\mathbf{A}^+ = (\mathbf{A}^*\mathbf{A})^{-1}\mathbf{A}^*$ and $\mathbf{B}^+ = \mathbf{B}^*(\mathbf{B}\mathbf{B}^*)^{-1}$, the two inverses existing because $\operatorname{rank}\mathbf{A} = n$ and $\operatorname{rank}\mathbf{B}^* = n$. Put

$$\mathbf{X} = \mathbf{B}^+\mathbf{A}^+ = \mathbf{B}^*(\mathbf{B}\mathbf{B}^*)^{-1}(\mathbf{A}^*\mathbf{A})^{-1}\mathbf{A}^*.$$

Throughout we use $\mathbf{A}^+\mathbf{A} = \mathbf{I}_n$ and $\mathbf{B}\mathbf{B}^+ = \mathbf{I}_n$, which the two formulas give at once.

(P1): $(\mathbf{AB})\mathbf{X}(\mathbf{AB}) = \mathbf{A}(\mathbf{B}\mathbf{B}^+)(\mathbf{A}^+\mathbf{A})\mathbf{B} = \mathbf{A}\mathbf{I}_n\mathbf{I}_n\mathbf{B} = \mathbf{AB}$.

(P2): $\mathbf{X}(\mathbf{AB})\mathbf{X} = \mathbf{B}^+(\mathbf{A}^+\mathbf{A})(\mathbf{B}\mathbf{B}^+)\mathbf{A}^+ = \mathbf{B}^+\mathbf{A}^+ = \mathbf{X}$.

(P3): $(\mathbf{AB})\mathbf{X} = \mathbf{A}(\mathbf{B}\mathbf{B}^+)\mathbf{A}^+ = \mathbf{A}\mathbf{A}^+ = \mathbf{A}(\mathbf{A}^*\mathbf{A})^{-1}\mathbf{A}^*$, which equals its own conjugate transpose, since $\mathbf{A}^*\mathbf{A}$ is Hermitian and so is its inverse.

(P4): $\mathbf{X}(\mathbf{AB}) = \mathbf{B}^+(\mathbf{A}^+\mathbf{A})\mathbf{B} = \mathbf{B}^+\mathbf{B} = \mathbf{B}^*(\mathbf{B}\mathbf{B}^*)^{-1}\mathbf{B}$, Hermitian for the same reason.

All four hold, so $\mathbf{X} = (\mathbf{AB})^+$ by Theorem 12.11.2.

Exercise C3: When the pseudoinverse is the adjoint.

Let $\mathbf{A} \in M_{m\times n}(F)$.

(a) Prove that $\mathbf{A}^+ = \mathbf{A}^*$ if and only if $\mathbf{A}\mathbf{A}^*\mathbf{A} = \mathbf{A}$.

(b) Deduce that $\mathbf{A}^+ = \mathbf{A}^*$ if and only if every non-zero singular value of $\mathbf{A}$ equals 1.

(c) Give an example of such an $\mathbf{A}$ in $M_2(\mathbb{R})$ which is neither unitary nor an orthogonal projection.

Solution.

(a) ($\Rightarrow$) If $\mathbf{A}^+ = \mathbf{A}^*$, then (P1) reads $\mathbf{A}\mathbf{A}^*\mathbf{A} = \mathbf{A}$.
($\Leftarrow$) Suppose $\mathbf{A}\mathbf{A}^*\mathbf{A} = \mathbf{A}$ and put $\mathbf{X} = \mathbf{A}^*$. Then (P1) is the hypothesis; (P2) is $\mathbf{A}^*\mathbf{A}\mathbf{A}^* = (\mathbf{A}\mathbf{A}^*\mathbf{A})^* = \mathbf{A}^*$; (P3) is $(\mathbf{A}\mathbf{A}^*)^* = \mathbf{A}\mathbf{A}^*$, true for every $\mathbf{A}$; and (P4) is $(\mathbf{A}^*\mathbf{A})^* = \mathbf{A}^*\mathbf{A}$, likewise. By Theorem 12.11.2, $\mathbf{A}^+ = \mathbf{A}^*$.

(b) With $\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^*$ we have $\mathbf{A}^* = \mathbf{V}\mathbf{\Sigma}^*\mathbf{U}^*$ and $\mathbf{A}^+ = \mathbf{V}\mathbf{\Sigma}^+\mathbf{U}^*$. Since $\mathbf{U}$ and $\mathbf{V}$ are invertible, $\mathbf{A}^+ = \mathbf{A}^*$ if and only if $\mathbf{\Sigma}^+ = \mathbf{\Sigma}^*$, that is if and only if $\sigma_i^{-1} = \sigma_i$ for every $i \le r$, that is if and only if every non-zero singular value is 1 (the equation $\sigma^2 = 1$ with $\sigma > 0$ forces $\sigma = 1$).

(c) Take

$$\mathbf{A} = \frac{1}{\sqrt{2}}\begin{pmatrix} 1 & 1 \\ 0 & 0 \end{pmatrix}.$$

Then $\mathbf{A}\mathbf{A}^\top = \left(\begin{smallmatrix} 1 & 0 \\ 0 & 0 \end{smallmatrix}\right)$, so $\mathbf{A}\mathbf{A}^\top\mathbf{A} = \mathbf{A}$ and (a) applies. Its singular values are 1 and 0, matching (b). It is not unitary, since it is singular, and not an orthogonal projection, since $\mathbf{A}^\top \neq \mathbf{A}$. Such a matrix maps $\operatorname{col}(\mathbf{A}^*)$ isometrically onto $\operatorname{col}(\mathbf{A})$ and sends $\operatorname{nul}(\mathbf{A})$ to $\mathbf{0}$: a unitary matrix on the part of the space where it is invertible, and nothing at all elsewhere.

12.12 Projections Revisited

Chapter 3 built projections out of nothing but a direct sum: given $V = U \oplus W$, the operator that keeps the U-piece and discards the W-piece satisfies $P^2 = P$, and every operator satisfying $P^2 = P$ arises this way. Chapter 10 built a second kind by taking $W = U^\perp$, the orthogonal projection P_U. The second is a special case of the first, and Chapter 3 left the comparison open, saying only that its projections "are often called **oblique** projections, to distinguish them from the orthogonal projections met later, in the chapters on inner product spaces". This section makes the distinction exact, measures how far an oblique projection is from being orthogonal, and closes Part III.

Throughout, V is a finite-dimensional inner product space over $F = \mathbb{R}$ or $\mathbb{C}$, and $n = \dim V$.

12.12.1 Which projections are orthogonal?

Two recollections, because the section is about the gap between them. From Chapter 3: an operator $P \in \mathcal{L}(V)$ with $P^2 = P$ is a **projection**, also called an **idempotent** (Definition 3.10.1); it satisfies $V = \operatorname{im} P \oplus \ker P$, it is the identity on $\operatorname{im} P$ and zero on $\ker P$, and each splitting $V = U \oplus W$ has exactly one projection with image U and kernel W (Theorem 3.10.1). No inner product appears there, and the field was arbitrary.

From Chapter 10: the splitting $V = U \oplus U^\perp$ of Theorem 10.3.2 is one of the many available, and P_U is the projection belonging to it (Definition 10.3.2). Chapter 3 warned that a subspace is the image of infinitely many projections, one per complement. Which one does the inner product pick out, and how is it recognized without being told the kernel?

A projection is orthogonal exactly when it throws away perpendicularly — and that is the same as costing nothing to move across the inner product.

Theorem 12.12.1 — Orthogonal Projections Among the Idempotents

Let V be a finite-dimensional inner product space over F and let $P \in \mathcal{L}(V)$ satisfy $P^2 = P$. The following are equivalent.

(a) P is the orthogonal projection onto its image: $P = P_U$ with $U = \operatorname{im} P$.
(b) $\ker P = (\operatorname{im} P)^{\perp}$.
(c) $P^* = P$.
(d) P is normal.
(e) $\|P\mathbf{v}\| \le \|\mathbf{v}\|$ **for every** $\mathbf{v} \in V$.

Idea. Conditions (a) and (b) say one thing twice, once about the operator and once about its two subspaces. Going from (b) to (c) is a computation Chapter 10 has already done for P_U. Coming back from (c) is the four-subspaces theorem: $\ker P^*$ is always $(\operatorname{im} P)^{\perp}$, so once $P^* = P$ the kernel is forced; normality is the same remark with $\ker P^*$ replaced by $\ker P$. The one direction with work in it is (e) $\Rightarrow$ (b), where a bound on lengths has to become a statement about angles. Feed P a vector $\mathbf{u} + t\mathbf{w}$ with $\mathbf{u} \in \operatorname{im} P$ and $\mathbf{w} \in \ker P$: its image is $\mathbf{u}$ whatever t is, so choosing t to make $\|\mathbf{u} + t\mathbf{w}\|$ as small as possible squeezes $\langle \mathbf{u}, \mathbf{w} \rangle$ to zero.

Proof. **(a) $\Leftrightarrow$ (b).** Write $U = \operatorname{im} P$. ($\Rightarrow$) If $P = P_U$, then $\ker P = \ker P_U = U^{\perp}$, since P_U is the projection onto U along $U^{\perp}$ (Definition 10.3.2 and Theorem 3.10.1 (b)). ($\Leftarrow$) If $\ker P = U^{\perp}$, then P is a projection with image U and kernel $U^{\perp}$, and so is P_U; by the uniqueness in Theorem 3.10.1 (b), applied to $V = U \oplus U^{\perp}$, the two are equal.

(b) $\Rightarrow$ (c). By the equivalence just proved, $P = P_U$ with $U = \operatorname{im} P$. By Theorem 10.3.3 (b), $\langle P\mathbf{u}, \mathbf{v} \rangle = \langle \mathbf{u}, P\mathbf{v} \rangle$ for all $\mathbf{u}, \mathbf{v} \in V$. That is the defining identity of the adjoint, so $P^* = P$ by the uniqueness in Definition 10.6.1.

(c) $\Rightarrow$ (d). If $P^* = P$ then $P^*P = P^2 = PP^*$, which is Definition 10.6.3.

(d) $\Rightarrow$ (b). Since P is normal, $\ker P = \ker P^*$ by Corollary 11.3.2 (a). By Theorem 10.6.5 (a), $\ker P^* = (\operatorname{im} P)^{\perp}$. Combining the two gives (b).

(b) $\Rightarrow$ (e). Let $\mathbf{v} \in V$ and split it as $\mathbf{v} = P\mathbf{v} + (\mathbf{v} - P\mathbf{v})$. The first piece lies in $\operatorname{im} P$, and the second lies in $\ker P$, because $P(\mathbf{v} - P\mathbf{v}) = P\mathbf{v} - P^2\mathbf{v} = \mathbf{0}$. By (b) the two pieces are orthogonal, so Theorem 10.1.3 gives

$$\|\mathbf{v}\|^2 = \|P\mathbf{v}\|^2 + \|\mathbf{v} - P\mathbf{v}\|^2 \ge \|P\mathbf{v}\|^2,$$

and taking non-negative square roots gives $\|P\mathbf{v}\| \le \|\mathbf{v}\|$.

(e) $\Rightarrow$ (b). We first show $\langle \mathbf{u}, \mathbf{w} \rangle = 0$ for every $\mathbf{u} \in \operatorname{im} P$ and every $\mathbf{w} \in \ker P$. There is nothing to prove when $\mathbf{w} = \mathbf{0}$, so assume $\mathbf{w} \neq \mathbf{0}$, write $z = \langle \mathbf{u}, \mathbf{w} \rangle$, and put

$$t = -\frac{z}{\|\mathbf{w}\|^2}, \qquad \mathbf{v} = \mathbf{u} + t\mathbf{w},$$

which is legitimate because $\|\mathbf{w}\| \neq 0$. Then $P\mathbf{v} = P\mathbf{u} + tP\mathbf{w} = \mathbf{u}$, since P is the identity on $\operatorname{im} P$ and zero on $\ker P$ (Theorem 3.10.1 (a)). Expanding the norm squared and using conjugate symmetry,

$$\begin{aligned} \|\mathbf{v}\|^2 &= \|\mathbf{u}\|^2 + \bar{t}\langle \mathbf{u}, \mathbf{w} \rangle + t\langle \mathbf{w}, \mathbf{u} \rangle + |t|^2\|\mathbf{w}\|^2 \\ &= \|\mathbf{u}\|^2 - \frac{|z|^2}{\|\mathbf{w}\|^2} - \frac{|z|^2}{\|\mathbf{w}\|^2} + \frac{|z|^2}{\|\mathbf{w}\|^2} = \|\mathbf{u}\|^2 - \frac{|z|^2}{\|\mathbf{w}\|^2}. \end{aligned}$$

Now (e) applied to this $\mathbf{v}$ says $\|\mathbf{u}\|^2 = \|P\mathbf{v}\|^2 \le \|\mathbf{v}\|^2$, which forces $|z|^2 \le 0$ and hence $z = 0$.

So $\ker P \subseteq (\operatorname{im} P)^{\perp}$. The two subspaces have the same dimension: $\dim \ker P = n - \operatorname{rank} P$ by Theorem 3.3.1, and $\dim (\operatorname{im} P)^{\perp} = n - \dim \operatorname{im} P = n - \operatorname{rank} P$ by Theorem 10.3.2 (c). A subspace contained in another of the same finite dimension equals it (Theorem 1.6.8), so $\ker P = (\operatorname{im} P)^{\perp}$. This closes the cycle and proves the theorem.

■

The theorem is the promised comparison. Every projection of Chapter 3 that is **not** self-adjoint is oblique, and now "oblique" has a precise meaning: its kernel is a complement of its image that is not the perpendicular one. Chapter 11 has already met a pair of such projections, in Example (Two Projections That Are Not Orthogonal), and the Quick check after Theorem 11.8.2 traced exactly what their obliqueness cost.

Clause (c) also settles Chapter 3's warning that "projection onto U" is incomplete information.

Corollary 12.12.2 — One Orthogonal Projection per Subspace

Let U be a subspace of a finite-dimensional inner product space V. Among the projections of V with image U — one for each complement of U, by Theorem 3.10.1 — exactly one is self-adjoint, namely P_U.

Proof. P_U has image U and is self-adjoint by Theorem 12.12.1, (a) $\Rightarrow$ (c). Conversely, let P be a self-adjoint projection with $\operatorname{im} P = U$. By the same theorem, (c) $\Rightarrow$ (b), $\ker P = U^{\perp}$, which is also $\ker P_U$. Two projections with the same image and the same kernel are equal, by the uniqueness in Theorem 3.10.1 (b).

■

Chapter 3's own example is now decided by inspection. On $\mathbb{R}^2$ with the dot product, $P(x, y) = (x, 0)$ and $P'(x, y) = (x - y, 0)$ are both projections onto the x-axis, with standard matrices

$$\mathbf{P} = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}, \qquad \mathbf{P}' = \begin{pmatrix} 1 & -1 \\ 0 & 0 \end{pmatrix}.$$

The standard basis is orthonormal, so Theorem 10.6.3 says self-adjointness is symmetry of these matrices. The first is symmetric, so $P = P_U$ for the x-axis U. The second is not, so P' is oblique — as the picture in Chapter 3 showed, it slides along the line $y = x$ rather than straight down. Clause (e) fails visibly at $\mathbf{v} = (1, -1)$: there $P'\mathbf{v} = (2, 0)$, and $\|P'\mathbf{v}\| = 2$ while $\|\mathbf{v}\| = \sqrt{2}$.

Quick check. Does $\mathbf{A} = \begin{pmatrix} 1 & 0 \\ 1 & 0 \end{pmatrix}$ act on $\mathbb{R}^2$ as a projection? If so, is it an orthogonal projection?

Solution. $\mathbf{A}^2 = \begin{pmatrix} 1 & 0 \\ 1 & 0 \end{pmatrix} = \mathbf{A}$, so yes, it is a projection. Its image is the span of its columns, $\operatorname{span}((1, 1))$, and its kernel is $\operatorname{span}(\mathbf{e}_2)$. Since $\langle (1, 1), \mathbf{e}_2 \rangle = 1 \neq 0$, the kernel is not $(\operatorname{im} \mathbf{A})^{\perp}$, so the projection is oblique by Theorem 12.12.1 (b). The quickest route is clause (c): $\mathbf{A}^{\top} \neq \mathbf{A}$.

Warning. **Clause (e) is a statement about every vector, and one vector proves nothing.** For the oblique $\mathbf{P}'$ above, $\|\mathbf{P}'\mathbf{e}_1\| = 1 = \|\mathbf{e}_1\|$ and $\|\mathbf{P}'(1, 1)\| = 0 \leq \sqrt{2}$; both are consistent with the bound, and both are worthless as evidence. The bound fails only

in the direction $(1, -1)$. If you want to certify a projection as orthogonal by hand, check $\mathbf{P}^* = \mathbf{P}$ in an orthonormal basis, not the length of one image.

Warning. **An orthogonal projection is almost never an orthogonal matrix.** If $\mathbf{P}$ is unitary and idempotent, it is invertible, so multiplying $\mathbf{P}^2 = \mathbf{P}$ by $\mathbf{P}^{-1}$ gives $\mathbf{P} = \mathbf{I}$. Apart from the identity, every orthogonal projection is singular. "Orthogonal" in P_U names the direction of the discarding, not membership in $\mathrm{O}(n)$.

12.12.2 The block that measures obliqueness

Chapter 3 already knows the shape of a projection up to a change of basis: with a basis of $\operatorname{im} P$ followed by a basis of $\ker P$, the matrix is $\operatorname{diag}(1, \dots, 1, 0, \dots, 0)$ with $\operatorname{rank} P$ ones (Corollary 3.10.2). That basis is built to fit P and is usually not orthonormal, so the normal form erases exactly the information we now want. Insisting on an orthonormal basis costs one extra block, and that block is the answer.

Theorem 12.12.3 — Canonical Form of an Idempotent in an Orthonormal Basis

Let V be an n-dimensional inner product space over F and let $P \in \mathcal{L}(V)$ be a projection of rank r. Let $(\mathbf{f}_1, \dots, \mathbf{f}_r)$ be any orthonormal basis of $\operatorname{im} P$ and $(\mathbf{f}_{r+1}, \dots, \mathbf{f}_n)$ any orthonormal basis of $(\operatorname{im} P)^{\perp}$. Then $\mathcal{B} = (\mathbf{f}_1, \dots, \mathbf{f}_n)$ is an orthonormal basis of V, and

$$[P]_{\mathcal{B}} = \begin{pmatrix} \mathbf{I}_r & \mathbf{X} \\ 0 & 0 \end{pmatrix}$$

for some $\mathbf{X} \in M_{r \times (n-r)}(F)$. Moreover P is an orthogonal projection if and only if $\mathbf{X} = 0$.

Idea. Only two facts are used, and both are already proved. First, P fixes its image, so the first r columns are forced to be $\mathbf{e}_1, \dots, \mathbf{e}_r$. Second, every output of P lies in $\operatorname{im} P$, so the last $n - r$ columns have nothing below row r. What sits **above** row r in those columns is unconstrained, and that is $\mathbf{X}$: it records where P sends the directions perpendicular to its image, which an orthogonal projection would send to $\mathbf{0}$.

Proof. Write $U = \operatorname{im} P$, so $\dim U = r$ and $\dim U^{\perp} = n - r$ by Theorem 10.3.2 (c). Each $\mathbf{f}_i$ with $i \le r$ is orthogonal to each $\mathbf{f}_j$ with $j > r$, since the first lies in U and the second in $U^{\perp}$; so $\mathcal{B}$ is an orthonormal list of n vectors, hence an orthonormal basis of V (Theorem 10.1.4).

For $i \le r$ we have $\mathbf{f}_i \in \operatorname{im} P$, so $P\mathbf{f}_i = \mathbf{f}_i$ by Theorem 3.10.1 (a), and column i of $[P]_{\mathcal{B}}$ is $\mathbf{e}_i$. For $j > r$ we have $P\mathbf{f}_j \in \operatorname{im} P = U = \operatorname{span}(\mathbf{f}_1, \dots, \mathbf{f}_r)$, so $P\mathbf{f}_j = \sum_{i \le r} x_{ij} \mathbf{f}_i$ for scalars $x_{ij} \in F$, and column j has zeros in rows $r+1, \dots, n$. Collecting the x_{ij} into $\mathbf{X}$ gives the displayed shape.

For the last claim, $\mathcal{B}$ is orthonormal, so $[P^*]_{\mathcal{B}} = ([P]_{\mathcal{B}})^*$ by Theorem 10.6.3, and

$$([P]_{\mathcal{B}})^* = \begin{pmatrix} \mathbf{I}_r & 0 \\ \mathbf{X}^* & 0 \end{pmatrix}.$$

The two matrices agree if and only if $\mathbf{X} = 0$. Since an operator is determined by its

matrix in a basis, $P^* = P$ if and only if $\mathbf{X} = 0$, and $P^* = P$ says P is an orthogonal projection by Theorem 12.12.1.

■

The block $\mathbf{X}$ is not unique, because the two orthonormal bases were not. Replacing them changes $\mathbf{X}$ into $\mathbf{A}^*\mathbf{X}\mathbf{B}$ for some unitary $\mathbf{A} \in M_r(F)$ and $\mathbf{B} \in M_{n-r}(F)$, and that leaves the singular values of $\mathbf{X}$ alone: since

$$(\mathbf{A}^*\mathbf{X}\mathbf{B})^*(\mathbf{A}^*\mathbf{X}\mathbf{B}) = \mathbf{B}^*(\mathbf{X}^*\mathbf{X})\mathbf{B},$$

the two matrices $(\mathbf{A}^*\mathbf{X}\mathbf{B})^*(\mathbf{A}^*\mathbf{X}\mathbf{B})$ and $\mathbf{X}^*\mathbf{X}$ are unitarily similar, so they have the same eigenvalues, and Definition 12.8.1 reads the singular values off those. So the list $\sigma_1(\mathbf{X}) \geq \sigma_2(\mathbf{X}) \geq \dots$ belongs to P itself, and P is an orthogonal projection exactly when that list is all zeros.

12.12.2.1 The two-dimensional case, in full

Take $n = 2$ and $r = 1$, so that $\mathbf{X}$ is a single scalar $x \in F$, and

$$[P]_{\mathcal{B}} = \begin{pmatrix} 1 & x \\ 0 & 0 \end{pmatrix}, \qquad \mathcal{B} = (\mathbf{f}_1, \mathbf{f}_2),$$

with $\mathbf{f}_1$ spanning the line $\operatorname{im} P$ and $\mathbf{f}_2$ spanning the perpendicular line $(\operatorname{im} P)^\perp$. Everything about P can be read off this one number.

The kernel. $P(a\mathbf{f}_1 + b\mathbf{f}_2) = (a + xb)\mathbf{f}_1$, which is $\mathbf{0}$ exactly when $a = -xb$. So

$$\ker P = \operatorname{span}(-x\mathbf{f}_1 + \mathbf{f}_2),$$

a line that meets $(\operatorname{im} P)^\perp = \operatorname{span}(\mathbf{f}_2)$ only at $\mathbf{0}$ unless $x = 0$.

The angle. Suppose $F = \mathbb{R}$. The two lines $\operatorname{im} P$ and $\ker P$ are distinct, since their intersection is $\{\mathbf{0}\}$; let $\theta \in (0, \pi/2]$ be the angle between them, meaning the angle of Definition 10.1.5 between $\mathbf{f}_1$ and whichever of $\pm(-x\mathbf{f}_1 + \mathbf{f}_2)$ makes it acute. With $\mathbf{k} = -x\mathbf{f}_1 + \mathbf{f}_2$ we have $\|\mathbf{k}\| = \sqrt{1 + x^2}$ and $\langle \mathbf{f}_1, \mathbf{k} \rangle = -x$, so

$$\cos\theta = \frac{|x|}{\sqrt{1 + x^2}}, \qquad \sin\theta = \frac{1}{\sqrt{1 + x^2}}, \qquad |x| = \cot\theta.$$

The dictionary is complete: $x = 0$ is $\theta = \pi/2$, the orthogonal case; and as the kernel tips toward the image, $\theta \to 0$ and $|x| \to \infty$. The single entry x **is** the obliqueness, in the units of a cotangent.

The stretching. For a unit vector $\mathbf{v} = a\mathbf{f}_1 + b\mathbf{f}_2$, we have $\|P\mathbf{v}\| = |a + xb| = |\langle (a, b), (1, \overline{x}) \rangle|$ in F^2 with the standard inner product, so Theorem 10.1.5 gives

$$\|P\mathbf{v}\| \leq \sqrt{1 + |x|^2},$$

with equality exactly when (a, b) is a multiple of $(1, \overline{x})$, for instance $(a, b) = (1, \overline{x})/\sqrt{1 + |x|^2}$. So the largest value of $\|P\mathbf{v}\|$ over unit vectors $\mathbf{v}$ is $\sqrt{1 + |x|^2}$, which over $\mathbb{R}$ is $1/\sin\theta$. Chapter 15 will give this number a name, the operator norm $\|P\|$; here it is enough to say that an orthogonal projection never lengthens a vector, while an oblique one lengthens some vector by $1/\sin\theta$, a factor that is unbounded as the kernel closes in on the image.

Example. (Two Oblique Projections, Measured)

For each of

$$\mathbf{P}' = \begin{pmatrix} 1 & -1 \\ 0 & 0 \end{pmatrix}, \qquad \mathbf{Q} = \begin{pmatrix} 2 & -1 \\ 2 & -1 \end{pmatrix}$$

on $\mathbb{R}^2$, verify that it is a projection, put it in the form of Theorem 12.12.3, and find the angle between its image and its kernel and the largest length of an image of a unit vector.

Solution. The matrix $\mathbf{P}'$. $(\mathbf{P}')^2 = \mathbf{P}'$ by direct multiplication, and $\operatorname{im}\mathbf{P}' = \operatorname{span}(\mathbf{e}_1)$, $\ker\mathbf{P}' = \operatorname{span}((1,1))$. Here $\mathbf{f}_1 = \mathbf{e}_1$ already spans the image and $\mathbf{f}_2 = \mathbf{e}_2$ spans its perpendicular, and the standard basis is orthonormal, so the given matrix **is** the canonical form, with $x = -1$. Hence $\cot\theta = 1$, that is $\theta = \pi/4$, and the largest value of $\|\mathbf{P}'\mathbf{v}\|$ on the unit circle is $\sqrt{1+1} = \sqrt{2}$, attained at $\mathbf{v} = (1,-1)/\sqrt{2}$. Both readings match Chapter 3's figure, where $\mathbf{P}'$ projects along the line $y = x$.

The matrix $\mathbf{Q}$. $\mathbf{Q}^2 = \begin{pmatrix} 4-2 & -2+1 \\ 4-2 & -2+1 \end{pmatrix} = \mathbf{Q}$, so $\mathbf{Q}$ is a projection, of rank 1. Its image is $\operatorname{span}((1,1))$ and its kernel is $\operatorname{span}((1,2))$, since $\mathbf{Q}(1,2) = (0,0)$. Take

$$\mathbf{f}_1 = \tfrac{1}{\sqrt{2}}(1,1), \qquad \mathbf{f}_2 = \tfrac{1}{\sqrt{2}}(1,-1),$$

an orthonormal basis of $\operatorname{im}\mathbf{Q}$ and of $(\operatorname{im}\mathbf{Q})^\perp$ respectively. Then $\mathbf{Q}\mathbf{f}_1 = \mathbf{f}_1$ and $\mathbf{Q}\mathbf{f}_2 = \tfrac{1}{\sqrt{2}}(3,3) = 3\mathbf{f}_1$, so $x = 3$ and

$$[\mathbf{Q}]_{\mathcal{B}} = \begin{pmatrix} 1 & 3 \\ 0 & 0 \end{pmatrix}.$$

Hence $\cot\theta = 3$. Checking against the two lines directly: the angle between $(1,1)$ and $(1,2)$ has $\cos\theta = 3/\sqrt{10}$ and $\sin\theta = 1/\sqrt{10}$, so $\cot\theta = 3$, and the largest value of $\|\mathbf{Q}\mathbf{v}\|$ on the unit circle is $\sqrt{1+9} = \sqrt{10} = 1/\sin\theta$. The two routes agree.

In higher rank the same block $\mathbf{X}$ does the same job, and Exercise (C3: How far an oblique projection can stretch) turns its largest singular value into the largest value of $\|P\mathbf{v}\|$ over unit $\mathbf{v}$, by the argument that just ran in the 2×2 case. The reason the singular values appear is the one this chapter has used throughout: $\mathbf{X}$ is a rectangular matrix, so its eigenvalues do not exist, and Theorem 12.8.1 is what measures it instead.

12.12.3 Looking back at Part III

Part III added one piece of structure to the vector spaces of Parts I and II, and spent three chapters finding out what it buys.

Chapter 10 added the inner product, and with it length, orthogonality and angle. Orthonormal bases made coordinates free, orthogonal complements split every space canonically, and projection onto a subspace solved the nearest-point problem, hence least squares. Its deepest construction was the **adjoint**, the price of moving an operator from one slot of the inner product to the other; the adjoint is what turned the kernel and the image into two orthogonal pairs of subspaces.

Chapter 11 asked which operators the inner product can diagonalize, and the adjoint

answered: over $\mathbb{C}$ the normal ones, over $\mathbb{R}$ the self-adjoint ones. Written without bases, the spectral theorem says $T = \sum_i \lambda_i P_i$ with the P_i orthogonal projections onto the eigenspaces — which is why the present section had to exist, and why Theorem 11.8.1 needed clause (b) at all. Once a matrix is diagonal in an orthonormal basis, anything can be done to its eigenvalues and undone afterwards, and that is the functional calculus.

Chapter 12 asked which self-adjoint operators behave like non-negative numbers, collected the equivalent answers in Theorem 12.1.4, and used them twice: to build the square root and the absolute value $|\mathbf{A}| = (\mathbf{A}^*\mathbf{A})^{1/2}$ of Definition 12.2.1, and then to get past the restriction that had hung over the whole part. The spectral theorem needs a square operator, and most matrices are not square — but $\mathbf{A}^*\mathbf{A}$ always **is** square, self-adjoint and positive semidefinite, whatever $\mathbf{A}$ is. Applying the spectral theorem to it and reading the result back through $\mathbf{A}$ gives Theorem 12.8.1, and with it orthonormal bases of all four fundamental subspaces (Corollary 12.8.4), the polar decomposition of Theorem 12.9.1, the best low-rank approximation and the pseudoinverse. A rectangular matrix has no eigenvalues; it has singular values, and they do the work.

So the part is one chain, each link an application of the last: **inner product** $\to$ **adjoint** $\to$ **spectral theorem** $\to$ **singular value decomposition**. Its named moves travel. To show a vector is zero, pair it with itself. To move an operator across the inner product, pay with the adjoint. Work with the norm squared. Fix an orthonormal basis. Project, then subtract. Test positivity with the single scalar $\langle \mathbf{Ax}, \mathbf{x}\rangle$, and factor a positive matrix as $\mathbf{B}^*\mathbf{B}$. Diagonalize, work on the eigenvalues, come back. When the matrix is not square, apply the spectral theorem to $\mathbf{A}^*\mathbf{A}$. And when the answer is a sum ordered by size, truncate it.

What comes next takes the quadratic form $\mathbf{x} \mapsto \langle \mathbf{Ax}, \mathbf{x}\rangle$, which was only a test in this chapter, and makes it the object of study: Chapter 13 classifies forms up to congruence, by inertia, over $\mathbb{R}$ and over $\mathbb{C}$. Chapter 15 gives the operator norm promised twice above, and Chapter 16 characterizes the eigenvalues of a Hermitian matrix as maxima and minima of $\langle \mathbf{Ax}, \mathbf{x}\rangle$ — at which point the test becomes the theory.

12.12.4 Exercises

12.12.4.1 A. Check your understanding

Exercise A1.

(a) Define what it means for $P \in \mathcal{L}(V)$ to be a projection, and what it means for it to be the orthogonal projection onto a subspace U. Which of the two definitions needs an inner product?

(b) State three conditions on a projection P, each equivalent to "P is an orthogonal projection".

(c) Determine whether the following is correct, and justify your answer: if $\|P\mathbf{v}\| \leq \|\mathbf{v}\|$ for some non-zero $\mathbf{v}$, then the projection P is orthogonal.

(d) Determine whether the following is correct, and justify your answer: every projection of rank r on an n-dimensional inner product space has matrix $\mathbf{I}_r \oplus 0$ in some orthonormal basis.

Solution.

(a) P is a projection when $P^2 = P$ (Definition 3.10.1); P is the orthogonal projection onto U when it is the projection onto U along $U^\perp$ (Definition 10.3.2). Only the second needs an inner product, since $U^\perp$ is undefined without one.

(b) By Theorem 12.12.1: $\ker P = (\operatorname{im} P)^\perp$; $P^* = P$; P is normal; $\|P\mathbf{v}\| \le \|\mathbf{v}\|$ for every $\mathbf{v}$. Any three of these will do.

(c) Incorrect. Take $\mathbf{P}' = \left(\begin{smallmatrix} 1 & -1 \\ 0 & 0 \end{smallmatrix}\right)$ on $\mathbb{R}^2$ and $\mathbf{v} = (1, 1)$. Then $\mathbf{P}'\mathbf{v} = \mathbf{0}$, so $\|\mathbf{P}'\mathbf{v}\| = 0 \le \sqrt{2}$, yet $\mathbf{P}'$ is oblique because $(\mathbf{P}')^\top \neq \mathbf{P}'$. Clause (e) of Theorem 12.12.1 quantifies over **every** $\mathbf{v}$.

(d) Incorrect in general, and correct exactly for the orthogonal projections. By Theorem 12.12.3 the matrix in a suitable orthonormal basis is $\left(\begin{smallmatrix} \mathbf{I}_r & \mathbf{X} \\ 0 & 0 \end{smallmatrix}\right)$, and it is $\mathbf{I}_r \oplus 0$ only when $\mathbf{X} = 0$. If some orthonormal basis gave $\mathbf{I}_r \oplus 0$, that matrix would be Hermitian, so P would be self-adjoint by Theorem 10.6.3. The matrix $\mathbf{P}'$ of part (c) is a counterexample. (In a basis that is merely a basis, $\mathbf{I}_r \oplus 0$ is always attainable: that is Corollary 3.10.2.)

12.12.4.2 B. Practice

Exercise B1: Which are orthogonal projections?.

Determine which of the following matrices are projections, and among those, which are orthogonal projections. Justify your answer. For the oblique ones over $\mathbb{R}$, find the angle between image and kernel.

(a) $\mathbf{A} = \frac{1}{5}\begin{pmatrix} 1 & 2 \\ 2 & 4 \end{pmatrix}$ on $\mathbb{R}^2$.

(b) $\mathbf{B} = \begin{pmatrix} 1 & 0 \\ -2 & 0 \end{pmatrix}$ on $\mathbb{R}^2$.

(c) $\mathbf{C} = \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix}$ on $\mathbb{R}^2$.

(d) $\mathbf{D} = \begin{pmatrix} 1 & i \\ 0 & 0 \end{pmatrix}$ on $\mathbb{C}^2$.

Solution.

(a) $\mathbf{A}^2 = \frac{1}{25}\left(\begin{smallmatrix} 5 & 10 \\ 10 & 20 \end{smallmatrix}\right) = \mathbf{A}$, so $\mathbf{A}$ is a projection, and $\mathbf{A}^\top = \mathbf{A}$. By Theorem 12.12.1 it is the orthogonal projection onto $\operatorname{im}\mathbf{A} = \operatorname{span}((1, 2))$.

(b) $\mathbf{B}^2 = \mathbf{B}$, so $\mathbf{B}$ is a projection, but $\mathbf{B}^\top \neq \mathbf{B}$, so it is oblique. Its image is $\operatorname{span}((1, -2))$ and its kernel is $\operatorname{span}(\mathbf{e}_2)$. The angle between these lines has $\cos\theta = |\langle(1, -2), (0, 1)\rangle|/(\sqrt{5} \cdot 1) = 2/\sqrt{5}$, so $\sin\theta = 1/\sqrt{5}$ and $\cot\theta = 2$; that is $\theta = \arctan(1/2)$, about $26.6°$.

(c) $\mathbf{C}^2 = \left(\begin{smallmatrix} 2 & 2 \\ 2 & 2 \end{smallmatrix}\right) = 2\mathbf{C} \neq \mathbf{C}$, so $\mathbf{C}$ is not a projection at all, although it is symmetric. Symmetry alone is not idempotence; $\frac{1}{2}\mathbf{C}$ is the orthogonal projection onto $\operatorname{span}((1, 1))$.

(d) $\mathbf{D}^2 = \mathbf{D}$, so $\mathbf{D}$ is a projection, and $\mathbf{D}^* = \left(\begin{smallmatrix} 1 & 0 \\ -i & 0 \end{smallmatrix}\right) \neq \mathbf{D}$, so it is oblique. It is already in the canonical form of Theorem 12.12.3, with $x = i$. There is no angle over $\mathbb{C}$ (Definition 10.1.5 is stated for real spaces), but $|x| = 1$, and the largest value of $\|\mathbf{D}\mathbf{v}\|$ over unit $\mathbf{v}$ is $\sqrt{1 + 1} = \sqrt{2}$, the same number the real matrix $\mathbf{P}'$ produced.

Exercise B2: Putting a projection in canonical form.

Let $\mathbf{A} = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}$ act on $\mathbb{R}^3$ with the dot product.

(a) Verify that $\mathbf{A}$ is a projection and find $\operatorname{im}\mathbf{A}$ and $\ker\mathbf{A}$.

(b) Find an orthonormal basis $\mathcal{B}$ of $\mathbb{R}^3$ as in Theorem 12.12.3 and write down $[\mathbf{A}]_{\mathcal{B}}$.

(c) Hence determine whether $\mathbf{A}$ is an orthogonal projection, and find $\operatorname{rank}\mathbf{A}$ without row reducing.

Solution.

(a) $\mathbf{A}^2 = \mathbf{A}$, by multiplying out: the second column of $\mathbf{A}^2$ is $\mathbf{A}(1,1,0) = (1,1,0)$, and the first and third columns are $\mathbf{0}$ and $\mathbf{e}_3$, unchanged. The columns of $\mathbf{A}$ span $\operatorname{im}\mathbf{A} = \operatorname{span}((1,1,0),\mathbf{e}_3)$, which is 2-dimensional. And $\mathbf{Ax} = (x_2,x_2,x_3)$ is $\mathbf{0}$ exactly when $x_2 = x_3 = 0$, so $\ker\mathbf{A} = \operatorname{span}(\mathbf{e}_1)$.

(b) $\operatorname{im}\mathbf{A}$ has the orthonormal basis $\mathbf{f}_1 = \frac{1}{\sqrt{2}}(1,1,0)$, $\mathbf{f}_2 = \mathbf{e}_3$, and $(\operatorname{im}\mathbf{A})^\perp = \operatorname{span}((1,-1,0))$ has the orthonormal basis $\mathbf{f}_3 = \frac{1}{\sqrt{2}}(1,-1,0)$. Now $\mathbf{Af}_1 = \mathbf{f}_1$ and $\mathbf{Af}_2 = \mathbf{f}_2$, while

$$\mathbf{Af}_3 = \tfrac{1}{\sqrt{2}}(-1,-1,0) = -\mathbf{f}_1.$$

Hence

$$[\mathbf{A}]_{\mathcal{B}} = \begin{pmatrix} 1 & 0 & -1 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \qquad \mathbf{X} = \begin{pmatrix} -1 \\ 0 \end{pmatrix}.$$

(c) $\mathbf{X} \neq 0$, so $\mathbf{A}$ is oblique by Theorem 12.12.3; indeed $\ker\mathbf{A} = \operatorname{span}(\mathbf{e}_1)$ is not $(\operatorname{im}\mathbf{A})^\perp = \operatorname{span}((1,-1,0))$. The rank is the number of ones in the canonical form, namely 2; equivalently $\operatorname{rank}\mathbf{A} = \operatorname{tr}\mathbf{A} = 0+1+1 = 2$ by Theorem 3.10.4.

Exercise B3: The complementary projection.

Let $P \in \mathcal{L}(V)$ be a projection on a finite-dimensional inner product space, with $U = \operatorname{im} P$.

(a) Prove that P is an orthogonal projection if and only if $\mathrm{id}_V - P$ is.

(b) Prove that in that case $\mathrm{id}_V - P = P_{U^\perp}$.

Hint: Exercise (B2: The complementary projection) identifies the image and the kernel of $\mathrm{id}_V - P$.

Solution.

(a) By Exercise (B2: The complementary projection) (a), $\mathrm{id}_V - P$ is a projection. By Theorem 10.6.2 (a), (b) and (d), $(\mathrm{id}_V - P)^* = \mathrm{id}_V - P^*$. Hence $(\mathrm{id}_V - P)^* = \mathrm{id}_V - P$ if and only if $P^* = P$, and Theorem 12.12.1 converts each side into the corresponding statement about orthogonal projections.

(b) Suppose P is an orthogonal projection. By Exercise (B2: The complementary projection) (b), $\operatorname{im}(\mathrm{id}_V - P) = \ker P$, which is $U^\perp$ by Theorem 12.12.1 (b). By

(a), $\mathrm{id}_V - P$ is an orthogonal projection, so by clause (a) of that theorem it is the orthogonal projection onto its own image, that is $P_{U^\perp}$.

12.12.4.3 C. Going deeper

Exercise C1: Products of orthogonal projections.

Let P and Q be orthogonal projections on a finite-dimensional inner product space V, with images U and W.

(a) Prove that PQ is an orthogonal projection if and only if $PQ = QP$.

(b) Suppose $PQ = QP$. Prove that $PQ = P_{U \cap W}$.

(c) Give an explicit example of two orthogonal projections on $\mathbb{R}^2$ whose product is not a projection.

Solution.

(a) ($\Leftarrow$) Suppose $PQ = QP$. Then $(PQ)^2 = P(QP)Q = P(PQ)Q = P^2Q^2 = PQ$, so PQ is a projection, and $(PQ)^* = Q^*P^* = QP = PQ$ by Theorem 10.6.2 (c) and self-adjointness of P and Q. By Theorem 12.12.1, PQ is an orthogonal projection. ($\Rightarrow$) Suppose PQ is an orthogonal projection. Then $PQ = (PQ)^* = Q^*P^* = QP$.

(b) Assume $PQ = QP$, so PQ is an orthogonal projection by (a), and by clause (a) of Theorem 12.12.1 it equals $P_{\mathrm{im}(PQ)}$. It remains to show $\mathrm{im}(PQ) = U \cap W$. ($\subseteq$) Every value $PQ\mathbf{v}$ lies in $\mathrm{im}\, P = U$; and $PQ\mathbf{v} = QP\mathbf{v}$ lies in $\mathrm{im}\, Q = W$. ($\supseteq$) If $\mathbf{v} \in U \cap W$, then $Q\mathbf{v} = \mathbf{v}$ and $P\mathbf{v} = \mathbf{v}$, since a projection fixes its image (Theorem 3.10.1 (a)), so $PQ\mathbf{v} = \mathbf{v}$ and $\mathbf{v} \in \mathrm{im}(PQ)$.

(c) Project onto the x-axis and onto the line $y = x$, with standard matrices

$$\mathbf{P} = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}, \qquad \mathbf{Q} = \tfrac{1}{2}\begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix}.$$

Both are symmetric and idempotent, hence orthogonal projections. But $\mathbf{PQ} = \frac{1}{2}\left(\begin{smallmatrix} 1 & 1 \\ 0 & 0 \end{smallmatrix}\right)$ and $(\mathbf{PQ})^2 = \frac{1}{4}\left(\begin{smallmatrix} 1 & 1 \\ 0 & 0 \end{smallmatrix}\right) \neq \mathbf{PQ}$, so the product is not even a projection. Consistently with (a), $\mathbf{QP} = \frac{1}{2}\left(\begin{smallmatrix} 1 & 0 \\ 1 & 0 \end{smallmatrix}\right) \neq \mathbf{PQ}$.

Exercise C2: The Frobenius norm detects obliqueness.

Let $\mathbf{P} \in M_n(F)$ be idempotent, of rank r.

(a) Prove that $\|\mathbf{P}\|_F^2 \geq r$.

(b) Prove that equality holds if and only if $\mathbf{P}$ is an orthogonal projection.

Hint: the canonical form of Theorem 12.12.3, together with the invariance of the Frobenius norm under a unitary change of orthonormal basis.

Solution. Apply Theorem 12.12.3 to the operator $\mathbf{x} \mapsto \mathbf{Px}$ on F^n, and let $\mathbf{U}$ be the matrix whose columns are the vectors of the orthonormal basis it produces. Then $\mathbf{U}$ is

unitary (Theorem 10.7.3 (f)), and the change-of-basis formula gives

$$\mathbf{U}^*\mathbf{P}\mathbf{U} = \mathbf{U}^{-1}\mathbf{P}\mathbf{U} = \begin{pmatrix} \mathbf{I}_r & \mathbf{X} \\ 0 & 0 \end{pmatrix}.$$

By Lemma 11.11.1, $\|\mathbf{P}\|_F = \|\mathbf{U}^*\mathbf{P}\mathbf{U}\|_F$.

(a) Summing the squared moduli of the entries of the block matrix,

$$\|\mathbf{P}\|_F^2 = \|\mathbf{I}_r\|_F^2 + \|\mathbf{X}\|_F^2 = r + \|\mathbf{X}\|_F^2 \geq r,$$

since $\|\mathbf{X}\|_F^2 \geq 0$.

(b) Equality holds if and only if $\|\mathbf{X}\|_F = 0$, that is $\mathbf{X} = 0$, which by Theorem 12.12.3 is exactly the condition that $\mathbf{P}$ be an orthogonal projection. (Note that $r = \operatorname{rank}\mathbf{P} = \operatorname{tr}\mathbf{P}$ by Theorem 3.10.4, so the criterion may also be written $\operatorname{tr}(\mathbf{P}^*\mathbf{P}) = \operatorname{tr}\mathbf{P}$.)

Exercise C3: How far an oblique projection can stretch.

Let P be a projection of rank r on an n-dimensional inner product space V over F, with $0 < r < n$, and let $\mathbf{X}$ be the block of Theorem 12.12.3, with largest singular value $\sigma_1 = \sigma_1(\mathbf{X})$.

(a) Prove that $\|\mathbf{X}\mathbf{z}\| \leq \sigma_1\|\mathbf{z}\|$ for every $\mathbf{z} \in F^{n-r}$, with equality for some $\mathbf{z} \neq \mathbf{0}$.

(b) Prove that the largest value of $\|P\mathbf{v}\|$ over unit vectors $\mathbf{v} \in V$ is $\sqrt{1+\sigma_1^2}$.

(c) Deduce the two-dimensional formula $\sqrt{1+|x|^2}$ of the text, and state what the answer becomes when P is an orthogonal projection.

Solution.

(a) Write $\mathbf{X} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^*$ as in Theorem 12.8.1, with $\mathbf{U}, \mathbf{V}$ unitary, and let p be the length of the list of singular values. For $\mathbf{z} \in F^{n-r}$ put $\mathbf{w} = \mathbf{V}^*\mathbf{z}$, so that $\|\mathbf{w}\| = \|\mathbf{z}\|$ and $\|\mathbf{X}\mathbf{z}\| = \|\mathbf{\Sigma}\mathbf{w}\|$, a unitary matrix preserving norms (Theorem 10.7.3). The vector $\mathbf{\Sigma}\mathbf{w}$ has entries $\sigma_i w_i$ for $i \leq p$ and 0 beyond, so

$$\|\mathbf{\Sigma}\mathbf{w}\|^2 = \sum_{i \leq p} \sigma_i^2 |w_i|^2 \leq \sigma_1^2 \sum_{i \leq p} |w_i|^2 \leq \sigma_1^2 \|\mathbf{w}\|^2 = \sigma_1^2 \|\mathbf{z}\|^2,$$

since σ_1 is the largest of the σ_i. Taking $\mathbf{z} = \mathbf{V}\mathbf{e}_1$, a unit vector, gives $\mathbf{w} = \mathbf{e}_1$ and $\|\mathbf{X}\mathbf{z}\| = \sigma_1$, so the bound is attained.

(b) Use the orthonormal basis $\mathcal{B}$ of Theorem 12.12.3 and write a vector of V by its coordinate vector $(\mathbf{y}, \mathbf{z})$ with $\mathbf{y} \in F^r$ and $\mathbf{z} \in F^{n-r}$; since $\mathcal{B}$ is orthonormal, Theorem 10.2.1 (c) gives $\|\mathbf{v}\|^2 = \|\mathbf{y}\|^2 + \|\mathbf{z}\|^2$, and $P\mathbf{v}$ has coordinates $(\mathbf{y} + \mathbf{X}\mathbf{z}, \mathbf{0})$. By Corollary 10.1.6, then (a), then Theorem 10.1.5 in $\mathbb{R}^2$ applied to $(\|\mathbf{y}\|, \|\mathbf{z}\|)$ and $(1, \sigma_1)$,

$$\begin{aligned} \|P\mathbf{v}\| = \|\mathbf{y} + \mathbf{X}\mathbf{z}\| &\leq \|\mathbf{y}\| + \sigma_1\|\mathbf{z}\| \\ &\leq \sqrt{1+\sigma_1^2}\,\sqrt{\|\mathbf{y}\|^2 + \|\mathbf{z}\|^2} = \sqrt{1+\sigma_1^2}\,\|\mathbf{v}\|. \end{aligned}$$

For equality, let $\mathbf{z}_0$ be the unit vector of (a), so $\mathbf{X}\mathbf{z}_0 = \sigma_1\mathbf{u}_0$ with $\|\mathbf{u}_0\| = 1$ (take

$\mathbf{u}_0 = \mathbf{X}\mathbf{z}_0/\sigma_1$ if $\sigma_1 > 0$; if $\sigma_1 = 0$ take any unit $\mathbf{u}_0$). Put

$$\mathbf{y} = \frac{\mathbf{u}_0}{\sqrt{1+\sigma_1^2}}, \qquad \mathbf{z} = \frac{\sigma_1 \mathbf{z}_0}{\sqrt{1+\sigma_1^2}}.$$

Then $\|\mathbf{y}\|^2 + \|\mathbf{z}\|^2 = 1$ and $\mathbf{y} + \mathbf{X}\mathbf{z} = (1+\sigma_1^2)\mathbf{u}_0/\sqrt{1+\sigma_1^2}$, whose norm is $\sqrt{1+\sigma_1^2}$.

(c) When $n = 2$ and $r = 1$, $\mathbf{X}$ is the 1×1 matrix (x), whose only singular value is $|x|$; the formula becomes $\sqrt{1+|x|^2}$. When P is an orthogonal projection, $\mathbf{X} = 0$, so $\sigma_1 = 0$ and the largest value is 1 — an orthogonal projection never lengthens a vector, which is clause (e) of Theorem 12.12.1 with the sharpest constant.

Chapter 13

Bilinear and Quadratic Forms

An inner product does two jobs at once. It **pairs** two vectors and returns a scalar, linearly in each of them; and it **measures**, because $\langle \mathbf{v}, \mathbf{v} \rangle$ is a positive number whenever $\mathbf{v} \neq \mathbf{0}$. Chapters 10 to 12 leaned on the second job constantly: lengths, angles, orthonormal bases, least squares, positive definiteness and the singular value decomposition are all consequences of positivity. This chapter keeps the pairing and throws the measuring away. What is left is a **bilinear form**, a function $\beta\colon V \times V \to F$ linear in each slot, with no sign condition, no symmetry required, and no field restriction. The question of the chapter is what survives.

A surprising amount does. Forms still have matrices, and the matrices still change by a rule when the basis changes — but the rule is $\mathbf{A} \mapsto \mathbf{P}^{\top}\mathbf{A}\mathbf{P}$, not $\mathbf{A} \mapsto \mathbf{P}^{-1}\mathbf{A}\mathbf{P}$. The organizing relation is therefore **congruence**, not similarity, and the two are genuinely different: congruent matrices need not share a single eigenvalue. What they do share is a rank, a symmetry type, and — over $\mathbb{R}$ — a triple of signs, which is Sylvester's law of inertia and the central classification theorem of the chapter. Beyond $\mathbb{R}$ the classification depends on the arithmetic of the field, and beyond symmetry there is a second world, the alternating forms, where every non-degenerate example looks like every other of the same size. Along the way we meet vectors on which a form vanishes without being zero, the groups that preserve a form, the geometry that physics runs on, and one algebra built to make a quadratic form into a square.

The field is a general F here. Since Chapter 9 the book has worked over $\mathbb{R}$ or $\mathbb{C}$, because inner products need them; this chapter opens the field back up, and that is the point rather than an afterthought. Chapters 10 to 12 turn out to have been the positive definite special case of one line of this theory. Two consequences of the general setting are worth flagging in advance. First, "positive" has no meaning over a field with no order, so the definiteness arguments of Chapter 12 simply cannot be run; what replaces them is either a square-class computation or nothing at all. Second, when $1 + 1 = 0$ — characteristic 2, Definition 0.7.2 — the identity $\beta(\mathbf{u}, \mathbf{v}) = \frac{1}{2}\big(q(\mathbf{u} + \mathbf{v}) - q(\mathbf{u}) - q(\mathbf{v})\big)$ is unavailable, and symmetric and alternating forms stop being complementary. Every statement below that needs a characteristic hypothesis carries one, and every statement without one holds over every field.

What you need. From Chapter 6, multilinearity and alternation, which this chapter reuses rather than redefines (Definition 6.2.1, Definition 6.2.2, Definition 6.2.3, Theorem 6.2.1, Theorem 6.2.2), together with the determinant and its multiplicativity (Definition 6.4.1, Theorem 6.5.4, Theorem 6.4.5). From Chapter 3, the matrix of a map, change of coordinates and similarity (Definition 3.6.1, Theorem 3.6.1, Definition 3.7.1, Theorem 3.7.1, Theorem 3.7.3, Definition 3.7.2), together with rank, equivalence of matrices and the rank normal form (Definition 3.3.2, Definition 3.8.1, Theorem 3.8.3). From Chapter 4, the dual space and its bases (Def-

inition 4.1.1, Definition 4.1.2, Theorem 4.1.3, Corollary 4.1.4, Theorem 4.5.1, Theorem 4.3.2). From Chapter 0, fields and characteristic (Definition 0.7.1, Definition 0.7.2, Theorem 0.7.5), the transpose and symmetry (Definition 0.9.10, Definition 0.9.11, Theorem 0.9.5), and groups (Definition 0.10.1, Definition 0.10.2). From Chapter 2, the $\mathbf{L}\mathbf{D}\mathbf{L}^\top$ factorization (Theorem 2.6.8). From Chapters 10 to 12, everything used for the real and complex specializations: the orthogonal and unitary groups (Definition 10.7.2, Definition 10.7.3), the real spectral theorem and principal axes (Theorem 11.5.1, Corollary 11.5.2, Theorem 11.5.5), the orthogonal group in low dimension (Proposition 10.7.4, Theorem 11.6.1), and positivity (Definition 12.1.1, Theorem 12.1.4, Theorem 12.1.5, Proposition 12.1.2, Theorem 12.4.1). Those last results are used **only** where the field is $\mathbb{R}$ or $\mathbb{C}$; they are never hypotheses of the general theory.

13.0.1 Roadmap

- **Bilinear forms and their matrices.** What a form is, the Gram matrix that records it, the bijection between forms and matrices, and the form's companion map $V \to V^*$, whose kernel is the radical and whose invertibility is non-degeneracy.
- **Congruence.** Changing the basis replaces $\mathbf{A}$ by $\mathbf{P}^\top\mathbf{A}\mathbf{P}$. What that relation preserves — rank, symmetry type, non-degeneracy, the square class of the determinant — and what it destroys, starting with the eigenvalues.
- **Three kinds of form.** Symmetric, alternating, skew-symmetric and Hermitian; why the middle two coincide exactly when the characteristic is not 2; polarization, and the quadratic form.
- **Completing the square.** Over any field of characteristic $\neq 2$, every symmetric form has an orthogonal basis. The proof is an induction, and the algorithm is symmetric row-and-column elimination.
- **Inertia.** Over $\mathbb{R}$ the number of positive, negative and zero diagonal entries does not depend on the diagonalization. This classifies real symmetric matrices up to congruence and reconciles congruence with the spectral theorem.
- **Definiteness revisited.** Chapter 12's tests, restated as statements about signatures, and the second-derivative test they decide.
- **Where the form vanishes.** Isotropic vectors, totally isotropic subspaces, hyperbolic planes, and the Witt decomposition of a non-degenerate space.
- **Witt's theorems.** An isometry between subspaces extends to the whole space; one summand of an orthogonal sum may be canceled from both sides.
- **Symplectic forms.** A non-degenerate alternating form lives only in even dimension and has exactly one shape, over every field, with no characteristic hypothesis anywhere.
- **The classical groups.** $\mathrm{O}(n)$, $\mathrm{O}(p,q)$, $\mathrm{U}(n)$ and the symplectic group, all read off one equation $\mathbf{P}^\top\mathbf{A}\mathbf{P} = \mathbf{A}$.
- **Minkowski space.** The signature $(1,3)$ form, the light cone, hyperbolic rotations, and the triangle inequality running backwards.
- **A first look at Clifford algebras.** Making a quadratic form into a square, and how $\mathbb{C}$ and the quaternions come out of it.

13.0.2 Named moves

- **Polarize.** A symmetric form and its quadratic function $q(\mathbf{v}) = \beta(\mathbf{v},\mathbf{v})$ carry the same information, because β can be recovered from q by expanding $q(\mathbf{u}+\mathbf{v})$ and dividing by 2. That division is the whole reason characteristic 2 is excluded whenever it is excluded.
- **Complete the square.** Every diagonalization theorem for symmetric forms in this chap-

ter is this one manipulation, applied by induction on the dimension: isolate a variable that actually appears, absorb its cross terms into a perfect square, and recurse on what is left.

- **Split off a hyperbolic plane.** For indefinite forms this replaces "peel off an eigenvector". A single non-zero isotropic vector forces a two-dimensional piece of standard shape to split off orthogonally, and the induction runs on the rest.
- **Count signs, not values.** The numbers on a diagonalized form are not invariants; their signs are. Whenever a quantity refuses to be an invariant, ask whether some coarser feature of it is.
- **Congruence, not similarity.** At every theorem, ask which relation is in play. If the matrix is eaten twice by the same vector, the relation is congruence and eigenvalues are not available; if it is eaten once and returns a vector, the relation is similarity and they are.

13.1 Bilinear Forms and Their Matrices

Chapter 6 needed a function of several vectors that was linear in each of them separately, and called it a multilinear form (Definition 6.2.1). Chapter 10 needed a function of two vectors that was linear in the first, conjugate-linear in the second, and positive on the diagonal, and called it an inner product. This section takes the common skeleton of the two — two slots, linear in each, nothing else assumed — and studies it on its own. The payoff is immediate: such a function is recorded by a square matrix, exactly as a linear map is, and the whole rest of the chapter is about how that matrix behaves.

Throughout, V is a vector space over a field F. From the second subsection on, V is finite-dimensional with $\dim V = n \geq 1$, and $\mathcal{B} = (\mathbf{v}_1, \ldots, \mathbf{v}_n)$ is an ordered basis of V. **No hypothesis on the characteristic of F is used anywhere in this section**, and none is used in the next one either.

13.1.1 Pairing without measuring

The dot product on F^n is a machine with two inputs and one scalar output. Over $\mathbb{R}$ it does two different jobs. It **pairs**: it takes $\mathbf{x}$ and $\mathbf{y}$ and returns $\sum_i x_i y_i$, linearly in each of them. And it **measures**: $\mathbf{x} \cdot \mathbf{x}$ is a sum of squares, so it is positive unless $\mathbf{x} = \mathbf{0}$, and from that one fact Chapter 10 extracted lengths, angles, orthonormal bases and everything built on them.

Measuring is the fragile half. It needs an order on F, so it is meaningless over $\mathbb{C}$ without a conjugation and meaningless over $\mathbb{F}_5$ altogether. Pairing needs nothing: $\sum_i x_i y_i$ makes sense over every field, and so do plenty of other two-slot expressions, such as $x_1y_2 - x_2y_1$ or $x_1y_1 - x_2y_2$. Chapter 6 already met the first of these as the signed area, and met the general notion as the case $k = 2$ of a multilinear form. We give that case its own name, because from here on it is the object of study rather than a step toward the determinant.

A bilinear form pairs two vectors of the same space into a scalar, linearly in each slot separately.

Definition 13.1.1 — Bilinear Form

Let V be a vector space over a field F. A **bilinear form** on V is a function $\beta\colon V \times V \to F$ that is linear in each argument when the other is held fixed: **for all** $\mathbf{u}, \mathbf{u}', \mathbf{v}, \mathbf{v}' \in V$ and

all $c \in F$,

(B1) $\beta(\mathbf{u}+\mathbf{u}', \mathbf{v}) = \beta(\mathbf{u}, \mathbf{v}) + \beta(\mathbf{u}', \mathbf{v})$ and $\beta(c\mathbf{u}, \mathbf{v}) = c\,\beta(\mathbf{u}, \mathbf{v})$;
(B2) $\beta(\mathbf{u}, \mathbf{v}+\mathbf{v}') = \beta(\mathbf{u}, \mathbf{v}) + \beta(\mathbf{u}, \mathbf{v}')$ and $\beta(\mathbf{u}, c\mathbf{v}) = c\,\beta(\mathbf{u}, \mathbf{v})$.

Equivalently, β is a 2-linear form on V in the sense of Definition 6.2.1.

In words: (B1) says that for each fixed $\mathbf{v}$, the function $\mathbf{u} \mapsto \beta(\mathbf{u}, \mathbf{v})$ is a linear functional on V (Definition 4.1.1), and (B2) says the same for $\mathbf{v} \mapsto \beta(\mathbf{u}, \mathbf{v})$ with $\mathbf{u}$ fixed. The word **fixed** is the whole content. Nothing is assumed about how the two slots compare: $\beta(\mathbf{u}, \mathbf{v})$ and $\beta(\mathbf{v}, \mathbf{u})$ may be unrelated, and $\beta(\mathbf{v}, \mathbf{v})$ may be any scalar at all, including 0 for a non-zero $\mathbf{v}$.

Two consequences come free from linearity in one slot. Taking $c = 0$ in (B1) gives $\beta(\mathbf{0}, \mathbf{v}) = 0$ for every $\mathbf{v}$, and likewise $\beta(\mathbf{u}, \mathbf{0}) = 0$. And by induction on the number of terms,

$$\beta\Big(\sum_i a_i\mathbf{u}_i,\ \sum_j b_j\mathbf{v}_j\Big) = \sum_{i,j} a_i b_j\,\beta(\mathbf{u}_i, \mathbf{v}_j),$$

which is the identity everything in this section rests on: a bilinear form is determined by its values on pairs drawn from a spanning set.

Example. (Six two-slot functions)

Decide which of the following are bilinear forms on the given space over the given field.

(a) The dot product on F^n: $\beta(\mathbf{x}, \mathbf{y}) = x_1y_1 + \cdots + x_ny_n$.
(b) On F^n, for a fixed $\mathbf{A} \in M_n(F)$: $\beta_{\mathbf{A}}(\mathbf{x}, \mathbf{y}) = \mathbf{x}^{\top}\mathbf{A}\mathbf{y}$.
(c) On F^2: $\beta(\mathbf{x}, \mathbf{y}) = x_1y_2 - x_2y_1$.
(d) On $\mathbb{R}[x]_{\le 2}$: $\beta(f, g) = \int_0^1 f(t)g(t)\,\mathrm{d}t$.
(e) On any V: the zero function $\beta(\mathbf{u}, \mathbf{v}) = 0$.
(f) On $\mathbb{R}^n$: $\beta(\mathbf{x}, \mathbf{y}) = \|\mathbf{x}\|\,\|\mathbf{y}\|$, the product of the Euclidean lengths.

Solution.

(a) Fix $\mathbf{y}$. Then $\mathbf{x} \mapsto \sum_i x_iy_i$ is a linear functional on F^n, since it is a fixed linear combination of the coordinate functionals (Theorem 4.1.1). Fixing $\mathbf{x}$ gives the same statement in $\mathbf{y}$. So (B1) and (B2) hold and the dot product is bilinear.

(b) With $\mathbf{A} = \mathbf{I}_n$ this is (a). In general, write out the entries: $\mathbf{x}^{\top}\mathbf{A}\mathbf{y} = \sum_{i,j} a_{ij}x_iy_j$. For fixed $\mathbf{y}$ this is $\sum_i \big(\sum_j a_{ij}y_j\big)x_i$, a fixed linear combination of the coordinates of $\mathbf{x}$, hence a linear functional; symmetrically in $\mathbf{y}$. So $\beta_{\mathbf{A}}$ is bilinear for **every** $\mathbf{A}$, symmetric or not. Part (c) below is the case $\mathbf{A} = \left(\begin{smallmatrix} 0 & 1 \\ -1 & 0 \end{smallmatrix}\right)$.

(c) This is the signed area of Chapter 6, and it is bilinear by Example (Alternating Forms) (a). It is worth noticing what it does on the diagonal: $\beta(\mathbf{x}, \mathbf{x}) = x_1x_2 - x_2x_1 = 0$ for **every** $\mathbf{x}$. A bilinear form may vanish identically on the diagonal without being the zero form.

(d) For fixed g, the map $f \mapsto \int_0^1 fg$ is linear, because the integral of a sum is the sum of the integrals and constants come out. Symmetrically in g. So β is bilinear. Here $\beta(f, f) = \int_0^1 f^2 \ge 0$, so over $\mathbb{R}$ this form does measure: it is the inner product of Chapter 10.

(e) Both clauses read $0 = 0 + 0$ and $0 = c \cdot 0$. The zero form is bilinear on every space

over every field. It is the degenerate case, and it matters: it shows that a bilinear form can carry no information whatsoever, and it is the form whose matrix below is the zero matrix.

(f) Not bilinear. Fix $\mathbf{y} = \mathbf{e}_1$. Then $\beta(\mathbf{e}_1, \mathbf{e}_1) + \beta(-\mathbf{e}_1, \mathbf{e}_1) = 1 + 1 = 2$, while $\beta(\mathbf{e}_1 + (-\mathbf{e}_1), \mathbf{e}_1) = \beta(\mathbf{0}, \mathbf{e}_1) = 0$. Additivity in the first slot fails, so (B1) fails. The homogeneity half of (B1) also fails, since $\beta(-\mathbf{e}_1, \mathbf{e}_1) = 1 \neq -\beta(\mathbf{e}_1, \mathbf{e}_1)$.

Item (f) is the non-example by minimal change worth remembering: the Cauchy–Schwarz inequality says that $|\mathbf{x} \cdot \mathbf{y}| \leq \|\mathbf{x}\|\|\mathbf{y}\|$, so $\|\mathbf{x}\|\|\mathbf{y}\|$ sits right next to the dot product numerically, and yet it is not a form at all, because the absolute value hidden in the norm destroys additivity. A second minimal change makes the same point more cheaply: $\beta(\mathbf{x}, \mathbf{y}) = x_1 y_1 + 1$ fails (B1) because $\beta(\mathbf{0}, \mathbf{0}) = 1 \neq 0$.

Warning. **Bilinear is not linear.** A bilinear form is not a linear function of the pair $(\mathbf{u}, \mathbf{v})$, and the two properties are not even compatible in general. For the dot product on $\mathbb{R}^2$, doubling both arguments multiplies the value by 4: $\beta(2\mathbf{e}_1, 2\mathbf{e}_1) = 4$, not $2\beta(\mathbf{e}_1, \mathbf{e}_1) = 2$. Sums may only be split **one slot at a time**, with the other slot held frozen. Chapter 6 gave this warning for multilinear forms in general; it is repeated here because it is the mistake readers make most often when a form is written with the familiar-looking symbol $\mathbf{x}^\top \mathbf{A} \mathbf{y}$.

Remark. The same definition with two different spaces, $\beta \colon V \times W \to F$ linear in each slot, is called a **bilinear pairing** of V and W. The basic example is the evaluation pairing $V^* \times V \to F$, $(\varphi, \mathbf{v}) \mapsto \varphi(\mathbf{v})$, which is linear in φ by the definition of the operations on V^* (Definition 4.1.2) and linear in $\mathbf{v}$ because φ is. We insist on $V = W$ in Definition 13.1.1 because the questions of this chapter — is $\beta(\mathbf{u}, \mathbf{v})$ equal to $\beta(\mathbf{v}, \mathbf{u})$, what is $\beta(\mathbf{v}, \mathbf{v})$, which vectors are orthogonal to which — only make sense when both slots hold vectors of the same space.

13.1.2 The matrix of a form

The displayed expansion above says that a bilinear form on a finite-dimensional space is determined by finitely many numbers: the values $\beta(\mathbf{v}_i, \mathbf{v}_j)$ on pairs of basis vectors. There are n^2 of them, they are indexed by a row and a column, and that is a matrix. Chapter 3 recorded a linear map by a matrix in exactly the same spirit (Definition 3.6.1); here the recipe is even simpler, because there is no basis of an output space to choose.

The matrix of a form is its table of values on pairs of basis vectors.

Definition 13.1.2 — Matrix of a Bilinear Form

Let β be a bilinear form on a finite-dimensional V with ordered basis $\mathcal{B} = (\mathbf{v}_1, \dots, \mathbf{v}_n)$. The **matrix of β with respect to $\mathcal{B}$**, also called its **Gram matrix**, is the matrix $[\beta]_{\mathcal{B}} \in M_n(F)$ with entries

$$\big([\beta]_{\mathcal{B}}\big)_{ij} := \beta(\mathbf{v}_i, \mathbf{v}_j).$$

In words: the entry in row i and column j is the value of β with the i-th basis vector in the **left** slot and the j-th in the **right** slot. The order matters, because $\beta(\mathbf{v}_i, \mathbf{v}_j)$ and $\beta(\mathbf{v}_j, \mathbf{v}_i)$ need not

agree; the convention chosen here is the one that makes the recovery formula below carry no transpose on the **matrix**.

Chapter 10 also called a matrix of pairings a Gram matrix, and the two conventions differ, so it is worth saying how. Definition 10.2.3 set $(\mathbf{G})_{ij} = \langle \mathbf{v}_j, \mathbf{v}_i \rangle$, with the indices crossed, because an inner product is conjugate-linear in its second slot and the crossing is what makes $\mathbf{G}$ Hermitian and $\mathbf{x}^*\mathbf{G}\mathbf{x}$ come out as a squared norm. A bilinear form has no conjugation to accommodate, so here the natural order is the uncrossed one, which is what makes the recovery formula below free of transposes. For a real symmetric form the two agree; in general each is the transpose of the other.

Nothing needs checking for well-definedness: once $\mathcal{B}$ is fixed, each entry is a single value of a function. What does need saying is that no information is lost.

Theorem 13.1.1 — Forms and Matrices Correspond

Let V be an n-dimensional vector space over F with ordered basis $\mathcal{B}$, and let β be a bilinear form on V with $\mathbf{A} = [\beta]_{\mathcal{B}}$.

(a) For all $\mathbf{u}, \mathbf{v} \in V$,
$$\beta(\mathbf{u}, \mathbf{v}) = [\mathbf{u}]_{\mathcal{B}}^{\top} \, \mathbf{A} \, [\mathbf{v}]_{\mathcal{B}}.$$

(b) $\mathbf{A}$ is the **only** matrix in $M_n(F)$ with this property.

(c) The assignment $\beta \mapsto [\beta]_{\mathcal{B}}$ is a bijection from the set of bilinear forms on V onto $M_n(F)$, and it respects sums and scalar multiples: $[\beta + \gamma]_{\mathcal{B}} = [\beta]_{\mathcal{B}} + [\gamma]_{\mathcal{B}}$ and $[c\beta]_{\mathcal{B}} = c\,[\beta]_{\mathcal{B}}$.

Idea. Part (a) is the expansion $\beta(\sum a_i \mathbf{v}_i, \sum b_j \mathbf{v}_j) = \sum_{i,j} a_i b_j \beta(\mathbf{v}_i, \mathbf{v}_j)$ with the double sum recognized as a matrix product. For (b), feed the property a pair of basis vectors and watch it return a single entry. For (c), (b) gives injectivity, and surjectivity is Example (Six two-slot functions) (b) transported to V through coordinates.

Proof.

(a) Write $[\mathbf{u}]_{\mathcal{B}} = (a_1, \dots, a_n)$ and $[\mathbf{v}]_{\mathcal{B}} = (b_1, \dots, b_n)$, so that $\mathbf{u} = \sum_i a_i \mathbf{v}_i$ and $\mathbf{v} = \sum_j b_j \mathbf{v}_j$. Expanding one slot at a time, by (B1) and then (B2),

$$\beta(\mathbf{u}, \mathbf{v}) = \sum_{i=1}^{n} \sum_{j=1}^{n} a_i b_j \, \beta(\mathbf{v}_i, \mathbf{v}_j) = \sum_{i,j} a_i \, a_{ij} \, b_j,$$

writing $a_{ij} = \beta(\mathbf{v}_i, \mathbf{v}_j)$ for the entries of $\mathbf{A}$. The last sum is the 1×1 matrix product $[\mathbf{u}]_{\mathcal{B}}^{\top} \mathbf{A} [\mathbf{v}]_{\mathcal{B}}$, by the definition of matrix multiplication (Definition 0.9.9).

(b) Suppose $\mathbf{M} \in M_n(F)$ also satisfies $\beta(\mathbf{u}, \mathbf{v}) = [\mathbf{u}]_{\mathcal{B}}^{\top} \mathbf{M} [\mathbf{v}]_{\mathcal{B}}$ for all $\mathbf{u}, \mathbf{v}$. Take $\mathbf{u} = \mathbf{v}_i$ and $\mathbf{v} = \mathbf{v}_j$. Then $[\mathbf{v}_i]_{\mathcal{B}} = \mathbf{e}_i$ and $[\mathbf{v}_j]_{\mathcal{B}} = \mathbf{e}_j$, so the right-hand side is $\mathbf{e}_i^{\top} \mathbf{M} \mathbf{e}_j = m_{ij}$, while the left-hand side is $\beta(\mathbf{v}_i, \mathbf{v}_j) = a_{ij}$. Hence $m_{ij} = a_{ij}$ for all i, j, that is, $\mathbf{M} = \mathbf{A}$.

(c) *Injective.* If $[\beta]_{\mathcal{B}} = [\gamma]_{\mathcal{B}}$, then by (a) the two forms agree at every pair $(\mathbf{u}, \mathbf{v})$, so $\beta = \gamma$.

Surjective. Given $\mathbf{M} \in M_n(F)$, define $\gamma(\mathbf{u}, \mathbf{v}) \coloneqq [\mathbf{u}]_{\mathcal{B}}^{\top} \mathbf{M} [\mathbf{v}]_{\mathcal{B}}$. The coordinate map $\mathbf{v} \mapsto [\mathbf{v}]_{\mathcal{B}}$ is linear (Corollary 3.5.5), and $(\mathbf{x}, \mathbf{y}) \mapsto \mathbf{x}^{\top} \mathbf{M} \mathbf{y}$ is bilinear on F^n by Example

(Six two-slot functions) (b); composing a bilinear form with a linear map in each slot leaves it bilinear, so γ is a bilinear form on V. By (b) its matrix is $\mathbf{M}$.

Linear. The forms $\beta+\gamma$ and $c\beta$ are defined pointwise, so their values at $(\mathbf{v}_i,\mathbf{v}_j)$ are $\beta(\mathbf{v}_i,\mathbf{v}_j)+\gamma(\mathbf{v}_i,\mathbf{v}_j)$ and $c\,\beta(\mathbf{v}_i,\mathbf{v}_j)$. These are the entries of $[\beta]_{\mathcal{B}}+[\gamma]_{\mathcal{B}}$ and of $c\,[\beta]_{\mathcal{B}}$. This proves the theorem.

■

So bilinear forms on an n-dimensional space are the same thing as $n\times n$ matrices, once a basis is fixed — and in particular they form a vector space of dimension n^2. The qualification "once a basis is fixed" is not decoration; the next section is entirely about what happens when the basis is changed.

Example. (Four Gram matrices)

Compute $[\beta]_{\mathcal{B}}$ in each case.

(a) The dot product on F^n, with $\mathcal{B}=\mathcal{E}$ the standard basis.
(b) $\beta_{\mathbf{A}}(\mathbf{x},\mathbf{y})=\mathbf{x}^{\top}\mathbf{A}\mathbf{y}$ on F^n, with $\mathcal{B}=\mathcal{E}$.
(c) The signed area $\beta(\mathbf{x},\mathbf{y})=x_1y_2-x_2y_1$ on F^2, with $\mathcal{B}=\mathcal{E}$.
(d) $\beta(f,g)=\int_0^1 fg$ on $\mathbb{R}[x]_{\le 2}$, with $\mathcal{B}=(1,x,x^2)$.

Solution.

(a) $\beta(\mathbf{e}_i,\mathbf{e}_j)=\delta_{ij}$, so $[\beta]_{\mathcal{E}}=\mathbf{I}_n$. The dot product is the form whose matrix is the identity.

(b) $\beta_{\mathbf{A}}(\mathbf{e}_i,\mathbf{e}_j)=\mathbf{e}_i^{\top}\mathbf{A}\mathbf{e}_j=a_{ij}$, so $[\beta_{\mathbf{A}}]_{\mathcal{E}}=\mathbf{A}$. Together with Theorem 13.1.1 (c) this says that on F^n with the standard basis, "form" and "matrix" are two words for the same data, and $\mathbf{x}^{\top}\mathbf{A}\mathbf{y}$ is the general form.

(c) $\beta(\mathbf{e}_1,\mathbf{e}_1)=0$, $\beta(\mathbf{e}_1,\mathbf{e}_2)=1$, $\beta(\mathbf{e}_2,\mathbf{e}_1)=-1$, $\beta(\mathbf{e}_2,\mathbf{e}_2)=0$, so

$$[\beta]_{\mathcal{E}}=\begin{pmatrix}0&1\\-1&0\end{pmatrix}.$$

The matrix is not symmetric, and its diagonal is zero — the two features that will separate this form from the dot product throughout the chapter.

(d) With $\mathcal{B}=(1,x,x^2)$ the (i,j) entry is $\int_0^1 t^{i-1}t^{j-1}\mathrm{d}t=1/(i+j-1)$, so

$$[\beta]_{\mathcal{B}}=\begin{pmatrix}1&\frac12&\frac13\\ \frac12&\frac13&\frac14\\ \frac13&\frac14&\frac15\end{pmatrix}.$$

This matrix is symmetric, as it must be, since $\beta(f,g)=\beta(g,f)$. Its determinant is $1/2160$, so it is invertible; what that means for β is the subject of the last part of this section.

Quick check. A bilinear form β on F^2 satisfies $\beta(\mathbf{e}_1,\mathbf{e}_1)=2$, $\beta(\mathbf{e}_1,\mathbf{e}_2)=-1$, $\beta(\mathbf{e}_2,\mathbf{e}_1)=3$ and $\beta(\mathbf{e}_2,\mathbf{e}_2)=0$. What is $\beta\big((1,1),(1,-1)\big)$?

Solution. The matrix is $\mathbf{A} = \left(\begin{smallmatrix} 2 & -1 \\ 3 & 0 \end{smallmatrix}\right)$, and by Theorem 13.1.1 (a),

$$\beta\big((1,1),(1,-1)\big) = \begin{pmatrix} 1 & 1 \end{pmatrix} \begin{pmatrix} 2 & -1 \\ 3 & 0 \end{pmatrix} \begin{pmatrix} 1 \\ -1 \end{pmatrix} = 6.$$

Expanding by hand gives the same. The pair is $(\mathbf{e}_1 + \mathbf{e}_2,\ \mathbf{e}_1 - \mathbf{e}_2)$, so the four terms are

$$\beta(\mathbf{e}_1,\mathbf{e}_1) - \beta(\mathbf{e}_1,\mathbf{e}_2) + \beta(\mathbf{e}_2,\mathbf{e}_1) - \beta(\mathbf{e}_2,\mathbf{e}_2),$$

which is $2-(-1)+3-0=6$. Note that the two off-diagonal values enter with **opposite** roles: $\beta(\mathbf{e}_1,\mathbf{e}_2)$ comes from the minus sign in the right slot, $\beta(\mathbf{e}_2,\mathbf{e}_1)$ from the plus sign in the left one. Since $\beta(\mathbf{e}_1,\mathbf{e}_2) \neq \beta(\mathbf{e}_2,\mathbf{e}_1)$ here, swapping them would change the answer.

Now the warning that the rest of the chapter exists to manage.

Warning. **The matrix of a form and the matrix of a map are different objects with the same name.** Both are square arrays attached to V and a basis, both are written $\mathbf{A}$, and both change when the basis changes — by **different rules**. If $\mathbf{P}$ is the change-of-coordinates matrix between the old and the new basis, then

$$\text{a map: } \mathbf{A} \mapsto \mathbf{P}^{-1}\mathbf{A}\mathbf{P}, \qquad \text{a form: } \mathbf{A} \mapsto \mathbf{P}^{\top}\mathbf{A}\mathbf{P}.$$

The first is Theorem 3.7.3; the second is proved in the next section. They agree only when $\mathbf{P}^{\top} = \mathbf{P}^{-1}$. Concretely, take $\mathbf{A} = \operatorname{diag}(1,2)$ and $\mathbf{P} = \left(\begin{smallmatrix} 1 & 1 \\ 0 & 1 \end{smallmatrix}\right)$. Then

$$\mathbf{P}^{-1}\mathbf{A}\mathbf{P} = \begin{pmatrix} 1 & -1 \\ 0 & 2 \end{pmatrix}, \qquad \mathbf{P}^{\top}\mathbf{A}\mathbf{P} = \begin{pmatrix} 1 & 1 \\ 1 & 3 \end{pmatrix}.$$

The first still has eigenvalues 1 and 2; the second has eigenvalues $2 \pm \sqrt{2}$. Same $\mathbf{A}$, same $\mathbf{P}$, two answers with nothing in common. Before writing $\mathbf{A}$ down, ask what it eats: a map eats one vector and returns a vector, so $\mathbf{A}\mathbf{x}$ is meaningful; a form eats two vectors and returns a scalar, so $\mathbf{x}^{\top}\mathbf{A}\mathbf{y}$ is meaningful and $\mathbf{A}\mathbf{x}$ is a meaningless intermediate. Almost every error in this chapter is this confusion.

13.1.3 The form as a map into the dual space

Fixing the right slot of β leaves a function of the left slot, and clause (B1) says that function is a linear functional. So each $\mathbf{v} \in V$ produces an element of V^* (Definition 4.1.2), and clause (B2) says the production is itself linear. That is a linear map $V \to V^*$, and it is the cleanest way to say what it means for a form to be non-degenerate.

Write $R_\beta \colon V \to V^*$ for the map sending $\mathbf{v}$ to the functional $\beta(\cdot,\mathbf{v})$, that is,

$$\big(R_\beta(\mathbf{v})\big)(\mathbf{u}) = \beta(\mathbf{u},\mathbf{v}) \qquad (\mathbf{u},\mathbf{v} \in V).$$

The letter is local to this section and the subscript names the form; R is for the **right** slot, the one that is fixed. That $R_\beta(\mathbf{v})$ lies in V^* is (B1), and that R_β is linear is (B2). Its kernel has a name.

Definition 13.1.3 — Radical of a Form

Let β be a bilinear form on V. The **radical** of β is

$$\operatorname{rad}(\beta) \coloneqq \{\, \mathbf{v} \in V : \beta(\mathbf{u}, \mathbf{v}) = 0 \text{ for every } \mathbf{u} \in V \,\} = \ker R_\beta,$$

a subspace of V. Its elements are the vectors that **every** vector is orthogonal to.

Definition 13.1.4 — Non-degenerate Form

A bilinear form β on V is **non-degenerate** if $\operatorname{rad}(\beta) = \{\mathbf{0}\}$, that is, if for every **non-zero** $\mathbf{v} \in V$ there **exists** $\mathbf{u} \in V$ with $\beta(\mathbf{u}, \mathbf{v}) \neq 0$. Otherwise β is **degenerate**.

In words: non-degeneracy says that no non-zero vector is invisible to the form. It does not say that $\beta(\mathbf{v}, \mathbf{v}) \neq 0$, and it does not say that β is positive in any sense; it only says that a vector which the form cannot distinguish from $\mathbf{0}$ must be $\mathbf{0}$. On a finite-dimensional space it is a rank condition.

Proposition 13.1.2 — Non-degeneracy is invertibility of the Gram matrix

Let β be a bilinear form on an n-dimensional V with ordered basis $\mathcal{B}$, and put $\mathbf{A} = [\beta]_{\mathcal{B}}$. Then:

(a) $\mathbf{A}$ is the matrix of R_β from the basis $\mathcal{B}$ to the dual basis $\mathcal{B}^*$; that is, $\mathbf{A} = [R_\beta]_{\mathcal{B}}^{\mathcal{B}^*}$.

(b) $\dim \operatorname{rad}(\beta) = n - \operatorname{rank} \mathbf{A}$.

(c) The following are equivalent: β is non-degenerate; $\mathbf{A}$ is invertible; R_β is an isomorphism $V \to V^*$.

Idea. Only (a) has content, and it is one line once the right formula is recalled: the coordinates of a functional in the dual basis are its values on $\mathcal{B}$ (Theorem 4.1.3 (c)), and the values of $R_\beta(\mathbf{v}_j)$ on $\mathcal{B}$ are the entries of the j-th column of $\mathbf{A}$. Parts (b) and (c) are then Rank–Nullity and the invertible matrix theorem, applied to a map we now know the matrix of.

Proof.

(a) By Definition 3.6.1, the j-th column of $[R_\beta]_{\mathcal{B}}^{\mathcal{B}^*}$ is $[R_\beta(\mathbf{v}_j)]_{\mathcal{B}^*}$. By Theorem 4.1.3 (c), a functional $\varphi \in V^*$ has $\varphi = \sum_i \varphi(\mathbf{v}_i)\varphi_i$ in the dual basis $\mathcal{B}^* = (\varphi_1, \dots, \varphi_n)$, so the i-th coordinate of $R_\beta(\mathbf{v}_j)$ is $\big(R_\beta(\mathbf{v}_j)\big)(\mathbf{v}_i) = \beta(\mathbf{v}_i, \mathbf{v}_j) = a_{ij}$. Hence the (i, j) entry of $[R_\beta]_{\mathcal{B}}^{\mathcal{B}^*}$ is a_{ij}, as claimed.

(b) By (a) and Theorem 3.6.5, $\operatorname{rank} R_\beta = \operatorname{rank} \mathbf{A}$. Since $\operatorname{rad}(\beta) = \ker R_\beta$, Rank–Nullity (Theorem 3.3.1) gives $\dim \operatorname{rad}(\beta) = n - \operatorname{rank} \mathbf{A}$.

(c) By (b), $\operatorname{rad}(\beta) = \{\mathbf{0}\}$ if and only if $\operatorname{rank} \mathbf{A} = n$, which by Theorem 2.4.4 is exactly invertibility of $\mathbf{A}$. Since $\dim V^* = n = \dim V$ (Corollary 4.1.4), the map R_β is an isomorphism if and only if it is injective (Corollary 3.3.2 (e)), that is, if and only if its kernel is $\{\mathbf{0}\}$ (Theorem 3.2.3). This proves the proposition.

■

Remark. Freezing the **left** slot instead gives a second map $\mathbf{u} \mapsto \beta(\mathbf{u}, \cdot)$, whose kernel is the **left radical** $\{\mathbf{u} : \beta(\mathbf{u}, \mathbf{v}) = 0 \text{ for all } \mathbf{v}\}$. The same computation shows its matrix is $\mathbf{A}^\top$, so by Theorem 2.5.5 and Theorem 3.3.1 the two radicals have the same dimension — although, as Exercise (B3: Two radicals) shows, they need not be the same subspace. In particular "non-degenerate" means the same thing read from either side, and for the symmetric forms that occupy most of this chapter the two radicals coincide.

Example. (Three radicals)

Find $\operatorname{rad}(\beta)$ and decide degeneracy.

(a) $\beta(\mathbf{x}, \mathbf{y}) = x_1 y_1$ on F^2.
(b) $\beta(\mathbf{x}, \mathbf{y}) = x_1 y_1 - x_2 y_2$ on $\mathbb{R}^2$.
(c) The zero form on any $V \neq \{\mathbf{0}\}$.

Solution.

(a) $[\beta]_{\mathcal{E}} = \left(\begin{smallmatrix} 1 & 0 \\ 0 & 0 \end{smallmatrix}\right)$, of rank 1, so the radical is one-dimensional by Proposition 13.1.2 (b). Explicitly, $\beta(\mathbf{u}, \mathbf{v}) = u_1 v_1$ vanishes for all $\mathbf{u}$ exactly when $v_1 = 0$, so $\operatorname{rad}(\beta) = \operatorname{span}(\mathbf{e}_2)$. Degenerate.

(b) $[\beta]_{\mathcal{E}} = \operatorname{diag}(1, -1)$, invertible, so β is non-degenerate. Yet $\beta\big((1,1),(1,1)\big) = 1 - 1 = 0$: a non-zero vector on which the form vanishes when paired **with itself**. Non-degeneracy forbids a vector orthogonal to everything; it says nothing about a vector orthogonal to itself. This form is the one this chapter returns to twice, in the sections on isotropic vectors and on Minkowski space.

(c) The matrix is 0, of rank 0, and $\operatorname{rad}(\beta) = V$. This is the extreme degenerate case: every vector is invisible.

Warning. **Non-degenerate does not mean definite, and the radical is not the set where $\beta(\mathbf{v}, \mathbf{v}) = 0$.** Example (b) above is non-degenerate, and the set $\{\mathbf{v} : \beta(\mathbf{v}, \mathbf{v}) = 0\}$ is the pair of lines $x_2 = \pm x_1$ — not a subspace, and not the radical, which is $\{\mathbf{0}\}$. Example (c) of Example (Six two-slot functions) has $\beta(\mathbf{v}, \mathbf{v}) = 0$ for **every** $\mathbf{v}$ and is still non-degenerate, since its matrix $\left(\begin{smallmatrix} 0 & 1 \\ -1 & 0 \end{smallmatrix}\right)$ is invertible. An inner-product-trained reader expects "$\beta(\mathbf{v}, \mathbf{v}) = 0 \Rightarrow \mathbf{v} = \mathbf{0}$", and that expectation is a theorem about positive definite forms over $\mathbb{R}$, not about forms.

Quick check. Let β be a bilinear form on a finite-dimensional V, and let $U = \operatorname{rad}(\beta)$. Is β non-degenerate on the subspace U?

Solution. No, unless $U = \{\mathbf{0}\}$ — and then only for a silly reason. The restriction of β to $U \times U$ is the **zero** form, since $\beta(\mathbf{u}, \mathbf{v}) = 0$ already for $\mathbf{u} \in V$ and $\mathbf{v} \in U$. The zero form on a non-zero space is degenerate, so the restriction is non-degenerate exactly when $U = \{\mathbf{0}\}$, that is, exactly when β was non-degenerate to begin with. The point of the question is that "non-degenerate" is a property of a form **on a specified space**, and restricting changes the space.

13.1.4 Exercises

13.1.4.1 A. Check your understanding

Exercise A1.

(a) Define what it means for $\beta\colon V \times V \to F$ to be a bilinear form, stating both clauses in full.

(b) Define the matrix $[\beta]_{\mathcal{B}}$ of a bilinear form with respect to an ordered basis $\mathcal{B}$, and state how $\beta(\mathbf{u}, \mathbf{v})$ is recovered from it.

(c) Determine whether the following is correct, with a reason: every bilinear form on F^n is $\beta(\mathbf{x}, \mathbf{y}) = \mathbf{x}^{\top}\mathbf{A}\mathbf{y}$ for exactly one $\mathbf{A} \in M_n(F)$.

(d) Define the radical of β and state what it means for β to be non-degenerate.

(e) Determine whether the following is correct, with a reason: if $\beta(\mathbf{v}, \mathbf{v}) = 0$ for some $\mathbf{v} \neq \mathbf{0}$, then β is degenerate.

Solution.

(a) Definition 13.1.1: linearity in the left slot for each fixed right argument, (B1), and linearity in the right slot for each fixed left argument, (B2).

(b) Definition 13.1.2: $\big([\beta]_{\mathcal{B}}\big)_{ij} = \beta(\mathbf{v}_i, \mathbf{v}_j)$. Recovery is Theorem 13.1.1 (a): $\beta(\mathbf{u}, \mathbf{v}) = [\mathbf{u}]_{\mathcal{B}}^{\top}[\beta]_{\mathcal{B}}[\mathbf{v}]_{\mathcal{B}}$.

(c) Correct. Existence and uniqueness are Theorem 13.1.1 (c) and (b) with $\mathcal{B} = \mathcal{E}$, for which $[\mathbf{x}]_{\mathcal{E}} = \mathbf{x}$.

(d) Definition 13.1.3 and Definition 13.1.4: $\operatorname{rad}(\beta) = \{\mathbf{v} : \beta(\mathbf{u}, \mathbf{v}) = 0 \text{ for all } \mathbf{u}\}$, and β is non-degenerate when this is $\{\mathbf{0}\}$.

(e) Incorrect. The two conditions are unrelated. The signed area on F^2 has $\beta(\mathbf{v}, \mathbf{v}) = 0$ for every $\mathbf{v}$ and is non-degenerate, since its matrix $\left(\begin{smallmatrix} 0 & 1 \\ -1 & 0 \end{smallmatrix}\right)$ is invertible (Proposition 13.1.2).

13.1.4.2 B. Practice

Exercise B1: Which are forms?.

Determine which of the following are bilinear forms on the given space. Justify your answer; for those that fail, name the clause that fails and give a witness.

(a) On $\mathbb{R}^2$: $\beta(\mathbf{x}, \mathbf{y}) = x_1y_1 + 2x_1y_2 - 3x_2y_1$.

(b) On $\mathbb{R}^2$: $\beta(\mathbf{x}, \mathbf{y}) = x_1y_1 + 1$.

(c) On $\mathbb{R}[x]_{\leq 2}$: $\beta(f, g) = f(1)g(2) - f(0)g(0)$.

(d) On $\mathbb{R}^2$: $\beta(\mathbf{x}, \mathbf{y}) = x_1^2y_1$.

(e) On $M_2(\mathbb{R})$: $\beta(\mathbf{X}, \mathbf{Y}) = \operatorname{tr}(\mathbf{X}^{\top}\mathbf{Y})$.

Solution.

(a) Bilinear: it is $\mathbf{x}^{\top}\mathbf{A}\mathbf{y}$ with $\mathbf{A} = \left(\begin{smallmatrix} 1 & 2 \\ -3 & 0 \end{smallmatrix}\right)$, so Example (Six two-slot functions) (b) applies.

(b) Not bilinear. Clause (B1) fails: $\beta(\mathbf{0},\mathbf{0}) = 1$, whereas homogeneity with $c = 0$ forces $\beta(\mathbf{0},\mathbf{y}) = 0$ for any bilinear form.

(c) Bilinear. Evaluation at a point is linear (Theorem 0.8.5), so for fixed g the map $f \mapsto g(2)f(1) - g(0)f(0)$ is a linear combination of two linear functionals, hence linear; symmetrically in g.

(d) Not bilinear. Clause (B1) fails in the additive half: with $\mathbf{y} = \mathbf{e}_1$, $\beta(\mathbf{e}_1+\mathbf{e}_1,\mathbf{e}_1) = 4$ while $\beta(\mathbf{e}_1,\mathbf{e}_1) + \beta(\mathbf{e}_1,\mathbf{e}_1) = 2$. The homogeneity half fails too, since $\beta(c\mathbf{x},\mathbf{y}) = c^2x_1^2y_1$.

(e) Bilinear. By Theorem 0.9.5 and linearity of the trace (Theorem 0.9.6), for fixed $\mathbf{Y}$ the map $\mathbf{X} \mapsto \operatorname{tr}(\mathbf{X}^\top\mathbf{Y})$ is linear, and for fixed $\mathbf{X}$ the map $\mathbf{Y} \mapsto \operatorname{tr}(\mathbf{X}^\top\mathbf{Y})$ is linear. This is the Frobenius inner product of Chapter 10, seen as a form.

Exercise B2: A Gram matrix from sample values.

On $V = \mathbb{R}[x]_{\le 2}$, define $\beta(f,g) = f(0)g(0) + f(1)g(1) + f(2)g(2)$.

(a) Verify that β is a bilinear form and compute $[\beta]_{\mathcal{B}}$ for $\mathcal{B} = (1, x, x^2)$.

(b) Compute $\beta(1+x,\ x^2-1)$ directly from the definition, and again from the matrix. Check that the answers agree.

(c) Hence decide whether β is non-degenerate.

Solution.

(a) Each of the three terms is a product of two evaluations, hence bilinear as in Exercise (B1: Which are forms?) (c), and a sum of bilinear forms is bilinear by Theorem 13.1.1 (c). Numbering rows and columns $1,2,3$ for $1, x, x^2$, the (i,j) entry is $\sum_{t\in\{0,1,2\}} t^{\,i-1}t^{\,j-1}$, with $0^0 = 1$. So

$$[\beta]_{\mathcal{B}} = \begin{pmatrix} 3 & 3 & 5 \\ 3 & 5 & 9 \\ 5 & 9 & 17 \end{pmatrix}.$$

(b) Directly: $f = 1+x$ takes the values $1,2,3$ at $0,1,2$, and $g = x^2-1$ takes the values $-1,0,3$. So $\beta(f,g) = 1(-1) + 2\cdot 0 + 3\cdot 3 = 8$. From the matrix, $[f]_{\mathcal{B}} = (1,1,0)$ and $[g]_{\mathcal{B}} = (-1,0,1)$, and

$$[\beta]_{\mathcal{B}}[g]_{\mathcal{B}} = (2,6,12), \qquad (1,1,0)\cdot(2,6,12) = 8.$$

(c) Let $\mathbf{M}$ be the matrix with rows $(1,t,t^2)$ for $t = 0,1,2$. Then $[\beta]_{\mathcal{B}} = \mathbf{M}^\top\mathbf{M}$, and $\det\mathbf{M} = 2$ by the Vandermonde formula (Theorem 6.8.1), so $\det[\beta]_{\mathcal{B}} = 4 \neq 0$ by Theorem 6.5.4 and Theorem 6.4.5. By Proposition 13.1.2, β is non-degenerate.

Exercise B3: Two radicals.

On F^3, let $\beta(\mathbf{x},\mathbf{y}) = \mathbf{x}^\top\mathbf{A}\mathbf{y}$ with

$$\mathbf{A} = \begin{pmatrix} 1 & 2 & 3 \\ 2 & 4 & 6 \\ 1 & 2 & 3 \end{pmatrix}.$$

Find $\operatorname{rad}(\beta)$ and the left radical, give a basis of each, and decide whether they are equal.

Solution. Every row of $\mathbf{A}$ is a multiple of $(1,2,3)$, so $\operatorname{rank}\mathbf{A} = 1$ and both radicals have dimension $3-1=2$, by Proposition 13.1.2 (b) and the remark following it.

The radical is $\operatorname{nul}(\mathbf{A}) = \{\mathbf{y} : y_1 + 2y_2 + 3y_3 = 0\}$, with basis $(-2,1,0)$ and $(-3,0,1)$.

The left radical is $\operatorname{nul}(\mathbf{A}^\top)$. Every row of $\mathbf{A}^\top$ is a multiple of $(1,2,1)$, so it is $\{\mathbf{x} : x_1 + 2x_2 + x_3 = 0\}$, with basis $(-2,1,0)$ and $(-1,0,1)$.

They are **not** equal: $(-3,0,1)$ lies in the radical but $-3+0+1 = -2 \neq 0$, so it is not in the left radical. Equal dimensions, different subspaces. In particular β is degenerate.

13.1.4.3 C. Going deeper

Exercise C1: Over $\mathbb{F}_2$.

Let $\beta(\mathbf{x},\mathbf{y}) = x_1y_1 + x_2y_2$ on $V = \mathbb{F}_2^2$.

(a) Write down $[\beta]_{\mathcal{E}}$ and prove that β is non-degenerate.
(b) Find every $\mathbf{v} \in V$ with $\beta(\mathbf{v},\mathbf{v}) = 0$.
(c) Hence explain why the argument "$\beta(\mathbf{v},\mathbf{v}) = 0$ only for $\mathbf{v} = \mathbf{0}$" cannot be used to prove non-degeneracy over a general field, even for the dot product.

Solution.

(a) $[\beta]_{\mathcal{E}} = \mathbf{I}_2$, which is invertible, so β is non-degenerate by Proposition 13.1.2.
(b) $\beta(\mathbf{v},\mathbf{v}) = v_1^2 + v_2^2$. In $\mathbb{F}_2$ every element satisfies $t^2 = t$, so this is $v_1 + v_2$, which vanishes for $\mathbf{v} = (0,0)$ and $\mathbf{v} = (1,1)$. So the non-zero vector $(1,1)$ satisfies $\beta(\mathbf{v},\mathbf{v}) = 0$.
(c) Over $\mathbb{R}$, $\beta(\mathbf{v},\mathbf{v}) = v_1^2 + v_2^2$ is a sum of squares and vanishes only at $\mathbf{0}$, so the implication holds there; the proof uses that a sum of non-negative reals is zero only when each term is. Over $\mathbb{F}_2$ there is no order, nothing is non-negative, and the conclusion is false for $(1,1)$ even though the form is the dot product and is non-degenerate. Non-degeneracy is a statement about the rank of a matrix and survives the change of field; the diagonal statement is a statement about positivity and does not.

Exercise C2: Orthogonal complements for a form.

Let β be a bilinear form on a vector space V with $\dim V = n$, and for a subspace $U \subseteq V$ put

$$U^{\perp_\beta} := \{\, \mathbf{v} \in V : \beta(\mathbf{u},\mathbf{v}) = 0 \text{ for every } \mathbf{u} \in U \,\}.$$

(a) Prove that $U^{\perp_\beta}$ is a subspace and that $\dim U^{\perp_\beta} \geq n - \dim U$.
(b) Prove that equality holds when β is non-degenerate.
(c) Give an example with $\dim U = 1$ in which the inequality in (a) is strict.

Hint: consider the map $V \to U^*$ that sends $\mathbf{v}$ to the restriction of $\beta(\cdot,\mathbf{v})$ to U.

Solution.

(a) Let $\rho\colon V^* \to U^*$ be the restriction map and $S = \rho R_\beta\colon V \to U^*$, so $S(\mathbf{v}) = \beta(\cdot, \mathbf{v})\big|_U$. Both factors are linear, so S is linear, and $U^{\perp_\beta} = \ker S$ by the definition of S; hence $U^{\perp_\beta}$ is a subspace. By Rank–Nullity (Theorem 3.3.1),

$$\dim U^{\perp_\beta} = n - \operatorname{rank} S \geq n - \dim U^* = n - \dim U,$$

using $\operatorname{im} S \subseteq U^*$ and $\dim U^* = \dim U$ (Corollary 4.1.4).

(b) If β is non-degenerate then R_β is an isomorphism (Proposition 13.1.2 (c)), and ρ is surjective (Theorem 4.5.1). So $S = \rho R_\beta$ is surjective, $\operatorname{rank} S = \dim U$, and the inequality in (a) is an equality.

(c) Take $\beta(\mathbf{x}, \mathbf{y}) = x_1 y_1$ on F^2 and $U = \operatorname{span}(\mathbf{e}_2)$. Then $\beta(\mathbf{e}_2, \mathbf{v}) = 0$ for every $\mathbf{v}$, so $U^{\perp_\beta} = F^2$ has dimension 2, while $n - \dim U = 1$. The form is degenerate, as (b) requires it to be.

Exercise C3: The evaluation pairing.

Let V be finite-dimensional and let $W = V^* \times V$. Define β on W by

$$\beta\big((\varphi, \mathbf{v}), (\psi, \mathbf{w})\big) := \psi(\mathbf{v}) + \varphi(\mathbf{w}).$$

(a) Prove that β is a bilinear form on W.

(b) Prove that β is non-degenerate. *Hint: the two summands of an element of the radical can be killed separately.*

(c) Deduce that if $\mathbf{v} \in V$ satisfies $\varphi(\mathbf{v}) = 0$ for every $\varphi \in V^*$, then $\mathbf{v} = \mathbf{0}$, and name the result of Chapter 4 this recovers.

Solution.

(a) Fix $(\psi, \mathbf{w})$. The map $(\varphi, \mathbf{v}) \mapsto \psi(\mathbf{v}) + \varphi(\mathbf{w})$ is the sum of $(\varphi, \mathbf{v}) \mapsto \psi(\mathbf{v})$, which is linear because ψ is and because projection onto the second summand is linear, and $(\varphi, \mathbf{v}) \mapsto \varphi(\mathbf{w}) = \mathrm{ev}_{\mathbf{w}}(\varphi)$, which is linear because $\mathrm{ev}_{\mathbf{w}} \in V^{**}$ (Theorem 4.3.1). So clause (B1) holds. Clause (B2) follows by the same argument with the roles of the two arguments exchanged, since the defining expression is symmetric in them.

(b) Suppose $(\psi, \mathbf{w}) \in \operatorname{rad}(\beta)$, so $\psi(\mathbf{v}) + \varphi(\mathbf{w}) = 0$ for all $\varphi \in V^*$ and all $\mathbf{v} \in V$. Taking $\varphi = 0$ gives $\psi(\mathbf{v}) = 0$ for every $\mathbf{v}$, so $\psi = 0$. Taking $\mathbf{v} = \mathbf{0}$ then gives $\varphi(\mathbf{w}) = 0$ for every $\varphi \in V^*$, so $\mathrm{ev}_{\mathbf{w}} = 0$ in V^{**}, and $\mathbf{w} = \mathbf{0}$ because ev_V is injective (Theorem 4.3.1). Hence the radical is $\{\mathbf{0}\}$.

(c) The second half of (b) is exactly that statement: $\varphi(\mathbf{v}) = 0$ for all $\varphi \in V^*$ forces $\mathbf{v} = \mathbf{0}$. It recovers the injectivity of the evaluation map $\mathrm{ev}_V : V \to V^{**}$ of Theorem 4.3.1, which is the first half of Theorem 4.3.2. So the non-degeneracy of this form is the statement that functionals separate points (Theorem 4.1.5).

13.2 Congruence

The matrix of a form in Definition 13.1.2 depends on a basis, and a basis is a choice. As with linear maps in Chapter 3, the useful question is therefore not "what is the matrix?" but "which matrices arise from the same form?". The answer here is $\mathbf{P}^{\top}\mathbf{A}\mathbf{P}$ rather than $\mathbf{P}^{-1}\mathbf{A}\mathbf{P}$, and one symbol's difference changes the whole theory: the new relation keeps the rank and the symmetry type of a matrix and throws its eigenvalues away. This section proves the change-of-basis rule, names the relation, sorts the invariants from the casualties, and settles the debt Chapters 11 and 12 ran up when they kept postponing all of this.

Throughout, V is a vector space over an arbitrary field F with $\dim V = n \geq 1$, and β is a bilinear form on V. **No hypothesis on the characteristic of F is needed in this section.**

13.2.1 The change-of-basis rule for a form

Two bases $\mathcal{B}$ and $\mathcal{B}'$ of V give two matrices for one form. The link between them is the change-of-coordinates matrix of Definition 3.7.1, and the computation is three lines, because Theorem 13.1.1 (a) already expresses the form through coordinates.

Theorem 13.2.1 — Change of Basis for a Form

Let β be a bilinear form on a finite-dimensional V, let $\mathcal{B}$ and $\mathcal{B}'$ be ordered bases of V, and let $\mathbf{P} = [\mathrm{id}]_{\mathcal{B}'}^{\mathcal{B}}$ be the change-of-coordinates matrix from $\mathcal{B}'$ to $\mathcal{B}$. Then

$$[\beta]_{\mathcal{B}'} = \mathbf{P}^{\top}\,[\beta]_{\mathcal{B}}\,\mathbf{P}.$$

Idea. There is nothing to discover: write the form in $\mathcal{B}$-coordinates, substitute $[\mathbf{v}]_{\mathcal{B}} = \mathbf{P}[\mathbf{v}]_{\mathcal{B}'}$ in both slots, and read off the matrix that appears between the two coordinate vectors. The uniqueness clause of Theorem 13.1.1 then says that matrix is the one we want, with no further checking.

Proof. Write $\mathbf{A} = [\beta]_{\mathcal{B}}$. By Theorem 3.7.1 (a), $[\mathbf{v}]_{\mathcal{B}} = \mathbf{P}[\mathbf{v}]_{\mathcal{B}'}$ for every $\mathbf{v} \in V$. So for all $\mathbf{u}, \mathbf{v} \in V$, using Theorem 13.1.1 (a) and then Theorem 0.9.5 (part 4),

$$\begin{aligned}\beta(\mathbf{u},\mathbf{v}) &= [\mathbf{u}]_{\mathcal{B}}^{\top}\,\mathbf{A}\,[\mathbf{v}]_{\mathcal{B}} \\ &= \left(\mathbf{P}[\mathbf{u}]_{\mathcal{B}'}\right)^{\top}\mathbf{A}\left(\mathbf{P}[\mathbf{v}]_{\mathcal{B}'}\right) \\ &= [\mathbf{u}]_{\mathcal{B}'}^{\top}\left(\mathbf{P}^{\top}\mathbf{A}\mathbf{P}\right)[\mathbf{v}]_{\mathcal{B}'}.\end{aligned}$$

Thus $\mathbf{P}^{\top}\mathbf{A}\mathbf{P}$ is a matrix with the property that characterizes $[\beta]_{\mathcal{B}'}$, and by the uniqueness in Theorem 13.1.1 (b) it **is** $[\beta]_{\mathcal{B}'}$. This proves the theorem. ∎

Notice that $\mathbf{P}$ is the same matrix as in Theorem 3.7.3: the change-of-coordinates matrix from the **new** basis to the **old** one, whose columns are the new basis vectors written in old coordinates. Only the way it acts has changed, from $\mathbf{P}^{-1}\mathbf{A}\mathbf{P}$ to $\mathbf{P}^{\top}\mathbf{A}\mathbf{P}$.

Example. (Killing the cross term)

On $\mathbb{R}^2$, let $\beta(\mathbf{x},\mathbf{y}) = x_1y_1 + 2x_1y_2 + 2x_2y_1 + x_2y_2$, so that

$$\mathbf{A} = [\beta]_{\mathcal{E}} = \begin{pmatrix} 1 & 2 \\ 2 & 1 \end{pmatrix}.$$

Compute $[\beta]_{\mathcal{B}'}$ for $\mathcal{B}' = \big((1,0),\ (-2,1)\big)$, both by Theorem 13.2.1 and directly from Definition 13.1.2.

Solution. The columns of $\mathbf{P} = [\mathrm{id}]^{\mathcal{E}}_{\mathcal{B}'}$ are the vectors of $\mathcal{B}'$ in standard coordinates, so

$$\mathbf{P} = \begin{pmatrix} 1 & -2 \\ 0 & 1 \end{pmatrix}, \qquad \mathbf{AP} = \begin{pmatrix} 1 & 0 \\ 2 & -3 \end{pmatrix},$$

and therefore

$$\mathbf{P}^{\top}\mathbf{AP} = \begin{pmatrix} 1 & 0 \\ -2 & 1 \end{pmatrix}\begin{pmatrix} 1 & 0 \\ 2 & -3 \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ 0 & -3 \end{pmatrix}.$$

Directly: with $\mathbf{v}'_1 = (1,0)$ and $\mathbf{v}'_2 = (-2,1)$, the four values are $\beta(\mathbf{v}'_1,\mathbf{v}'_1) = 1$, $\beta(\mathbf{v}'_1,\mathbf{v}'_2) = \beta(\mathbf{v}'_2,\mathbf{v}'_1) = 0$ and $\beta(\mathbf{v}'_2,\mathbf{v}'_2) = -3$. The two computations agree.

The new basis was not guessed. In coordinates the form reads $q(\mathbf{x}) = x_1^2 + 4x_1x_2 + x_2^2 = (x_1 + 2x_2)^2 - 3x_2^2$, a perfect square plus a leftover, and the substitution $y_1 = x_1 + 2x_2$, $y_2 = x_2$ — that is, $\mathbf{x} = \mathbf{Py}$ — is what completing the square asks for. A later section turns this into a theorem and an algorithm.

13.2.2 Congruent matrices

Every invertible $\mathbf{P}$ is a change-of-coordinates matrix between some pair of bases (Proposition 3.7.2), so Theorem 13.2.1 says exactly this: the matrices of one form, over all bases, are the matrices $\mathbf{P}^{\top}\mathbf{AP}$ with $\mathbf{P}$ invertible. That set deserves a name, and the name is the organizing idea of the chapter.

Two matrices are congruent when they record the same form in two bases.

Definition 13.2.1 — Congruent Matrices

Let $\mathbf{A},\mathbf{B} \in M_n(F)$. We say $\mathbf{A}$ is **congruent** to $\mathbf{B}$, written $\mathbf{A} \simeq \mathbf{B}$, if there **exists** an **invertible** $\mathbf{P} \in M_n(F)$ such that

$$\mathbf{B} = \mathbf{P}^{\top}\mathbf{AP}.$$

In words: congruence allows one matrix to be sandwiched by an invertible matrix and its transpose. The word **invertible** is essential; without it, $\mathbf{A} \mapsto \mathbf{P}^{\top}\mathbf{AP}$ with $\mathbf{P} = 0$ would relate everything to 0. The **transpose**, not the inverse, is what distinguishes the relation from similarity (Definition 3.7.2), and the symbol $\simeq$ is chosen to sit near $\sim$ without being it.

Three immediate readings. First, by Theorem 13.2.1, $\mathbf{A} \simeq \mathbf{B}$ if and only if $\mathbf{A}$ and $\mathbf{B}$ are the matrices of a single bilinear form in two bases. Second, in the language of quadratic expressions on F^n, $\mathbf{A} \simeq \mathbf{B}$ says that the substitution $\mathbf{x} = \mathbf{Py}$ turns $\mathbf{x}^{\top}\mathbf{Ax}$ into $\mathbf{y}^{\top}\mathbf{By}$: congruence is

invertible change of variables in a quadratic expression. Third, over $\mathbb{R}$ it is the relation $\mathbf{A} \mapsto \mathbf{S}^*\mathbf{A}\mathbf{S}$ of Chapter 12, because there the star is the transpose.

Example. (Congruences and a non-congruence)

(a) $\mathbf{I}_2 \simeq \left(\begin{smallmatrix} 1 & 1 \\ 1 & 2 \end{smallmatrix}\right)$ over any field.
(b) $\mathbf{I}_2 \simeq \operatorname{diag}(4, 1)$ over $\mathbb{Q}$.
(c) $\mathbf{A} \simeq \mathbf{A}$ for every $\mathbf{A}$.
(d) $\mathbf{I}_2 \not\simeq \left(\begin{smallmatrix} 1 & 1 \\ 0 & 1 \end{smallmatrix}\right)$ over any field.

Solution.

(a) Take $\mathbf{P} = \left(\begin{smallmatrix} 1 & 1 \\ 0 & 1 \end{smallmatrix}\right)$, which is invertible with determinant 1. Then $\mathbf{P}^\top \mathbf{I}_2 \mathbf{P} = \mathbf{P}^\top \mathbf{P} = \left(\begin{smallmatrix} 1 & 1 \\ 1 & 2 \end{smallmatrix}\right)$.
(b) Take $\mathbf{P} = \operatorname{diag}(2, 1)$, invertible over $\mathbb{Q}$. Then $\mathbf{P}^\top \mathbf{I}_2 \mathbf{P} = \operatorname{diag}(4, 1)$. Scaling a basis vector by c scales the corresponding diagonal entry by c^2, which is the single most useful congruence to have in mind.
(c) Take $\mathbf{P} = \mathbf{I}_n$.
(d) Suppose $\left(\begin{smallmatrix} 1 & 1 \\ 0 & 1 \end{smallmatrix}\right) = \mathbf{P}^\top \mathbf{I}_2 \mathbf{P} = \mathbf{P}^\top \mathbf{P}$ for some $\mathbf{P}$. Then, by Theorem 0.9.5, $(\mathbf{P}^\top \mathbf{P})^\top = \mathbf{P}^\top \mathbf{P}$, so the matrix would be symmetric; it is not. This is the non-example by minimal change: one entry of $\left(\begin{smallmatrix} 1 & 1 \\ 1 & 2 \end{smallmatrix}\right)$ in (a) is altered, and congruence to $\mathbf{I}_2$ is lost — not for a subtle reason, but because the altered matrix is not the matrix of a symmetric form in any basis. The general statement is Proposition 13.2.4 below.

Before using the word "congruent" in both directions, we owe the usual check.

Proposition 13.2.2 — Congruence is an equivalence relation

Congruence is an equivalence relation on $M_n(F)$ (Definition 0.5.2).

Proof. Reflexive: $\mathbf{A} = \mathbf{I}_n^\top \mathbf{A} \mathbf{I}_n$.

Symmetric: suppose $\mathbf{B} = \mathbf{P}^\top \mathbf{A} \mathbf{P}$ with $\mathbf{P}$ invertible, and put $\mathbf{Q} = \mathbf{P}^{-1}$, which is invertible. By Theorem 0.9.5 (part 4), $\mathbf{Q}^\top \mathbf{P}^\top = (\mathbf{P}\mathbf{Q})^\top = \mathbf{I}_n^\top = \mathbf{I}_n$, so

$$\mathbf{Q}^\top \mathbf{B} \mathbf{Q} = \big(\mathbf{Q}^\top \mathbf{P}^\top\big) \mathbf{A} \big(\mathbf{P}\mathbf{Q}\big) = \mathbf{I}_n \mathbf{A} \mathbf{I}_n = \mathbf{A}.$$

Transitive: if $\mathbf{B} = \mathbf{P}^\top \mathbf{A} \mathbf{P}$ and $\mathbf{C} = \mathbf{Q}^\top \mathbf{B} \mathbf{Q}$ with $\mathbf{P}, \mathbf{Q}$ invertible, then $\mathbf{P}\mathbf{Q}$ is invertible and $\mathbf{C} = \mathbf{Q}^\top \mathbf{P}^\top \mathbf{A} \mathbf{P} \mathbf{Q} = (\mathbf{P}\mathbf{Q})^\top \mathbf{A} (\mathbf{P}\mathbf{Q})$. This proves the proposition.

■

So the matrices in $M_n(F)$ fall into congruence classes, and the classification problem of this chapter is to describe them. The rest of the section collects the tools for telling classes apart.

13.2.3 What congruence preserves

Three invariants come out of the definition with almost no work. The first is the rank, which we already know is the co-dimension of the radical (Proposition 13.1.2).

Theorem 13.2.3 — Congruence preserves rank

Let $\mathbf{A}, \mathbf{B} \in M_n(F)$ with $\mathbf{A} \simeq \mathbf{B}$. Then $\operatorname{rank} \mathbf{A} = \operatorname{rank} \mathbf{B}$. Consequently, whether the associated form is non-degenerate is a property of the congruence class, and it is legitimate to speak of the **rank of a bilinear form**, meaning the rank of its matrix in any basis.

Proof. Write $\mathbf{B} = \mathbf{P}^{\top}\mathbf{A}\mathbf{P}$ with $\mathbf{P}$ invertible. Then $\mathbf{P}^{\top}$ is invertible, with inverse $(\mathbf{P}^{-1})^{\top}$ (Theorem 0.9.5). Multiplying by invertible matrices on either side does not change the rank (Theorem 2.5.9), so $\operatorname{rank} \mathbf{B} = \operatorname{rank}(\mathbf{A}\mathbf{P}) = \operatorname{rank} \mathbf{A}$. Non-degeneracy is the condition $\operatorname{rank} \mathbf{A} = n$ by Proposition 13.1.2 (c), so it too depends only on the class. The last sentence follows because, by Theorem 13.2.1, any two matrices of one form are congruent.

■

The second invariant is the symmetry type. Here "alternating" is used in the matrix sense that Definition 6.2.2 suggests: a **zero diagonal** on top of skew-symmetry. The next section separates the three conditions carefully; for now we only need that congruence respects each of them.

Proposition 13.2.4 — Congruence preserves the symmetry type

Let $\mathbf{A}, \mathbf{B} \in M_n(F)$ with $\mathbf{B} = \mathbf{P}^{\top}\mathbf{A}\mathbf{P}$ for an invertible $\mathbf{P}$.

(a) If $\mathbf{A}^{\top} = \mathbf{A}$, then $\mathbf{B}^{\top} = \mathbf{B}$.
(b) If $\mathbf{A}^{\top} = -\mathbf{A}$, then $\mathbf{B}^{\top} = -\mathbf{B}$.
(c) If $\mathbf{A}^{\top} = -\mathbf{A}$ and every diagonal entry of $\mathbf{A}$ is 0, the same holds for $\mathbf{B}$.

Each implication is an equivalence, since congruence is symmetric (Proposition 13.2.2).

Proof. By Theorem 0.9.5, $\mathbf{B}^{\top} = (\mathbf{P}^{\top}\mathbf{A}\mathbf{P})^{\top} = \mathbf{P}^{\top}\mathbf{A}^{\top}\mathbf{P}$.

(a) If $\mathbf{A}^{\top} = \mathbf{A}$, this is $\mathbf{P}^{\top}\mathbf{A}\mathbf{P} = \mathbf{B}$.
(b) If $\mathbf{A}^{\top} = -\mathbf{A}$, it is $\mathbf{P}^{\top}(-\mathbf{A})\mathbf{P} = -\mathbf{B}$.
(c) Assume the hypothesis of (c). Then $\mathbf{B}$ is skew-symmetric by (b), so only the diagonal is left to check. For any $\mathbf{x} \in F^n$, grouping the terms of the double sum in pairs,

$$\mathbf{x}^{\top}\mathbf{A}\mathbf{x} = \sum_{i<j} (a_{ij} + a_{ji}) x_i x_j + \sum_i a_{ii} x_i^2 = 0,$$

since $a_{ij} + a_{ji} = 0$ by skew-symmetry and $a_{ii} = 0$ by hypothesis. Writing $\mathbf{p}_1, \dots, \mathbf{p}_n$ for the columns of $\mathbf{P}$, the i-th diagonal entry of $\mathbf{B} = \mathbf{P}^{\top}\mathbf{A}\mathbf{P}$ is $b_{ii} = \mathbf{e}_i^{\top}\mathbf{P}^{\top}\mathbf{A}\mathbf{P}\mathbf{e}_i = \mathbf{p}_i^{\top}\mathbf{A}\mathbf{p}_i$, which is 0 by the display. This proves the proposition.

■

The third invariant is the determinant, but only in a weakened sense: congruence multiplies it by a square.

Theorem 13.2.5 — Congruence changes the determinant by a square

Let $\mathbf{A}, \mathbf{B} \in M_n(F)$ with $\mathbf{B} = \mathbf{P}^\top \mathbf{A} \mathbf{P}$ for an invertible $\mathbf{P}$. Then

$$\det \mathbf{B} = (\det \mathbf{P})^2 \det \mathbf{A},$$

with $\det \mathbf{P} \neq 0$. In particular $\det \mathbf{A} = 0$ if and only if $\det \mathbf{B} = 0$, and when they are non-zero, $\det \mathbf{B} = c^2 \det \mathbf{A}$ for some $c \in F \setminus \{0\}$.

Proof. By Theorem 6.5.4 and Theorem 6.4.5,

$$\det \mathbf{B} = \det(\mathbf{P}^\top) \det \mathbf{A} \det \mathbf{P} = (\det \mathbf{P})^2 \det \mathbf{A}.$$

Since $\mathbf{P}$ is invertible, $\det \mathbf{P} \neq 0$ (Theorem 6.5.2), so $(\det \mathbf{P})^2 \neq 0$ and the two determinants vanish together. Taking $c = \det \mathbf{P}$ gives the last claim.

■

The determinant itself is therefore **not** a congruence invariant — Example (Congruences and a non-congruence) (b) moved it from 1 to 4. What is invariant is the determinant read modulo squares. Write $F^\times = F \setminus \{0\}$, and for $a, b \in F^\times$ declare a and b equivalent when $a = c^2 b$ for some $c \in F^\times$. This is an equivalence relation on $F^\times$ (Definition 0.5.2): it is reflexive with $c = 1$, symmetric with c^{-1}, and transitive by multiplying the two scalars. Its classes are called **square classes**, and the set of them is commonly written $F^\times / (F^\times)^2$.

Definition 13.2.2 — Discriminant

Let β be a **non-degenerate** bilinear form on an n-dimensional V. The **discriminant** of β is the square class of $\det [\beta]_{\mathcal{B}}$ in $F^\times$, for any ordered basis $\mathcal{B}$ of V.

This is well defined by Theorem 13.2.5 and Theorem 13.2.1: another basis changes the determinant by the square $(\det \mathbf{P})^2$, hence not its class. The discriminant is coarse but genuinely useful, and how much it sees depends entirely on the field. Over $\mathbb{C}$ every non-zero number is a square, so there is only one class and the discriminant says nothing. Over $\mathbb{R}$ there are two, $\{t > 0\}$ and $\{t < 0\}$, so the discriminant records one bit: the sign of the determinant. Over $\mathbb{Q}$ there are infinitely many, and the discriminant is a strong invariant.

Quick check. Over $\mathbb{R}$, are $\operatorname{diag}(1, 1)$ and $\operatorname{diag}(-1, -1)$ distinguished by their discriminants?

Solution. No. Both determinants equal 1, so the discriminants agree. And yet the two matrices are not congruent over $\mathbb{R}$. Suppose $\operatorname{diag}(-1, -1) = \mathbf{P}^\top \mathbf{I}_2 \mathbf{P} = \mathbf{P}^\top \mathbf{P}$ for an

invertible $\mathbf{P}$. Evaluating both sides on $\mathbf{x} = \mathbf{e}_1$ gives

$$-1 = \mathbf{e}_1^{\top} \operatorname{diag}(-1,-1)\mathbf{e}_1 = \mathbf{e}_1^{\top}\mathbf{P}^{\top}\mathbf{P}\mathbf{e}_1 = \|\mathbf{P}\mathbf{e}_1\|^2 \geq 0,$$

a contradiction. So the discriminant is not a complete invariant, even over $\mathbb{R}$ and even for 2×2 matrices. Proving that the full "sign pattern" *is* an invariant, and that it is the complete one over $\mathbb{R}$, is the law of inertia, proved later in this chapter.

13.2.4 What congruence destroys

Now the negative result of the section, and the reason the previous three chapters could not have been this one.

Example. (Congruent, with no eigenvalue in common)

(a) $\mathbf{I}_2 \simeq \left(\begin{smallmatrix} 1 & 1 \\ 1 & 2 \end{smallmatrix}\right)$ by Example (Congruences and a non-congruence) (a). Compare their eigenvalues.

(b) $\left(\begin{smallmatrix} 1 & 2 \\ 2 & 1 \end{smallmatrix}\right) \simeq \operatorname{diag}(1,-3)$ by Example (Killing the cross term). Compare their eigenvalues.

Solution.

(a) $\mathbf{I}_2$ has the single eigenvalue 1, twice. The characteristic polynomial of $\left(\begin{smallmatrix} 1 & 1 \\ 1 & 2 \end{smallmatrix}\right)$ is $x^2 - 3x + 1$, whose roots are $(3 \pm \sqrt{5})/2$, that is, approximately 2.618 and 0.382. The two matrices share no eigenvalue. They do share a rank, 2; a symmetry type, symmetric; and a discriminant, since $\det = 1$ for both.

(b) The characteristic polynomial of $\left(\begin{smallmatrix} 1 & 2 \\ 2 & 1 \end{smallmatrix}\right)$ is $x^2 - 2x - 3 = (x-3)(x+1)$, so its eigenvalues are 3 and -1. Those of $\operatorname{diag}(1,-3)$ are 1 and -3. Again no eigenvalue in common — but this time one positive and one negative on each side, and the determinants are -3 both times. The signs survived; the numbers did not. That is the pattern the law of inertia will explain.

Chapter 12 introduced this operation twice and both times deferred it to here. Section 1 of that chapter wrote that "the operation $\mathbf{A} \mapsto \mathbf{S}^*\mathbf{A}\mathbf{S}$ is called **congruence**, and Chapter 13 studies it for its own sake", keeping only that it preserves the sign of a positive form (Proposition 12.1.2). Section 4 repeated the promise in fuller form: "Chapter 13 studies congruence in its own right, including what it does preserve; for now, note that it certainly does **not** preserve eigenvalues, since $\mathbf{S}^*\mathbf{I}\mathbf{S} = \mathbf{S}^*\mathbf{S}$ can be any positive definite matrix at all."

Both debts are now paid, and it is worth saying the answer in one place. **What congruence preserves:** the rank (Theorem 13.2.3), and with it non-degeneracy and the dimension of the radical; the symmetry type (Proposition 13.2.4); and the square class of the determinant when that is non-zero (Theorem 13.2.5), the discriminant. Over $\mathbb{R}$ it preserves one thing more, the triple of signs, and that is the deepest of the four; it is proved in the section on inertia. **What congruence destroys:** the eigenvalues, and therefore the characteristic polynomial, the trace and the determinant itself. Not every similarity invariant is lost — rank and invertibility, parts (a) and (b) of Proposition 3.7.6, survive both relations — but every invariant that reads the eigenvalues is. Chapter 12's parenthetical remark is exactly right and can be made sharper: taking $\mathbf{A} = \mathbf{I}_n$ in Definition 13.2.1, the congruence class of $\mathbf{I}_n$ over $\mathbb{R}$ is the set of all matrices $\mathbf{P}^{\top}\mathbf{P}$ with $\mathbf{P}$ invertible, which by Theorem 12.1.5 (c) is the set of **all** positive definite matrices.

One class, every spectrum with all eigenvalues positive.

Warning. **Congruent and similar are different relations, and neither implies the other.** By Example (Congruent, with no eigenvalue in common) (a), $\mathbf{I}_2 \simeq \left(\begin{smallmatrix} 1 & 1 \\ 1 & 2 \end{smallmatrix}\right)$, while the only matrix similar to $\mathbf{I}_2$ is $\mathbf{I}_2$ itself, since $\mathbf{P}^{-1}\mathbf{I}_2\mathbf{P} = \mathbf{I}_2$ for every invertible $\mathbf{P}$. In the other direction, $\operatorname{diag}(1,2)$ is similar to $\left(\begin{smallmatrix} 1 & -1 \\ 0 & 2 \end{smallmatrix}\right)$ — conjugate by $\left(\begin{smallmatrix} 1 & 1 \\ 0 & 1 \end{smallmatrix}\right)$ — but not congruent to it, because $\operatorname{diag}(1,2)$ is symmetric and the other matrix is not (Proposition 13.2.4). So do not carry any habit across. In particular, "diagonalizable" means two different things in this chapter, and a matrix that is diagonalizable by congruence need not be diagonalizable by similarity, nor conversely.

13.2.5 Where the two relations meet

There is exactly one situation in which the confusion is harmless: when the change-of-basis matrix satisfies $\mathbf{P}^{\top} = \mathbf{P}^{-1}$, that is, when $\mathbf{P}$ is orthogonal (Definition 10.7.3).

Proposition 13.2.6 — An orthogonal change of basis is both

Let $\mathbf{A} \in M_n(\mathbb{R})$ and $\mathbf{Q} \in \mathrm{O}(n)$. Then $\mathbf{Q}^{\top}\mathbf{A}\mathbf{Q} = \mathbf{Q}^{-1}\mathbf{A}\mathbf{Q}$, so this matrix is at once congruent and similar to $\mathbf{A}$. Consequently, if $\mathbf{A}$ is symmetric, then $\mathbf{A}$ is congruent to the diagonal matrix $\mathbf{D}$ of its eigenvalues, listed with multiplicity in any prescribed order.

Proof. The first statement is the definition of an orthogonal matrix, $\mathbf{Q}^{\top}\mathbf{Q} = \mathbf{I}_n$, which gives $\mathbf{Q}^{\top} = \mathbf{Q}^{-1}$; the matrix $\mathbf{Q}^{\top}\mathbf{A}\mathbf{Q}$ is then congruent to $\mathbf{A}$ by Definition 13.2.1, since $\mathbf{Q}$ is invertible, and similar to $\mathbf{A}$ by Definition 3.7.2.

For the second statement, let $\mathbf{A}$ be symmetric. By Corollary 11.5.2 there are $\mathbf{Q} \in \mathrm{O}(n)$ and a real diagonal $\mathbf{D}$, carrying the eigenvalues of $\mathbf{A}$ in any prescribed order, with $\mathbf{A} = \mathbf{Q}\mathbf{D}\mathbf{Q}^{\top}$. Multiplying on the left by $\mathbf{Q}^{\top}$ and on the right by $\mathbf{Q}$ gives $\mathbf{D} = \mathbf{Q}^{\top}\mathbf{A}\mathbf{Q}$, which is a congruence. This proves the proposition.

■

This is why the real spectral theorem is so strong, and it is what Chapter 11 meant when it said, of the principal axis theorem, that "an orthogonal change of variables is a similarity *and* a congruence, so it keeps the eigenvalues and the geometry at once". The general theory of this chapter has no orthogonal matrices to call on — a general field has no inner product, hence no orthogonal group in that sense — so the two relations part company and only congruence remains. What Proposition 13.2.6 gives over $\mathbb{R}$ is a bridge: it says that every real symmetric matrix is congruent to a diagonal matrix, and it identifies the diagonal entries as eigenvalues. The section on inertia will show that the entries are free to move but their signs are not, which is how the two pictures are finally reconciled.

Quick check. Over $\mathbb{R}$, which matrices are congruent to $\mathbf{I}_n$?

Solution. Exactly the positive definite symmetric matrices. If $\mathbf{B} = \mathbf{P}^{\top}\mathbf{I}_n\mathbf{P} = \mathbf{P}^{\top}\mathbf{P}$ with $\mathbf{P}$ invertible, then $\mathbf{B}$ is symmetric and $\mathbf{x}^{\top}\mathbf{B}\mathbf{x} = \|\mathbf{P}\mathbf{x}\|^2 > 0$ for $\mathbf{x} \neq \mathbf{0}$, since $\mathbf{P}\mathbf{x} \neq \mathbf{0}$. Conversely every positive definite $\mathbf{B}$ is $\mathbf{P}^{\top}\mathbf{P}$ for an invertible $\mathbf{P}$ by Theorem 12.1.5. Compare the similarity class of $\mathbf{I}_n$, which contains $\mathbf{I}_n$ alone: one relation collapses this

class to a point, the other spreads it over every positive definite matrix there is.

13.2.6 Exercises

13.2.6.1 A. Check your understanding

Exercise A1.

(a) State the change-of-basis rule for the matrix of a bilinear form, saying which matrix $\mathbf{P}$ appears.

(b) Define what it means for $\mathbf{A}, \mathbf{B} \in M_n(F)$ to be congruent.

(c) For each of rank, symmetry, determinant, eigenvalues and the square class of a non-zero determinant, say whether it is a congruence invariant.

(d) Determine whether the following is correct, with a reason: congruent matrices are similar.

(e) State the one circumstance in which a change of basis is simultaneously a similarity and a congruence.

Solution.

(a) Theorem 13.2.1: $[\beta]_{\mathcal{B}'} = \mathbf{P}^\top [\beta]_{\mathcal{B}} \mathbf{P}$, where $\mathbf{P} = [\mathrm{id}]^{\mathcal{B}}_{\mathcal{B}'}$ is the change-of-coordinates matrix from the new basis to the old one.

(b) Definition 13.2.1: $\mathbf{B} = \mathbf{P}^\top \mathbf{A} \mathbf{P}$ for some invertible $\mathbf{P} \in M_n(F)$.

(c) Invariant: rank (Theorem 13.2.3); symmetry (Proposition 13.2.4); the square class of a non-zero determinant (Theorem 13.2.5). Not invariant: the determinant itself, and the eigenvalues (Example (Congruent, with no eigenvalue in common)).

(d) Incorrect. $\mathbf{I}_2 \simeq \left(\begin{smallmatrix} 1 & 1 \\ 1 & 2 \end{smallmatrix}\right)$, but the only matrix similar to $\mathbf{I}_2$ is $\mathbf{I}_2$.

(e) When the change-of-coordinates matrix $\mathbf{P}$ satisfies $\mathbf{P}^\top = \mathbf{P}^{-1}$, that is, when $\mathbf{P}$ is orthogonal (Proposition 13.2.6).

13.2.6.2 B. Practice

Exercise B1: A congruence in $\mathbb{Q}$.

Let $\mathbf{A} = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$ and $\mathbf{P} = \left(\begin{smallmatrix} 1 & 1 \\ 1 & -1 \end{smallmatrix}\right)$, both over $\mathbb{Q}$.

(a) Compute $\mathbf{P}^\top \mathbf{A} \mathbf{P}$, and hence write down a matrix congruent to $\mathbf{A}$ that is diagonal.

(b) Find the eigenvalues of both matrices and compare them.

(c) Compute the discriminant of the form $\mathbf{x}^\top \mathbf{A} \mathbf{y}$ and check that it agrees for the two matrices.

Solution.

(a) $\mathbf{P}$ is invertible, with $\det \mathbf{P} = -2 \neq 0$. Then

$$\mathbf{A}\mathbf{P} = \begin{pmatrix} 1 & -1 \\ 1 & 1 \end{pmatrix}, \qquad \mathbf{P}^\top \mathbf{A} \mathbf{P} = \begin{pmatrix} 2 & 0 \\ 0 & -2 \end{pmatrix}.$$

So $\mathbf{A} \simeq \operatorname{diag}(2,-2)$ over $\mathbb{Q}$.

(b) The characteristic polynomial of $\mathbf{A}$ is x^2-1, so its eigenvalues are 1 and -1; those of $\operatorname{diag}(2,-2)$ are 2 and -2. No eigenvalue is shared, and each matrix has one positive and one negative eigenvalue.

(c) $\det \mathbf{A} = -1$ and $\det \operatorname{diag}(2,-2) = -4 = (-2)^2 \cdot (-1)$, which is the relation $\det \mathbf{B} = (\det \mathbf{P})^2 \det \mathbf{A}$ of Theorem 13.2.5. The two determinants differ by the square 4, so they lie in the same square class of $\mathbb{Q}^\times$ and the discriminants agree, as Definition 13.2.2 requires.

Exercise B2: A non-congruence over $\mathbb{Q}$.

(a) Prove that $\operatorname{diag}(1,1)$ and $\operatorname{diag}(1,2)$ are **not** congruent over $\mathbb{Q}$.

(b) Prove that they **are** congruent over $\mathbb{R}$, by exhibiting $\mathbf{P}$.

(c) Explain in one sentence why (a) and (b) are consistent.

Solution.

(a) Suppose $\operatorname{diag}(1,2) = \mathbf{P}^\top \operatorname{diag}(1,1)\mathbf{P}$ with $\mathbf{P} \in M_2(\mathbb{Q})$ invertible. By Theorem 13.2.5, $2 = (\det \mathbf{P})^2 \cdot 1$, so $\det \mathbf{P} \in \mathbb{Q}$ would satisfy $(\det \mathbf{P})^2 = 2$. No rational number squares to 2 (Theorem 0.2.3), a contradiction. Hence the two are not congruent over $\mathbb{Q}$.

(b) Take $\mathbf{P} = \operatorname{diag}(1, 1/\sqrt{2})$, which is invertible over $\mathbb{R}$. Then $\mathbf{P}^\top \operatorname{diag}(1,2)\mathbf{P} = \operatorname{diag}(1,1)$, and congruence is symmetric (Proposition 13.2.2).

(c) Congruence is a relation **over a specified field**: the matrix $\mathbf{P}$ is required to have entries in that field, and $1/\sqrt{2}$ is available in $\mathbb{R}$ but not in $\mathbb{Q}$. Equivalently, 2 is a square in $\mathbb{R}^\times$ and not in $\mathbb{Q}^\times$, so the discriminant separates the two matrices over $\mathbb{Q}$ and not over $\mathbb{R}$.

Exercise B3: Completing the square, again.

On $\mathbb{R}^2$, let $\beta(\mathbf{x},\mathbf{y}) = x_1y_1 - x_1y_2 - x_2y_1 + 2x_2y_2$.

(a) Write down $\mathbf{A} = [\beta]_{\mathcal{E}}$ and expand $q(\mathbf{x}) = \beta(\mathbf{x},\mathbf{x})$ as a polynomial in x_1, x_2.

(b) Complete the square to find a basis $\mathcal{B}'$ with $[\beta]_{\mathcal{B}'} = \mathbf{I}_2$. Verify by computing $\mathbf{P}^\top\mathbf{A}\mathbf{P}$.

(c) Hence find the eigenvalues of $\mathbf{A}$ and compare them with those of $\mathbf{I}_2$.

Solution.

(a) $\mathbf{A} = \left(\begin{smallmatrix} 1 & -1 \\ -1 & 2 \end{smallmatrix}\right)$, and $q(\mathbf{x}) = x_1^2 - 2x_1x_2 + 2x_2^2$.

(b) $q(\mathbf{x}) = (x_1 - x_2)^2 + x_2^2$. So the substitution $y_1 = x_1 - x_2$, $y_2 = x_2$, that is $x_1 = y_1 + y_2$ and $x_2 = y_2$, makes $q = y_1^2 + y_2^2$. This is $\mathbf{x} = \mathbf{P}\mathbf{y}$ with

$$\mathbf{P} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}, \qquad \mathbf{A}\mathbf{P} = \begin{pmatrix} 1 & 0 \\ -1 & 1 \end{pmatrix}, \qquad \mathbf{P}^\top\mathbf{A}\mathbf{P} = \mathbf{I}_2.$$

By Theorem 13.2.1 the basis is $\mathcal{B}' = \big((1,0),\ (1,1)\big)$, the columns of $\mathbf{P}$.

(c) The characteristic polynomial of $\mathbf{A}$ is x^2-3x+1, with roots $(3\pm\sqrt{5})/2$; $\mathbf{I}_2$ has the eigenvalue 1 twice. The two matrices are congruent with no eigenvalue in common. What they share is that all eigenvalues are positive on both sides, which by the check above is no accident: the congruence class of $\mathbf{I}_2$ over $\mathbb{R}$ consists of exactly the positive definite matrices.

13.2.6.3 C. Going deeper

Exercise C1: Congruence versus equivalence.

(a) Prove that if $\mathbf{A}\simeq\mathbf{B}$ then $\mathbf{A}$ and $\mathbf{B}$ are equivalent in the sense of Definition 3.8.1.

(b) Give two matrices in $M_2(\mathbb{Q})$ that are equivalent but not congruent, and justify your example.

(c) Hence explain what "the congruence classes refine the equivalence classes" means, and say what extra information a congruence class carries that a rank does not.

Solution.

(a) If $\mathbf{B}=\mathbf{P}^\top\mathbf{A}\mathbf{P}$ with $\mathbf{P}$ invertible, then $\mathbf{P}^\top$ is invertible (Theorem 0.9.5), so $\mathbf{B}=\mathbf{Q}\mathbf{A}\mathbf{P}$ with $\mathbf{Q}=\mathbf{P}^\top$ and $\mathbf{P}$ both invertible, which is Definition 3.8.1.

(b) Take $\operatorname{diag}(1,1)$ and $\operatorname{diag}(1,2)$. Both have rank 2, so they are equivalent by Theorem 3.8.3 (c). They are not congruent over $\mathbb{Q}$ by Exercise (B2: A non-congruence over $\mathbb{Q}$) (a).

(c) By (a), each congruence class lies inside a single equivalence class, and by (b) an equivalence class may split into more than one congruence class; that is what "refine" means. An equivalence class is named by the rank alone (Theorem 3.8.3 (c)). A congruence class remembers the rank, and in addition the symmetry type and the discriminant — and over $\mathbb{R}$, the signs. Equivalence allows two independent changes of basis, one in each slot; congruence allows only one, used twice, and the extra invariants are the price of that constraint.

Exercise C2: Orthogonal congruence.

Let $\mathbf{A}\in M_n(\mathbb{R})$ be symmetric with eigenvalues $\lambda_1,\dots,\lambda_n$, listed with multiplicity.

(a) Prove that $\mathbf{A}\simeq\operatorname{diag}(\lambda_1,\dots,\lambda_n)$.

(b) Deduce that if every λ_i is non-zero, then $\mathbf{A}$ is congruent to a diagonal matrix all of whose entries are ±1.

(c) Give two real symmetric 2×2 matrices that are congruent and have no eigenvalue in common.

Hint for (b): recall from Example (Congruences and a non-congruence) (b) what scaling a basis vector does to a diagonal entry.

Solution.

(a) This is Proposition 13.2.6: by Corollary 11.5.2 there is $\mathbf{Q}\in\mathrm{O}(n)$ with $\mathbf{Q}^\top\mathbf{A}\mathbf{Q}=\mathbf{D}=\operatorname{diag}(\lambda_1,\dots,\lambda_n)$, and $\mathbf{Q}$ is invertible, so $\mathbf{A}\simeq\mathbf{D}$.

(b) Let $\mathbf{S} = \operatorname{diag}(c_1, \dots, c_n)$ with $c_i = 1/\sqrt{|\lambda_i|}$, which is defined and non-zero because $\lambda_i \neq 0$. Then $\mathbf{S}$ is invertible and $\mathbf{S}^\top \mathbf{D}\mathbf{S} = \operatorname{diag}(c_1^2\lambda_1, \dots, c_n^2\lambda_n)$, whose i-th entry is $\lambda_i/|\lambda_i| = \pm 1$ according to the sign of λ_i. By (a) and transitivity (Proposition 13.2.2), $\mathbf{A}$ is congruent to that matrix.

(c) By (b), $\operatorname{diag}(1, -3)$ and $\operatorname{diag}(2, -1)$ are both congruent to $\operatorname{diag}(1, -1)$, hence to each other by Proposition 13.2.2; explicitly, $\mathbf{P} = \operatorname{diag}(\sqrt{2}, 1/\sqrt{3})$ gives $\mathbf{P}^\top \operatorname{diag}(1, -3)\mathbf{P} = \operatorname{diag}(2, -1)$. Their eigenvalues are $\{1, -3\}$ and $\{2, -1\}$, which are disjoint. Note that the **signs** match, one positive and one negative on each side; part (b) is the reason, and the law of inertia will say it is forced.

Exercise C3: How much the discriminant sees.

(a) Show that $\mathbb{C}^\times$ has exactly one square class, and that $\mathbb{R}^\times$ has exactly two.

(b) List the squares in $\mathbb{F}_5^\times$ and show that $\mathbb{F}_5^\times$ has exactly two square classes.

(c) Hence determine, for each of $\mathbb{C}$, $\mathbb{R}$ and $\mathbb{F}_5$, the largest number of pairwise non-congruent invertible matrices in M_n that the discriminant alone can distinguish.

Solution.

(a) Over $\mathbb{C}$, every $a \neq 0$ has a square root (Example (Square Roots of $5 - 12i$)), so $a = c^2 \cdot 1$ and every element is equivalent to 1: one class. Over $\mathbb{R}$, squares of non-zero reals are exactly the positive reals, so a and b are equivalent precisely when $a/b > 0$, which happens exactly when they have the same sign. The classes are the positive reals and the negative reals: two classes, and they are distinct since 1 and -1 are not related.

(b) The squares are $1^2 = 1$, $2^2 = 4$, $3^2 = 4$, $4^2 = 1$, so the set of non-zero squares is $\{1, 4\}$. Multiplying $\{1, 4\}$ by 2 gives $\{2, 3\}$, so the classes are $\{1, 4\}$ and $\{2, 3\}$: two classes, each of size 2, covering all four elements of $\mathbb{F}_5^\times$.

(c) The discriminant takes one value per square class, so it can separate at most as many classes as there are square classes: one over $\mathbb{C}$, two over $\mathbb{R}$ and two over $\mathbb{F}_5$. Over $\mathbb{C}$ it is therefore useless, and over $\mathbb{R}$ and $\mathbb{F}_5$ it sorts invertible matrices into at most two piles. By Exercise (C2: Orthogonal congruence) (b), over $\mathbb{R}$ every invertible symmetric matrix is congruent to one of the $n + 1$ matrices $\mathbf{I}_p \oplus -\mathbf{I}_{n-p}$, whose determinant is $(-1)^{n-p}$; so the discriminant sees only the parity of $n - p$, and for $n \geq 2$ it cannot separate, say, $\mathbf{I}_2$ from $-\mathbf{I}_2$. That the $n + 1$ matrices really are pairwise non-congruent is the law of inertia, not anything the discriminant can deliver.

13.3 Three Kinds of Form

A bilinear form has two slots, and so far nothing has related them. Almost every form that occurs in practice does relate them: the dot product does not care which vector goes first, while the determinant of a 2×2 matrix changes sign when its columns are swapped. This section names the three symmetry conditions the rest of the chapter runs on, shows that two of them are the same condition exactly when $1 + 1 \neq 0$ in the field, and extracts from a symmetric form the single-variable function $q(\mathbf{v}) = \beta(\mathbf{v}, \mathbf{v})$ that carries all of its information.

Throughout, V is a finite-dimensional vector space over a field F, and β is a bilinear form on V (Definition 13.1.1). The characteristic hypothesis is stated wherever it is needed and nowhere else.

13.3.1 Symmetric forms

The dot product on F^n satisfies $\mathbf{x}\cdot\mathbf{y} = \mathbf{y}\cdot\mathbf{x}$, and so does every integral pairing $\int_0^1 fg$, and so does $\mathbf{x}^\top\mathbf{A}\mathbf{y}$ whenever $\mathbf{A}$ happens to satisfy $\mathbf{A}^\top = \mathbf{A}$. The condition recurs, so it gets a name.

A symmetric form cannot tell its two arguments apart.

Definition 13.3.1 — Symmetric Bilinear Form

A bilinear form $\beta\colon V\times V\to F$ is **symmetric** if

$$\beta(\mathbf{u},\mathbf{v}) = \beta(\mathbf{v},\mathbf{u})$$

for all $\mathbf{u},\mathbf{v}\in V$.

In words: the value is unchanged by swapping the two inputs. The condition is imposed for **every** pair, not just for pairs of basis vectors — although, as the next result shows, checking it on basis vectors is enough.

Three examples and one non-example.

- **The dot product** on F^n, $\beta(\mathbf{x},\mathbf{y}) = x_1y_1+\cdots+x_ny_n$. Each product x_iy_i is unchanged by the swap because multiplication in F is commutative.
- **A symmetric matrix**, $\beta(\mathbf{x},\mathbf{y}) = \mathbf{x}^\top\mathbf{A}\mathbf{y}$ with $\mathbf{A}^\top = \mathbf{A}$ (Definition 0.9.11). Here $\mathbf{x}^\top\mathbf{A}\mathbf{y}$ is a 1×1 matrix, so it equals its own transpose $\mathbf{y}^\top\mathbf{A}^\top\mathbf{x} = \mathbf{y}^\top\mathbf{A}\mathbf{x}$ by Theorem 0.9.5.
- **Evaluation pairings.** On $F[x]_{\le n}$, fix scalars $t_1,\dots,t_k\in F$ and set $\beta(p,q) = \sum_i p(t_i)q(t_i)$. Symmetry is again commutativity of F.
- **A non-example by minimal change.** On F^2 put $\beta(\mathbf{x},\mathbf{y}) = x_1y_2$. It is bilinear, by the one-slot check of Definition 6.2.1. But $\beta(\mathbf{e}_1,\mathbf{e}_2) = 1$ and $\beta(\mathbf{e}_2,\mathbf{e}_1) = 0$, so the symmetry clause fails at that one pair. Exactly one clause has been broken: bilinearity survives untouched.

The matrix of a form (Definition 13.1.2) turns the condition into a matrix condition, and turns "for all $\mathbf{u},\mathbf{v}$" into a finite check.

Proposition 13.3.1 — Symmetry Is Visible in the Matrix

Let $\mathcal{B}$ be a basis of V and $\mathbf{A} = [\beta]_{\mathcal{B}}$. Then β is symmetric if and only if $\mathbf{A}^\top = \mathbf{A}$.

Proof. ($\Rightarrow$) Suppose β is symmetric. Writing $\mathcal{B} = (\mathbf{v}_1,\dots,\mathbf{v}_n)$, the entries of $\mathbf{A}$ are $a_{ij} = \beta(\mathbf{v}_i,\mathbf{v}_j)$, so $a_{ij} = \beta(\mathbf{v}_j,\mathbf{v}_i) = a_{ji}$, which is Definition 0.9.11.

($\Leftarrow$) Suppose $\mathbf{A}^\top = \mathbf{A}$, and let $\mathbf{u},\mathbf{v}\in V$. By Theorem 13.1.1,

$$\beta(\mathbf{u},\mathbf{v}) = [\mathbf{u}]_{\mathcal{B}}^\top\mathbf{A}[\mathbf{v}]_{\mathcal{B}}.$$

The right-hand side is a 1×1 matrix, hence equal to its transpose, which by Theorem 0.9.5 is $[\mathbf{v}]_{\mathcal{B}}^{\top}\mathbf{A}^{\top}[\mathbf{u}]_{\mathcal{B}} = [\mathbf{v}]_{\mathcal{B}}^{\top}\mathbf{A}[\mathbf{u}]_{\mathcal{B}} = \beta(\mathbf{v},\mathbf{u})$. This proves the equivalence.

■

Because congruence sends $\mathbf{A}$ to $\mathbf{P}^{\top}\mathbf{A}\mathbf{P}$ and $(\mathbf{P}^{\top}\mathbf{A}\mathbf{P})^{\top} = \mathbf{P}^{\top}\mathbf{A}^{\top}\mathbf{P}$ by Theorem 0.9.5, a congruent copy of a symmetric matrix is symmetric. So the condition $\mathbf{A}^{\top} = \mathbf{A}$ does not depend on which basis was used to build $\mathbf{A}$ — as it must not, since by Proposition 13.3.1 it says something about β alone.

13.3.2 Alternating and skew-symmetric forms

Chapter 6 needed two ways of saying "the value collapses when two arguments coincide", and found that they are not the same condition. Both were defined there for k-linear forms, and a bilinear form is the case $k = 2$, so nothing needs redefining. Read at $k = 2$:

- β is **alternating** (Definition 6.2.2) if $\beta(\mathbf{v},\mathbf{v}) = 0$ for **every** $\mathbf{v} \in V$;
- β is **skew-symmetric** (Definition 6.2.3) if $\beta(\mathbf{u},\mathbf{v}) = -\beta(\mathbf{v},\mathbf{u})$ for **all** $\mathbf{u},\mathbf{v} \in V$.

The standard example of both is the signed area $\beta(\mathbf{x},\mathbf{y}) = x_1y_2 - x_2y_1$ on F^2, which is the determinant of the matrix with columns $\mathbf{x}$ and $\mathbf{y}$. A second family, the one Section 9 will be about, is the **standard alternating form** on F^{2m},

$$\beta(\mathbf{x},\mathbf{y}) = \sum_{i=1}^{m}\big(x_iy_{m+i} - x_{m+i}y_i\big),$$

which pairs the first block of coordinates against the second.

Each condition reads off the matrix, and the two readings differ by the diagonal.

Proposition 13.3.2 — Alternation and Skewness in the Matrix

Let $\mathcal{B} = (\mathbf{v}_1,\dots,\mathbf{v}_n)$ be a basis of V and $\mathbf{A} = [\beta]_{\mathcal{B}}$. Then:

(a) β is skew-symmetric if and only if $\mathbf{A}^{\top} = -\mathbf{A}$;

(b) β is alternating if and only if $\mathbf{A}^{\top} = -\mathbf{A}$ **and** $a_{ii} = 0$ for every i.

Proof.

(a) repeats the proof of Proposition 13.3.1 with a minus sign throughout.

(b) ($\Rightarrow$) If β is alternating then $a_{ii} = \beta(\mathbf{v}_i,\mathbf{v}_i) = 0$, and β is skew-symmetric by Theorem 6.2.1 (a), so $\mathbf{A}^{\top} = -\mathbf{A}$ by (a).

($\Leftarrow$) Suppose $\mathbf{A}^{\top} = -\mathbf{A}$ with zero diagonal, and let $\mathbf{v} \in V$ have coordinates $[\mathbf{v}]_{\mathcal{B}} = (c_1,\dots,c_n)$. By Theorem 13.1.1 and bilinearity,

$$\beta(\mathbf{v},\mathbf{v}) = \sum_{i,j} c_ic_ja_{ij} = \sum_{i} c_i^2a_{ii} + \sum_{i<j} c_ic_j\big(a_{ij} + a_{ji}\big),$$

where the second sum collects the terms (i,j) and (j,i) together. Every a_{ii} is 0, and every $a_{ij} + a_{ji}$ is 0 because $\mathbf{A}^{\top} = -\mathbf{A}$. So $\beta(\mathbf{v},\mathbf{v}) = 0$. This proves the equivalence.

■

Part (b) is the whole difficulty in one line: a skew-symmetric matrix has $a_{ii} = -a_{ii}$, and *usually* that forces $a_{ii} = 0$. Usually, but not always.

13.3.3 Where characteristic 2 earns its keep

Chapter 0 warned that in a field of characteristic 2 the argument "$x = -x$, so $2x = 0$, so $x = 0$" divides by $2 = 1+1$, which is 0 there, and it promised that this is why later results on symmetric bilinear forms would carry the hypothesis "characteristic $\neq 2$" (Definition 0.7.2). This is the theorem the promise was about.

Theorem 13.3.3 — Alternating Versus Skew-Symmetric

Let F be a field and let V be a vector space over F.

(a) Every alternating bilinear form on V is skew-symmetric. No hypothesis on F or on V is needed.

(b) If $\operatorname{char} F \neq 2$, every skew-symmetric bilinear form on V is alternating. Again V is arbitrary.

(c) If $\operatorname{char} F = 2$ and $V \neq \{\mathbf{0}\}$, there is a skew-symmetric bilinear form on V that is **not** alternating.

So the converse of (a) holds **if and only if** $\operatorname{char} F \neq 2$.

Idea. For (a), feed $\mathbf{u} + \mathbf{v}$ into both slots and expand: the two diagonal terms vanish by hypothesis, and what is left is exactly the skew identity. For (b), feed $\mathbf{v}$ into both slots of the skew identity, which gives $\beta(\mathbf{v}, \mathbf{v}) = -\beta(\mathbf{v}, \mathbf{v})$; canceling needs $1 + 1$ to be invertible, and that is precisely what characteristic $\neq 2$ supplies. For (c), notice that in characteristic 2 the words "skew-symmetric" and "symmetric" mean the same thing, so any symmetric form that is non-zero on some vector **paired with itself** is a witness — and the dot product is one.

Proof.

(a) Let β be alternating and let $\mathbf{u}, \mathbf{v} \in V$. Expanding by bilinearity,

$$0 = \beta(\mathbf{u} + \mathbf{v}, \mathbf{u} + \mathbf{v}) = \beta(\mathbf{u}, \mathbf{u}) + \beta(\mathbf{u}, \mathbf{v}) + \beta(\mathbf{v}, \mathbf{u}) + \beta(\mathbf{v}, \mathbf{v}),$$

and the first and last terms are 0 because β is alternating. Hence $\beta(\mathbf{u}, \mathbf{v}) = -\beta(\mathbf{v}, \mathbf{u})$. (This is Theorem 6.2.1 (a) at $k = 2$.)

(b) Let β be skew-symmetric and $\mathbf{v} \in V$. Taking $\mathbf{u} = \mathbf{v}$ in the defining identity gives $\beta(\mathbf{v}, \mathbf{v}) = -\beta(\mathbf{v}, \mathbf{v})$, that is, $(1 + 1)\beta(\mathbf{v}, \mathbf{v}) = 0$. Since $\operatorname{char} F \neq 2$, we have $1 + 1 \neq 0$ in F: otherwise the smallest positive n with $n \cdot 1 = 0$ would be 2, which is Definition 0.7.2. A non-zero element of a field is invertible, so multiplying by $(1 + 1)^{-1}$ gives $\beta(\mathbf{v}, \mathbf{v}) = 0$. (This is Theorem 6.2.2 at $k = 2$.)

(c) Suppose $\operatorname{char} F = 2$, so that $-1 = 1$ in F. Since $V \neq \{\mathbf{0}\}$ is finite-dimensional, it has a basis with at least one vector, and we may take $\varphi \in V^*$ to be the coordinate

functional of its first vector $\mathbf{v}_1$, so that $\varphi(\mathbf{v}_1) = 1$. Define

$$\beta(\mathbf{u}, \mathbf{v}) = \varphi(\mathbf{u})\,\varphi(\mathbf{v}).$$

This is bilinear, being a product of two linear functionals, and it is symmetric. Because $-1 = 1$, symmetric and skew-symmetric say the same thing, so β is skew-symmetric. But $\beta(\mathbf{v}_1, \mathbf{v}_1) = 1 \neq 0$, so β is not alternating.

Finally, (b) and (c) together say that the converse of (a) holds exactly when $\operatorname{char} F \neq 2$. This proves the theorem.

■

The concrete witness is worth writing down.

Example. (The dot product over the field with two elements)

Let $F = \mathbb{F}_2$ and $V = \mathbb{F}_2^2$, and let β be the dot product, $\beta(\mathbf{x}, \mathbf{y}) = x_1y_1 + x_2y_2$. Decide whether β is symmetric, skew-symmetric and alternating, and compute the function $\mathbf{v} \mapsto \beta(\mathbf{v}, \mathbf{v})$ on all four vectors of V.

Solution. The matrix of β in the standard basis is $\mathbf{I}_2$. It is symmetric, so β is symmetric by Proposition 13.3.1. Over $\mathbb{F}_2$ we have $-\mathbf{I}_2 = \mathbf{I}_2$, so the matrix also satisfies $\mathbf{I}_2^{\top} = -\mathbf{I}_2$, and β is skew-symmetric by Proposition 13.3.2 (a). It is **not** alternating: the diagonal entries of $\mathbf{I}_2$ are $1 \neq 0$, and indeed $\beta(\mathbf{e}_1, \mathbf{e}_1) = 1$.

On the four vectors, $\beta(\mathbf{v}, \mathbf{v}) = v_1^2 + v_2^2$. In $\mathbb{F}_2$ both elements satisfy $c^2 = c$, so this equals $v_1 + v_2$:

$$\beta(\mathbf{0}, \mathbf{0}) = 0, \quad \beta(\mathbf{e}_1, \mathbf{e}_1) = 1, \quad \beta(\mathbf{e}_2, \mathbf{e}_2) = 1, \quad \beta(\mathbf{1}, \mathbf{1}) = 0.$$

Notice what that list is: the function $\mathbf{v} \mapsto \beta(\mathbf{v}, \mathbf{v})$ is the **linear** functional $v_1 + v_2$. In characteristic 2 a "quadratic" function coming from a bilinear form can be linear, which is the first sign that the notions below will not behave.

Warning. **In characteristic 2, "skew-symmetric" carries no information beyond "symmetric".** Since $-1 = 1$, the two conditions are literally the same condition, and the useful notion is the strictly stronger one, alternating. This is why Chapter 6 built the determinant on alternation rather than skewness, and why every statement below that pairs symmetric against alternating needs $\operatorname{char} F \neq 2$.

13.3.4 Splitting a form into two halves

In characteristic $\neq 2$ the two conditions are complementary in the strongest possible sense: every bilinear form is a symmetric one plus an alternating one, in exactly one way. The recipe is the one that splits a function on $\mathbb{R}$ into its even and odd parts.

Theorem 13.3.4 — Symmetric Plus Alternating

Let $\operatorname{char} F \neq 2$ and let β be a bilinear form on V. Then there are a **unique** symmetric

form β_s and a **unique** alternating form β_a on V with $\beta = \beta_s + \beta_a$, namely

$$\beta_s(\mathbf{u},\mathbf{v}) = \tfrac{1}{2}\big(\beta(\mathbf{u},\mathbf{v}) + \beta(\mathbf{v},\mathbf{u})\big),$$
$$\beta_a(\mathbf{u},\mathbf{v}) = \tfrac{1}{2}\big(\beta(\mathbf{u},\mathbf{v}) - \beta(\mathbf{v},\mathbf{u})\big).$$

In matrices: $\mathbf{A} = \tfrac{1}{2}(\mathbf{A} + \mathbf{A}^{\top}) + \tfrac{1}{2}(\mathbf{A} - \mathbf{A}^{\top})$.

Proof. Since $\operatorname{char} F \neq 2$, the element $1+1$ is non-zero, hence invertible, and $\frac{1}{2}$ denotes $(1+1)^{-1}$. Both displayed formulas are bilinear, being combinations of the bilinear maps $(\mathbf{u},\mathbf{v}) \mapsto \beta(\mathbf{u},\mathbf{v})$ and $(\mathbf{u},\mathbf{v}) \mapsto \beta(\mathbf{v},\mathbf{u})$, and their sum is β. Swapping $\mathbf{u}$ and $\mathbf{v}$ leaves β_s unchanged, so β_s is symmetric; and $\beta_a(\mathbf{v},\mathbf{v}) = \frac{1}{2}(\beta(\mathbf{v},\mathbf{v}) - \beta(\mathbf{v},\mathbf{v})) = 0$, so β_a is alternating.

For uniqueness, suppose $\beta_s + \beta_a = \beta_s' + \beta_a'$ with β_s, β_s' symmetric and β_a, β_a' alternating, and put $\delta = \beta_s - \beta_s' = \beta_a' - \beta_a$. Then δ is symmetric, being a difference of symmetric forms, and alternating, being a difference of alternating forms. By Theorem 13.3.3 (a) it is also skew-symmetric, so for all $\mathbf{u},\mathbf{v}$,

$$\delta(\mathbf{u},\mathbf{v}) = \delta(\mathbf{v},\mathbf{u}) = -\delta(\mathbf{u},\mathbf{v}),$$

giving $(1+1)\delta(\mathbf{u},\mathbf{v}) = 0$ and hence $\delta(\mathbf{u},\mathbf{v}) = 0$. Therefore $\beta_s = \beta_s'$ and $\beta_a = \beta_a'$, as claimed. ∎

Both halves of the argument divided by $1+1$, and both failures are real. In characteristic 2 the formulas are meaningless, and more than that, the statement itself is false: alternating forms are then a *subset* of the symmetric ones, not a complement to them.

Warning. **In characteristic 2, symmetric and alternating forms are not complementary.** Over $\mathbb{F}_2$ take $\beta(\mathbf{x},\mathbf{y}) = x_1y_2$ on $\mathbb{F}_2^2$. An alternating form is skew-symmetric (Theorem 13.3.3 (a)), and skew-symmetric means symmetric here, so **every** sum of a symmetric form and an alternating form is symmetric. But $\beta(\mathbf{e}_1,\mathbf{e}_2) = 1$ while $\beta(\mathbf{e}_2,\mathbf{e}_1) = 0$, so β is not symmetric and therefore cannot be written as such a sum at all. The decomposition does not merely lose uniqueness; existence fails.

13.3.5 The quadratic form

A bilinear form is a function of two vectors, which makes it awkward to plot, to differentiate, or to write on a page. Feeding the same vector into both slots turns it into a function of one vector. Chapter 11 met this function on $\mathbb{R}^n$ under the name **quadratic form** and used it to identify conics; here is the general definition, and the surprising fact that nothing is lost.

A quadratic form is what a bilinear form sees when both of its arguments are the same vector.

Definition 13.3.2 — Quadratic Form

Let β be a bilinear form on V. The **quadratic form associated with** β is the function

$$q\colon V \to F, \qquad q(\mathbf{v}) = \beta(\mathbf{v},\mathbf{v}).$$

A function $q\colon V \to F$ is called **a quadratic form on** V if $q(\mathbf{v}) = \beta(\mathbf{v},\mathbf{v})$ for some **symmetric** bilinear form β on V.

Two clauses deserve separate readings. The first says how to build q from a given β, for **any** β over **any** field. The second says which functions $V \to F$ are entitled to the name, and it insists on a **symmetric** β; the polarization theorem below will show that over a field of characteristic $\neq 2$ this symmetric β is then unique, so that "the" bilinear form of a quadratic form is well defined.

Insisting on symmetry costs nothing in characteristic $\neq 2$. If $q(\mathbf{v}) = \beta(\mathbf{v},\mathbf{v})$ for some bilinear β, then by Theorem 13.3.4 we may split $\beta = \beta_s + \beta_a$, and $\beta_a(\mathbf{v},\mathbf{v}) = 0$, so $q(\mathbf{v}) = \beta_s(\mathbf{v},\mathbf{v})$ with β_s symmetric. The alternating part is invisible to q.

In coordinates, with $\mathbf{A} = [\beta]_{\mathcal{B}}$ symmetric and $\mathbf{x} = [\mathbf{v}]_{\mathcal{B}}$,

$$q(\mathbf{v}) = \mathbf{x}^{\top}\mathbf{A}\mathbf{x} = \sum_{i} a_{ii}x_i^2 + 2\sum_{i<j} a_{ij}x_i x_j, \tag{13.3.1}$$

which is a homogeneous polynomial of degree 2 in the coordinates: hence the name. Reading Eq. 13.3.1 backwards recovers $\mathbf{A}$ from the polynomial: a_{ii} is the coefficient of x_i^2, and a_{ij} for $i \neq j$ is **half** the coefficient of $x_i x_j$. That is word for word the recipe Chapter 11 gave for the symmetric matrix of a real quadratic form, and the halving is the same division by $1+1$ as everywhere else in this section.

Example. (From a polynomial to its matrix and back)

Over $\mathbb{Q}$, let $q(x_1,x_2,x_3) = 2x_1^2 - x_2^2 + 6x_1x_2 - 4x_2x_3$. Find the symmetric matrix $\mathbf{A}$ with $q(\mathbf{x}) = \mathbf{x}^{\top}\mathbf{A}\mathbf{x}$, and evaluate $q(1,1,1)$ both from the polynomial and from $\mathbf{A}$.

Solution. The squared terms give $a_{11} = 2$, $a_{22} = -1$ and $a_{33} = 0$. The cross terms give $a_{12} = a_{21} = 3$ (half of 6), $a_{23} = a_{32} = -2$ (half of -4), and $a_{13} = a_{31} = 0$ since x_1x_3 does not appear. So

$$\mathbf{A} = \begin{pmatrix} 2 & 3 & 0 \\ 3 & -1 & -2 \\ 0 & -2 & 0 \end{pmatrix}.$$

From the polynomial, $q(1,1,1) = 2 - 1 + 6 - 4 = 3$. From the matrix, $\mathbf{A}(1,1,1) = (5,0,-2)$ and $(1,1,1)\cdot(5,0,-2) = 3$. The two agree.

Now the theorem that makes q as good as β.

Theorem 13.3.5 — Polarization

Let $\operatorname{char} F \neq 2$. The map $\beta \mapsto q$, $q(\mathbf{v}) = \beta(\mathbf{v},\mathbf{v})$, is a bijection from the set of symmetric bilinear forms on V onto the set of quadratic forms on V. Its inverse is given by either of

$$\begin{aligned}\beta(\mathbf{u},\mathbf{v}) &= \tfrac{1}{2}\big(q(\mathbf{u}+\mathbf{v}) - q(\mathbf{u}) - q(\mathbf{v})\big) \\ &= \tfrac{1}{4}\big(q(\mathbf{u}+\mathbf{v}) - q(\mathbf{u}-\mathbf{v})\big).\end{aligned}$$

In particular a symmetric form is determined by its quadratic form: if $\beta(\mathbf{v},\mathbf{v}) = \beta'(\mathbf{v},\mathbf{v})$ for all $\mathbf{v}$, then $\beta = \beta'$.

Idea. Only one computation is needed, and it is the expansion of $q(\mathbf{u}\pm\mathbf{v})$ by bilinearity. Symmetry merges the two cross terms into one, so the cross term appears with a factor $1+1$, and dividing by it is the whole trick. Surjectivity is the definition of "quadratic form"; injectivity is the displayed formula.

Proof. Let β be symmetric with quadratic form q, and let $\mathbf{u},\mathbf{v}\in V$. By bilinearity and then symmetry,

$$q(\mathbf{u}\pm\mathbf{v}) = \beta(\mathbf{u},\mathbf{u}) \pm \beta(\mathbf{u},\mathbf{v}) \pm \beta(\mathbf{v},\mathbf{u}) + \beta(\mathbf{v},\mathbf{v}),$$

so $q(\mathbf{u}\pm\mathbf{v}) = q(\mathbf{u}) + q(\mathbf{v}) \pm (1+1)\beta(\mathbf{u},\mathbf{v})$. Since $\operatorname{char} F \neq 2$, the element $1+1$ is invertible, and taking the upper sign gives the first formula. Subtracting the two versions gives $q(\mathbf{u}+\mathbf{v}) - q(\mathbf{u}-\mathbf{v}) = (1+1)^2\beta(\mathbf{u},\mathbf{v})$, which is the second.

The map $\beta \mapsto q$ is onto the set of quadratic forms by Definition 13.3.2, which defines that set as the image. It is injective because the first displayed formula recovers $\beta(\mathbf{u},\mathbf{v})$ from q alone; so if two symmetric forms have the same q, the formula returns the same value for each, and they are equal. Hence the map is a bijection with the stated inverse. This proves the theorem.

■

Quick check. Which bilinear forms are both symmetric and alternating, over a field of characteristic $\neq 2$?

Solution. Only the zero form. If β is alternating then $q=0$, and if β is also symmetric then Theorem 13.3.5 recovers $\beta(\mathbf{u},\mathbf{v}) = \frac{1}{2}(0-0-0) = 0$. (Over $\mathbb{F}_2$ the answer is different: every alternating form is symmetric there, as Theorem 13.3.3 shows, and there are plenty of non-zero ones.)

The second formula of Theorem 13.3.5 should look familiar. Over $\mathbb{R}$, an inner product is a symmetric bilinear form whose quadratic form is $q(\mathbf{v}) = \|\mathbf{v}\|^2$, and the formula reads

$$\langle \mathbf{u},\mathbf{v}\rangle = \tfrac{1}{4}\big(\|\mathbf{u}+\mathbf{v}\|^2 - \|\mathbf{u}-\mathbf{v}\|^2\big),$$

which is exactly Lemma 10.7.2 (a). Chapter 10 proved it to show that an isometry automatically preserves angles; the content here is the same, stripped of positivity and of $\mathbb{R}$. What Chapter 10 needed positivity for was the *norm*, not the identity.

13.3.6 Hermitian forms

Over $\mathbb{C}$ the pattern changes, because $\langle \mathbf{v},\mathbf{v}\rangle$ is required to be a positive real number and no bilinear form can deliver that: bilinearity gives $\beta(i\mathbf{v},i\mathbf{v}) = i^2\beta(\mathbf{v},\mathbf{v}) = -\beta(\mathbf{v},\mathbf{v})$, so the values at $\mathbf{v}$ and $i\mathbf{v}$ have opposite signs. Chapter 10 solved this by making the second slot conjugate-linear. That fix has nothing to do with positivity, so it can be made here too.

Definition 13.3.3 — Hermitian Form

Let V be a vector space over $\mathbb{C}$. A function $\beta\colon V\times V\to\mathbb{C}$ is a **Hermitian form** if it

is **linear in the first argument**, and

$$\beta(\mathbf{v},\mathbf{u}) = \overline{\beta(\mathbf{u},\mathbf{v})} \qquad \text{for all } \mathbf{u},\mathbf{v} \in V.$$

Two remarks on the clauses. First, the two conditions together force conjugate-linearity in the second argument: $\beta(\mathbf{u},c\mathbf{v}) = \overline{\beta(c\mathbf{v},\mathbf{u})} = \overline{c\,\beta(\mathbf{v},\mathbf{u})} = \overline{c}\,\beta(\mathbf{u},\mathbf{v})$. So a Hermitian form is **not** bilinear, and Definition 13.1.1 does not cover it. Second, taking $\mathbf{u}=\mathbf{v}$ gives $\beta(\mathbf{v},\mathbf{v}) = \overline{\beta(\mathbf{v},\mathbf{v})}$, so the associated function $q(\mathbf{v}) = \beta(\mathbf{v},\mathbf{v})$ takes **real** values even though β does not.

The examples are the ones from Chapter 10 with positivity dropped: $\beta(\mathbf{x},\mathbf{y}) = \mathbf{y}^{*}\mathbf{A}\mathbf{x}$ on $\mathbb{C}^n$ for any $\mathbf{A}$ with $\mathbf{A}^{*}=\mathbf{A}$, including indefinite choices such as $\mathbf{A} = \operatorname{diag}(1,-1)$. The matrix criterion is the same proof as Proposition 13.3.1 with stars in place of transposes.

Proposition 13.3.6 — Hermitian Forms and Hermitian Matrices

Let β be linear in the first argument and conjugate-linear in the second, let $\mathcal{B} = (\mathbf{v}_1,\dots,\mathbf{v}_n)$ be a basis of V, and let $\mathbf{A}$ be the matrix with entries $a_{ij} = \beta(\mathbf{v}_j,\mathbf{v}_i)$. Then β is Hermitian if and only if $\mathbf{A}^{*}=\mathbf{A}$, and in that case $\beta(\mathbf{u},\mathbf{v}) = [\mathbf{v}]_{\mathcal{B}}^{*}\mathbf{A}[\mathbf{u}]_{\mathcal{B}}$.

Proof. The index order $a_{ij} = \beta(\mathbf{v}_j,\mathbf{v}_i)$ is the one used for Gram matrices in Chapter 10 ($\mathbf{G}$ in Definition 10.2.3), chosen so that the displayed formula comes out with no transposing of the answer. Expanding $\mathbf{u} = \sum_j c_j\mathbf{v}_j$ and $\mathbf{v} = \sum_i d_i\mathbf{v}_i$ by linearity in the first slot and conjugate-linearity in the second,

$$\beta(\mathbf{u},\mathbf{v}) = \sum_{i,j} c_j\overline{d_i}\,\beta(\mathbf{v}_j,\mathbf{v}_i) = \sum_{i,j}\overline{d_i}\,a_{ij}c_j,$$

which is the matrix product $[\mathbf{v}]_{\mathcal{B}}^{*}\mathbf{A}[\mathbf{u}]_{\mathcal{B}}$. If β is Hermitian then in particular $a_{ji} = \beta(\mathbf{v}_i,\mathbf{v}_j) = \overline{\beta(\mathbf{v}_j,\mathbf{v}_i)} = \overline{a_{ij}}$, which is $\mathbf{A}^{*}=\mathbf{A}$. Conversely, if $a_{ji} = \overline{a_{ij}}$ then conjugating the display gives

$$\overline{\beta(\mathbf{u},\mathbf{v})} = \sum_{i,j} d_i\,\overline{a_{ij}}\,\overline{c_j} = \sum_{i,j}\overline{c_j}\,a_{ji}\,d_i = \beta(\mathbf{v},\mathbf{u}),$$

so β is Hermitian. ∎

Polarization works for Hermitian forms too, and it is the four-term identity rather than the two-term one: by Lemma 10.7.2 (b) with $q(\mathbf{v}) = \beta(\mathbf{v},\mathbf{v})$,

$$\beta(\mathbf{u},\mathbf{v}) = \tfrac{1}{4}\sum_{k=0}^{3} i^{k}\,q(\mathbf{u}+i^{k}\mathbf{v}).$$

The computation in Chapter 10 expanded each term using linearity in the first slot, conjugate-linearity in the second and $\beta(\mathbf{v},\mathbf{u}) = \overline{\beta(\mathbf{u},\mathbf{v})}$, and used positivity nowhere, so it proves this identity too. Note the contrast with the real case: over $\mathbb{C}$ there is no characteristic to worry about, since $\operatorname{char}\mathbb{C} = 0$, and the reason a Hermitian form is recoverable from q is the extra room provided by i.

Warning. **A quadratic form over a field of characteristic 2 is a different object, and this book does not define it.** Two things go wrong there, and Theorem 13.3.5 repairs neither. *The form is not determined by q.* Over $\mathbb{F}_2$, the symmetric form $\beta(\mathbf{x},\mathbf{y}) =$

$x_1y_2 + x_2y_1$ has $q(\mathbf{x}) = 2x_1x_2 = 0$, the same q as the zero form, so $\beta \mapsto q$ is not injective on symmetric forms. *And Definition 13.3.2 names too few functions.* The function $q(\mathbf{x}) = x_1x_2$ on $\mathbb{F}_2^2$ is $\beta(\mathbf{x}, \mathbf{x})$ for the bilinear $\beta(\mathbf{x}, \mathbf{y}) = x_1y_2$, yet it is $\beta(\mathbf{x}, \mathbf{x})$ for **no symmetric** β: for a symmetric $\mathbf{A}$, Eq. 13.3.1 gives $a_{11}x_1^2 + a_{22}x_2^2 = a_{11}x_1 + a_{22}x_2$ over $\mathbb{F}_2$, whose values at $(1,1)$, $(1,0)$ and $(0,1)$ are $a_{11}+a_{22}$, a_{11} and a_{22}, and no choice makes those $1, 0, 0$. The theory of quadratic forms in characteristic 2 therefore defines q first, by the axioms $q(c\mathbf{v}) = c^2q(\mathbf{v})$ and "$q(\mathbf{u}+\mathbf{v}) - q(\mathbf{u}) - q(\mathbf{v})$ is bilinear", and treats β as derived data. Everything that follows assumes $\operatorname{char} F \neq 2$ precisely to stay out of that theory.

Three kinds of form, then, and three matrix shapes: symmetric, alternating, Hermitian. The next two sections take the first of them and classify it up to congruence, first over any field of characteristic $\neq 2$, then over $\mathbb{R}$.

13.3.7 Exercises

13.3.7.1 A. Check your understanding

Exercise A1.

(a) Define what it means for a bilinear form β on V to be **symmetric**, **alternating** and **skew-symmetric**.

(b) State the relationship between alternating and skew-symmetric forms, including the exact role of the characteristic.

(c) Write down the matrix condition, in a fixed basis, for each of the three notions in (a).

(d) Determine whether the following statement is correct, and justify your answer: over $\mathbb{Q}$, a bilinear form is determined by the function $\mathbf{v} \mapsto \beta(\mathbf{v}, \mathbf{v})$.

(e) Why is a Hermitian form not an example of Definition 13.1.1?

Solution.

(a) Symmetric: $\beta(\mathbf{u}, \mathbf{v}) = \beta(\mathbf{v}, \mathbf{u})$ for all $\mathbf{u}, \mathbf{v}$. Alternating: $\beta(\mathbf{v}, \mathbf{v}) = 0$ for all $\mathbf{v}$. Skew-symmetric: $\beta(\mathbf{u}, \mathbf{v}) = -\beta(\mathbf{v}, \mathbf{u})$ for all $\mathbf{u}, \mathbf{v}$.

(b) Alternating always implies skew-symmetric (Theorem 13.3.3 (a)). The converse holds if and only if $\operatorname{char} F \neq 2$; in characteristic 2 the dot product on $\mathbb{F}_2^2$ is skew-symmetric and not alternating.

(c) With $\mathbf{A} = [\beta]_{\mathcal{B}}$: symmetric means $\mathbf{A}^\top = \mathbf{A}$; skew-symmetric means $\mathbf{A}^\top = -\mathbf{A}$; alternating means $\mathbf{A}^\top = -\mathbf{A}$ together with $a_{ii} = 0$ for all i (Proposition 13.3.1, Proposition 13.3.2).

(d) Incorrect. Since $\operatorname{char} \mathbb{Q} = 0 \neq 2$, only the **symmetric** part is determined: any alternating form has $\beta(\mathbf{v}, \mathbf{v}) = 0$ identically, so β and $\beta + \beta_a$ have the same quadratic form for every alternating β_a. What is true is Theorem 13.3.5, which determines β among *symmetric* forms.

(e) It is not linear in the second argument: $\beta(\mathbf{u}, c\mathbf{v}) = \overline{c}\,\beta(\mathbf{u}, \mathbf{v})$, and $\overline{c} \neq c$ for $c \notin \mathbb{R}$.

13.3.7.2 B. Practice

Exercise B1: Determine which of the following.

Over $\mathbb{Q}$, with $V = \mathbb{Q}^2$ and $\mathbf{x} = (x_1, x_2)$, $\mathbf{y} = (y_1, y_2)$, determine for each of the following bilinear forms whether it is symmetric, whether it is alternating, and whether it is skew-symmetric. Justify each answer.

(a) $\beta(\mathbf{x}, \mathbf{y}) = x_1y_1 - x_2y_2$.
(b) $\beta(\mathbf{x}, \mathbf{y}) = 3x_1y_2 - 3x_2y_1$.
(c) $\beta(\mathbf{x}, \mathbf{y}) = x_1y_2 + 2x_2y_1$.
(d) $\beta(\mathbf{x}, \mathbf{y}) = 0$.

Solution. Write down the matrix $\mathbf{A}$ in the standard basis in each case and apply Proposition 13.3.1 and Proposition 13.3.2.

(a) $\mathbf{A} = \operatorname{diag}(1, -1)$, which satisfies $\mathbf{A}^\top = \mathbf{A}$: symmetric. Not skew-symmetric, since $\mathbf{A}^\top = -\mathbf{A}$ would need $1 = -1$ in $\mathbb{Q}$. Not alternating, since $\beta(\mathbf{e}_1, \mathbf{e}_1) = 1$.
(b) $\mathbf{A} = \left(\begin{smallmatrix} 0 & 3 \\ -3 & 0 \end{smallmatrix}\right)$, with $\mathbf{A}^\top = -\mathbf{A}$ and zero diagonal: skew-symmetric and alternating. Not symmetric, since $3 \neq -3$.
(c) $\mathbf{A} = \left(\begin{smallmatrix} 0 & 1 \\ 2 & 0 \end{smallmatrix}\right)$. Symmetry would need $1 = 2$ and skewness would need $1 = -2$, both false in $\mathbb{Q}$; so it is neither, and it is not alternating either, since an alternating form is skew-symmetric. (Its diagonal entries do vanish, so $\beta(\mathbf{e}_i, \mathbf{e}_i) = 0$ for the two basis vectors — but $\beta(\mathbf{1}, \mathbf{1}) = 1 + 2 = 3 \neq 0$. Checking the basis vectors alone is not enough.)
(d) The zero form is symmetric, skew-symmetric and alternating at once; its matrix is $\mathbf{0}$, which satisfies every condition. By the Quick check above it is the only form that is both symmetric and alternating over $\mathbb{Q}$.

Exercise B2: Polarizing a quadratic form.

Over $\mathbb{R}$, let $q(x_1, x_2, x_3) = x_1^2 + 4x_1x_2 - 2x_2x_3 + 5x_3^2$.

(a) Find the symmetric matrix $\mathbf{A}$ with $q(\mathbf{x}) = \mathbf{x}^\top \mathbf{A}\mathbf{x}$.
(b) Compute $\beta(\mathbf{e}_1 + \mathbf{e}_2, \mathbf{e}_3)$ directly from $\mathbf{A}$, and again from the polarization formula $\frac{1}{2}(q(\mathbf{u} + \mathbf{v}) - q(\mathbf{u}) - q(\mathbf{v}))$.

Solution.

(a) The squared terms give $a_{11} = 1$, $a_{22} = 0$, $a_{33} = 5$; the cross terms give $a_{12} = a_{21} = 2$, $a_{23} = a_{32} = -1$, $a_{13} = a_{31} = 0$. So

$$\mathbf{A} = \begin{pmatrix} 1 & 2 & 0 \\ 2 & 0 & -1 \\ 0 & -1 & 5 \end{pmatrix}.$$

(b) Put $\mathbf{u} = (1, 1, 0)$ and $\mathbf{v} = (0, 0, 1)$. Directly, $\mathbf{A}\mathbf{v} = (0, -1, 5)$ and $\mathbf{u}^\top(\mathbf{A}\mathbf{v}) = 0 - 1 = -1$.

By polarization, $q(\mathbf{u}) = 1 + 4 = 5$ and $q(\mathbf{v}) = 5$, while $\mathbf{u} + \mathbf{v} = (1, 1, 1)$ gives $q(\mathbf{u} + \mathbf{v}) =$

$1+4-2+5=8$. Hence $\frac{1}{2}(8-5-5)=-1$. The two agree, as Theorem 13.3.5 says they must.

Exercise B3: Splitting a form.

Let $\mathbf{A}=\begin{pmatrix}1 & 5\\ -1 & 4\end{pmatrix}$ over $\mathbb{Q}$, and let $\beta(\mathbf{x},\mathbf{y})=\mathbf{x}^{\top}\mathbf{A}\mathbf{y}$. Write $\beta=\beta_s+\beta_a$ as in Theorem 13.3.4, giving the matrix of each part, and verify that β and β_s have the same quadratic form.

Solution. We have $\mathbf{A}^{\top}=\left(\begin{smallmatrix}1 & -1\\ 5 & 4\end{smallmatrix}\right)$, so

$$\tfrac{1}{2}(\mathbf{A}+\mathbf{A}^{\top})=\begin{pmatrix}1 & 2\\ 2 & 4\end{pmatrix},\qquad \tfrac{1}{2}(\mathbf{A}-\mathbf{A}^{\top})=\begin{pmatrix}0 & 3\\ -3 & 0\end{pmatrix}.$$

The first is symmetric and the second is alternating, and they sum to $\mathbf{A}$. For the quadratic forms, $\mathbf{x}^{\top}\mathbf{A}\mathbf{x}=x_1^2+5x_1x_2-x_2x_1+4x_2^2=x_1^2+4x_1x_2+4x_2^2$, and the symmetric part gives $x_1^2+2x_1x_2+2x_2x_1+4x_2^2$, the same polynomial. The alternating part contributes $3x_1x_2-3x_2x_1=0$.

13.3.7.3 C. Going deeper

Exercise C1: Is this still true over $\mathbb{F}_2$?.

Let V be a vector space over $\mathbb{F}_2$ with $\dim V=n\geq 1$.

(a) Prove that every alternating bilinear form on V is symmetric.

(b) Prove that the alternating forms on V form a subspace of the space of all bilinear forms, and compute its dimension.

(c) Deduce that for $n=2$ there is exactly one non-zero alternating form on V, and write down its matrix.

Hint: for (b), use Proposition 13.3.2.

Solution.

(a) Let β be alternating. By Theorem 13.3.3 (a), $\beta(\mathbf{u},\mathbf{v})=-\beta(\mathbf{v},\mathbf{u})$. Over $\mathbb{F}_2$ we have $-1=1$, so $-\beta(\mathbf{v},\mathbf{u})=\beta(\mathbf{v},\mathbf{u})$ and β is symmetric.

(b) Fix a basis $\mathcal{B}$. The map $\beta\mapsto[\beta]_{\mathcal{B}}$ is a linear bijection from bilinear forms to $M_n(\mathbb{F}_2)$ (Theorem 13.1.1). By Proposition 13.3.2 (b), β is alternating exactly when its matrix satisfies $\mathbf{A}^{\top}=-\mathbf{A}$ with zero diagonal; over $\mathbb{F}_2$ the first condition is $\mathbf{A}^{\top}=\mathbf{A}$, so the image is the set of symmetric matrices with zero diagonal. Such a matrix is determined freely by its entries a_{ij} with $i<j$, of which there are $\binom{n}{2}$. These conditions are linear, so the set of alternating forms is a subspace, of dimension $n(n-1)/2$.

(c) For $n=2$ the dimension is 1, so the space of alternating forms is $\{\mathbf{0},\beta\}$ for a single non-zero β, whose matrix must be $\left(\begin{smallmatrix}0 & 1\\ 1 & 0\end{smallmatrix}\right)$ — the only symmetric $\mathbb{F}_2$-matrix with zero diagonal other than $\mathbf{0}$. Concretely $\beta(\mathbf{x},\mathbf{y})=x_1y_2+x_2y_1$, and indeed $\beta(\mathbf{x},\mathbf{x})=2x_1x_2=0$.

Exercise C2: How much of a form does q see?.

Let $\operatorname{char} F \neq 2$ and let β be any bilinear form on V, with $q(\mathbf{v}) = \beta(\mathbf{v}, \mathbf{v})$.

(a) Prove that two bilinear forms have the same quadratic form if and only if their difference is alternating.

(b) Deduce that the set of bilinear forms with a given quadratic form q contains exactly one symmetric form.

(c) For $\dim V = n$, how many bilinear forms share a given quadratic form when $F = \mathbb{F}_3$?

Solution.

(a) ($\Rightarrow$) Suppose $\beta_1(\mathbf{v}, \mathbf{v}) = \beta_2(\mathbf{v}, \mathbf{v})$ for all $\mathbf{v}$. Then $\delta = \beta_1 - \beta_2$ is bilinear with $\delta(\mathbf{v}, \mathbf{v}) = 0$ for all $\mathbf{v}$, which is Definition 6.2.2 at $k = 2$.
($\Leftarrow$) If $\delta = \beta_1 - \beta_2$ is alternating then $\beta_1(\mathbf{v}, \mathbf{v}) - \beta_2(\mathbf{v}, \mathbf{v}) = \delta(\mathbf{v}, \mathbf{v}) = 0$ for every $\mathbf{v}$.

(b) Existence: by Theorem 13.3.4 write $\beta = \beta_s + \beta_a$; then β_s is symmetric with the same quadratic form, since $\beta_a(\mathbf{v}, \mathbf{v}) = 0$. Uniqueness: two symmetric forms with the same q are equal by Theorem 13.3.5.

(c) By (a), the forms sharing q are exactly $\beta_s + \beta_a$ with β_a alternating, so there are as many as there are alternating forms. Over a field with 3 elements, an alternating form corresponds by Proposition 13.3.2 (b) to a matrix with $\mathbf{A}^{\top} = -\mathbf{A}$ and zero diagonal, which is determined freely by the $\binom{n}{2}$ entries above the diagonal. So there are $3^{n(n-1)/2}$ of them.

Exercise C3: A Hermitian form is a real symmetric form in disguise.

Let β be a Hermitian form on $\mathbb{C}^n$ with matrix $\mathbf{A} = \mathbf{A}^*$ as in Proposition 13.3.6, and regard $\mathbb{C}^n$ as a real vector space of dimension $2n$ by forgetting multiplication by i.

(a) Prove that $\tau(\mathbf{u}, \mathbf{v}) = \operatorname{Re} \beta(\mathbf{u}, \mathbf{v})$ is a symmetric $\mathbb{R}$-bilinear form on that real space, with $\tau(\mathbf{v}, \mathbf{v}) = \beta(\mathbf{v}, \mathbf{v})$.

(b) Prove that $\omega(\mathbf{u}, \mathbf{v}) = \operatorname{Im} \beta(\mathbf{u}, \mathbf{v})$ is an alternating $\mathbb{R}$-bilinear form.

(c) For $n = 1$ and $\mathbf{A} = (1)$, write both τ and ω as explicit forms on $\mathbb{R}^2$.

Solution.

(a) Taking real parts of an $\mathbb{R}$-linear identity is $\mathbb{R}$-linear, and β is additive in each slot and commutes with real scalars in each slot (conjugation fixes $\mathbb{R}$), so τ is $\mathbb{R}$-bilinear. Symmetry: $\beta(\mathbf{v}, \mathbf{u}) = \overline{\beta(\mathbf{u}, \mathbf{v})}$, and conjugate numbers have equal real parts, so $\tau(\mathbf{v}, \mathbf{u}) = \tau(\mathbf{u}, \mathbf{v})$. Finally $\beta(\mathbf{v}, \mathbf{v})$ is real, as noted after Definition 13.3.3, so $\tau(\mathbf{v}, \mathbf{v}) = \beta(\mathbf{v}, \mathbf{v})$.

(b) $\mathbb{R}$-bilinearity is the same argument with imaginary parts. Conjugate numbers have opposite imaginary parts, so $\omega(\mathbf{v}, \mathbf{u}) = -\omega(\mathbf{u}, \mathbf{v})$: ω is skew-symmetric, and since $\operatorname{char} \mathbb{R} = 0 \neq 2$, Theorem 13.3.3 (b) makes it alternating. (Directly: $\beta(\mathbf{v}, \mathbf{v})$ is real, so its imaginary part is 0.)

(c) Here $\beta(u, v) = u\overline{v}$ for $u, v \in \mathbb{C}$. Writing $u = x_1 + ix_2$ and $v = y_1 + iy_2$, we get $u\overline{v} = (x_1y_1 + x_2y_2) + i(x_2y_1 - x_1y_2)$. So τ is the dot product on $\mathbb{R}^2$ and

$\omega(\mathbf{x}, \mathbf{y}) = x_2y_1 - x_1y_2$, the negative of the signed area.

13.4 Completing the Square

Every symmetric matrix over $\mathbb{R}$ can be diagonalized by an orthogonal matrix, which is Chapter 11's spectral theorem. That theorem needs $\mathbb{R}$, an inner product and the existence of eigenvalues. This section proves a weaker conclusion under far weaker hypotheses: over **any** field of characteristic $\neq 2$, with no inner product, no order and no eigenvalues available, every symmetric form still becomes diagonal after a change of basis — provided we ask only for congruence, not for similarity. The proof is one algebraic manipulation, completing the square, run by induction; and the induction has a case that a careless proof loses.

Throughout, F is a field with $\operatorname{char} F \neq 2$ (Definition 0.7.2), V is a finite-dimensional vector space over F, β is a **symmetric** bilinear form on V (Definition 13.3.1), and $q(\mathbf{v}) = \beta(\mathbf{v}, \mathbf{v})$ is its quadratic form (Definition 13.3.2).

13.4.1 Orthogonality without an inner product

Chapter 10 called two vectors orthogonal when their inner product vanished. The word survives the loss of positivity unchanged, because only the vanishing was ever used.

Definition 13.4.1 — Orthogonal Basis for a Form

Let β be a bilinear form on V. Vectors $\mathbf{u}, \mathbf{v} \in V$ are **orthogonal with respect to** β if $\beta(\mathbf{u}, \mathbf{v}) = 0$. An ordered basis $\mathcal{B} = (\mathbf{v}_1, \dots, \mathbf{v}_n)$ of V is an **orthogonal basis for** β if

$$\beta(\mathbf{v}_i, \mathbf{v}_j) = 0 \qquad \text{whenever } i \neq j.$$

The definition is engineered to say exactly one thing about matrices: by Definition 13.1.2, $\mathcal{B}$ is an orthogonal basis for β precisely when $[\beta]_{\mathcal{B}}$ is a **diagonal** matrix, with $q(\mathbf{v}_1), \dots, q(\mathbf{v}_n)$ down the diagonal. Two warnings come free. The vectors of such a basis are not required to satisfy $q(\mathbf{v}_i) = 1$, and over a general field they usually cannot be rescaled to. And a vector may be orthogonal to itself: $q(\mathbf{v}_i) = 0$ is allowed, and for a degenerate form it is unavoidable.

What an orthogonal basis buys is that q becomes a sum of squares with no cross terms. If $\mathbf{v} = c_1\mathbf{v}_1 + \cdots + c_n\mathbf{v}_n$ and $d_i = q(\mathbf{v}_i)$, then expanding by bilinearity and deleting the $i \neq j$ terms,

$$q(\mathbf{v}) = \sum_{i=1}^{n} d_i\, c_i^2. \tag{13.4.1}$$

That is the "sum of squares" a reader has met when completing the square in two variables, and Eq. 13.4.1 is the reason the whole section is called what it is.

13.4.2 The theorem, and the case that breaks it

Here is the naive argument, and it is worth seeing it fail. To make $q(\mathbf{v}) = ax_1^2 + 2bx_1x_2 + cx_2^2$ into a sum of squares, write

$$q = a\Big(x_1 + \frac{b}{a}x_2\Big)^2 + \Big(c - \frac{b^2}{a}\Big)x_2^2,$$

which is exactly a change of variable. The step divides by $a = q(\mathbf{e}_1)$. If $a = 0$ there is nothing to complete, and one may hope to start with x_2 instead — but $q(\mathbf{x}) = 2x_1x_2$ has $q(\mathbf{e}_1) = q(\mathbf{e}_2) = 0$, and neither variable offers a foothold. The repair is to change the vector, not the variable: $q(\mathbf{e}_1 + \mathbf{e}_2) = 2 \neq 0$. That repair is a lemma, and it is where $\operatorname{char} F \neq 2$ is spent.

Lemma 13.4.1 — A Non-Zero Form Is Non-Zero Somewhere on the Diagonal

Let $\operatorname{char} F \neq 2$ and let β be a symmetric bilinear form on V with $\beta \neq 0$. Then there exists $\mathbf{v} \in V$ with $q(\mathbf{v}) \neq 0$.

Proof. Since $\beta \neq 0$, there are $\mathbf{u}, \mathbf{w} \in V$ with $a = \beta(\mathbf{u}, \mathbf{w}) \neq 0$. If $q(\mathbf{u}) \neq 0$ or $q(\mathbf{w}) \neq 0$ we are done. So suppose $q(\mathbf{u}) = q(\mathbf{w}) = 0$. Expanding by bilinearity and using symmetry,

$$q(\mathbf{u} + \mathbf{w}) = q(\mathbf{u}) + 2\beta(\mathbf{u}, \mathbf{w}) + q(\mathbf{w}) = (1 + 1)a.$$

Since $\operatorname{char} F \neq 2$, the element $1 + 1$ is non-zero, and a product of two non-zero elements of a field is non-zero, so $q(\mathbf{u} + \mathbf{w}) \neq 0$. This proves the lemma. ∎

Contrapositively: if q vanishes identically then $\beta = 0$. That is the case the induction must handle separately, and the lemma is what lets it be handled in one line.

Theorem 13.4.2 — Diagonalization of a Symmetric Form

Let F be a field with $\operatorname{char} F \neq 2$, let V be a finite-dimensional vector space over F, and let β be a symmetric bilinear form on V. Then V has an orthogonal basis for β.

Equivalently: every symmetric $\mathbf{A} \in M_n(F)$ is congruent to a diagonal matrix, that is, there is an invertible $\mathbf{P} \in M_n(F)$ with $\mathbf{P}^{\top}\mathbf{A}\mathbf{P}$ diagonal.

Idea. Induction on $\dim V$. The step wants to peel off one basis vector and recurse on a complement, exactly as "peel off an eigenvector" does in Chapter 8 — but the complement here is the set of vectors orthogonal to the chosen one, not an invariant subspace, and it is available only if the chosen $\mathbf{v}_1$ has $q(\mathbf{v}_1) \neq 0$. So the proof splits into two steps: ① if q vanishes everywhere, the form is zero and **every** basis is orthogonal; ② otherwise Lemma 13.4.1 supplies a $\mathbf{v}_1$ with $q(\mathbf{v}_1) \neq 0$, the linear functional $\mathbf{w} \mapsto \beta(\mathbf{v}_1, \mathbf{w})$ is non-zero, its kernel W is a hyperplane meeting $\operatorname{span}(\mathbf{v}_1)$ trivially, and the induction hypothesis applies to β restricted to W. Step ① is not a formality: without it the argument has no base for the recursion when the form degenerates, and the word "equivalently" in the statement would be unearned.

Proof. We induct on $n = \dim V$. If $n = 0$ the empty basis is orthogonal, vacuously; if $n = 1$ any basis $(\mathbf{v}_1)$ is orthogonal, since there is no pair $i \neq j$. Let $n \geq 2$ and suppose the result holds for all spaces of dimension $n - 1$ over F.

Step 1: the form vanishes on the diagonal. Suppose $q(\mathbf{v}) = 0$ for every $\mathbf{v} \in V$. By Lemma 13.4.1, read contrapositively, $\beta = 0$. Then $\beta(\mathbf{v}_i, \mathbf{v}_j) = 0$ for every pair of vectors whatsoever, so **any** basis of V is an orthogonal basis for β, and its matrix is $\mathbf{0}$, which is diagonal.

Step 2: the form does not vanish on the diagonal. Otherwise there is $\mathbf{v}_1 \in V$ with $c = q(\mathbf{v}_1) \neq 0$; in particular $\mathbf{v}_1 \neq \mathbf{0}$. Define

$$\varphi \colon V \to F, \qquad \varphi(\mathbf{w}) = \beta(\mathbf{v}_1, \mathbf{w}).$$

Then φ is linear, because β is linear in its second argument, and $\varphi(\mathbf{v}_1) = c \neq 0$, so $\varphi \neq 0$. A non-zero functional is surjective onto F (Proposition 4.1.2), so $\operatorname{rank} \varphi = 1$ and, by the Rank–Nullity Theorem (Theorem 3.3.1), $W = \ker \varphi$ has $\dim W = n - 1$.

Moreover $\operatorname{span}(\mathbf{v}_1) \cap W = \{\mathbf{0}\}$: if $a\mathbf{v}_1 \in W$ then $0 = \varphi(a\mathbf{v}_1) = ac$, and $c \neq 0$ forces $a = 0$. So the sum $\operatorname{span}(\mathbf{v}_1) + W$ is direct, and $\dim(\operatorname{span}(\mathbf{v}_1) + W) = 1 + (n - 1) = n$, both by Theorem 1.7.4. A subspace of V of dimension $\dim V$ is all of V (Theorem 1.6.8), so

$$V = \operatorname{span}(\mathbf{v}_1) \oplus W.$$

The restriction of β to $W \times W$ is a bilinear form on W, and it is symmetric because β is. As $\dim W = n - 1$, the induction hypothesis provides an orthogonal basis $(\mathbf{v}_2, \dots, \mathbf{v}_n)$ of W for that restriction.

Concatenating bases of the summands of a direct sum gives a basis of it (Theorem 1.7.5, (a) $\Leftrightarrow$ (d)), so $\mathcal{B} = (\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_n)$ is a basis of V. It is orthogonal for β: for $j \geq 2$ we have $\mathbf{v}_j \in W = \ker \varphi$, so $\beta(\mathbf{v}_1, \mathbf{v}_j) = \varphi(\mathbf{v}_j) = 0$, and $\beta(\mathbf{v}_j, \mathbf{v}_1) = 0$ by symmetry; and for $2 \leq i \neq j$ the value $\beta(\mathbf{v}_i, \mathbf{v}_j)$ is 0 by the choice of the basis of W. This completes the induction.

For the matrix statement, let $\mathbf{A} \in M_n(F)$ be symmetric and let $\beta(\mathbf{x}, \mathbf{y}) = \mathbf{x}^{\top}\mathbf{A}\mathbf{y}$ on $V = F^n$, which is symmetric by Proposition 13.3.1 and has $[\beta]_{\mathcal{E}} = \mathbf{A}$ in the standard basis $\mathcal{E}$. Take an orthogonal basis $\mathcal{B}$ as above and let $\mathbf{P} = [\mathrm{id}]_{\mathcal{B}}^{\mathcal{E}}$, the matrix whose columns are the vectors of $\mathcal{B}$, which is invertible. By Theorem 13.2.1, $[\beta]_{\mathcal{B}} = \mathbf{P}^{\top}\mathbf{A}\mathbf{P}$, and this matrix is diagonal. This proves the theorem.

■

Two hypotheses did visible work. Symmetry was used twice: to make $\beta(\mathbf{v}_j, \mathbf{v}_1)$ vanish along with $\beta(\mathbf{v}_1, \mathbf{v}_j)$, and to keep the restriction to W symmetric so the induction could run. The characteristic hypothesis was used exactly once, inside Lemma 13.4.1 — and that single use is essential: Exercise C2 below exhibits a symmetric matrix over $\mathbb{F}_2$ that is congruent to no diagonal matrix at all.

Warning. **Diagonal does not mean "the diagonal entries are eigenvalues".** The matrix $\mathbf{P}^{\top}\mathbf{A}\mathbf{P}$ of Theorem 13.4.2 is congruent to $\mathbf{A}$, not similar to it, and its entries are the values $q(\mathbf{v}_i)$ at whatever basis the algorithm happened to produce. Over $\mathbb{R}$ they can be scaled at will: replacing $\mathbf{v}_i$ by $t\mathbf{v}_i$ replaces d_i by $t^2 d_i$. There is no canonical list of numbers here. The next section finds what there *is*.

Quick check. In Theorem 13.4.2, how many of the diagonal entries d_i are zero?

Solution. Exactly $n - \operatorname{rank} \mathbf{A}$ of them. A diagonal matrix has rank equal to its number of non-zero entries, and congruence preserves rank (Theorem 13.2.3), so the count is the same for every orthogonal basis even though the individual d_i are not. In the language of Section 1, those $\mathbf{v}_i$ with $d_i = 0$ span the radical $\operatorname{rad}(\beta)$ of Definition 13.1.3, since in an orthogonal basis such a $\mathbf{v}_i$ pairs to zero with every basis vector; and β is non-degenerate (Definition 13.1.4) exactly when no d_i is zero.

13.4.3 The algorithm: symmetric row and column operations

The proof is constructive, but running it by hand means chasing kernels of functionals. There is a bookkeeping device that does the same work on the matrix directly, and it is the practical content of this section.

The key observation is that a congruence by an elementary matrix is a **pair** of operations. Let $\mathbf{E}$ be an elementary matrix (Definition 2.4.1). Right multiplication $\mathbf{AE}$ performs a column operation, and left multiplication $\mathbf{E}^{\top}\mathbf{A}$ performs the corresponding row operation. So $\mathbf{A} \mapsto \mathbf{E}^{\top}\mathbf{AE}$ performs both, and the result is congruent to $\mathbf{A}$ and again symmetric. Doing the operations in pairs is exactly what keeps the matrix symmetric, and that is the whole idea.

Algorithm. To diagonalize a symmetric $\mathbf{A} \in M_n(F)$ by congruence, write $\mathbf{A}$ and $\mathbf{I}_n$ side by side and repeat, for $i = 1, 2, \dots, n$ in turn:

- **If** $a_{ii} = 0$ **but some** $a_{jj} \neq 0$ **with** $j > i$, swap rows i, j and then columns i, j.
- **If** $a_{ii} = 0$ **and every** $a_{jj} = 0$ **for** $j \geq i$, look for an entry $a_{ij} \neq 0$ with $j > i$. If there is none, then row i and column i are already zero in every position, so move on to $i + 1$. If there is one, add row j to row i, then column j to column i; the new a_{ii} is $2a_{ij} \neq 0$.
- **Now** $a_{ii} \neq 0$**.** For each $j > i$ with $a_{ij} \neq 0$, subtract (a_{ij}/a_{ii}) times row i from row j, then (a_{ij}/a_{ii}) times column i from column j.

Over a field where division is inconvenient — $\mathbb{Q}$ or $\mathbb{Z}$-valued data by hand — the clearing step may instead be done as row $j \mapsto a_{ii}\,\text{row } j - a_{ij}\,\text{row } i$, with the matching column operation. That is the same move composed with scaling row and column j by $a_{ii} \neq 0$, which is itself a congruence, so it is legitimate; it keeps the entries integral and changes the diagonal result only by square factors. The worked example below takes this route.

Perform only the **column** half of each operation on the matrix standing to the right. When $\mathbf{A}$ has become diagonal, that matrix is $\mathbf{P}$, and $\mathbf{P}^{\top}\mathbf{AP}$ is the diagonal result.

The second bullet is Lemma 13.4.1 made mechanical, and the factor $2 = 1 + 1$ in it is where the algorithm would stop in characteristic 2. The right-hand matrix works because applying the column operations $\mathbf{E}_1, \mathbf{E}_2, \dots, \mathbf{E}_k$ in order turns $\mathbf{I}$ into $\mathbf{E}_1\mathbf{E}_2 \cdots \mathbf{E}_k$, which is the product whose transpose and self sandwich $\mathbf{A}$.

Example. (Diagonalizing a symmetric matrix with zero diagonal)

Over $\mathbb{Q}$, diagonalize

$$\mathbf{A} = \begin{pmatrix} 0 & 1 & 1 \\ 1 & 0 & 1 \\ 1 & 1 & 0 \end{pmatrix}$$

by congruence, producing an invertible $\mathbf{P}$ with $\mathbf{P}^\top \mathbf{A}\mathbf{P}$ diagonal.

Solution. The form is $q(\mathbf{x}) = 2x_1x_2 + 2x_1x_3 + 2x_2x_3$: every diagonal entry is 0, so there is no square to complete yet, and the second bullet applies.

Step 1 (create a pivot). Add row 2 to row 1, then column 2 to column 1. The matrix becomes

$$\begin{pmatrix} 1 & 1 & 2 \\ 1 & 0 & 1 \\ 1 & 1 & 0 \end{pmatrix} \longrightarrow \begin{pmatrix} 2 & 1 & 2 \\ 1 & 0 & 1 \\ 2 & 1 & 0 \end{pmatrix},$$

the left matrix after the row operation and the right one after the matching column operation. The new corner entry is $q(\mathbf{e}_1 + \mathbf{e}_2) = 2$.

Step 2 (clear the first row and column, in two paired moves). Rather than divide by 2, use the operation "row $2 \mapsto 2 \cdot$ row $2 -$ row 1", which is a scaling followed by an addition, hence a congruence by a product of two elementary matrices, and legitimate because $2 \neq 0$ in $\mathbb{Q}$. Apply it and its column partner. This keeps every entry an integer:

$$\begin{pmatrix} 2 & 1 & 2 \\ 0 & -1 & 0 \\ 2 & 1 & 0 \end{pmatrix} \longrightarrow \begin{pmatrix} 2 & 0 & 2 \\ 0 & -2 & 0 \\ 2 & 0 & 0 \end{pmatrix}.$$

Then "row $3 \mapsto$ row $3 -$ row 1" and its column partner:

$$\begin{pmatrix} 2 & 0 & 2 \\ 0 & -2 & 0 \\ 0 & 0 & -2 \end{pmatrix} \longrightarrow \begin{pmatrix} 2 & 0 & 0 \\ 0 & -2 & 0 \\ 0 & 0 & -2 \end{pmatrix}.$$

The transforming matrix. Applying the three **column** operations to $\mathbf{I}_3$ in the same order gives

$$\mathbf{I}_3 \to \begin{pmatrix} 1 & 0 & 0 \\ 1 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \to \begin{pmatrix} 1 & -1 & 0 \\ 1 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \to \begin{pmatrix} 1 & -1 & -1 \\ 1 & 1 & -1 \\ 0 & 0 & 1 \end{pmatrix} = \mathbf{P}.$$

Here $\det \mathbf{P} = 2 \neq 0$, so $\mathbf{P}$ is invertible, and

$$\mathbf{P}^\top \mathbf{A}\mathbf{P} = \operatorname{diag}(2, -2, -2).$$

The check is one column at a time: with $\mathbf{p}_1 = (1, 1, 0)$, $\mathbf{p}_2 = (-1, 1, 0)$ and $\mathbf{p}_3 = (-1, -1, 1)$, we get $q(\mathbf{p}_1) = 2$, $q(\mathbf{p}_2) = -2$ and $q(\mathbf{p}_3) = 2 - 2 - 2 = -2$, while $\beta(\mathbf{p}_1, \mathbf{p}_2) = \mathbf{p}_1^\top \mathbf{A}\mathbf{p}_2 = (1, 1, 0) \cdot (1, -1, 0) = 0$ and similarly for the other two pairs.

Two observations about that example. The determinants are $\det \mathbf{A} = 2$ and $\det(\mathbf{P}^\top \mathbf{A}\mathbf{P}) = 8$, and they differ by $(\det \mathbf{P})^2 = 4$: a congruence multiplies the determinant by a square, which is the discriminant statement of Section 2. And the eigenvalues of $\mathbf{A}$ are $2, -1, -1$, whose signs are $+, -, -$ — the same pattern of signs as $2, -2, -2$, with none of the same numbers. That

coincidence is Section 5.

13.4.4 Over the complex numbers, and over a general field

The diagonal entries produced by the algorithm are not canonical, but there is a precise statement of how much freedom remains.

Proposition 13.4.3 — Diagonal Entries Are Defined Only up to Squares

Let $\mathcal{B} = (\mathbf{v}_1, \dots, \mathbf{v}_n)$ be an orthogonal basis for β with $d_i = q(\mathbf{v}_i)$, and let $t_1, \dots, t_n \in F$ be non-zero. Then $(t_1\mathbf{v}_1, \dots, t_n\mathbf{v}_n)$ is again an orthogonal basis for β, with diagonal entries $t_i^2 d_i$.

Proof. Scaling basis vectors by non-zero scalars again gives a basis. For $i \neq j$, bilinearity gives $\beta(t_i\mathbf{v}_i, t_j\mathbf{v}_j) = t_i t_j \beta(\mathbf{v}_i, \mathbf{v}_j) = 0$, so the new basis is orthogonal; and $q(t_i\mathbf{v}_i) = t_i^2 q(\mathbf{v}_i) = t_i^2 d_i$. ∎

So each non-zero d_i can be changed to any other element of its coset in the group $F^\times/(F^\times)^2$ of **square classes**, and no further, by this move. How much that costs depends entirely on the arithmetic of F:

- Over $\mathbb{C}$, every element is a square, so there is exactly one non-zero square class and every non-zero d_i can be turned into 1.
- Over $\mathbb{R}$, the squares are the positive numbers, so there are two classes and every non-zero d_i can be turned into 1 or -1, according to its sign — the subject of the next section.
- Over $\mathbb{Q}$ there are infinitely many classes ($2, 3, 5, \dots$ are pairwise inequivalent), so the 1-dimensional forms $q(x) = x^2$ and $q(x) = 2x^2$ are already non-congruent.
- Over $\mathbb{F}_p$ with p odd there are exactly two classes, as for $\mathbb{R}$, but "which class" is not a matter of sign.

The complex case collapses completely.

Corollary 13.4.4 — Classification of Complex Symmetric Matrices by Rank

Let $\mathbf{A} \in M_n(\mathbb{C})$ be symmetric of rank r. Then $\mathbf{A}$ is congruent to

$$\mathbf{I}_r \oplus \mathbf{0}_{n-r} = \operatorname{diag}(\underbrace{1, \dots, 1}_{r}, 0, \dots, 0).$$

Consequently two symmetric matrices in $M_n(\mathbb{C})$ are congruent if and only if they have the same rank, and there are exactly $n + 1$ congruence classes.

Proof. By Theorem 13.4.2 (with $\operatorname{char}\mathbb{C} = 0$) there is an invertible $\mathbf{P}_1$ with $\mathbf{P}_1^\top \mathbf{A}\mathbf{P}_1 = \mathbf{D} = \operatorname{diag}(d_1, \dots, d_n)$ diagonal. Congruence preserves rank (Theorem 13.2.3), and the rank of a diagonal matrix is its number of non-zero entries, so exactly r of the d_i are non-zero. Permuting the basis vectors is a congruence by a permutation matrix $\mathbf{P}_2$, so we may assume $d_1, \dots, d_r \neq 0$ and $d_{r+1} = \cdots = d_n = 0$.

Every non-zero complex number has a square root, so choose $s_i \in \mathbb{C}$ with $s_i^2 = d_i$ for $i \leq r$, and set $t_i = 1/s_i$ for $i \leq r$ and $t_i = 1$ otherwise. By Proposition 13.4.3 the congruence by $\mathbf{P}_3 = \operatorname{diag}(t_1, \dots, t_n)$ replaces d_i by $t_i^2 d_i$, which is 1 for $i \leq r$ and 0 otherwise. So $\mathbf{P}^\top \mathbf{A}\mathbf{P} = \mathbf{I}_r \oplus \mathbf{0}_{n-r}$ with $\mathbf{P} = \mathbf{P}_1\mathbf{P}_2\mathbf{P}_3$.

For the classification: congruent matrices have equal rank by Theorem 13.2.3, and matrices of equal rank are both congruent to the same normal form, hence to each other by Proposition 13.2.2. The possible ranks are $0, 1, \dots, n$, giving $n + 1$ classes. This proves the corollary.

■

Contrast this with similarity, where complex symmetric matrices are not classified by anything so simple: the matrix $\left(\begin{smallmatrix} 1 & i \\ i & -1 \end{smallmatrix}\right)$ is symmetric, non-zero, and satisfies $\mathbf{A}^2 = \mathbf{0}$, so it is not even diagonalizable as an operator. Congruence is a coarser relation than similarity on symmetric matrices, and over $\mathbb{C}$ it is coarse enough to be finite.

13.4.5 Exercises

13.4.5.1 A. Check your understanding

Exercise A1.

(a) Define what it means for an ordered basis to be an **orthogonal basis for a bilinear form** β, and say what that means about $[\beta]_{\mathcal{B}}$.

(b) State Theorem 13.4.2 with all of its hypotheses.

(c) Which step of the proof uses $\operatorname{char} F \neq 2$, and what exactly is divided by?

(d) Determine whether the following statement is correct, and justify your answer: if $\mathbf{P}^\top \mathbf{A}\mathbf{P} = \operatorname{diag}(d_1, \dots, d_n)$, then the d_i are the eigenvalues of $\mathbf{A}$.

(e) Describe the pair of operations that a congruence by an elementary matrix performs.

Solution.

(a) $\mathcal{B} = (\mathbf{v}_1, \dots, \mathbf{v}_n)$ is orthogonal for β if $\beta(\mathbf{v}_i, \mathbf{v}_j) = 0$ whenever $i \neq j$. Equivalently $[\beta]_{\mathcal{B}}$ is diagonal, with entries $q(\mathbf{v}_i)$.

(b) If $\operatorname{char} F \neq 2$, V is finite-dimensional over F and β is a symmetric bilinear form on V, then V has an orthogonal basis for β; equivalently every symmetric $\mathbf{A} \in M_n(F)$ is congruent to a diagonal matrix.

(c) Lemma 13.4.1, inside Step 2 of the proof. It produces $q(\mathbf{u} + \mathbf{w}) = (1 + 1)\beta(\mathbf{u}, \mathbf{w})$ and needs $1 + 1 \neq 0$ to conclude that this is non-zero. Equivalently, the algorithm's repair move multiplies by 2, so it needs $2 \neq 0$.

(d) Incorrect. The relation is congruence, not similarity. In Example (Diagonalizing a symmetric matrix with zero diagonal) the diagonal entries are $2, -2, -2$ while the eigenvalues are $2, -1, -1$. Only the signs matched there, and Section 5 explains why.

(e) A column operation and the matching row operation: $\mathbf{A} \mapsto \mathbf{E}^{\top}\mathbf{A}\mathbf{E}$. Performing both keeps the matrix symmetric and keeps it in the same congruence class.

13.4.5.2 B. Practice

Exercise B1: Symmetric elimination.

Over $\mathbb{Q}$, let

$$\mathbf{A} = \begin{pmatrix} 1 & 2 & 0 \\ 2 & 1 & 3 \\ 0 & 3 & 1 \end{pmatrix}.$$

Diagonalize $\mathbf{A}$ by paired row and column operations, exhibiting $\mathbf{P}$ and $\mathbf{P}^{\top}\mathbf{A}\mathbf{P}$.

Solution. Here $a_{11} = 1 \neq 0$, so the pivot is already available.

Clear the first row and column. Subtract $2\times$ row 1 from row 2, then $2\times$ column 1 from column 2. The entry a_{13} is already 0, so nothing else is needed in this round:

$$\begin{pmatrix} 1 & 2 & 0 \\ 0 & -3 & 3 \\ 0 & 3 & 1 \end{pmatrix} \longrightarrow \begin{pmatrix} 1 & 0 & 0 \\ 0 & -3 & 3 \\ 0 & 3 & 1 \end{pmatrix}.$$

Clear the second row and column. The pivot is -3, and $a_{23} = 3$, so add row 2 to row 3 and then column 2 to column 3:

$$\begin{pmatrix} 1 & 0 & 0 \\ 0 & -3 & 3 \\ 0 & 0 & 4 \end{pmatrix} \longrightarrow \begin{pmatrix} 1 & 0 & 0 \\ 0 & -3 & 0 \\ 0 & 0 & 4 \end{pmatrix}.$$

The transforming matrix. Applying the two column operations to $\mathbf{I}_3$ gives

$$\mathbf{P} = \begin{pmatrix} 1 & -2 & -2 \\ 0 & 1 & 1 \\ 0 & 0 & 1 \end{pmatrix}, \qquad \mathbf{P}^{\top}\mathbf{A}\mathbf{P} = \operatorname{diag}(1, -3, 4).$$

As a check, $\det \mathbf{P} = 1$ and $\det \mathbf{A} = -12 = \det \operatorname{diag}(1, -3, 4)$.

Exercise B2: No pivot on the diagonal.

Over $\mathbb{Q}$, let $\mathbf{A} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$ and $q(\mathbf{x}) = 2x_1x_2$.

(a) Find a vector $\mathbf{v}$ with $q(\mathbf{v}) \neq 0$, as in Lemma 13.4.1.

(b) Diagonalize $\mathbf{A}$ by paired operations and exhibit $\mathbf{P}$.

(c) Write q as a difference of two squares in the new coordinates.

Solution.

(a) Both $\mathbf{e}_1$ and $\mathbf{e}_2$ give $q = 0$, so take $\mathbf{v} = \mathbf{e}_1 + \mathbf{e}_2$: $q(\mathbf{v}) = 2 \neq 0$.

(b) Add row 2 to row 1, then column 2 to column 1, reaching $\left(\begin{smallmatrix} 2 & 1 \\ 1 & 0 \end{smallmatrix}\right)$. Then apply "row $2 \mapsto 2 \cdot$ row $2 -$ row 1" and its column partner, reaching $\operatorname{diag}(2, -2)$. Applying the same two column operations to $\mathbf{I}_2$ gives

$$\mathbf{P} = \begin{pmatrix} 1 & -1 \\ 1 & 1 \end{pmatrix}, \qquad \mathbf{P}^\top \mathbf{A} \mathbf{P} = \operatorname{diag}(2, -2).$$

Check directly: $\mathbf{P}^\top \mathbf{A} = \left(\begin{smallmatrix} 1 & 1 \\ 1 & -1 \end{smallmatrix}\right)$ and multiplying by $\mathbf{P}$ gives $\left(\begin{smallmatrix} 2 & 0 \\ 0 & -2 \end{smallmatrix}\right)$.

(c) With $\mathbf{x} = \mathbf{P}\mathbf{y}$, that is $x_1 = y_1 - y_2$ and $x_2 = y_1 + y_2$, we get $q = 2(y_1 - y_2)(y_1 + y_2) = 2y_1^2 - 2y_2^2$. This is the familiar identity $ab = \left(\frac{a+b}{2}\right)^2 - \left(\frac{a-b}{2}\right)^2$ read as a change of variable, and it needs 2 to be invertible.

Exercise B3: Reading off the rank.

Let $\mathbf{A} \in M_4(\mathbb{C})$ be symmetric with $\operatorname{rank} \mathbf{A} = 3$. Write down the normal form of $\mathbf{A}$ under congruence, and say how many congruence classes of symmetric matrices there are in $M_4(\mathbb{C})$.

Solution. By Corollary 13.4.4, $\mathbf{A}$ is congruent to $\mathbf{I}_3 \oplus \mathbf{0}_1 = \operatorname{diag}(1, 1, 1, 0)$. Since rank is a complete invariant there, the classes correspond to the possible ranks $0, 1, 2, 3, 4$, so there are 5 of them.

13.4.5.3 C. Going deeper

Exercise C1: Square classes over a finite field.

Work over $\mathbb{F}_5$, whose non-zero squares are 1 and 4.

(a) Prove that the 1×1 matrices (1) and (2) are not congruent over $\mathbb{F}_5$.

(b) Prove that $\mathbf{I}_2$ and $2\mathbf{I}_2$ **are** congruent over $\mathbb{F}_5$, by exhibiting a $\mathbf{P}$.

(c) Explain why (a) and (b) are consistent with Proposition 13.4.3.

Hint: for (b), look for two vectors $\mathbf{p}_1, \mathbf{p}_2$ with $\mathbf{p}_i \cdot \mathbf{p}_i = 2$ and $\mathbf{p}_1 \cdot \mathbf{p}_2 = 0$.

Solution.

(a) A congruence of 1×1 matrices is $(a) \mapsto (p^2 a)$ with $p \neq 0$. So (1) and (2) are congruent exactly when $2 = p^2$ for some $p \in \mathbb{F}_5^\times$. The squares of $1, 2, 3, 4$ are $1, 4, 4, 1$, so 2 is not a square and the two are not congruent.

(b) Take $\mathbf{p}_1 = (1, 1)$ and $\mathbf{p}_2 = (1, 4)$. Then $\mathbf{p}_1 \cdot \mathbf{p}_1 = 2$, $\mathbf{p}_2 \cdot \mathbf{p}_2 = 1 + 16 = 17 = 2$ and $\mathbf{p}_1 \cdot \mathbf{p}_2 = 1 + 4 = 5 = 0$ in $\mathbb{F}_5$. With

$$\mathbf{P} = \begin{pmatrix} 1 & 1 \\ 1 & 4 \end{pmatrix}, \qquad \det \mathbf{P} = 4 - 1 = 3 \neq 0,$$

we get $\mathbf{P}^\top \mathbf{I}_2 \mathbf{P} = \mathbf{P}^\top \mathbf{P} = \operatorname{diag}(2, 2) = 2\mathbf{I}_2$.

(c) Proposition 13.4.3 only says what **rescaling a single basis vector** can do, and that move cannot change a square class. Part (b) does not contradict it, because the congruence there is not diagonal: it mixes the two coordinates, and both diagonal entries change square class at once. What is invariant is the class of their product, the **determinant**: $\det \mathbf{I}_2 = 1$ and $\det(2\mathbf{I}_2) = 4$ differ by $4 = 2^2$, a square.

Exercise C2: Is this still true over $\mathbb{F}_2$?.

Let $\mathbf{A} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$ over $\mathbb{F}_2$, and let $\beta(\mathbf{x}, \mathbf{y}) = \mathbf{x}^\top \mathbf{A}\mathbf{y}$ on $\mathbb{F}_2^2$.

(a) Prove that β is alternating.

(b) Prove that if $\mathbf{P} \in M_2(\mathbb{F}_2)$ is invertible, then every diagonal entry of $\mathbf{P}^\top \mathbf{A}\mathbf{P}$ is 0.

(c) Deduce that $\mathbf{A}$ is congruent to **no** diagonal matrix except the zero matrix, and hence that Theorem 13.4.2 fails over $\mathbb{F}_2$.

Solution.

(a) By Proposition 13.3.2 (b): over $\mathbb{F}_2$ we have $-\mathbf{A} = \mathbf{A}$, so $\mathbf{A}^\top = \mathbf{A} = -\mathbf{A}$, and the diagonal entries of $\mathbf{A}$ are 0. (Directly: $\beta(\mathbf{x}, \mathbf{x}) = 2x_1x_2 = 0$.)

(b) The i-th diagonal entry of $\mathbf{P}^\top \mathbf{A}\mathbf{P}$ is $\mathbf{p}_i^\top \mathbf{A}\mathbf{p}_i = q(\mathbf{p}_i)$, where $\mathbf{p}_i$ is the i-th column of $\mathbf{P}$. By (a), q vanishes identically, so every diagonal entry is 0.

(c) A diagonal matrix congruent to $\mathbf{A}$ has all diagonal entries 0 by (b), hence is the zero matrix. But congruence preserves rank (Theorem 13.2.3) and $\operatorname{rank} \mathbf{A} = 2 \neq 0 = \operatorname{rank} \mathbf{0}$. So no diagonal matrix is congruent to $\mathbf{A}$. Since $\mathbf{A}$ is symmetric over $\mathbb{F}_2$, the conclusion of Theorem 13.4.2 fails there, and the hypothesis $\operatorname{char} F \neq 2$ cannot be dropped.

Exercise C3: Diagonalizing the restriction.

Let $\operatorname{char} F \neq 2$, let β be a symmetric bilinear form on V, and let $U \subseteq V$ be a subspace.

(a) Prove that U has an orthogonal basis for the restriction of β to U.

(b) Give an example, with $\dim V = 2$, in which β is non-degenerate but its restriction to some 1-dimensional U is the zero form.

(c) Deduce that an orthogonal basis of U cannot always be extended to an orthogonal basis of V by adding vectors of U alone, and say in one sentence what Theorem 13.4.2 does guarantee instead.

Solution.

(a) The restriction $\beta|_{U \times U}$ is bilinear, since it is the same function on a smaller domain, and symmetric for the same reason. U is finite-dimensional, being a subspace of a finite-dimensional space (Theorem 1.6.7). So Theorem 13.4.2 applies to $(U, \beta|_{U \times U})$ directly.

(b) Over $\mathbb{Q}$ take $\beta(\mathbf{x}, \mathbf{y}) = x_1y_2 + x_2y_1$ on $\mathbb{Q}^2$, with matrix $\left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$, which is invertible, so β is non-degenerate. Put $U = \operatorname{span}(\mathbf{e}_1)$. Then $\beta(a\mathbf{e}_1, b\mathbf{e}_1) = 0$ for all a, b, so the restriction is the zero form even though β is not.

(c) In (b) the single vector $\mathbf{e}_1$ is an orthogonal basis of U, but no vector of U can be added to it, and any orthogonal basis of V for this β must consist of vectors $\mathbf{v}$ with $q(\mathbf{v}) \neq 0$ (its matrix is diagonal and invertible), so $\mathbf{e}_1$ belongs to none of them. What the theorem guarantees is only the existence of *some* orthogonal basis of V, built from scratch; it promises nothing about extending a given orthogonal list, and Section 8 is where a correct extension statement finally appears.

13.5 Sylvester's Law of Inertia

The previous section produced a diagonal matrix and then took it away again: the diagonal entries are not invariants, because rescaling the i-th basis vector by t multiplies the i-th entry by t^2. Over $\mathbb{R}$ the squares are exactly the positive numbers, so rescaling can change the size of an entry but never its sign. This section proves that the signs are all that survives, and that they survive completely: the number of positive, negative and zero entries is the same for every diagonalization. That is the classification of real symmetric matrices up to congruence, and it is also the missing link between congruence and the spectral theorem.

Throughout this section the field is $\mathbb{R}$. Every form is a symmetric bilinear form on a finite-dimensional real vector space V, and every matrix is a real symmetric matrix. The words "positive" and "negative" have no meaning over a general field, and almost nothing in this section survives the move to one; Corollary 13.4.4 already showed that over $\mathbb{C}$ the answer is different, since rank alone classifies there.

13.5.1 Normalizing the diagonal

Start from Theorem 13.4.2, which applies because $\operatorname{char}\mathbb{R} = 0$. It gives an orthogonal basis $(\mathbf{v}_1, \dots, \mathbf{v}_n)$ for β, with $q(\mathbf{v}_i) = d_i$. Over $\mathbb{R}$ we may go one step further and scale.

By Proposition 13.4.3, replacing $\mathbf{v}_i$ by $t_i\mathbf{v}_i$ replaces d_i by $t_i^2 d_i$. Choosing $t_i = 1/\sqrt{|d_i|}$ when $d_i \neq 0$, and $t_i = 1$ when $d_i = 0$, turns every diagonal entry into 1, -1 or 0. A permutation of the basis then sorts them, so after a further congruence by a permutation matrix the matrix of β is

$$\mathbf{I}_{n_+} \oplus (-\mathbf{I}_{n_-}) \oplus \mathbf{0}_{n_0}, \tag{13.5.1}$$

where n_+ counts the positive d_i, n_- the negative ones and n_0 the zeros, and $n_+ + n_- + n_0 = n$. Nothing yet says that these three counts do not depend on the orthogonal basis we started from. That is the theorem.

Quick check. One of the three counts is already known to be an invariant, by a result of Section 2. Which one, and why?

Solution. The count n_0. A diagonal matrix has rank equal to its number of non-zero entries, so $n_+ + n_- = \operatorname{rank}[\beta]_{\mathcal{B}}$, and congruence preserves rank (Theorem 13.2.3). Hence $n_+ + n_-$ is the same for every orthogonal basis, and so is $n_0 = n - (n_+ + n_-)$. What is **not** yet known is how that total splits into positives and negatives — which is exactly the work left for the theorem below.

13.5.2 The law of inertia

Theorem 13.5.1 — Sylvester's Law of Inertia

Let β be a symmetric bilinear form on a real vector space V with $\dim V = n$, and let $\mathcal{B}$ and $\mathcal{B}'$ be two orthogonal bases for β. Let (n_+, n_-, n_0) be the numbers of positive, negative and zero diagonal entries of $[\beta]_{\mathcal{B}}$, and (n'_+, n'_-, n'_0) the corresponding numbers for $[\beta]_{\mathcal{B}'}$. Then

$$n_+ = n'_+, \qquad n_- = n'_-, \qquad n_0 = n'_0.$$

Idea. Rank has already delivered $n_+ + n_- = n'_+ + n'_-$, so it is enough to prove $n_+ = n'_+$, and for that we may suppose $n_+ > n'_+$ and look for a disaster. The two bases carve out two subspaces with incompatible behavior: on $U = \operatorname{span}(\mathbf{v}_1, \dots, \mathbf{v}_{n_+})$ the form is **strictly positive** away from $\mathbf{0}$, because Eq. 13.4.1 has only positive coefficients there; on $U' = \operatorname{span}(\mathbf{v}'_{n'_+ + 1}, \dots, \mathbf{v}'_n)$ it is ≤ 0 everywhere, because there the coefficients are all ≤ 0. A non-zero vector in both would have $q(\mathbf{v}) > 0$ and $q(\mathbf{v}) \le 0$ at once, so the two subspaces meet only in $\mathbf{0}$. But their dimensions add up to more than n, and two such subspaces of an n-dimensional space cannot meet only in $\mathbf{0}$. Contradiction plus a dimension count.

Proof. Write $\mathcal{B} = (\mathbf{v}_1, \dots, \mathbf{v}_n)$ and $\mathcal{B}' = (\mathbf{v}'_1, \dots, \mathbf{v}'_n)$, and order each so that the positive entries come first, then the negative ones, then the zeros; reordering a basis does not change the three counts. Put $d_i = q(\mathbf{v}_i)$ and $d'_j = q(\mathbf{v}'_j)$, so that

$$d_1, \dots, d_{n_+} > 0, \qquad d'_{n'_+ + 1}, \dots, d'_n \le 0.$$

As in the Quick check, $n_+ + n_- = \operatorname{rank}[\beta]_{\mathcal{B}} = \operatorname{rank}[\beta]_{\mathcal{B}'} = n'_+ + n'_-$ by Theorem 13.2.3, and $n_0 = n - (n_+ + n_-)$. So it suffices to prove $n_+ = n'_+$; the other two equalities then follow.

Suppose not. Swapping the names of the two bases if necessary, we may assume $n_+ > n'_+$. Put

$$U = \operatorname{span}(\mathbf{v}_1, \dots, \mathbf{v}_{n_+}), \qquad U' = \operatorname{span}(\mathbf{v}'_{n'_+ + 1}, \dots, \mathbf{v}'_n),$$

so that $\dim U = n_+$ and $\dim U' = n - n'_+$.

Claim: $U \cap U' = \{\mathbf{0}\}$. Let $\mathbf{v} \in U \cap U'$ with $\mathbf{v} \neq \mathbf{0}$. Writing $\mathbf{v} = \sum_{i \le n_+} c_i \mathbf{v}_i$ and using Eq. 13.4.1 for the basis $\mathcal{B}$, whose later coordinates of $\mathbf{v}$ are zero,

$$q(\mathbf{v}) = \sum_{i=1}^{n_+} d_i c_i^2 > 0,$$

because every d_i with $i \le n_+$ is positive, every $c_i^2 \ge 0$, and at least one $c_i \neq 0$ since $\mathbf{v} \neq \mathbf{0}$. Writing instead $\mathbf{v} = \sum_{j > n'_+} b_j \mathbf{v}'_j$ and using Eq. 13.4.1 for $\mathcal{B}'$,

$$q(\mathbf{v}) = \sum_{j=n'_+ + 1}^{n} d'_j b_j^2 \le 0,$$

because every d'_j with $j > n'_+$ is ≤ 0 and every $b_j^2 \ge 0$. A real number cannot be both > 0 and ≤ 0, so no such $\mathbf{v}$ exists, which proves the claim.

On the other hand, $U + U'$ is a subspace of V, so $\dim(U + U') \le n$, and the dimension formula (Theorem 1.7.3) gives

$$\begin{aligned}\dim(U \cap U') &= \dim U + \dim U' - \dim(U + U') \\ &\ge n_+ + (n - n'_+) - n \\ &= n_+ - n'_+ > 0.\end{aligned}$$

So $U \cap U'$ contains a non-zero vector, contradicting the claim. Therefore $n_+ = n'_+$, and with it $n_- = n'_-$ and $n_0 = n'_0$. This proves the theorem.

■

The name comes from mechanics, where the form is an inertia tensor and the theorem says that a change of coordinates cannot turn a direction of positive inertia into one of negative inertia. The invariant has a name of its own.

Definition 13.5.1 — Inertia and Signature

Let β be a symmetric bilinear form on a real vector space V of dimension n, diagonalized in some orthogonal basis. The triple

$$(n_+, n_-, n_0)$$

of numbers of positive, negative and zero diagonal entries is the **inertia** of β, and it is well defined by Theorem 13.5.1. The pair (n_+, n_-) is the **signature** of β, and $n_+ + n_- = \operatorname{rank}\beta$ while $n_0 = n - \operatorname{rank}\beta$. The same words are used for a real symmetric matrix $\mathbf{A}$, through the form $\beta(\mathbf{x}, \mathbf{y}) = \mathbf{x}^{\top}\mathbf{A}\mathbf{y}$, and we write $n_+(\mathbf{A})$, $n_-(\mathbf{A})$, $n_0(\mathbf{A})$.

Two conventions are in circulation and both are called the signature: the pair (n_+, n_-), used here, and the single integer $n_+ - n_-$. They carry the same information once the rank is known, and the difference is only ever notational; where a source writes "signature 2" it means $n_+ - n_- = 2$. The triple (n_+, n_-, n_0) is the safest thing to quote, since it also records the degeneracy.

13.5.3 The classification over the reals

Corollary 13.5.2 — Classification of Real Symmetric Matrices by Signature

Let $\mathbf{A}, \mathbf{B} \in M_n(\mathbb{R})$ be symmetric. Then:

(a) $\mathbf{A}$ is congruent to $\mathbf{I}_{n_+} \oplus (-\mathbf{I}_{n_-}) \oplus \mathbf{0}_{n_0}$, where (n_+, n_-, n_0) is the inertia of $\mathbf{A}$, and to no other matrix of this shape;

(b) $\mathbf{A} \simeq \mathbf{B}$ if and only if $\mathbf{A}$ and $\mathbf{B}$ have the same inertia;

(c) the number of congruence classes of symmetric matrices in $M_n(\mathbb{R})$ is $\frac{1}{2}(n+1)(n+2)$.

Proof.

(a) The congruence to $\mathbf{I}_{n_+} \oplus (-\mathbf{I}_{n_-}) \oplus \mathbf{0}_{n_0}$ is Eq. 13.5.1, obtained from Theorem 13.4.2

followed by the scaling and sorting described above. That matrix is itself diagonal with inertia (n_+, n_-, n_0), so by Theorem 13.5.1 no matrix of the same shape with a different triple can be congruent to $\mathbf{A}$.

(b) ($\Rightarrow$) A congruence $\mathbf{B} = \mathbf{P}^\top \mathbf{A}\mathbf{P}$ with $\mathbf{P}$ invertible is a change of basis for the form (Theorem 13.2.1), so an orthogonal basis diagonalizing $\mathbf{B}$ yields one diagonalizing $\mathbf{A}$ with the same diagonal, and Theorem 13.5.1 makes the inertia equal.
($\Leftarrow$) If $\mathbf{A}$ and $\mathbf{B}$ have the same inertia, each is congruent to the same matrix $\mathbf{I}_{n_+} \oplus (-\mathbf{I}_{n_-}) \oplus \mathbf{0}_{n_0}$ by (a), hence to each other, since congruence is an equivalence relation (Proposition 13.2.2).

(c) By (b) the classes correspond to the triples (n_+, n_-, n_0) of non-negative integers summing to n, equivalently to the pairs (n_+, n_-) with $n_+ + n_- \le n$. For each value $k = n_+ + n_- \in \{0, 1, \dots, n\}$ there are $k+1$ choices of n_+, so the total is $1 + 2 + \cdots + (n+1) = \frac{1}{2}(n+1)(n+2)$. This proves the corollary.

■

So congruence over $\mathbb{R}$ has a complete and finite list of invariants, in sharp contrast to similarity, where even 2×2 real symmetric matrices fall into infinitely many classes (one for each unordered pair of eigenvalues). Congruence forgets a great deal; the point of the law of inertia is that what it forgets is precisely everything except the signs.

13.5.4 Reconciling congruence with the spectral theorem

Chapter 11 diagonalized a real symmetric matrix a different way, by an **orthogonal** $\mathbf{Q}$, and got the eigenvalues on the diagonal. Chapter 11 also pointed out why that theorem is special: because $\mathbf{Q}^\top = \mathbf{Q}^{-1}$, the one equation $\mathbf{Q}^\top \mathbf{A}\mathbf{Q} = \mathbf{D}$ can be read twice, and "an orthogonal change of variables is a similarity *and* a congruence, so it keeps the eigenvalues and the geometry at once". Reading the same equation twice is all that is needed to identify the inertia.

Theorem 13.5.3 — Inertia Is the Sign Pattern of the Spectrum

Let $\mathbf{A} \in M_n(\mathbb{R})$ be symmetric. Then $n_+(\mathbf{A})$ is the number of positive eigenvalues of $\mathbf{A}$, counted with multiplicity, $n_-(\mathbf{A})$ the number of negative ones, and $n_0(\mathbf{A})$ the multiplicity of 0.

Proof. By Corollary 11.5.2 there is an orthogonal $\mathbf{Q} \in \mathrm{O}(n)$ and a real diagonal $\mathbf{D} = \mathrm{diag}(\lambda_1, \dots, \lambda_n)$ with $\mathbf{A} = \mathbf{Q}\mathbf{D}\mathbf{Q}^\top$, where $\lambda_1, \dots, \lambda_n$ is the eigenvalue list of $\mathbf{A}$ with multiplicity. Equivalently $\mathbf{D} = \mathbf{Q}^\top \mathbf{A}\mathbf{Q}$.

Read as a **similarity**: $\mathbf{Q}^\top = \mathbf{Q}^{-1}$, so $\mathbf{D} = \mathbf{Q}^{-1}\mathbf{A}\mathbf{Q}$ and the diagonal entries of $\mathbf{D}$ are the eigenvalues of $\mathbf{A}$.

Read as a **congruence**: $\mathbf{Q}$ is invertible, so $\mathbf{D} = \mathbf{Q}^\top \mathbf{A}\mathbf{Q}$ exhibits $\mathbf{D}$ as congruent to $\mathbf{A}$ (Definition 13.2.1). Being diagonal, $\mathbf{D}$ is the matrix of the form of $\mathbf{A}$ in an orthogonal basis, namely the columns of $\mathbf{Q}$. By Theorem 13.5.1 its numbers of positive, negative and zero entries are the inertia of $\mathbf{A}$.

The same list of numbers is being counted both times, so the counts agree. This proves

the theorem.

■

This is what Chapter 12 promised when, having diagonalized a pencil and found $\mathbf{S}^\top\mathbf{B}\mathbf{S} = \operatorname{diag}(-1, 3)$ while the eigenvalues of $\mathbf{B}$ were $3 \pm 3\sqrt{2}$, it observed that the signs $(-, +)$ "match the signs of the eigenvalues of $\mathbf{B}$ itself" and said that Chapter 13 would show this is no coincidence. It is not: the congruence $\mathbf{S}^\top\mathbf{B}\mathbf{S}$ has the inertia of $\mathbf{B}$ by Theorem 13.5.1, and that inertia is the sign pattern of the spectrum by Theorem 13.5.3. Here $3 + 3\sqrt{2} > 0$ and $3 - 3\sqrt{2} < 0$ — since $3\sqrt{2} > 4$ — so the inertia of $\mathbf{B}$ is $(1, 1, 0)$, and any congruent diagonal matrix must show exactly one positive and one negative entry, as $\operatorname{diag}(-1, 3)$ does.

The same reading settles the definiteness tests of Chapter 12 in one line: $\mathbf{A} \succ 0$ means $\mathbf{x}^\top\mathbf{A}\mathbf{x} > 0$ for all $\mathbf{x} \neq \mathbf{0}$, which by Theorem 12.1.5 is the statement that every eigenvalue is positive, which by Theorem 13.5.3 is the statement that the inertia is $(n, 0, 0)$. Section 6 takes that dictionary further.

Warning. **Congruent matrices have the same inertia and unrelated eigenvalues.** Take $\mathbf{A} = \operatorname{diag}(1, -1)$ and $\mathbf{P} = \operatorname{diag}(2, 3)$. Then

$$\mathbf{P}^\top\mathbf{A}\mathbf{P} = \operatorname{diag}(4, -9),$$

so $\mathbf{A} \simeq \operatorname{diag}(4, -9)$, yet the eigenvalues have moved from $1, -1$ to $4, -9$. Nothing about their sizes, their ratios, their sum or their product is preserved — tr goes from 0 to -5, det from -1 to -36 — and only the pattern $(+, -)$ survives. For a second witness with no scaling in sight, $\mathbf{I}_2$ is congruent to $\mathbf{S}^\top\mathbf{S} = \left(\begin{smallmatrix} 1 & 1 \\ 1 & 2 \end{smallmatrix}\right)$ with $\mathbf{S} = \left(\begin{smallmatrix} 1 & 1 \\ 0 & 1 \end{smallmatrix}\right)$; the eigenvalues change from $1, 1$ to $(3 \pm \sqrt{5})/2$, and the inertia stays $(2, 0, 0)$.

13.5.5 Computing a signature

Theorem 13.5.3 gives a method — find the eigenvalues and count signs — but it is the expensive one, since it needs the roots of a degree-n polynomial. The cheap method is the algorithm of the previous section, which needs only arithmetic: diagonalize by paired row and column operations and read off the signs. The eigenvalues are never computed and never needed.

Example. (A signature by symmetric elimination)

Find the inertia of

$$\mathbf{A} = \begin{pmatrix} 1 & 1 & 2 \\ 1 & 2 & 3 \\ 2 & 3 & 1 \end{pmatrix},$$

and say whether the form $q(\mathbf{x}) = \mathbf{x}^\top\mathbf{A}\mathbf{x}$ is positive definite.

Solution. The corner entry is 1, so no repair move is needed.

Clear the first row and column. Subtract row 1 from row 2 and $2\times$ row 1 from row 3,

then do the same two operations on columns:

$$\begin{pmatrix} 1 & 1 & 2 \\ 0 & 1 & 1 \\ 0 & 1 & -3 \end{pmatrix} \longrightarrow \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 1 \\ 0 & 1 & -3 \end{pmatrix}.$$

Clear the second row and column. The pivot is 1 and $a_{23} = 1$, so subtract row 2 from row 3 and then column 2 from column 3:

$$\begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 1 \\ 0 & 0 & -4 \end{pmatrix} \longrightarrow \operatorname{diag}(1, 1, -4).$$

So the inertia is $(2, 1, 0)$ and the signature is $(2, 1)$. The form is **not** positive definite: it is negative at the third basis vector of the new basis, namely the third column of

$$\mathbf{P} = \begin{pmatrix} 1 & -1 & -1 \\ 0 & 1 & -1 \\ 0 & 0 & 1 \end{pmatrix},$$

which is $\mathbf{p}_3 = (-1, -1, 1)$. Checking directly, $\mathbf{A}\mathbf{p}_3 = (0, 0, -4)$ and $\mathbf{p}_3 \cdot (0, 0, -4) = -4 < 0$.

The eigenvalue route would have to factor $\det(x\mathbf{I} - \mathbf{A}) = x^3 - 4x^2 - 9x + 4$, whose roots are irrational; the elimination never met them. As a partial check on the arithmetic, $\det \mathbf{A} = -4$ and $\det \operatorname{diag}(1, 1, -4) = -4$, consistent with $\det \mathbf{P} = 1$.

Over $\mathbb{R}$, then, a symmetric matrix carries exactly two pieces of congruence data, and both are cheap: its rank and how that rank splits into positive and negative directions. The next section reads the same two numbers as a statement about definiteness, and uses them to decide maxima and minima.

13.5.6 Exercises

13.5.6.1 A. Check your understanding

Exercise A1.

(a) Define the **inertia** and the **signature** of a real symmetric matrix.

(b) State Theorem 13.5.1, with all hypotheses.

(c) Which part of the inertia is already an invariant before the law of inertia is proved, and by which earlier result?

(d) Determine whether the following statement is correct, and justify your answer: congruent real symmetric matrices have the same trace.

(e) Explain in one sentence why an orthogonal change of basis lets the spectral theorem compute an inertia.

Solution.

(a) Diagonalize the associated form in an orthogonal basis. The inertia is the triple (n_+, n_-, n_0) of numbers of positive, negative and zero diagonal entries, and the signature is the pair (n_+, n_-).

(b) If β is a symmetric bilinear form on a finite-dimensional real vector space and $\mathcal{B}, \mathcal{B}'$ are two orthogonal bases for β, then the two matrices $[\beta]_{\mathcal{B}}$ and $[\beta]_{\mathcal{B}'}$ have the same numbers of positive, negative and zero diagonal entries.

(c) The count n_0, equivalently the sum $n_+ + n_-$, because that sum is the rank and congruence preserves rank (Theorem 13.2.3).

(d) Incorrect. $\operatorname{diag}(1, -1)$ and $\operatorname{diag}(4, -9)$ are congruent, by the congruence with $\mathbf{P} = \operatorname{diag}(2, 3)$, and their traces are 0 and -5. Trace is a similarity invariant (Theorem 3.7.5), not a congruence invariant.

(e) For an orthogonal $\mathbf{Q}$ we have $\mathbf{Q}^{\top} = \mathbf{Q}^{-1}$, so the single equation $\mathbf{Q}^{\top}\mathbf{A}\mathbf{Q} = \mathbf{D}$ is simultaneously a similarity, which puts the eigenvalues on the diagonal, and a congruence, which makes that diagonal compute the inertia.

13.5.6.2 B. Practice

Exercise B1: Signatures by elimination.

Find the inertia of each of the following real symmetric matrices by paired row and column operations. Do not compute any eigenvalues.

(a) $\mathbf{A} = \begin{pmatrix} 1 & 2 & 0 \\ 2 & 1 & 3 \\ 0 & 3 & 1 \end{pmatrix}$.

(b) $\mathbf{B} = \begin{pmatrix} 0 & 1 & 1 \\ 1 & 0 & 1 \\ 1 & 1 & 0 \end{pmatrix}$.

(c) $\mathbf{C} = \begin{pmatrix} 1 & 2 \\ 2 & 4 \end{pmatrix}$.

Solution.

(a) By Exercise (B1: Symmetric elimination), $\mathbf{A}$ is congruent to $\operatorname{diag}(1, -3, 4)$. Inertia $(2, 1, 0)$.

(b) By Example (Diagonalizing a symmetric matrix with zero diagonal), $\mathbf{B}$ is congruent to $\operatorname{diag}(2, -2, -2)$. Inertia $(1, 2, 0)$.

(c) Subtract $2\times$ row 1 from row 2, then $2\times$ column 1 from column 2:

$$\begin{pmatrix} 1 & 2 \\ 0 & 0 \end{pmatrix} \longrightarrow \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}.$$

Inertia $(1, 0, 1)$: the form $q(\mathbf{x}) = (x_1 + 2x_2)^2$ is degenerate, vanishing on the line $x_1 = -2x_2$.

Exercise B2: Which of these are congruent?.

Sort the following real symmetric matrices into congruence classes, justifying each an-

swer.

$$\mathbf{A}_1 = \operatorname{diag}(1,1,-1), \quad \mathbf{A}_2 = \operatorname{diag}(5,2,-7), \quad \mathbf{A}_3 = \operatorname{diag}(1,-1,-1),$$

$$\mathbf{A}_4 = \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix}, \qquad \mathbf{A}_5 = \begin{pmatrix} 2 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & -3 \end{pmatrix}.$$

Solution. Compute each inertia and apply Corollary 13.5.2 (b).

$\mathbf{A}_1$: $(2,1,0)$. $\mathbf{A}_2$: $(2,1,0)$. $\mathbf{A}_3$: $(1,2,0)$. $\mathbf{A}_5$: $(1,1,1)$.

For $\mathbf{A}_4$, the top-left 2×2 block is the form $2x_1x_2$, which Exercise (B2: No pivot on the diagonal) diagonalizes to $\operatorname{diag}(2,-2)$; so $\mathbf{A}_4$ is congruent to $\operatorname{diag}(2,-2,1)$, with inertia $(2,1,0)$.

Therefore the classes are $\{\mathbf{A}_1, \mathbf{A}_2, \mathbf{A}_4\}$, $\{\mathbf{A}_3\}$ and $\{\mathbf{A}_5\}$. Note that $\mathbf{A}_1$ and $\mathbf{A}_3$ have the same rank and are still not congruent, so rank alone does not classify over $\mathbb{R}$ — unlike over $\mathbb{C}$ (Corollary 13.4.4).

Exercise B3: Inertia from a characteristic polynomial.

Let $\mathbf{A} \in M_3(\mathbb{R})$ be symmetric with $\det(x\mathbf{I} - \mathbf{A}) = x^3 - 2x^2 - 5x + 6$.

(a) Find the inertia of $\mathbf{A}$.

(b) Is $\mathbf{A}$ congruent to $\operatorname{diag}(1,1,-1)$? Is it similar to it?

Solution.

(a) The polynomial factors as $(x-1)(x+2)(x-3)$, since 1 is a root and dividing gives $x^2 - x - 6$. The eigenvalues are $1, 3, -2$, so by Theorem 13.5.3 the inertia is $(2,1,0)$.

(b) Congruent: yes, since $\operatorname{diag}(1,1,-1)$ also has inertia $(2,1,0)$ and Corollary 13.5.2 (b) applies. Similar: no, because similar matrices have equal characteristic polynomials, and $\operatorname{diag}(1,1,-1)$ has $(x-1)^2(x+1) \neq (x-1)(x-3)(x+2)$.

13.5.6.3 C. Going deeper

Exercise C1: An intrinsic description of n_+.

Let β be a symmetric bilinear form on a real vector space V of dimension n, with quadratic form q. Call a subspace $U \subseteq V$ **positive** if $q(\mathbf{v}) > 0$ for every $\mathbf{v} \in U$ with $\mathbf{v} \neq \mathbf{0}$.

(a) Prove that n_+ is the largest dimension of a positive subspace of V.

(b) Deduce Theorem 13.5.1 again from (a), in two lines.

(c) State and prove the corresponding description of n_-.

Hint: for (a), use an orthogonal basis to produce one positive subspace of dimension n_+, and the dimension formula to rule out a larger one.

Solution.

(a) Fix an orthogonal basis $(\mathbf{v}_1, \dots, \mathbf{v}_n)$ ordered so that $d_1, \dots, d_{n_+} > 0$ and $d_j \le 0$ for $j > n_+$.
A positive subspace of dimension n_+. Put $U = \operatorname{span}(\mathbf{v}_1, \dots, \mathbf{v}_{n_+})$. For $\mathbf{v} = \sum_{i \le n_+} c_i \mathbf{v}_i$ non-zero, Eq. 13.4.1 gives $q(\mathbf{v}) = \sum_{i \le n_+} d_i c_i^2 > 0$, since all $d_i > 0$ and some $c_i \neq 0$. So U is positive and $\dim U = n_+$.
No larger one. Let X be positive with $\dim X = k$, and put $W = \operatorname{span}(\mathbf{v}_{n_+ + 1}, \dots, \mathbf{v}_n)$, of dimension $n - n_+$. Every $\mathbf{w} \in W$ has $q(\mathbf{w}) = \sum_{j > n_+} d_j c_j^2 \le 0$. If $k > n_+$ then by Theorem 1.7.3,

$$\dim(X \cap W) \ge k + (n - n_+) - n = k - n_+ > 0,$$

so there is a non-zero $\mathbf{v} \in X \cap W$ with $q(\mathbf{v}) > 0$ and $q(\mathbf{v}) \le 0$, which is impossible. Hence $k \le n_+$, and the maximum is n_+.

(b) The right-hand side of (a) — the largest dimension of a positive subspace — is defined from β alone and mentions no basis. So the number n_+ computed from any orthogonal basis equals that basis-free quantity, hence is the same for all of them. Then $n_+ + n_- = \operatorname{rank} \beta$ is basis-free too (Theorem 13.2.3), so n_- and n_0 are determined as well.

(c) n_- is the largest dimension of a **negative** subspace, one on which $q(\mathbf{v}) < 0$ for every $\mathbf{v} \neq \mathbf{0}$. Apply (a) to the form $-\beta$, whose diagonal entries in any orthogonal basis are the negatives of those of β, so that $n_+(-\beta) = n_-(\beta)$, and whose positive subspaces are exactly the negative subspaces of β.

Exercise C2: Congruence cannot be read off the eigenvalues, and inertia can.

(a) Give two real symmetric 2×2 matrices that are congruent but have no eigenvalue in common.

(b) Prove that if $\mathbf{A}$ and $\mathbf{B}$ are real symmetric and **similar**, then they are congruent.

(c) Give two real symmetric 2×2 matrices that are congruent but not similar, so that the converse of (b) fails.

Solution.

(a) $\operatorname{diag}(1, -1)$ and $\operatorname{diag}(4, -9)$, congruent by $\mathbf{P} = \operatorname{diag}(2, 3)$. Their spectra are $\{1, -1\}$ and $\{4, -9\}$, which are disjoint.

(b) Similar matrices have the same characteristic polynomial (Theorem 6.10.3), hence the same eigenvalues with multiplicity. By Theorem 13.5.3 they then have the same inertia, and by Corollary 13.5.2 (b) they are congruent. (Alternatively and more directly: by Corollary 11.5.2 each is orthogonally congruent to the diagonal matrix of its eigenvalues, and those diagonal matrices agree up to a permutation.)

(c) The pair in (a) again: $\operatorname{diag}(1, -1)$ and $\operatorname{diag}(4, -9)$ are congruent, but their characteristic polynomials are $x^2 - 1$ and $x^2 + 5x - 36$, so they are not similar (Theorem 6.10.3). Congruence is strictly coarser than similarity on real symmetric matrices.

Exercise C3: Inertia of a block matrix.

Let $\mathbf{A} \in M_m(\mathbb{R})$ and $\mathbf{B} \in M_k(\mathbb{R})$ be symmetric. Let also $\mathbf{D} \in M_n(\mathbb{R})$ be symmetric and invertible, let $\mathbf{b} \in \mathbb{R}^n$, let $c \in \mathbb{R}$, and put

$$\mathbf{M} = \begin{pmatrix} \mathbf{D} & \mathbf{b} \\ \mathbf{b}^{\top} & c \end{pmatrix} \in M_{n+1}(\mathbb{R}).$$

(a) Prove that the inertia of $\mathbf{A} \oplus \mathbf{B}$ is the entrywise sum of the inertias of $\mathbf{A}$ and $\mathbf{B}$.

(b) Prove that $\mathbf{M}$ is congruent to $\mathbf{D} \oplus (c - \mathbf{b}^{\top}\mathbf{D}^{-1}\mathbf{b})$.

(c) Hence find the inertia of $\mathbf{M}$ when $\mathbf{D} = \operatorname{diag}(1, -1)$, $\mathbf{b} = (1, 1)$ and $c = 0$.

Hint: for (b), the congruence is the block elimination of Chapter 7, and the leftover scalar is a Schur complement.

Solution.

(a) Let $\mathbf{P}^{\top}\mathbf{A}\mathbf{P}$ and $\mathbf{Q}^{\top}\mathbf{B}\mathbf{Q}$ be the canonical forms of Corollary 13.5.2 (a). Then $\mathbf{P} \oplus \mathbf{Q}$ is invertible and

$$(\mathbf{P} \oplus \mathbf{Q})^{\top}(\mathbf{A} \oplus \mathbf{B})(\mathbf{P} \oplus \mathbf{Q}) = (\mathbf{P}^{\top}\mathbf{A}\mathbf{P}) \oplus (\mathbf{Q}^{\top}\mathbf{B}\mathbf{Q}),$$

a diagonal matrix whose positive, negative and zero entries are those of the two blocks together. By Theorem 13.5.1 those counts are the inertia of $\mathbf{A} \oplus \mathbf{B}$.

(b) Put

$$\mathbf{S} = \begin{pmatrix} \mathbf{I}_n & -\mathbf{D}^{-1}\mathbf{b} \\ \mathbf{0}^{\top} & 1 \end{pmatrix},$$

which is invertible, being unit upper triangular. Multiplying, the first block row of $\mathbf{M}\mathbf{S}$ is $(\mathbf{D} \mid \mathbf{D}(-\mathbf{D}^{-1}\mathbf{b}) + \mathbf{b}) = (\mathbf{D} \mid \mathbf{0})$, and then

$$\mathbf{S}^{\top}\mathbf{M}\mathbf{S} = \begin{pmatrix} \mathbf{D} & \mathbf{0} \\ \mathbf{0}^{\top} & c - \mathbf{b}^{\top}\mathbf{D}^{-1}\mathbf{b} \end{pmatrix},$$

using $\mathbf{D}^{\top} = \mathbf{D}$. This is $\mathbf{D} \oplus (c - \mathbf{b}^{\top}\mathbf{D}^{-1}\mathbf{b})$, the Schur complement $\mathbf{M}/\mathbf{D}$ sitting in the corner.

(c) Here $\mathbf{D}^{-1} = \operatorname{diag}(1, -1)$, so $\mathbf{b}^{\top}\mathbf{D}^{-1}\mathbf{b} = 1 - 1 = 0$ and the leftover scalar is $c - 0 = 0$. By (b) and (a), the inertia of $\mathbf{M}$ is the inertia of $\operatorname{diag}(1, -1)$ plus that of the 1×1 zero matrix, namely $(1, 1, 0) + (0, 0, 1) = (1, 1, 1)$. In particular $\mathbf{M}$ is singular.

13.6 Definiteness and Second Derivatives

Chapter 12 studied positive definite matrices at length, and the previous section showed that the signature is what congruence remembers. Putting the two together costs almost nothing and buys two things: a vocabulary that covers the forms Chapter 12 had no name for, the indefinite and the semidefinite ones, and the classical application that made quadratic forms worth studying in the first place. Nothing from Chapter 12 is reproved here. The field is $\mathbb{R}$ throughout, since none of the five words below means anything without an order.

Throughout, V is a finite-dimensional real vector space, β is a **symmetric** bilinear form on V (Definition 13.3.1), $q(\mathbf{v}) = \beta(\mathbf{v}, \mathbf{v})$ is its quadratic form (Definition 13.3.2), and $\mathbf{A} = [\beta]_{\mathcal{B}}$ is its matrix in a basis $\mathcal{B}$ (Definition 13.1.2), a real symmetric matrix.

13.6.1 Five words for the sign of a form

Chapter 12 named two of the possible behaviors of q: never negative, and always positive away from $\mathbf{0}$. There are three more, and the missing ones are not exotic. The form $q(x_1, x_2) = x_1^2 - x_2^2$ is positive at $\mathbf{e}_1$, negative at $\mathbf{e}_2$, and nothing in Chapter 12's vocabulary describes it.

A form is definite when q has one strict sign, semidefinite when it has one sign but is allowed to vanish, and indefinite when it has both signs.

Definition 13.6.1 — Definiteness of a Real Symmetric Form

Let β be a symmetric bilinear form on a real vector space V, with quadratic form q. Then β is:

(a) **positive definite** if $q(\mathbf{v}) > 0$ for **every non-zero** $\mathbf{v} \in V$;
(b) **positive semidefinite** if $q(\mathbf{v}) \geq 0$ for every $\mathbf{v} \in V$;
(c) **negative definite** if $q(\mathbf{v}) < 0$ for every non-zero $\mathbf{v} \in V$;
(d) **negative semidefinite** if $q(\mathbf{v}) \leq 0$ for every $\mathbf{v} \in V$;
(e) **indefinite** if there exist $\mathbf{u}, \mathbf{w} \in V$ with $q(\mathbf{u}) > 0$ and $q(\mathbf{w}) < 0$.

The same five words apply to a real symmetric matrix $\mathbf{A}$, through the form $\beta(\mathbf{x}, \mathbf{y}) = \mathbf{x}^\top \mathbf{A}\mathbf{y}$ on $\mathbb{R}^n$.

The small words carry the weight. In (a) and (c) the inequality is **strict** and the vector must be **non-zero**; in (b) and (d) it is weak and $\mathbf{v} = \mathbf{0}$ is allowed, where $q(\mathbf{0}) = 0$ makes the condition automatic. Definite implies semidefinite of the same sign. Clause (e) is not the negation of (b): $q(x_1, x_2) = -x_1^2$ is neither positive semidefinite nor indefinite. For matrices, (a) and (b) are Definition 12.1.1 restricted to $F = \mathbb{R}$, so $\mathbf{A} \succ 0$ and $\mathbf{A} \succeq 0$ keep their meanings, and the negative versions are the positive ones for $-\mathbf{A}$.

Four examples on $\mathbb{R}^2$, all diagonal so that q can be read off Eq. 13.4.1: $x_1^2 + x_2^2$ is positive definite; x_1^2 is positive semidefinite but not definite, since it vanishes at $\mathbf{e}_2 \neq \mathbf{0}$; $-x_1^2 - x_2^2$ is negative definite; $x_1^2 - x_2^2$ is indefinite. The zero form is the degenerate case, satisfying (b) and (d) and nothing else — which is why the five classes overlap rather than partition. Changing one sign in the third gives the non-example $-x_1^2 + x_2^2$: it is no longer negative semidefinite, and the clause that fails is (d) at $\mathbf{v} = \mathbf{e}_2$, where $q = 1 > 0$.

Now the reading through the signature, which makes all five conditions into statements about three integers.

Theorem 13.6.1 — Definiteness Is the Signature

Let β be a symmetric bilinear form on a real vector space V of dimension n, with inertia (n_+, n_-, n_0) (Definition 13.5.1). Then:

(a) β is positive definite $\iff (n_+, n_-, n_0) = (n, 0, 0)$;
(b) β is positive semidefinite $\iff n_- = 0$;
(c) β is negative definite $\iff (n_+, n_-, n_0) = (0, n, 0)$;
(d) β is negative semidefinite $\iff n_+ = 0$;
(e) β is indefinite $\iff n_+ > 0$ and $n_- > 0$.

Idea. Fix an orthogonal basis. Then q is $\sum_i d_i c_i^2$ with no cross terms, and each of the five conditions becomes a visible condition on the signs of the d_i: plugging in a basis vector reads off one d_i, and a general $\mathbf{v}$ mixes the d_i with non-negative weights. Sylvester's law is what lets us fix one basis and still be talking about β.

Proof. By Theorem 13.4.2 there is an orthogonal basis $\mathcal{B} = (\mathbf{v}_1, \dots, \mathbf{v}_n)$ for β; put $d_i = q(\mathbf{v}_i)$. By Theorem 13.5.1 the numbers of positive, negative and zero d_i are n_+, n_- and n_0, whichever orthogonal basis is used. For $\mathbf{v} = \sum_i c_i \mathbf{v}_i$, Eq. 13.4.1 gives

$$q(\mathbf{v}) = \sum_{i=1}^{n} d_i c_i^2.$$

(b) ($\Rightarrow$) If some $d_j < 0$ then $q(\mathbf{v}_j) = d_j < 0$, so β is not positive semidefinite. ($\Leftarrow$) If no d_i is negative then every term $d_i c_i^2$ is ≥ 0, so $q(\mathbf{v}) \geq 0$.

(c) ($\Rightarrow$) A positive definite β is positive semidefinite, so $n_- = 0$ by (b); and if some $d_j = 0$ then $q(\mathbf{v}_j) = 0$ with $\mathbf{v}_j \neq \mathbf{0}$, a contradiction. Hence $n_0 = 0$ and $n_+ = n$. ($\Leftarrow$) If every $d_i > 0$ and $\mathbf{v} \neq \mathbf{0}$, some $c_j \neq 0$, so $q(\mathbf{v}) \geq d_j c_j^2 > 0$, the other terms being ≥ 0.

(d) and (d) follow by applying (a) and (b) to $-\beta$, whose diagonal entries are $-d_i$ and whose inertia is therefore (n_-, n_+, n_0).

(e) ($\Rightarrow$) Suppose $q(\mathbf{u}) > 0$ and $q(\mathbf{w}) < 0$. Then β is neither positive semidefinite nor negative semidefinite, so $n_- > 0$ by (b) and $n_+ > 0$ by (d). ($\Leftarrow$) If $n_+ > 0$ and $n_- > 0$, some $d_i > 0$ and some $d_j < 0$, and the basis vectors $\mathbf{v}_i, \mathbf{v}_j$ are the required $\mathbf{u}, \mathbf{w}$. This proves the theorem.

■

So the five words sort the $\frac{1}{2}(n+1)(n+2)$ congruence classes of Corollary 13.5.2 into named families, and every one of them is decided by counting signs. Two of these five verdicts were already settled in Chapter 12 by other means, and it is worth putting the tests side by side.

Proposition 13.6.2 — Chapter 12's Tests, in the Language of Forms

Let β be a symmetric bilinear form on an n-dimensional real vector space, $\mathbf{A} = [\beta]_{\mathcal{B}}$ its matrix in any basis, and $\mathbf{A}_k$ the top-left $k \times k$ corner of $\mathbf{A}$. Then:

(a) β is positive definite $\iff$ every eigenvalue of $\mathbf{A}$ is positive $\iff \det \mathbf{A}_k > 0$ for $k = 1, \dots, n$;

(b) β is negative definite $\iff$ every eigenvalue of $\mathbf{A}$ is negative $\iff (-1)^k \det \mathbf{A}_k > 0$ for $k = 1, \dots, n$.

Proof.

(a) By Definition 13.1.2 and Theorem 13.1.1, $q(\mathbf{v}) = \mathbf{x}^{\top}\mathbf{A}\mathbf{x}$ where $\mathbf{x} = [\mathbf{v}]_{\mathcal{B}}$, and $\mathbf{v} \neq \mathbf{0}$ exactly when $\mathbf{x} \neq \mathbf{0}$. So β is positive definite exactly when $\mathbf{A} \succ 0$, and the two stated tests are Theorem 12.1.5 (b) and (d), the second being Sylvester's criterion.

(b) Apply (a) to $-\beta$, whose matrix is $-\mathbf{A}$. The eigenvalues of $-\mathbf{A}$ are the negatives of those of $\mathbf{A}$, and $(-\mathbf{A})_k = -\mathbf{A}_k$ has $\det(-\mathbf{A}_k) = (-1)^k \det \mathbf{A}_k$, since scaling each of the k rows by -1 multiplies the determinant by -1 once per row (Theorem 6.5.1 (b)). This proves the proposition.

■

The eigenvalue test is the one to think with, the minor test the one to compute with; cheapest of all is the symmetric elimination of Section 4, which returns the whole signature rather than a verdict. Nothing is said about the semidefinite cases on purpose: Sylvester's criterion has no weak version, as Chapter 12 showed with $\operatorname{diag}(0, -1)$, whose leading minors are both 0.

Quick check. A real symmetric $\mathbf{A} \in M_3(\mathbb{R})$ has $\det \mathbf{A}_1 = -2$, $\det \mathbf{A}_2 = 5$, $\det \mathbf{A}_3 = -1$. What is its definiteness?

Solution. Negative definite. The signs alternate starting with a negative one, so $(-1)^k \det \mathbf{A}_k > 0$ for $k = 1, 2, 3$: indeed $(-1)(-2) = 2 > 0$, $(+1)(5) = 5 > 0$, $(-1)(-1) = 1 > 0$. By Proposition 13.6.2 (b) the form is negative definite, and by Theorem 13.6.1 (c) its inertia is $(0, 3, 0)$. Note that $\det \mathbf{A}_3 = \det \mathbf{A} < 0$ on its own would have been no evidence at all.

13.6.2 The second-derivative test

Here is the use. A differentiable function $f\colon \mathbb{R}^n \to \mathbb{R}$ is constant to first order at a critical point, so whether the point is a minimum, a maximum or neither is decided — usually — by the second-order behavior. That behavior is a quadratic form, and Theorem 13.6.1 decides it. The linear algebra is the whole content; what has to be imported is one theorem of analysis, and we state it rather than hide it.

Definition 13.6.2 — Hessian

Let f be a real-valued function on an open set $U \subseteq \mathbb{R}^n$, twice continuously differentiable on U, and let $\mathbf{a} \in U$. The **Hessian** of f at $\mathbf{a}$ is the matrix

$$\mathbf{H}_f(\mathbf{a}) \in M_n(\mathbb{R}), \qquad \big(\mathbf{H}_f(\mathbf{a})\big)_{ij} = \frac{\partial^2 f}{\partial x_i \, \partial x_j}(\mathbf{a}).$$

A point $\mathbf{a} \in U$ with $\nabla f(\mathbf{a}) = \mathbf{0}$ is a **critical point** of f.

Two facts about $\mathbf{H}_f(\mathbf{a})$ are needed, and neither is linear algebra. They are exactly the analysis this book imports, so we set them out as assumptions rather than let them pass unnoticed. Let f be twice continuously differentiable on an open $U \subseteq \mathbb{R}^n$ and let $\mathbf{a} \in U$.

(A1) *(Symmetry of the second derivatives.)* The mixed partial derivatives satisfy $\partial^2 f/\partial x_i \partial x_j = \partial^2 f/\partial x_j \partial x_i$ on U, so $\mathbf{H}_f(\mathbf{a})$ is a **symmetric** matrix.

(A2) *(Taylor's theorem with a second-order remainder.)* For every $\mathbf{h}$ small enough that $\mathbf{a}+\mathbf{h} \in U$,

$$f(\mathbf{a}+\mathbf{h}) = f(\mathbf{a}) + \nabla f(\mathbf{a}) \cdot \mathbf{h} + \tfrac{1}{2}\,\mathbf{h}^{\top}\mathbf{H}_f(\mathbf{a})\mathbf{h} + r(\mathbf{h}),$$

where the remainder satisfies $r(\mathbf{h})/\|\mathbf{h}\|^2 \to 0$ as $\mathbf{h} \to \mathbf{0}$.

These are two standard theorems of multivariable calculus. This book proves neither. They are quoted so that the theorem below has hypotheses to stand on, and Chapter 17 quotes them again for its second-derivative test of convexity, exactly as the theorem of Abel and Ruffini was quoted in Chapter 10. Everything after them is linear algebra.

By (A1) the Hessian is a real symmetric matrix, so it has an inertia, and by Theorem 13.6.1 that inertia decides the definiteness of the quadratic form $\mathbf{h} \mapsto \mathbf{h}^{\top}\mathbf{H}_f(\mathbf{a})\mathbf{h}$. One small lemma converts definiteness into a quantitative bound, and it is the only place where a real number is needed rather than a sign.

Lemma 13.6.3 — A Positive Definite Form Is Bounded Below by a Multiple of the Norm Squared

Let $\mathbf{A} \in M_n(\mathbb{R})$ be symmetric and positive definite, and let λ be its smallest eigenvalue. Then $\lambda > 0$ and

$$\mathbf{x}^{\top}\mathbf{A}\mathbf{x} \;\geq\; \lambda\|\mathbf{x}\|^2 \qquad \text{for every } \mathbf{x} \in \mathbb{R}^n.$$

Proof. By Corollary 11.5.2 there are an orthogonal $\mathbf{Q} \in \mathrm{O}(n)$ and a diagonal $\mathbf{D} = \operatorname{diag}(\lambda_1, \dots, \lambda_n)$ listing the eigenvalues of $\mathbf{A}$ with $\mathbf{A} = \mathbf{Q}\mathbf{D}\mathbf{Q}^{\top}$. By Theorem 12.1.5 (b) every $\lambda_i > 0$, so $\lambda = \min_i \lambda_i > 0$. Put $\mathbf{y} = \mathbf{Q}^{\top}\mathbf{x}$. Then

$$\mathbf{x}^{\top}\mathbf{A}\mathbf{x} = \mathbf{y}^{\top}\mathbf{D}\mathbf{y} = \sum_{i=1}^{n} \lambda_i y_i^2 \;\geq\; \lambda \sum_{i=1}^{n} y_i^2 = \lambda\|\mathbf{y}\|^2,$$

using $\lambda_i \geq \lambda$ and $y_i^2 \geq 0$ termwise. Finally $\mathbf{Q}\mathbf{Q}^{\top} = \mathbf{I}$, so $\|\mathbf{y}\|^2 = \mathbf{x}^{\top}\mathbf{Q}\mathbf{Q}^{\top}\mathbf{x} = \|\mathbf{x}\|^2$. This proves the lemma. ∎

Theorem 13.6.4 — The Second-Derivative Test

Let f be a real-valued function, twice continuously differentiable on an open set $U \subseteq \mathbb{R}^n$, let $\mathbf{a} \in U$ be a critical point of f, and let (n_+, n_-, n_0) be the inertia of $\mathbf{H}_f(\mathbf{a})$. Then:

(a) if $\mathbf{H}_f(\mathbf{a})$ is positive definite, that is $(n_+, n_-, n_0) = (n, 0, 0)$, then $\mathbf{a}$ is a strict local minimum of f;

(b) if $\mathbf{H}_f(\mathbf{a})$ is negative definite, that is $(n_+, n_-, n_0) = (0, n, 0)$, then $\mathbf{a}$ is a strict local maximum of f;

(c) if $\mathbf{H}_f(\mathbf{a})$ is indefinite, that is $n_+ > 0$ and $n_- > 0$, then $\mathbf{a}$ is neither a local minimum nor a local maximum: every neighborhood of $\mathbf{a}$ contains points where $f > f(\mathbf{a})$ and points where $f < f(\mathbf{a})$. Such an $\mathbf{a}$ is a **saddle point**.

If $n_0 > 0$ and $\mathbf{a}$ is not covered by (a)–(c), the test gives no information.

Idea. Taylor says $f(\mathbf{a}+\mathbf{h}) - f(\mathbf{a})$ is $\frac{1}{2}q(\mathbf{h})$ plus a remainder that is smaller than $\|\mathbf{h}\|^2$ near $\mathbf{0}$, where $q(\mathbf{h}) = \mathbf{h}^\top \mathbf{H}_f(\mathbf{a})\mathbf{h}$. For (a) the quadratic term is at least $\frac{1}{2}\lambda\|\mathbf{h}\|^2$ by Lemma 13.6.3, which beats a remainder eventually smaller than $\frac{1}{4}\lambda\|\mathbf{h}\|^2$; so the difference is positive. For (c) there is no bound in every direction, and none is needed: walk along a single line $\mathbf{h} = t\mathbf{u}$ where $q(\mathbf{u}) > 0$, and the whole thing is t^2 times something tending to $\frac{1}{2}q(\mathbf{u}) > 0$. One direction up, one direction down, and no extremum.

Proof. Write $\mathbf{H} = \mathbf{H}_f(\mathbf{a})$ and $q(\mathbf{h}) = \mathbf{h}^\top \mathbf{H}\mathbf{h}$. Since $\mathbf{a}$ is critical, $\nabla f(\mathbf{a}) = \mathbf{0}$, so (A2) reads

$$f(\mathbf{a}+\mathbf{h}) - f(\mathbf{a}) = \tfrac{1}{2}q(\mathbf{h}) + r(\mathbf{h}), \qquad \frac{r(\mathbf{h})}{\|\mathbf{h}\|^2} \to 0. \tag{$*$}$$

(a) Let $\lambda > 0$ be the smallest eigenvalue of $\mathbf{H}$, so that $q(\mathbf{h}) \geq \lambda\|\mathbf{h}\|^2$ by Lemma 13.6.3. Since $r(\mathbf{h})/\|\mathbf{h}\|^2 \to 0$, there is $\delta > 0$ with $\mathbf{a}+\mathbf{h} \in U$ and $|r(\mathbf{h})| \leq \frac{1}{4}\lambda\|\mathbf{h}\|^2$ whenever $0 < \|\mathbf{h}\| < \delta$. For such $\mathbf{h}$, by $(*)$,

$$f(\mathbf{a}+\mathbf{h}) - f(\mathbf{a}) \;\geq\; \tfrac{1}{2}\lambda\|\mathbf{h}\|^2 - \tfrac{1}{4}\lambda\|\mathbf{h}\|^2 = \tfrac{1}{4}\lambda\|\mathbf{h}\|^2 > 0.$$

So $f(\mathbf{a}+\mathbf{h}) > f(\mathbf{a})$ for every $\mathbf{h} \neq \mathbf{0}$ with $\|\mathbf{h}\| < \delta$, which is what "strict local minimum" says.

(b) The Hessian of $-f$ at $\mathbf{a}$ is $-\mathbf{H}$, whose inertia is $(n, 0, 0)$ because that of $\mathbf{H}$ is $(0, n, 0)$; so $-\mathbf{H}$ is positive definite by Theorem 13.6.1 (a). Part (a) applied to $-f$ makes $\mathbf{a}$ a strict local minimum of $-f$, that is a strict local maximum of f.

(c) By Theorem 13.6.1 (e) there are $\mathbf{u}, \mathbf{w} \in \mathbb{R}^n$ with $q(\mathbf{u}) > 0$ and $q(\mathbf{w}) < 0$; both are non-zero, since $q(\mathbf{0}) = 0$. Fix $t \neq 0$ small and put $\mathbf{h} = t\mathbf{u}$. Then $q(t\mathbf{u}) = t^2 q(\mathbf{u})$, so $(*)$ gives

$$\frac{f(\mathbf{a}+t\mathbf{u}) - f(\mathbf{a})}{t^2} = \tfrac{1}{2}q(\mathbf{u}) + \frac{r(t\mathbf{u})}{t^2}.$$

Now $r(t\mathbf{u})/t^2 = \|\mathbf{u}\|^2 \cdot r(t\mathbf{u})/\|t\mathbf{u}\|^2 \to 0$ as $t \to 0$, because $\|t\mathbf{u}\| \to 0$ and $\|\mathbf{u}\|^2$ is a constant. So for all small enough $t \neq 0$ the right-hand side is at least $\frac{1}{4}q(\mathbf{u}) > 0$, and hence $f(\mathbf{a}+t\mathbf{u}) > f(\mathbf{a})$. The same computation with $\mathbf{w}$ in place of $\mathbf{u}$ gives $f(\mathbf{a}+t\mathbf{w}) < f(\mathbf{a})$ for all small enough $t \neq 0$. Every neighborhood of $\mathbf{a}$ contains points of both kinds, so $\mathbf{a}$ is neither a local minimum nor a local maximum. This proves the theorem.

■

Cases (a)–(c) exhaust the non-degenerate ones: if $n_0 = 0$ then $n_+ + n_- = n$, so either $n_+ = n$, or $n_- = n$, or both are positive. What is left undecided is exactly $n_0 > 0$, and there the test is silent because it has to be.

Example. (Two critical points of a cubic surface)

Find the critical points of $f(x, y) = x^3 - 3xy + y^3$ on $\mathbb{R}^2$ and classify each one.

Solution. The partial derivatives are $f_x = 3x^2 - 3y$ and $f_y = -3x + 3y^2$. Setting both to zero gives $y = x^2$ and $x = y^2$, hence $x = x^4$, so $x(x^3 - 1) = 0$ and $x \in \{0, 1\}$. The real critical points are $(0, 0)$ and $(1, 1)$.

Differentiating again,

$$\mathbf{H}_f(x,y) = \begin{pmatrix} 6x & -3 \\ -3 & 6y \end{pmatrix}.$$

At $(0,0)$ the Hessian is $\left(\begin{smallmatrix} 0 & -3 \\ -3 & 0 \end{smallmatrix}\right)$, with $\det = -9 < 0$. A 2×2 symmetric matrix with negative determinant has eigenvalue product -9, hence one eigenvalue of each sign, so its inertia is $(1,1,0)$ by Theorem 13.5.3 and the form is indefinite. By Theorem 13.6.4 (c), $(0,0)$ is a saddle point. Concretely $f(t,t) = 2t^3 - 3t^2 < 0$ and $f(t,-t) = 3t^2 > 0$ for small $t > 0$.

At $(1,1)$ the Hessian is $\left(\begin{smallmatrix} 6 & -3 \\ -3 & 6 \end{smallmatrix}\right)$, whose leading principal minors are $6 > 0$ and $36 - 9 = 27 > 0$. By Proposition 13.6.2 (a) it is positive definite, so $(1,1)$ is a strict local minimum, with value $f(1,1) = -1$.

Example. (One Hessian, three answers)

The three functions

$$g_1 = x^2 + y^4, \qquad g_2 = x^2 - y^4, \qquad g_3 = x^2$$

all have $\nabla g_i(0,0) = \mathbf{0}$ and the same Hessian at the origin. What is that Hessian, and what happens at the origin in each case?

Solution. Every second derivative of y^4 vanishes at $y = 0$, so all three have

$$\mathbf{H}_{g_i}(0,0) = \begin{pmatrix} 2 & 0 \\ 0 & 0 \end{pmatrix},$$

with inertia $(1,0,1)$: positive semidefinite, not definite, not indefinite. The test is silent, and it must be, because the three answers differ. For g_1 the origin is a strict local minimum, since $x^2 + y^4 > 0$ away from $\mathbf{0}$. For g_2 it is a saddle: $g_2(t,0) = t^2 > 0$ and $g_2(0,t) = -t^4 < 0$ for $t \neq 0$. For g_3 it is a minimum but not a strict one, since g_3 vanishes along the whole y-axis. The quadratic term decided nothing here; the quartic term decided everything.

Warning. **The test reads the signature, not the determinant.** In two variables the familiar rule is "$\det \mathbf{H} > 0$ and $f_{xx} > 0$ means a minimum", and the second half is not decoration: $\operatorname{diag}(-1,-1)$ has $\det = 1 > 0$, and $-x^2 - y^2$ has a strict local **maximum** at the origin. All $\det \mathbf{H} > 0$ says in two variables is that $n_0 = 0$ and n_- is even — definite, of a sign the determinant cannot see. In three variables it says even less: $\operatorname{diag}(1,-1,-1)$ has $\det = 1 > 0$ and is indefinite.

13.6.3 Exercises

13.6.3.1 A. Check your understanding

Exercise A1.

(a) Define what it means for a symmetric bilinear form on a real vector space to be

indefinite.

(b) State the signature condition equivalent to negative semidefiniteness, and the one equivalent to positive definiteness.

(c) Determine whether the following statement is correct, and justify your answer: a symmetric form that is not positive semidefinite is indefinite.

(d) Name the two results of analysis that Theorem 13.6.4 assumes, and say which part of its proof uses each.

(e) A critical point has $n_0 = 2$ and $n_- = 0$. What does Theorem 13.6.4 conclude?

Solution.

(a) β is indefinite if there exist $\mathbf{u}$ and $\mathbf{w}$ in V with $q(\mathbf{u}) > 0$ and $q(\mathbf{w}) < 0$, where $q(\mathbf{v}) = \beta(\mathbf{v}, \mathbf{v})$.

(b) Negative semidefinite $\iff n_+ = 0$; positive definite $\iff (n_+, n_-, n_0) = (n, 0, 0)$, equivalently $n_+ = n$. Both are Theorem 13.6.1.

(c) Incorrect. The form $q(x_1, x_2) = -x_1^2$ has inertia $(0, 1, 1)$; it is not positive semidefinite, since $q(\mathbf{e}_1) = -1$, and not indefinite, since q is never positive. Failing (b) of Definition 13.6.1 means only $n_- > 0$; being indefinite needs $n_+ > 0$ as well.

(d) Symmetry of the mixed second partial derivatives, which makes the Hessian symmetric so that it has an inertia at all; and Taylor's theorem with a second-order remainder, which is the identity $(*)$ that every part of the proof manipulates.

(e) Nothing. Here $n_+ = n - 2$ and $n_- = 0$, so the Hessian is positive semidefinite but not definite and not indefinite, and none of (a), (b), (c) applies. Example (One Hessian, three answers) shows that all of "strict minimum", "non-strict minimum" and "saddle" really do occur in this situation.

13.6.3.2 B. Practice

Exercise B1: Classify by the signature.

Determine the definiteness of each of the following real symmetric matrices, and give the inertia of each. Justify your answers.

$$\mathbf{A}_1 = \begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix}, \quad \mathbf{A}_2 = \begin{pmatrix} -1 & 2 \\ 2 & -5 \end{pmatrix}, \quad \mathbf{A}_3 = \begin{pmatrix} 1 & 2 \\ 2 & 1 \end{pmatrix}.$$

Solution. For $\mathbf{A}_1$: $\det(\mathbf{A}_1)_1 = 2 > 0$ and $\det \mathbf{A}_1 = 4 - 1 = 3 > 0$, so $\mathbf{A}_1$ is positive definite by Proposition 13.6.2 (a), with inertia $(2, 0, 0)$.

For $\mathbf{A}_2$: $(-1)^1 \det(\mathbf{A}_2)_1 = 1 > 0$ and $(-1)^2 \det \mathbf{A}_2 = 5 - 4 = 1 > 0$, so $\mathbf{A}_2$ is negative definite by Proposition 13.6.2 (b), with inertia $(0, 2, 0)$.

For $\mathbf{A}_3$: $\det \mathbf{A}_3 = 1 - 4 = -3 < 0$, so the two eigenvalues have product -3 and hence opposite signs. The inertia is $(1, 1, 0)$ by Theorem 13.5.3, and $\mathbf{A}_3$ is indefinite by Theorem 13.6.1 (e). Explicitly $q(1, 1) = 6 > 0$ and $q(1, -1) = -2 < 0$.

Exercise B2: Critical points of a quartic.

Find all critical points of $f(x,y) = x^4 + y^4 - 4xy$ and classify each with Theorem 13.6.4.

Solution. $f_x = 4x^3 - 4y$ and $f_y = 4y^3 - 4x$, so $y = x^3$ and $x = y^3 = x^9$. Then $x(x^8 - 1) = 0$, so $x \in \{0, 1, -1\}$ and the critical points are $(0,0)$, $(1,1)$, $(-1,-1)$. The Hessian is

$$\mathbf{H}_f(x,y) = \begin{pmatrix} 12x^2 & -4 \\ -4 & 12y^2 \end{pmatrix}.$$

At $(0,0)$ it is $\left(\begin{smallmatrix} 0 & -4 \\ -4 & 0 \end{smallmatrix}\right)$, with determinant $-16 < 0$, hence inertia $(1,1,0)$ and a saddle point. At $(\pm 1, \pm 1)$ it is $\left(\begin{smallmatrix} 12 & -4 \\ -4 & 12 \end{smallmatrix}\right)$, with leading minors $12 > 0$ and $144 - 16 = 128 > 0$, hence positive definite: both are strict local minima, each of value $f = 1 + 1 - 4 = -2$.

13.6.3.3 C. Going deeper

Exercise C1: The signature measures positive subspaces.

Let β be a symmetric bilinear form on a real vector space V of dimension n, with inertia (n_+, n_-, n_0). Call a subspace $U \subseteq V$ **positive** if $q(\mathbf{v}) > 0$ for every non-zero $\mathbf{v} \in U$.

(a) Prove that V has a positive subspace of dimension n_+.

(b) Prove that every positive subspace has dimension at most n_+. *Hint: consider a subspace on which $q \leq 0$ of the largest available dimension.*

(c) Hence deduce that n_+ equals the largest dimension of a positive subspace, and that this gives a second proof that n_+ does not depend on the orthogonal basis.

Solution. Fix an orthogonal basis $\mathcal{B} = (\mathbf{v}_1, \ldots, \mathbf{v}_n)$ for β, ordered so that $d_i = q(\mathbf{v}_i) > 0$ for $i \leq n_+$, then negative, then zero.

(a) Put $U = \operatorname{span}(\mathbf{v}_1, \ldots, \mathbf{v}_{n_+})$. For a non-zero $\mathbf{v} = \sum_{i \leq n_+} c_i \mathbf{v}_i$, Eq. 13.4.1 gives $q(\mathbf{v}) = \sum_{i \leq n_+} d_i c_i^2 > 0$, since every $d_i > 0$ and some $c_i \neq 0$. So U is positive of dimension n_+.

(b) Put $U' = \operatorname{span}(\mathbf{v}_{n_+ + 1}, \ldots, \mathbf{v}_n)$, of dimension $n - n_+$. For $\mathbf{v} \in U'$, Eq. 13.4.1 gives $q(\mathbf{v}) = \sum_{i > n_+} d_i c_i^2 \leq 0$, every d_i there being ≤ 0. Let W be any positive subspace. Then $W \cap U' = \{\mathbf{0}\}$, since a non-zero vector in the intersection would have $q > 0$ and $q \leq 0$. By the dimension formula (Theorem 1.7.3),

$$\dim W + (n - n_+) = \dim(W + U') \leq n,$$

so $\dim W \leq n_+$.

(c) By (a) and (b) the largest dimension of a positive subspace is exactly n_+. That description mentions only β and V, no basis, so n_+ is an invariant of β. Together with the invariance of $\operatorname{rank} \beta = n_+ + n_-$ under congruence (Theorem 13.2.3) this recovers Theorem 13.5.1.

Exercise C2: A saddle the determinant hides.

Let $f(x,y,z) = x^2 - y^2 - z^2 + xyz$.

(a) Verify that the origin is a critical point and compute $\mathbf{H}_f(\mathbf{0})$ and its determinant.

(b) Classify the origin, and explain why the sign of $\det \mathbf{H}_f(\mathbf{0})$ alone would have been

useless.

(c) Prove that no twice continuously differentiable $g\colon \mathbb{R}^3 \to \mathbb{R}$ has a strict local maximum at a critical point $\mathbf{0}$ with $\det \mathbf{H}_g(\mathbf{0}) > 0$, and give a $g\colon \mathbb{R}^2 \to \mathbb{R}$ that does. Which feature of the dimension is responsible?

Solution.

(a) $f_x = 2x + yz$, $f_y = -2y + xz$, $f_z = -2z + xy$, all zero at $\mathbf{0}$. The second derivatives at $\mathbf{0}$ are $f_{xx} = 2$, $f_{yy} = f_{zz} = -2$, and $f_{xy} = z$, $f_{xz} = y$, $f_{yz} = x$, all zero at $\mathbf{0}$. So $\mathbf{H}_f(\mathbf{0}) = \operatorname{diag}(2, -2, -2)$, with $\det = 8 > 0$.

(b) The inertia is $(1, 2, 0)$, so the Hessian is indefinite and $\mathbf{0}$ is a saddle point by Theorem 13.6.4 (c). The determinant is the product of the eigenvalues (Corollary 11.1.5) and therefore records only the parity of n_-; here $\det > 0$ says n_- is even, which is equally true of the negative definite $\operatorname{diag}(-2, -2, -2)$ and of the positive definite $\mathbf{I}_3$. It cannot distinguish them.

(c) Suppose $\mathbf{0}$ is a local maximum of g and write $q(\mathbf{h}) = \mathbf{h}^\top \mathbf{H}_g(\mathbf{0})\mathbf{h}$. If $q(\mathbf{u}) > 0$ for some $\mathbf{u}$, the computation in the proof of Theorem 13.6.4 (c) gives $g(t\mathbf{u}) > g(\mathbf{0})$ for all small $t \neq 0$, contradicting the maximum. So $q(\mathbf{u}) \leq 0$ for every $\mathbf{u}$, that is $\mathbf{H}_g(\mathbf{0})$ is negative semidefinite and $n_+ = 0$ by Theorem 13.6.1 (d). If moreover $\det \mathbf{H}_g(\mathbf{0}) > 0$ then 0 is not an eigenvalue, so $n_0 = 0$ and the inertia is $(0, 3, 0)$. But then $\det \mathbf{H}_g(\mathbf{0}) = \lambda_1\lambda_2\lambda_3$ is a product of three negative numbers, hence negative — a contradiction. On $\mathbb{R}^2$ there is no obstruction: $g(x, y) = -x^2 - y^2$ has $\mathbf{H}_g(\mathbf{0}) = -2\mathbf{I}_2$, determinant $4 > 0$, and a strict local maximum at $\mathbf{0}$. The responsible feature is the parity of the dimension: the determinant is the product of n eigenvalues, so a negative definite Hessian has det of sign $(-1)^n$.

13.7 Where the Form Vanishes

Sections 4 and 5 diagonalized a symmetric form and counted the signs on the diagonal. Over $\mathbb{R}$ that is the whole story, but it hides the feature that makes indefinite forms geometrically different from inner products: there are non-zero vectors on which the form vanishes. This section takes those vectors seriously. They are not defects to be quarantined; they organize the space, because each one forces a two-dimensional piece of completely standard shape to split off. The result is a decomposition of any non-degenerate space into a pile of identical planes plus a remainder on which the form vanishes nowhere.

Throughout, F is a field with $\operatorname{char} F \neq 2$ (Definition 0.7.2), V is a finite-dimensional vector space over F with $\dim V = n$, and β is a **symmetric** bilinear form on V (Definition 13.3.1) with quadratic form $q(\mathbf{v}) = \beta(\mathbf{v}, \mathbf{v})$ (Definition 13.3.2). Two vectors are orthogonal when β pairs them to 0 (Definition 13.4.1). For a subspace $U \subseteq V$ we write, as in Exercise (C2: Orthogonal complements for a form),

$$U^{\perp_\beta} = \{\, \mathbf{v} \in V : \beta(\mathbf{u}, \mathbf{v}) = 0 \text{ for every } \mathbf{u} \in U \,\},$$

and we write $V = U \perp W$ to say that $V = U \oplus W$ with every vector of U orthogonal to every vector of W — an **orthogonal direct sum**. The subscript β is dropped when only one form is in play.

13.7.1 An intuition to give up

Thirteen chapters have trained one reflex above all others: $\langle \mathbf{v}, \mathbf{v} \rangle = 0$ forces $\mathbf{v} = \mathbf{0}$. It is how we proved that an isometry is injective, that an orthogonal list is independent, that a Gram matrix determines its vectors. It is also the first thing that goes.

Take $V = \mathbb{R}^2$ with

$$q(x_1, x_2) = x_1^2 - x_2^2, \qquad \mathbf{A} = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}.$$

The vector $\mathbf{v} = (1, 1)$ has $q(\mathbf{v}) = 1 - 1 = 0$. It is not $\mathbf{0}$, and the form is not defective: $\det \mathbf{A} = -1 \neq 0$, so β is non-degenerate (Proposition 13.1.2). Indeed $\beta(\mathbf{v}, (1, -1)) = 1 - (1)(-1) = 2 \neq 0$, so $\mathbf{v}$ is perfectly visible to β — it is only invisible to *itself*. The line $\operatorname{span}(\mathbf{v})$ is a line of "length zero" inside a space where length is otherwise perfectly well behaved.

It gets worse, and the worse case is the one worth internalizing. Take $V = \mathbb{R}^4$ with

$$q(\mathbf{x}) = x_1^2 + x_2^2 - x_3^2 - x_4^2,$$

of signature $(2, 2)$ and therefore non-degenerate. Let $W = \operatorname{span}(\mathbf{e}_1 + \mathbf{e}_3,\ \mathbf{e}_2 + \mathbf{e}_4)$, a plane. For $\mathbf{w} = a(\mathbf{e}_1 + \mathbf{e}_3) + b(\mathbf{e}_2 + \mathbf{e}_4)$,

$$q(\mathbf{w}) = a^2 + b^2 - a^2 - b^2 = 0,$$

and in fact β vanishes on every pair from W, since $\beta(\mathbf{e}_1 + \mathbf{e}_3, \mathbf{e}_2 + \mathbf{e}_4) = 0$ too. So β restricted to W is the **zero form** on a two-dimensional subspace of a four-dimensional space on which β is non-degenerate.

Say that again, because it is the sentence an inner-product-trained reader will refuse. A non-degenerate form can vanish identically on a subspace of half the dimension of the whole space. Non-degeneracy is a statement about V; it says that no vector is orthogonal to *everything*. It says nothing whatsoever about what β does inside a subspace. The vectors of W above are orthogonal to each other and to themselves; they are not orthogonal to $\mathbf{e}_1 - \mathbf{e}_3$, and that is all non-degeneracy ever promised.

Once that is accepted, the rest of the section is straightforward. The vanishing vectors get a name, and then a structure theorem.

13.7.2 Isotropic vectors and totally isotropic subspaces

An isotropic vector is a non-zero vector that the form cannot tell from zero when it looks at it twice.

Definition 13.7.1 — Isotropic and Anisotropic

Let β be a symmetric bilinear form on V with quadratic form q.

(a) A vector $\mathbf{v} \in V$ is **isotropic** if $\mathbf{v} \neq \mathbf{0}$ and $q(\mathbf{v}) = 0$, and **anisotropic** if $q(\mathbf{v}) \neq 0$.

(b) The form β is **anisotropic** if it has no isotropic vectors: that is, if $q(\mathbf{v}) = 0$ implies $\mathbf{v} = \mathbf{0}$. Otherwise β is **isotropic**.

Both clauses hinge on small words. In (a) the vector is required to be **non-zero**, so $\mathbf{0}$ is neither isotropic nor anisotropic; the zero vector always has $q(\mathbf{0}) = 0$ and carries no information. In (b), "anisotropic" is a property of the **form on a particular space**. Anisotropy passes down to subspaces, since a subspace has fewer vectors to test; isotropy does not, and a form isotropic on V is very often anisotropic on a subspace. The word comes from *iso* (equal) and *tropos* (direction): a vector along which the form does not distinguish one direction from another.

Examples, over several fields.

- **A positive definite form has no isotropic vectors.** If $q(\mathbf{v}) > 0$ for $\mathbf{v} \neq \mathbf{0}$ then $q(\mathbf{v}) = 0$ forces $\mathbf{v} = \mathbf{0}$. So every inner product is anisotropic, which is exactly the reflex described above. The same holds for negative definite forms.
- **Over $\mathbb{R}$, signature $(1,1)$.** For $q = x_1^2 - x_2^2$ the isotropic vectors are the non-zero multiples of $(1,1)$ and of $(1,-1)$, since $q = (x_1 - x_2)(x_1 + x_2)$. Two lines, and nothing else.
- **Over $\mathbb{C}$.** For $q = x_1^2 + x_2^2$ on $\mathbb{C}^2$ the factorization $q = (x_1 + ix_2)(x_1 - ix_2)$ is available, so $(1, i)$ and $(1, -i)$ are isotropic. Over $\mathbb{R}$ the same q is positive definite. **Isotropy depends on the field**, not only on the polynomial.
- **Over $\mathbb{F}_3$ and $\mathbb{F}_5$.** For $q = x_1^2 + x_2^2$ the squares in $\mathbb{F}_3$ are 0 and 1, so $q(\mathbf{x}) = 0$ needs $x_1 = x_2 = 0$ and the form is anisotropic. In $\mathbb{F}_5$, however, $1^2 + 2^2 = 5 = 0$, so $(1, 2)$ is isotropic. The same formula, two finite fields, two answers.
- **The degenerate case.** Every non-zero vector of the radical is isotropic, since $\mathbf{v} \in \operatorname{rad}(\beta)$ gives $\beta(\mathbf{u}, \mathbf{v}) = 0$ for every $\mathbf{u}$, in particular for $\mathbf{u} = \mathbf{v}$. So a degenerate form is automatically isotropic. The converse fails, and the $\mathbb{R}^2$ example above is the witness.

When a whole subspace consists of isotropic vectors, more is true than the definition says, and it deserves its own name.

Definition 13.7.2 — Totally Isotropic Subspace

A subspace $W \subseteq V$ is **totally isotropic** for β if $\beta(\mathbf{u}, \mathbf{w}) = 0$ for **all** $\mathbf{u}, \mathbf{w} \in W$; equivalently, if $W \subseteq W^{\perp_\beta}$. The zero subspace is totally isotropic, trivially.

The two formulations agree because $W \subseteq W^{\perp_\beta}$ says exactly that every $\mathbf{w} \in W$ is orthogonal to every $\mathbf{u} \in W$. A third formulation is available in characteristic $\neq 2$ and is the one to use in practice: W is totally isotropic if and only if $q(\mathbf{w}) = 0$ for every $\mathbf{w} \in W$. One direction is immediate; the other is Theorem 13.3.5 applied to the restricted form, which recovers β on W from q on W and so makes it zero. In the $\mathbb{R}^4$ example above we checked exactly this: q vanished on W, and therefore so did β.

Before the first theorem, one dimension count has to be on the table, because almost everything in this section and the next is a step away from it. Exercise (C2: Orthogonal complements for a form) set it as an exercise in Section 1; here it is with a proof, so that the results below rest on it rather than on the exercise.

Lemma 13.7.1 — Dimension of an Orthogonal Complement

Let β be a **non-degenerate** bilinear form on V with $\dim V = n$, and let $U \subseteq V$ be a

subspace. Then $U^{\perp_\beta}$ is a subspace of V, and

$$\dim U^{\perp_\beta} = n - \dim U.$$

Idea. Freezing the second slot of β turns it into a map $V \to V^*$, and restricting a functional to U turns V^* into U^*. The composite has kernel exactly $U^{\perp_\beta}$, and non-degeneracy makes both maps surjective, so Rank–Nullity converts "onto U^*" into the count.

Proof. Let $R\colon V \to V^*$ send $\mathbf{v}$ to the functional $\beta(\cdot, \mathbf{v})$ — the map called R_β in Section 1 — and let $\rho\colon V^* \to U^*$ be restriction to U. Both are linear, so $S \coloneqq \rho \circ R\colon V \to U^*$ is linear, and $S(\mathbf{v}) = \beta(\cdot, \mathbf{v})\big|_U$. By the definition of $U^{\perp_\beta}$, a vector $\mathbf{v}$ lies in $U^{\perp_\beta}$ exactly when $\beta(\mathbf{u}, \mathbf{v}) = 0$ for every $\mathbf{u} \in U$, that is, exactly when $S(\mathbf{v}) = 0$. Hence $U^{\perp_\beta} = \ker S$, which is a subspace.

Since β is non-degenerate, R is an isomorphism (Proposition 13.1.2 (c)), and ρ is surjective (Theorem 4.5.1). A composite of two surjections is a surjection, so $\operatorname{rank} S = \dim U^* = \dim U$ (Corollary 4.1.4). By Rank–Nullity (Theorem 3.3.1),

$$\dim U^{\perp_\beta} = \dim \ker S = n - \operatorname{rank} S = n - \dim U,$$

as claimed.

■

Totally isotropic subspaces cannot be too large.

Proposition 13.7.2 — Half the Dimension, at Most

Let β be a non-degenerate symmetric form on V with $\dim V = n$, and let $W \subseteq V$ be totally isotropic. Then $\dim W \le n/2$.

Proof. Since β is non-degenerate, $\dim W^{\perp_\beta} = n - \dim W$ by Lemma 13.7.1. Since W is totally isotropic, $W \subseteq W^{\perp_\beta}$, so $\dim W \le n - \dim W$, which is the claim.

■

Warning. **An isotropic vector is not a zero vector, and a form that vanishes on a subspace need not be degenerate.** These are two different errors and both are common. The first confuses $q(\mathbf{v}) = 0$ with $\mathbf{v} = \mathbf{0}$; over $\mathbb{R}^2$ with $q = x_1^2 - x_2^2$ the vector $(1, 1)$ separates them. The second confuses "β vanishes on $W \times W$" with "β vanishes on $\{\mathbf{v}\} \times V$". Degeneracy is about the **second**: the radical consists of vectors killed by pairing with *everything*. The plane W of the $\mathbb{R}^4$ example carries the zero form and contains no radical vector at all.

Quick check. Is the plane $\operatorname{span}(\mathbf{e}_1, \mathbf{e}_2) \subseteq \mathbb{R}^4$ totally isotropic for $q(\mathbf{x}) = x_1^2 + x_2^2 - x_3^2 - x_4^2$? What about $\operatorname{span}(\mathbf{e}_1 + \mathbf{e}_3, \mathbf{e}_1 - \mathbf{e}_3)$?

Solution. No to both. On $\operatorname{span}(\mathbf{e}_1, \mathbf{e}_2)$ the form restricts to $x_1^2 + x_2^2$, which is positive definite, so that plane is as far from totally isotropic as possible: it is anisotropic. The second plane is $\operatorname{span}(\mathbf{e}_1, \mathbf{e}_3)$, on which q restricts to $x_1^2 - x_3^2$; its two spanning vectors

$\mathbf{e}_1 \pm \mathbf{e}_3$ are indeed isotropic, but $\beta(\mathbf{e}_1 + \mathbf{e}_3, \mathbf{e}_1 - \mathbf{e}_3) = 1 - (-1) = 2 \neq 0$, so the plane is not totally isotropic. Containing isotropic vectors is not the same as being totally isotropic.

13.7.3 Splitting off a non-degenerate piece

Everything below rests on one mechanism: if a subspace carries a non-degenerate restriction, it splits off orthogonally and the rest of the space is again non-degenerate. That is the analogue of "restrict to an invariant complement", and it is what makes induction possible.

Proposition 13.7.3 — A Non-degenerate Subspace Splits Off

Let β be a non-degenerate symmetric form on V with $\dim V = n$, and let $U \subseteq V$ be a subspace such that $\beta|_{U\times U}$ is non-degenerate. Then

$$V = U \perp U^{\perp_\beta},$$

and β restricted to $U^{\perp_\beta}$ is non-degenerate.

Idea. Two things to check and one dimension count. The intersection $U \cap U^{\perp_\beta}$ is precisely the radical of the restricted form, which the hypothesis kills; the dimension of $U^{\perp_\beta}$ is $n - \dim U$ because the global form is non-degenerate; and a vector of $U^{\perp_\beta}$ orthogonal to $U^{\perp_\beta}$ is orthogonal to all of V, hence zero.

Proof. Write $U^\perp = U^{\perp_\beta}$. A vector $\mathbf{v} \in U \cap U^\perp$ lies in U and satisfies $\beta(\mathbf{u}, \mathbf{v}) = 0$ for every $\mathbf{u} \in U$, so $\mathbf{v} \in \operatorname{rad}(\beta|_{U\times U})$, which is $\{\mathbf{0}\}$ by hypothesis (Definition 13.1.4). Hence $U \cap U^\perp = \{\mathbf{0}\}$ and the sum $U + U^\perp$ is direct (Theorem 1.7.4).

Since β is non-degenerate on V, Lemma 13.7.1 gives $\dim U^\perp = n - \dim U$. So $\dim(U \oplus U^\perp) = n$, and a subspace of V of dimension n is V (Theorem 1.6.8). The sum is orthogonal by the definition of $U^\perp$ together with the symmetry of β, so $V = U \perp U^\perp$.

Finally let $\mathbf{w} \in U^\perp$ satisfy $\beta(\mathbf{x}, \mathbf{w}) = 0$ for every $\mathbf{x} \in U^\perp$. For $\mathbf{u} \in U$ we also have $\beta(\mathbf{u}, \mathbf{w}) = 0$, since $\mathbf{w} \in U^\perp$. Every $\mathbf{v} \in V$ is $\mathbf{u} + \mathbf{x}$ with $\mathbf{u} \in U$ and $\mathbf{x} \in U^\perp$, so $\beta(\mathbf{v}, \mathbf{w}) = 0$ for every $\mathbf{v} \in V$, that is $\mathbf{w} \in \operatorname{rad}(\beta) = \{\mathbf{0}\}$. This proves the proposition. ∎

13.7.4 Hyperbolic planes

Which two-dimensional forms are isotropic? Over $\mathbb{R}$ with signature $(1, 1)$ we found two isotropic lines, and the example $q = x_1^2 - x_2^2$ can be rewritten by the substitution $u = x_1 + x_2$, $w = (x_1 - x_2)/2$ as $q = 2uw$ — the cross term alone, with no squares at all. That shape is the model, and it is the same over every field.

Definition 13.7.3 — Hyperbolic Pair, Hyperbolic Plane

Let β be a symmetric bilinear form on V. A **hyperbolic pair** is an ordered pair $(\mathbf{e}, \mathbf{f})$ of vectors of V with

$$q(\mathbf{e}) = 0, \qquad q(\mathbf{f}) = 0, \qquad \beta(\mathbf{e}, \mathbf{f}) = 1.$$

The subspace $H = \operatorname{span}(\mathbf{e}, \mathbf{f})$ is then called a **hyperbolic plane**, and $(\mathbf{e}, \mathbf{f})$ is a **hyperbolic basis** of it.

Four things follow at once. First, $\mathbf{e}$ and $\mathbf{f}$ are linearly independent: if $\mathbf{f} = c\mathbf{e}$ then $\beta(\mathbf{e}, \mathbf{f}) = c\,q(\mathbf{e}) = 0 \neq 1$. So H really is a plane, $\dim H = 2$. Second, in the basis $(\mathbf{e}, \mathbf{f})$ the Gram matrix of $\beta|_H$ is

$$[\beta|_H]_{(\mathbf{e},\mathbf{f})} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix},$$

whose determinant is $-1 \neq 0$, so $\beta|_H$ is **non-degenerate** (Proposition 13.1.2) and Proposition 13.7.3 applies to it. Third, $q(a\mathbf{e} + b\mathbf{f}) = 2ab$, so on a hyperbolic plane q takes **every** value in F: given $c \in F$, take $a = c/2$ and $b = 1$. Fourth, over $\mathbb{R}$ the Gram matrix has eigenvalues 1 and -1, so a hyperbolic plane has signature $(1, 1)$ and is the unique real example up to congruence.

Now the workhorse of this section and the next. It says that one isotropic vector is enough to manufacture a whole hyperbolic plane around it.

Lemma 13.7.4 — Every Isotropic Vector Lies in a Hyperbolic Plane

Let $\operatorname{char} F \neq 2$, let β be a **non-degenerate** symmetric bilinear form on V, and let $\mathbf{e} \in V$ be isotropic. Then there is $\mathbf{f} \in V$ such that $(\mathbf{e}, \mathbf{f})$ is a hyperbolic pair. In particular $\mathbf{e}$ lies in a hyperbolic plane $H = \operatorname{span}(\mathbf{e}, \mathbf{f})$, and $\beta|_H$ is non-degenerate.

Idea. Non-degeneracy hands us some $\mathbf{u}$ with $\beta(\mathbf{e}, \mathbf{u}) \neq 0$, and rescaling makes $\beta(\mathbf{e}, \mathbf{u}) = 1$. Only one condition is still missing, $q(\mathbf{u}) = 0$, and $\mathbf{u}$ can be corrected without disturbing what has been achieved: adding a multiple of $\mathbf{e}$ changes $q(\mathbf{u})$ but not $\beta(\mathbf{e}, \mathbf{u})$, because $q(\mathbf{e}) = 0$. Solving for the multiple is one line, and it divides by 2 — which is where the characteristic hypothesis is spent, for the third time in this chapter.

Proof. Since $\mathbf{e} \neq \mathbf{0}$ and β is non-degenerate, there is $\mathbf{u}_0 \in V$ with $c = \beta(\mathbf{e}, \mathbf{u}_0) \neq 0$ (Definition 13.1.4). Put $\mathbf{u} = c^{-1}\mathbf{u}_0$, so that

$$\beta(\mathbf{e}, \mathbf{u}) = 1.$$

Now set

$$\mathbf{f} = \mathbf{u} - \tfrac{1}{2}q(\mathbf{u})\,\mathbf{e},$$

which is legitimate because $\operatorname{char} F \neq 2$ makes $2 = 1{+}1$ invertible. Then, using bilinearity, symmetry and $q(\mathbf{e}) = 0$,

$$\beta(\mathbf{e}, \mathbf{f}) = \beta(\mathbf{e}, \mathbf{u}) - \tfrac{1}{2}q(\mathbf{u})\,q(\mathbf{e}) = 1 - 0 = 1,$$

and

$$\begin{aligned} q(\mathbf{f}) &= q(\mathbf{u}) - 2 \cdot \tfrac{1}{2}q(\mathbf{u})\,\beta(\mathbf{u}, \mathbf{e}) + \tfrac{1}{4}q(\mathbf{u})^2\,q(\mathbf{e}) \\ &= q(\mathbf{u}) - q(\mathbf{u}) + 0 = 0. \end{aligned}$$

Together with $q(\mathbf{e}) = 0$, this shows that $(\mathbf{e}, \mathbf{f})$ is a hyperbolic pair. As noted after Definition 13.7.3, $\mathbf{e}$ and $\mathbf{f}$ are independent, so $H = \operatorname{span}(\mathbf{e}, \mathbf{f})$ is a plane, and the Gram matrix $\left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$ is invertible, so $\beta|_H$ is non-degenerate. This proves the lemma.

■

Remark. Non-degeneracy of β is not decoration here. On $\mathbb{R}^2$ with $q(\mathbf{x}) = x_1^2$, the vector $\mathbf{e}_2$ is isotropic and lies in no hyperbolic plane, because $\beta(\mathbf{e}_2, \mathbf{v}) = 0$ for every $\mathbf{v}$ and a hyperbolic pair needs $\beta(\mathbf{e}, \mathbf{f}) = 1$. What fails is the very first line of the proof.

13.7.5 The Witt decomposition

Peeling off a hyperbolic plane and repeating is now a two-line induction, and it is the structural theorem of the section: it does for indefinite forms what "peel off an eigenvector" did for operators in Chapter 8.

Theorem 13.7.5 — Witt Decomposition

Let $\operatorname{char} F \neq 2$ and let β be a non-degenerate symmetric bilinear form on a finite-dimensional V. Then there are an integer $m \geq 0$, hyperbolic planes $H_1, \dots, H_m \subseteq V$ and a subspace $V_0 \subseteq V$ such that

$$V = H_1 \perp H_2 \perp \cdots \perp H_m \perp V_0$$

and β restricted to V_0 is **anisotropic**. In particular $\dim V = 2m + \dim V_0$.

Idea. Induction on $\dim V$. Either β is anisotropic, in which case take $m = 0$ and $V_0 = V$ and stop; or there is an isotropic vector, in which case Lemma 13.7.4 wraps a hyperbolic plane H_1 around it, Proposition 13.7.3 peels H_1 off with a non-degenerate remainder $H_1^{\perp}$ of dimension $\dim V - 2$, and the induction hypothesis finishes the job there.

Proof. Induct on $\dim V$. If $\dim V = 0$, take $m = 0$ and $V_0 = \{\mathbf{0}\}$, on which the form is anisotropic vacuously. Let $\dim V \geq 1$ and suppose the statement holds for every non-degenerate symmetric form on a space of smaller dimension.

If β is anisotropic, take $m = 0$ and $V_0 = V$.

Otherwise β has an isotropic vector $\mathbf{e}$. By Lemma 13.7.4 there is $\mathbf{f}$ with $(\mathbf{e}, \mathbf{f})$ a hyperbolic pair, and $H_1 = \operatorname{span}(\mathbf{e}, \mathbf{f})$ is a hyperbolic plane with $\beta|_{H_1}$ non-degenerate. By Proposition 13.7.3,

$$V = H_1 \perp H_1^{\perp_\beta},$$

and β restricted to $V' = H_1^{\perp_\beta}$ is non-degenerate, with $\dim V' = \dim V - 2 < \dim V$. The induction hypothesis applied to $(V', \beta|_{V'})$ gives hyperbolic planes $H_2, \dots, H_m \subseteq V'$ and an anisotropic $V_0 \subseteq V'$ with $V' = H_2 \perp \cdots \perp H_m \perp V_0$. Each H_i with $i \geq 2$ and V_0 lie inside $V' = H_1^{\perp_\beta}$, so all the summands are pairwise orthogonal, and

$$V = H_1 \perp H_2 \perp \cdots \perp H_m \perp V_0.$$

Counting dimensions, $\dim V = 2m + \dim V_0$. This completes the induction.

■

Two questions are now unavoidable: is m the same for every such decomposition, and is V_0 determined? The first has an answer here, and it comes from a quantity that mentions no decomposition at all.

Definition 13.7.4 — Witt Index

Let β be a non-degenerate symmetric bilinear form on a finite-dimensional V. The **Witt index** of β is

$$\operatorname{ind}(\beta) := \max\{\dim W : W \subseteq V \text{ totally isotropic}\},$$

the largest dimension of a totally isotropic subspace. By Proposition 13.7.2 it satisfies $\operatorname{ind}(\beta) \le n/2$, and it is 0 exactly when β is anisotropic.

The maximum exists because the dimensions in question form a non-empty finite set of integers: $W = \{\mathbf{0}\}$ is always totally isotropic, and all dimensions are at most n. Nothing in the definition refers to a basis or a decomposition, so the Witt index is an invariant of (V, β) by construction. It is also exactly the number of planes.

Proposition 13.7.6 — The Number of Hyperbolic Planes Is the Witt Index

In any decomposition $V = H_1 \perp \cdots \perp H_m \perp V_0$ as in Theorem 13.7.5, $m = \operatorname{ind}(\beta)$. In particular m is the same for every such decomposition, and so is $\dim V_0 = n - 2m$.

Idea. One inequality is a construction: the first vectors $\mathbf{e}_1, \dots, \mathbf{e}_m$ of the m hyperbolic bases span a totally isotropic subspace of dimension m, since each is isotropic and different planes are orthogonal. The other inequality is an induction that trades one plane for one dimension: given a totally isotropic W, the vectors of W orthogonal to $\mathbf{e}_1$ project into $H_1^{\perp}$ as a totally isotropic subspace of dimension at least $\dim W - 1$. Repeating m times lands inside the anisotropic V_0, where the only totally isotropic subspace is $\{\mathbf{0}\}$.

Proof. Let $(\mathbf{e}_i, \mathbf{f}_i)$ be a hyperbolic basis of H_i for each i.

Step 1: $\operatorname{ind}(\beta) \ge m$. Put $W = \operatorname{span}(\mathbf{e}_1, \dots, \mathbf{e}_m)$. The $\mathbf{e}_i$ lie in different summands of a direct sum and are non-zero, so they are independent and $\dim W = m$. For $i \ne j$ we have $\beta(\mathbf{e}_i, \mathbf{e}_j) = 0$ because $H_i \perp H_j$, and $\beta(\mathbf{e}_i, \mathbf{e}_i) = q(\mathbf{e}_i) = 0$. By bilinearity β vanishes on $W \times W$, so W is totally isotropic of dimension m.

Step 2: a plane can be traded for a dimension.

> *Claim.* Let β be non-degenerate on V, let $H = \operatorname{span}(\mathbf{e}, \mathbf{f}) \subseteq V$ be a hyperbolic plane, let $V' = H^{\perp_\beta}$, and let $W \subseteq V$ be totally isotropic. Then V' contains a totally isotropic subspace of dimension at least $\dim W - 1$.

Proof. By Proposition 13.7.3, $V = H \perp V'$; let $P\colon V \to V'$ be the projection with kernel H, so that $\mathbf{v} - P(\mathbf{v}) \in H$ for every $\mathbf{v}$. Put

$$W_1 = \{\, \mathbf{w} \in W : \beta(\mathbf{e}, \mathbf{w}) = 0 \,\},$$

the kernel of a linear functional on W, so $\dim W_1 \geq \dim W - 1$.

For $\mathbf{w} \in V$ write $\mathbf{w} - P(\mathbf{w}) = a\mathbf{e} + b\mathbf{f}$. Since $\mathbf{e} \in H$ is orthogonal to V',

$$\beta(\mathbf{e}, \mathbf{w}) = \beta(\mathbf{e}, a\mathbf{e} + b\mathbf{f}) = a\, q(\mathbf{e}) + b = b.$$

So $\mathbf{w} \in W_1$ forces $\mathbf{w} - P(\mathbf{w}) \in \operatorname{span}(\mathbf{e})$. Consequently, for $\mathbf{w}, \mathbf{w}' \in W_1$ the vectors $\mathbf{w} - P(\mathbf{w})$ and $\mathbf{w}' - P(\mathbf{w}')$ both lie in $\operatorname{span}(\mathbf{e})$, where β vanishes because $q(\mathbf{e}) = 0$; hence

$$\beta(P(\mathbf{w}), P(\mathbf{w}')) = \beta(\mathbf{w}, \mathbf{w}') - \beta\big(\mathbf{w} - P(\mathbf{w}),\, \mathbf{w}' - P(\mathbf{w}')\big) = 0 - 0 = 0,$$

the first equality using the orthogonality of H and V'. So $P(W_1)$ is a totally isotropic subspace of V'.

It remains to bound its dimension. By Rank–Nullity (Theorem 3.3.1) applied to $P|_{W_1}$, whose kernel is $W_1 \cap H$,

$$\dim P(W_1) = \dim W_1 - \dim(W_1 \cap H).$$

If $W_1 \cap H = \{\mathbf{0}\}$, then $\dim P(W_1) = \dim W_1 \geq \dim W - 1$ and we are done. Otherwise pick $\mathbf{x} \neq \mathbf{0}$ in $W_1 \cap H$. Then $P(\mathbf{x}) = \mathbf{0}$, so $\mathbf{x} = \mathbf{x} - P(\mathbf{x}) \in \operatorname{span}(\mathbf{e})$ by the paragraph above, whence $\mathbf{e} \in W$. But then $\beta(\mathbf{e}, \mathbf{w}) = 0$ for every $\mathbf{w} \in W$, because W is totally isotropic and $\mathbf{e} \in W$; so $W_1 = W$. Moreover every $\mathbf{x} \in W_1 \cap H$ lies in $\operatorname{span}(\mathbf{e})$ by the same argument, so $W_1 \cap H = \operatorname{span}(\mathbf{e})$ has dimension 1, and $\dim P(W_1) = \dim W - 1$. Either way the claim holds.

■

Step 3: $\operatorname{ind}(\beta) \leq m$. Let $W \subseteq V$ be totally isotropic. Apply Step 2 to $H = H_1$: since $H_1^{\perp_\beta} = H_2 \perp \cdots \perp H_m \perp V_0$ carries a non-degenerate form, we obtain a totally isotropic subspace of it of dimension at least $\dim W - 1$. Repeating with $H_2, \ldots, H_m$ in turn produces a totally isotropic subspace of V_0 of dimension at least $\dim W - m$. But $\beta|_{V_0}$ is anisotropic, so a non-zero vector of V_0 has $q \neq 0$ and the only totally isotropic subspace of V_0 is $\{\mathbf{0}\}$. Hence $\dim W - m \leq 0$.

Steps 1 and 3 give $\operatorname{ind}(\beta) = m$, and $\dim V_0 = n - 2m$ follows by counting. This proves the proposition.

■

So the number of planes is pinned down. What is not yet pinned down is V_0 itself: different decompositions produce different subspaces, and the claim one wants is that they all carry *the same form* in a suitable sense. Making that precise needs the word "isometry" for forms, and proving it needs Witt's theorems; both are the business of the next section.

13.7.6 The two familiar fields

Over $\mathbb{R}$ and $\mathbb{C}$ everything can be computed, because the classification is already known.

Proposition 13.7.7 — The Witt Index over the Reals and the Complexes (a)

Let β be a non-degenerate symmetric form on a real V with signature (n_+, n_-) (Definition 13.5.1), so $n_+ + n_- = n$. Then $\operatorname{ind}(\beta) = \min(n_+, n_-)$, and the anisotropic part has dimension $|n_+ - n_-|$ and is definite.

(b) Let β be a non-degenerate symmetric form on a complex V with $\dim V = n$. Then $\operatorname{ind}(\beta) = \lfloor n/2 \rfloor$. In particular every such form with $n \geq 2$ has an isotropic vector, and the anisotropic part has dimension 0 or 1.

Proof.

(a) Put $k = \min(n_+, n_-)$. By Theorem 13.4.2 and the rescaling that produced Eq. 13.5.1, together with $n_0 = 0$, there is an orthogonal basis $(\mathbf{v}_1, \dots, \mathbf{v}_n)$ with $q(\mathbf{v}_i) = 1$ for $i \leq n_+$, $q(\mathbf{v}_i) = -1$ for $n_+ < i \leq n$, and distinct basis vectors orthogonal. For $1 \leq i \leq k$ set

$$\mathbf{e}_i = \mathbf{v}_i + \mathbf{v}_{n_+ + i}, \qquad \mathbf{f}_i = \tfrac{1}{2}\big(\mathbf{v}_i - \mathbf{v}_{n_+ + i}\big).$$

Then $q(\mathbf{e}_i) = 1 + (-1) = 0$ and $q(\mathbf{f}_i) = \tfrac{1}{4}(1 + (-1)) = 0$, while

$$\beta(\mathbf{e}_i, \mathbf{f}_i) = \tfrac{1}{2}\big(q(\mathbf{v}_i) - q(\mathbf{v}_{n_+ + i})\big) = \tfrac{1}{2}(1 + 1) = 1,$$

so $(\mathbf{e}_i, \mathbf{f}_i)$ is a hyperbolic pair and $H_i = \operatorname{span}(\mathbf{e}_i, \mathbf{f}_i)$ a hyperbolic plane. These planes are pairwise orthogonal, since for $i \neq j$ their spanning vectors involve disjoint sets of the $\mathbf{v}$'s. Let V_0 be the span of the remaining $|n_+ - n_-|$ basis vectors, all of the same sign; then $V = H_1 \perp \cdots \perp H_k \perp V_0$, and $\beta|_{V_0}$ is definite, hence anisotropic. By Proposition 13.7.6, $\operatorname{ind}(\beta) = k$.

(b) By Corollary 13.4.4 and non-degeneracy, there is a basis $(\mathbf{v}_1, \dots, \mathbf{v}_n)$ with $q(\mathbf{v}_j) = 1$ for every j and distinct basis vectors orthogonal. Write $n = 2k + r$ with $r \in \{0, 1\}$, and let i denote the imaginary unit. For $1 \leq j \leq k$ set

$$\mathbf{e}_j = \mathbf{v}_{2j-1} + i\,\mathbf{v}_{2j}, \qquad \mathbf{f}_j = \tfrac{1}{2}\big(\mathbf{v}_{2j-1} - i\,\mathbf{v}_{2j}\big).$$

Then $q(\mathbf{e}_j) = 1 + i^2 = 0$ and likewise $q(\mathbf{f}_j) = \tfrac{1}{4}(1 + i^2) = 0$, while $\beta(\mathbf{e}_j, \mathbf{f}_j) = \tfrac{1}{2}(1 + 1) = 1$. As in (a) these span k pairwise orthogonal hyperbolic planes, and what is left is the span of $\mathbf{v}_n$ when $r = 1$, on which $q(c\mathbf{v}_n) = c^2 \neq 0$ for $c \neq 0$, and $\{\mathbf{0}\}$ when $r = 0$. So $\operatorname{ind}(\beta) = k = \lfloor n/2 \rfloor$ by Proposition 13.7.6. This proves the proposition.

■

Two readings are worth recording. Over $\mathbb{R}$ the Witt index is the smaller of the two counts of signs: a definite form has index 0, and a form of signature (m, m) has the largest possible index $m = n/2$ — the $\mathbb{R}^4$ example that opened the section, with $n_+ = n_- = 2$, sits exactly there. Over $\mathbb{C}$ the index is as large as it can be for every non-degenerate form, because -1 is a square and so a sum of two squares always factors; the only anisotropic complex spaces are $\{\mathbf{0}\}$ and the lines.

Quick check. A non-degenerate real form has signature $(3, 1)$. What is its Witt index, and what is the anisotropic part?

Solution. The index is $\min(3, 1) = 1$, so exactly one hyperbolic plane splits off and $\dim V_0 = 4-2 = 2$. By Proposition 13.7.7 (a), V_0 carries a definite form of dimension $|3-1| = 2$, positive definite here since the positive signs are the ones in surplus. Concretely $\mathbb{R}^{3,1}$ with $q = x_1^2 + x_2^2 + x_3^2 - x_4^2$ splits as one hyperbolic plane, spanned by $\mathbf{e}_3 \pm \mathbf{e}_4$ after rescaling, orthogonal to the positive definite plane $\operatorname{span}(\mathbf{e}_1, \mathbf{e}_2)$. The largest totally isotropic subspace is a line, and the lines of this kind sweep out the light cone that Section 11 studies.

13.7.7 Exercises

13.7.7.1 A. Check your understanding

Exercise A1.

(a) Define **isotropic vector**, **totally isotropic subspace** and **hyperbolic pair**.

(b) Determine whether the following statement is correct, and justify your answer: a non-degenerate form has no isotropic vectors.

(c) What is the Witt index of a positive definite form on a space of dimension n? Of a form of signature $(4, 4)$?

(d) State the Gram matrix of a hyperbolic plane in a hyperbolic basis, and say why it shows the restricted form is non-degenerate.

(e) Which hypothesis of Lemma 13.7.4 fails for the form $q(\mathbf{x}) = x_1^2$ on $\mathbb{R}^2$ at the isotropic vector $\mathbf{e}_2$?

Solution.

(a) A vector $\mathbf{v}$ is isotropic if $\mathbf{v} \neq \mathbf{0}$ and $q(\mathbf{v}) = 0$. A subspace W is totally isotropic if $\beta(\mathbf{u}, \mathbf{w}) = 0$ for all $\mathbf{u}, \mathbf{w} \in W$. A hyperbolic pair is a pair $(\mathbf{e}, \mathbf{f})$ with $q(\mathbf{e}) = q(\mathbf{f}) = 0$ and $\beta(\mathbf{e}, \mathbf{f}) = 1$.

(b) Incorrect. Non-degeneracy says $\operatorname{rad}(\beta) = \{\mathbf{0}\}$, a statement about pairing with **every** vector. On $\mathbb{R}^2$ with $q = x_1^2 - x_2^2$ the form is non-degenerate, since its Gram matrix has determinant -1, and $(1, 1)$ is isotropic.

(c) 0 for a positive definite form, since it is anisotropic, so the only totally isotropic subspace is $\{\mathbf{0}\}$. For signature $(4, 4)$ the index is $\min(4, 4) = 4$ by Proposition 13.7.7 (a), the largest value Proposition 13.7.2 permits in dimension 8.

(d) It is $\left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$, of determinant $-1 \neq 0$, and a form is non-degenerate exactly when its Gram matrix is invertible (Proposition 13.1.2).

(e) Non-degeneracy of β. Here $\mathbf{e}_2 \in \operatorname{rad}(\beta)$, so there is no $\mathbf{u}$ with $\beta(\mathbf{e}_2, \mathbf{u}) \neq 0$ and the first line of the proof has nothing to choose.

13.7.7.2 B. Practice

Exercise B1: Find the isotropic vectors.

For each of the following real quadratic forms, find all isotropic vectors, give the signature, and state the Witt index.

(a) $q(x_1, x_2) = x_1^2 + 2x_1x_2$ on $\mathbb{R}^2$.
(b) $q(x_1, x_2, x_3) = x_1x_2$ on $\mathbb{R}^3$. *(Is this form non-degenerate?)*
(c) $q(x_1, x_2, x_3) = x_1^2 + x_2^2 + x_3^2$ on $\mathbb{R}^3$.

Solution.

(a) $q = x_1(x_1 + 2x_2)$, so $q = 0$ exactly on the two lines $x_1 = 0$ and $x_1 = -2x_2$. The isotropic vectors are the non-zero multiples of $(0, 1)$ and of $(-2, 1)$. The Gram matrix is $\left(\begin{smallmatrix} 1 & 1 \\ 1 & 0 \end{smallmatrix}\right)$, of determinant $-1 < 0$, so the eigenvalues have opposite signs and the signature is $(1, 1)$. The Witt index is $\min(1, 1) = 1$; indeed $(0, 1)$ is isotropic and by Lemma 13.7.4 the whole space is one hyperbolic plane.

(b) The Gram matrix is $\left(\begin{smallmatrix} 0 & 1/2 & 0 \\ 1/2 & 0 & 0 \\ 0 & 0 & 0 \end{smallmatrix}\right)$, of rank 2, so the form is **degenerate** with $\operatorname{rad}(\beta) = \operatorname{span}(\mathbf{e}_3)$ and the notion of Witt index does not apply as defined. The isotropic vectors are those with $x_1x_2 = 0$, namely the union of the two planes $x_1 = 0$ and $x_2 = 0$, minus $\mathbf{0}$. On the non-degenerate part $\operatorname{span}(\mathbf{e}_1, \mathbf{e}_2)$ the signature is $(1, 1)$ and the index is 1.

(c) There are none: q is positive definite, so $q(\mathbf{x}) = 0$ forces $\mathbf{x} = \mathbf{0}$. The signature is $(3, 0)$ and the Witt index is 0.

Exercise B2: Build a hyperbolic basis.

(a) For $q(x_1, x_2) = x_1^2 + x_2^2$ on $\mathbb{C}^2$, find a hyperbolic pair.
(b) For $q(x_1, x_2, x_3) = x_1^2 + x_2^2 - x_3^2$ on $\mathbb{R}^3$, find a hyperbolic pair $(\mathbf{e}, \mathbf{f})$ with $\mathbf{e} = \mathbf{e}_1 + \mathbf{e}_3$, and identify the anisotropic part $\operatorname{span}(\mathbf{e}, \mathbf{f})^{\perp_\beta}$.

Solution.

(a) Take $\mathbf{e} = (1, i)$, so $q(\mathbf{e}) = 1 + i^2 = 0$. The vector $\mathbf{u} = (1, -i)$ has $\beta(\mathbf{e}, \mathbf{u}) = 1 \cdot 1 + i \cdot (-i) = 2$, so rescale: $\mathbf{f} = \tfrac{1}{2}(1, -i)$ gives $\beta(\mathbf{e}, \mathbf{f}) = 1$ and $q(\mathbf{f}) = \tfrac{1}{4}(1 + i^2) = 0$. So $\big((1, i), \tfrac{1}{2}(1, -i)\big)$ is a hyperbolic pair, and $\mathbb{C}^2$ is a single hyperbolic plane.

(b) $q(\mathbf{e}) = 1 - 1 = 0$, so $\mathbf{e}$ is isotropic. Follow the proof of Lemma 13.7.4: $\mathbf{u}_0 = \mathbf{e}_1$ gives $\beta(\mathbf{e}, \mathbf{e}_1) = 1$, so take $\mathbf{u} = \mathbf{e}_1$, and $q(\mathbf{u}) = 1$, whence

$$\mathbf{f} = \mathbf{e}_1 - \tfrac{1}{2}(\mathbf{e}_1 + \mathbf{e}_3) = \tfrac{1}{2}(\mathbf{e}_1 - \mathbf{e}_3).$$

Check: $q(\mathbf{f}) = \tfrac{1}{4}(1 - 1) = 0$ and $\beta(\mathbf{e}, \mathbf{f}) = \tfrac{1}{2}(1 + 1) = 1$. For the complement, $\mathbf{v} = (v_1, v_2, v_3)$ is orthogonal to both $\mathbf{e}$ and $\mathbf{f}$ exactly when $v_1 - v_3 = 0$ and $v_1 + v_3 = 0$, that is $v_1 = v_3 = 0$. So $\operatorname{span}(\mathbf{e}, \mathbf{f})^{\perp_\beta} = \operatorname{span}(\mathbf{e}_2)$, on which $q = x_2^2$ is positive definite. This is the decomposition of Theorem 13.7.5 with $m = 1$, matching $\min(2, 1) = 1$.

Exercise B3: A totally isotropic subspace of the largest size.

Let $q(\mathbf{x}) = x_1x_4 + x_2x_3$ on $\mathbb{R}^4$.

(a) Write down the Gram matrix and verify that β is non-degenerate.

(b) Exhibit a totally isotropic subspace of dimension 2, and explain why none of dimension 3 exists.

(c) Determine the signature of q and confirm the Witt index by Proposition 13.7.7 (a).

Solution.

(a) Halving the cross-term coefficients (Eq. 13.3.1),

$$\mathbf{A} = \tfrac{1}{2}\begin{pmatrix} 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \end{pmatrix},$$

whose determinant is $\frac{1}{16}$ det of the reversal permutation matrix, namely $\frac{1}{16} \cdot 1 \neq 0$. So β is non-degenerate by Proposition 13.1.2.

(b) Take $W = \operatorname{span}(\mathbf{e}_1, \mathbf{e}_2)$. Every $\mathbf{w} = (a, b, 0, 0)$ has $q(\mathbf{w}) = 0$, and $\beta(\mathbf{e}_1, \mathbf{e}_2) = 0$ from the matrix, so W is totally isotropic of dimension 2. No totally isotropic subspace has dimension 3, because Proposition 13.7.2 caps it at $4/2 = 2$.

(c) The two planes $\operatorname{span}(\mathbf{e}_1, \mathbf{e}_4)$ and $\operatorname{span}(\mathbf{e}_2, \mathbf{e}_3)$ are orthogonal, and $(\mathbf{e}_1, 2\mathbf{e}_4)$ is a hyperbolic pair, since $q(\mathbf{e}_1) = q(2\mathbf{e}_4) = 0$ and $\beta(\mathbf{e}_1, 2\mathbf{e}_4) = 2 \cdot \frac{1}{2} = 1$; the same works for $(\mathbf{e}_2, 2\mathbf{e}_3)$. So each plane is hyperbolic, of signature $(1, 1)$. Hence q has signature $(2, 2)$ and, by Proposition 13.7.7 (a), Witt index $\min(2, 2) = 2$, attained by the W of part (b).

13.7.7.3 C. Going deeper

Exercise C1: Isotropy makes the form surjective.

Let β be a non-degenerate symmetric form on V over a field F with $\operatorname{char} F \neq 2$.

(a) Prove that if β has an isotropic vector, then $q\colon V \to F$ is surjective.

(b) Deduce that if some $c \in F$ is not of the form $q(\mathbf{v})$, then β is anisotropic.

(c) Use (b) to show that the form $q(x_1, x_2) = x_1^2 + x_2^2$ on $\mathbb{F}_3^2$ is anisotropic, and give its Witt index.

Solution.

(a) Let $\mathbf{e}$ be isotropic. By Lemma 13.7.4 there is $\mathbf{f}$ with $(\mathbf{e}, \mathbf{f})$ a hyperbolic pair. For $c \in F$, put $\mathbf{v} = \frac{c}{2}\mathbf{e} + \mathbf{f}$; this is legitimate since $\operatorname{char} F \neq 2$. Then

$$q(\mathbf{v}) = \tfrac{c^2}{4}q(\mathbf{e}) + 2 \cdot \tfrac{c}{2}\beta(\mathbf{e}, \mathbf{f}) + q(\mathbf{f}) = 0 + c + 0 = c.$$

So every $c \in F$ is a value of q.

(b) Contrapositive of (a): if q is not surjective then β has no isotropic vector.

(c) The squares in $\mathbb{F}_3$ are $0^2 = 0$, $1^2 = 1$, $2^2 = 1$, so the values of $x_1^2 + x_2^2$ are $0, 1, 2$ — which is all of $\mathbb{F}_3$, so (b) gives nothing directly. Argue instead from the definition: $q(\mathbf{x}) = 0$ needs $x_1^2 = -x_2^2 = 2x_2^2$. If $x_2 \neq 0$ then $x_2^2 = 1$, so $x_1^2 = 2$, which is not a square in $\mathbb{F}_3$; hence $x_2 = 0$ and then $x_1 = 0$. The form is anisotropic, its Witt index is 0, and the Gram matrix $\mathbf{I}_2$ shows it is non-degenerate. Over $\mathbb{F}_5$ the same form is isotropic, since $1^2 + 2^2 = 0$.

Exercise C2: A maximal totally isotropic subspace and its complement.

Let β be non-degenerate symmetric on V with $\dim V = n$, and let $W \subseteq V$ be totally isotropic with $\dim W = \operatorname{ind}(\beta) = m$.

(a) Prove that $\dim W^{\perp_\beta} = n - m$ and $W \subseteq W^{\perp_\beta}$.

(b) Prove that the form induced by β on the quotient $W^{\perp_\beta}/W$ is well defined and anisotropic. *Hint: a coset with an isotropic representative would enlarge W.*

(c) Deduce that $n - 2m = \dim(W^{\perp_\beta}/W)$ agrees with the dimension of the anisotropic part in Theorem 13.7.5.

Solution.

(a) The dimension is Lemma 13.7.1, using non-degeneracy, and the inclusion is Definition 13.7.2.

(b) For $\mathbf{u}, \mathbf{v} \in W^{\perp_\beta}$ and $\mathbf{w}, \mathbf{w}' \in W$,

$$\beta(\mathbf{u} + \mathbf{w}, \mathbf{v} + \mathbf{w}') = \beta(\mathbf{u}, \mathbf{v}),$$

because each of the three remaining terms pairs a vector of W with a vector of $W^{\perp_\beta} \supseteq W$, hence vanishes. So $\bar{\beta}(\mathbf{u}+W, \mathbf{v}+W) := \beta(\mathbf{u}, \mathbf{v})$ is well defined, and it is bilinear and symmetric. Suppose $\bar{q}(\mathbf{u}+W) = 0$ with $\mathbf{u} \notin W$, that is $q(\mathbf{u}) = 0$ with $\mathbf{u} \in W^{\perp_\beta} \setminus W$. Then $W + \operatorname{span}(\mathbf{u})$ is totally isotropic: it is spanned by isotropic vectors, $\beta(\mathbf{u}, \mathbf{w}) = 0$ for $\mathbf{w} \in W$ because $\mathbf{u} \in W^{\perp_\beta}$, and β vanishes on $W \times W$. Its dimension is $m + 1 > \operatorname{ind}(\beta)$, a contradiction. So $\bar{\beta}$ is anisotropic.

(c) By (a), $\dim(W^{\perp_\beta}/W) = (n - m) - m = n - 2m$. By Proposition 13.7.6 the anisotropic part V_0 of a Witt decomposition also has dimension $n - 2m$, since the index is m. (That the two anisotropic forms agree, and not merely their dimensions, is proved in the next section.)

Exercise C3: Where characteristic 2 breaks.

Work over $\mathbb{F}_2$ and let β be the dot product on $\mathbb{F}_2^2$, with Gram matrix $\mathbf{I}_2$.

(a) Verify that β is symmetric and non-degenerate, and find all $\mathbf{v}$ with $q(\mathbf{v}) = 0$.

(b) Show that β has a vector with $q(\mathbf{v}) = 0$ and $\mathbf{v} \neq \mathbf{0}$ that lies in no hyperbolic plane, and identify which line of the proof of Lemma 13.7.4 fails.

(c) Explain in one sentence why the third description of "totally isotropic" given after Definition 13.7.2 is unavailable here.

Solution.

(a) The Gram matrix $\mathbf{I}_2$ is symmetric and invertible, so β is symmetric and non-degenerate (Proposition 13.1.2). Here $q(\mathbf{x}) = x_1^2 + x_2^2 = (x_1 + x_2)^2$ over $\mathbb{F}_2$, which vanishes exactly when $x_1 = x_2$. So $q(\mathbf{v}) = 0$ for $\mathbf{v} = \mathbf{0}$ and for $\mathbf{v} = (1, 1)$.

(b) Take $\mathbf{v} = (1, 1)$. A hyperbolic plane containing it would need $\mathbf{f}$ with $q(\mathbf{f}) = 0$ and $\beta(\mathbf{v}, \mathbf{f}) = 1$. The only non-zero vector with $q = 0$ is $\mathbf{v}$ itself, and $\beta(\mathbf{v}, \mathbf{v}) = q(\mathbf{v}) = 0 \neq 1$. The step that fails is the correction $\mathbf{f} = \mathbf{u} - \frac{1}{2}q(\mathbf{u})\mathbf{e}$: the element $2 = 1 + 1$ is 0 in $\mathbb{F}_2$ and is not invertible, so $\frac{1}{2}$ does not exist.

(c) Because it is Theorem 13.3.5, which needs $\operatorname{char} F \neq 2$ to divide by 2; over $\mathbb{F}_2$ the line $\operatorname{span}((1, 1))$ has $q \equiv 0$ on it and is indeed totally isotropic here, but the implication "q vanishes on W implies β vanishes on $W \times W$" is not available in general.

13.8 Witt's Extension and Cancellation Theorems

The previous section left one question open. A non-degenerate space splits as hyperbolic planes plus an anisotropic remainder, and the number of planes is pinned down by the Witt index — but the remainder is a subspace chosen along the way, and different choices give different subspaces. What should be true is that they all carry the same form. Proving it needs a theorem with a much wider reach: any isometry between two subspaces of a non-degenerate space is the restriction of an isometry of the whole space. That theorem is the longest proof of the chapter, and the cancellation statement that finishes Section 7 falls out of it in four lines.

Throughout, F is a field with $\operatorname{char} F \neq 2$ (Definition 0.7.2), all spaces are finite-dimensional over F, and all forms are **symmetric** bilinear forms (Definition 13.3.1). Orthogonal complements $U^{\perp_\beta}$, orthogonal direct sums $U \perp W$, and isotropic and hyperbolic vocabulary are as in Section 7.

13.8.1 Isometries of forms

Chapter 10 called a linear map an isometry when it preserved the inner product (Definition 10.7.1). The same word works here, with the form in place of the inner product and with no positivity anywhere.

An isometry is a change of variables that the form does not notice.

Definition 13.8.1 — Isometry of Bilinear Spaces

Let β be a bilinear form on V and β' one on V'. An **isometry** from (V, β) to (V', β') is a linear **bijection** $\sigma\colon V \to V'$ with

$$\beta'\big(\sigma(\mathbf{u}), \sigma(\mathbf{v})\big) = \beta(\mathbf{u}, \mathbf{v}) \qquad \text{for all } \mathbf{u}, \mathbf{v} \in V.$$

The two spaces are **isometric**, written $(V, \beta) \cong (V', \beta')$ or just $V \cong V'$, if such a σ exists. An isometry of (V, β) with itself is an **isometry of** V.

When $U \subseteq V$ and $U' \subseteq V'$ are subspaces, "an isometry $U \to U'$" always means an

isometry for the **restricted** forms $\beta|_{U\times U}$ and $\beta'|_{U'\times U'}$.

Two clauses need pointing at. The map must be a **bijection**, so that the inverse is again an isometry; and the identity must hold for **all** pairs, though by bilinearity it is enough to check it on a pair of bases. The symbol $\cong$ is the one used for isomorphism throughout the book, and no confusion arises: an isometry is an isomorphism that also respects the form, and within this chapter $\cong$ between spaces carrying forms always means isometric.

Three readings make the notion concrete.

- **Isometry is congruence in disguise.** If $\mathcal{B}$ is a basis of V and $\mathcal{B}'$ one of V', then σ is an isometry exactly when the Gram matrices satisfy $[\beta]_{\mathcal{B}} = \mathbf{P}^{\top}\,[\beta']_{\mathcal{B}'}\,\mathbf{P}$ with $\mathbf{P} = [\sigma]_{\mathcal{B}}^{\mathcal{B}'}$. So $(V,\beta) \cong (V',\beta')$ if and only if their Gram matrices are congruent (Definition 13.2.1). Every classification theorem of this chapter is therefore a classification up to isometry.
- **Over $\mathbb{R}$.** Two real spaces with non-degenerate symmetric forms are isometric exactly when they have the same signature, by Corollary 13.5.2. So, writing $\mathbb{R}^{p,q}$ for $\mathbb{R}^{p+q}$ carrying the form of signature (p,q), we have $\mathbb{R}^{2,1} \ncong \mathbb{R}^{1,2}$ even though both are three-dimensional and both non-degenerate.
- **The degenerate case.** An isometry carries $\operatorname{rad}(\beta)$ onto $\operatorname{rad}(\beta')$, because $\beta'(\sigma\mathbf{u},\sigma\mathbf{v}) = \beta(\mathbf{u},\mathbf{v})$ and σ is onto. In particular isometric spaces have radicals of equal dimension.

The isometries of a fixed (V,β) form a group under composition; Section 10 names the classical examples. For now only two kinds are needed, and the second is built from the first.

13.8.2 Reflections

Chapter 10 §08 built Householder reflections out of an inner product, to clear a column. The same formula works for any symmetric form, provided the vector we reflect in is anisotropic, and it is the only explicit isometry this section needs.

Definition 13.8.2 — Reflection in an Anisotropic Vector

Let β be a symmetric bilinear form on V and let $\mathbf{w} \in V$ be anisotropic, that is $q(\mathbf{w}) \neq 0$. The **reflection in $\mathbf{w}$** is the map

$$\tau_{\mathbf{w}} \colon V \to V, \qquad \tau_{\mathbf{w}}(\mathbf{v}) = \mathbf{v} - \frac{2\beta(\mathbf{v},\mathbf{w})}{q(\mathbf{w})}\,\mathbf{w}.$$

The formula is Definition 10.8.1 with $\langle \mathbf{v},\mathbf{w}\rangle$ replaced by $\beta(\mathbf{v},\mathbf{w})$ and $\|\mathbf{w}\|^2$ by $q(\mathbf{w})$; the division is legitimate precisely because $\mathbf{w}$ is anisotropic.

Proposition 13.8.1 — Reflections Are Involutive Isometries

Let β be a symmetric bilinear form on V and $\mathbf{w} \in V$ anisotropic. Then $\tau_{\mathbf{w}}$ is linear, and:

(a) $\tau_{\mathbf{w}}(\mathbf{w}) = -\mathbf{w}$, and $\tau_{\mathbf{w}}(\mathbf{v}) = \mathbf{v}$ for every $\mathbf{v}$ with $\beta(\mathbf{v},\mathbf{w}) = 0$;
(b) $\tau_{\mathbf{w}} \circ \tau_{\mathbf{w}} = \mathrm{id}_V$; in particular $\tau_{\mathbf{w}}$ is bijective;
(c) $\beta(\tau_{\mathbf{w}}\mathbf{u}, \tau_{\mathbf{w}}\mathbf{v}) = \beta(\mathbf{u},\mathbf{v})$ for all $\mathbf{u},\mathbf{v} \in V$.

Hence $\tau_{\mathbf{w}}$ is an isometry of V.

Proof. Linearity holds because $\mathbf{v} \mapsto \beta(\mathbf{v}, \mathbf{w})$ is linear and $q(\mathbf{w})$ is a fixed non-zero scalar. Write $c(\mathbf{v}) = 2\beta(\mathbf{v}, \mathbf{w})/q(\mathbf{w})$.

(a) $c(\mathbf{w}) = 2q(\mathbf{w})/q(\mathbf{w}) = 2$, so $\tau_{\mathbf{w}}(\mathbf{w}) = \mathbf{w} - 2\mathbf{w} = -\mathbf{w}$. If $\beta(\mathbf{v}, \mathbf{w}) = 0$ then $c(\mathbf{v}) = 0$ and $\tau_{\mathbf{w}}(\mathbf{v}) = \mathbf{v}$.

(b) By (a) and linearity, $\beta(\tau_{\mathbf{w}}\mathbf{v}, \mathbf{w}) = \beta(\mathbf{v}, \mathbf{w}) - c(\mathbf{v})q(\mathbf{w}) = -\beta(\mathbf{v}, \mathbf{w})$, so $c(\tau_{\mathbf{w}}\mathbf{v}) = -c(\mathbf{v})$ and

$$\tau_{\mathbf{w}}(\tau_{\mathbf{w}}\mathbf{v}) = \big(\mathbf{v} - c(\mathbf{v})\mathbf{w}\big) + c(\mathbf{v})\mathbf{w} = \mathbf{v}.$$

(c) Expanding by bilinearity and using symmetry,

$$\begin{aligned}\beta(\tau_{\mathbf{w}}\mathbf{u}, \tau_{\mathbf{w}}\mathbf{v}) = \beta(\mathbf{u}, \mathbf{v}) &- c(\mathbf{v})\beta(\mathbf{u}, \mathbf{w}) - c(\mathbf{u})\beta(\mathbf{w}, \mathbf{v}) \\ &+ c(\mathbf{u})c(\mathbf{v})q(\mathbf{w}).\end{aligned}$$

Now $c(\mathbf{u})c(\mathbf{v})q(\mathbf{w}) = 4\beta(\mathbf{u}, \mathbf{w})\beta(\mathbf{v}, \mathbf{w})/q(\mathbf{w})$, while the two middle terms together contribute $-4\beta(\mathbf{u}, \mathbf{w})\beta(\mathbf{v}, \mathbf{w})/q(\mathbf{w})$. They cancel, leaving $\beta(\mathbf{u}, \mathbf{v})$. Together with (b) this makes $\tau_{\mathbf{w}}$ a bijective linear map preserving β, that is an isometry.

■

The use of reflections is that they move one anisotropic vector to any other of the same value — the one explicit construction the long proof below will need.

Lemma 13.8.2 — Moving One Anisotropic Vector to Another

Let $\operatorname{char} F \neq 2$, let β be a symmetric bilinear form on V, and let $\mathbf{u}, \mathbf{u}' \in V$ satisfy

$$q(\mathbf{u}) = q(\mathbf{u}') \neq 0.$$

Then there is an isometry ρ of V with $\rho(\mathbf{u}) = \mathbf{u}'$, and ρ may be taken to be a reflection or a product of two reflections.

Idea. The reflection in $\mathbf{u} - \mathbf{u}'$ is the natural candidate, and it works whenever $\mathbf{u} - \mathbf{u}'$ is anisotropic. It need not be — but $\mathbf{u} + \mathbf{u}'$ then is, because the two values $q(\mathbf{u} - \mathbf{u}')$ and $q(\mathbf{u} + \mathbf{u}')$ add up to $4q(\mathbf{u}) \neq 0$ and so cannot both vanish. Reflecting in $\mathbf{u} + \mathbf{u}'$ overshoots to $-\mathbf{u}'$, and one more reflection, in $\mathbf{u}'$ itself, brings it back.

Proof. Expanding both by bilinearity and adding,

$$q(\mathbf{u} - \mathbf{u}') + q(\mathbf{u} + \mathbf{u}') = 2q(\mathbf{u}) + 2q(\mathbf{u}') = 4q(\mathbf{u}) \neq 0,$$

where the last step uses $q(\mathbf{u}) = q(\mathbf{u}') \neq 0$. So at least one of $q(\mathbf{u} - \mathbf{u}')$ and $q(\mathbf{u} + \mathbf{u}')$ is non-zero.

Case 1: $q(\mathbf{u} - \mathbf{u}') \neq 0$. Put $\mathbf{w} = \mathbf{u} - \mathbf{u}'$. Then

$$q(\mathbf{w}) = q(\mathbf{u}) - 2\beta(\mathbf{u}, \mathbf{u}') + q(\mathbf{u}') = 2\big(q(\mathbf{u}) - \beta(\mathbf{u}, \mathbf{u}')\big),$$

while $\beta(\mathbf{u},\mathbf{w}) = q(\mathbf{u}) - \beta(\mathbf{u},\mathbf{u}')$. Hence $2\beta(\mathbf{u},\mathbf{w})/q(\mathbf{w}) = 1$, and

$$\tau_{\mathbf{w}}(\mathbf{u}) = \mathbf{u} - \mathbf{w} = \mathbf{u}'.$$

Take $\rho = \tau_{\mathbf{w}}$.

Case 2: $q(\mathbf{u}-\mathbf{u}') = 0$. Then $q(\mathbf{u}+\mathbf{u}') = 4q(\mathbf{u}) \neq 0$; put $\mathbf{w} = \mathbf{u}+\mathbf{u}'$. The same computation with $-\mathbf{u}'$ in place of $\mathbf{u}'$ gives $q(\mathbf{w}) = 2(q(\mathbf{u}) + \beta(\mathbf{u},\mathbf{u}'))$ and $\beta(\mathbf{u},\mathbf{w}) = q(\mathbf{u}) + \beta(\mathbf{u},\mathbf{u}')$, so again $2\beta(\mathbf{u},\mathbf{w})/q(\mathbf{w}) = 1$ and

$$\tau_{\mathbf{w}}(\mathbf{u}) = \mathbf{u} - \mathbf{w} = -\mathbf{u}'.$$

Since $q(\mathbf{u}') \neq 0$, the reflection $\tau_{\mathbf{u}'}$ is defined, and $\tau_{\mathbf{u}'}(-\mathbf{u}') = \mathbf{u}'$ by Proposition 13.8.1 (a). Take $\rho = \tau_{\mathbf{u}'} \circ \tau_{\mathbf{w}}$, a composition of two isometries and hence an isometry. This proves the lemma.

■

Quick check. In $\mathbb{R}^3$ with $q(\mathbf{x}) = x_1^2 + x_2^2 - x_3^2$, find a reflection carrying $\mathbf{e}_1$ to $\mathbf{e}_2$.

Solution. Both have $q = 1 \neq 0$, so Lemma 13.8.2 applies. Case 1 works: $\mathbf{w} = \mathbf{e}_1 - \mathbf{e}_2$ has $q(\mathbf{w}) = 1 + 1 = 2 \neq 0$, so

$$\tau_{\mathbf{w}}(\mathbf{v}) = \mathbf{v} - \beta(\mathbf{v},\mathbf{w})\,\mathbf{w},$$

since $2/q(\mathbf{w}) = 1$. Then $\beta(\mathbf{e}_1,\mathbf{w}) = 1$ and $\tau_{\mathbf{w}}(\mathbf{e}_1) = \mathbf{e}_1 - (\mathbf{e}_1 - \mathbf{e}_2) = \mathbf{e}_2$, as required. The reflection fixes $\mathbf{e}_1 + \mathbf{e}_2$ and $\mathbf{e}_3$, which are the vectors orthogonal to $\mathbf{w}$.

13.8.3 Witt's extension theorem

Here is the chapter's long theorem. Read the statement carefully: the two subspaces live in the **same** space V, and the form on V is required to be non-degenerate, but nothing at all is assumed about the restrictions to U and U' — they may be degenerate, they may be zero.

Theorem 13.8.3 — Witt's Extension Theorem

Let F be a field with $\operatorname{char} F \neq 2$, let V be a finite-dimensional vector space over F, and let β be a **non-degenerate** symmetric bilinear form on V. Let $U, U' \subseteq V$ be subspaces and let

$$\sigma : U \to U'$$

be an isometry for the restricted forms. Then there is an isometry φ of V with $\varphi|_U = \sigma$.

Idea. Induction, but on what? Two different moves are available, and each improves a different number.

① If $\beta|_U$ is **non-degenerate**, then U contains an anisotropic vector $\mathbf{u}_1$. A reflection moves $\sigma(\mathbf{u}_1)$ back to $\mathbf{u}_1$, so we may assume σ fixes $\mathbf{u}_1$; then everything of U orthogonal to $\mathbf{u}_1$ stays inside the hyperplane $\mathbf{u}_1^{\perp}$, which is again non-degenerate and **one dimension smaller**. Recurse there and glue.

② If $\beta|_U$ is **degenerate**, pick a non-zero $\mathbf{z}$ in its radical. Non-degeneracy of β on V produces a partner $\mathbf{w}$ making $(\mathbf{z}, \mathbf{w})$ a hyperbolic pair orthogonal to the rest of U, and σ extends to $U \oplus F\mathbf{w}$ by sending $\mathbf{w}$ to the matching partner on the other side. The subspace has grown, but its **radical has shrunk by one**.

So the induction runs on the pair $(\dim V,\ \dim \operatorname{rad}(\beta|_U))$ read lexicographically: ① lowers the first entry, ② keeps it and lowers the second. Step 0 disposes of $U = \{\mathbf{0}\}$.

Proof. We prove the statement for every triple (V, U, σ) satisfying the hypotheses, by induction on the pair

$$\big(\dim V,\ \dim \operatorname{rad}(\beta|_{U\times U})\big)$$

ordered lexicographically: one pair precedes another if its first entry is smaller, or the first entries agree and the second is smaller. This order on pairs of non-negative integers has no infinite descending chain, so the induction is legitimate. Write $R = \operatorname{rad}(\beta|_{U\times U}) = U \cap U^{\perp_\beta}$.

Step 0: $U = \{\mathbf{0}\}$. Then $U' = \{\mathbf{0}\}$ and $\varphi = \mathrm{id}_V$ works.

Step 1: $U \neq \{\mathbf{0}\}$ and $R = \{\mathbf{0}\}$. Since $\beta|_U$ is non-degenerate and $U \neq \{\mathbf{0}\}$, the form $\beta|_U$ is not the zero form. By Lemma 13.4.1, applied to $\beta|_U$ on U and using $\operatorname{char} F \neq 2$, there is $\mathbf{u}_1 \in U$ with $q(\mathbf{u}_1) \neq 0$.

Claim. We may assume $\sigma(\mathbf{u}_1) = \mathbf{u}_1$.

Proof. Put $\mathbf{u}_1' = \sigma(\mathbf{u}_1)$. Then $q(\mathbf{u}_1') = \beta(\sigma\mathbf{u}_1, \sigma\mathbf{u}_1) = q(\mathbf{u}_1) \neq 0$, so Lemma 13.8.2 gives an isometry ρ of V with $\rho(\mathbf{u}_1) = \mathbf{u}_1'$. The composite $\tau = \rho^{-1} \circ \sigma$ is an isometry from U onto $\rho^{-1}(U')$ with $\tau(\mathbf{u}_1) = \mathbf{u}_1$, and if φ_0 is an isometry of V extending τ, then $\rho \circ \varphi_0$ is an isometry of V extending σ. So it suffices to treat τ. ∎

Assume then that $\sigma(\mathbf{u}_1) = \mathbf{u}_1$. The map $\mathbf{u} \mapsto \beta(\mathbf{u}_1, \mathbf{u})$ is a linear functional on U taking the non-zero value $q(\mathbf{u}_1)$ at $\mathbf{u}_1$, so its kernel

$$U_1 = \{\, \mathbf{u} \in U : \beta(\mathbf{u}_1, \mathbf{u}) = 0 \,\}$$

has $\dim U_1 = \dim U - 1$ by Rank–Nullity (Theorem 3.3.1), and $U = \operatorname{span}(\mathbf{u}_1) \oplus U_1$, since $a\mathbf{u}_1 \in U_1$ forces $a\, q(\mathbf{u}_1) = 0$ and hence $a = 0$.

Because $q(\mathbf{u}_1) \neq 0$, the form restricted to $\operatorname{span}(\mathbf{u}_1)$ is non-degenerate, so Proposition 13.7.3 gives

$$V = \operatorname{span}(\mathbf{u}_1) \perp W, \qquad W = \operatorname{span}(\mathbf{u}_1)^{\perp_\beta},$$

with $\beta|_W$ non-degenerate and $\dim W = \dim V - 1$. Now $U_1 \subseteq W$ by definition, and $\sigma(U_1) \subseteq W$ as well: for $\mathbf{u} \in U_1$,

$$\beta(\mathbf{u}_1, \sigma\mathbf{u}) = \beta(\sigma\mathbf{u}_1, \sigma\mathbf{u}) = \beta(\mathbf{u}_1, \mathbf{u}) = 0.$$

So $\sigma|_{U_1} : U_1 \to \sigma(U_1)$ is an isometry between two subspaces of W, and $(W, \beta|_W)$ satisfies the hypotheses of the theorem with $\dim W < \dim V$. By the induction hypothesis there is an isometry θ of W with $\theta|_{U_1} = \sigma|_{U_1}$.

Define $\varphi\colon V \to V$ by

$$\varphi(a\mathbf{u}_1 + \mathbf{x}) = a\mathbf{u}_1 + \theta(\mathbf{x}) \qquad (a \in F,\ \mathbf{x} \in W),$$

which is well defined and linear because $V = \operatorname{span}(\mathbf{u}_1) \oplus W$, and bijective because θ is. It is an isometry: using the orthogonality of $\operatorname{span}(\mathbf{u}_1)$ and W on both sides,

$$\begin{aligned} \beta\big(\varphi(a\mathbf{u}_1 + \mathbf{x}), \varphi(b\mathbf{u}_1 + \mathbf{y})\big) &= ab\, q(\mathbf{u}_1) + \beta(\theta\mathbf{x}, \theta\mathbf{y}) \\ &= ab\, q(\mathbf{u}_1) + \beta(\mathbf{x}, \mathbf{y}) \\ &= \beta(a\mathbf{u}_1 + \mathbf{x},\ b\mathbf{u}_1 + \mathbf{y}). \end{aligned}$$

Finally φ extends σ: a vector $\mathbf{u} \in U$ is $a\mathbf{u}_1 + \mathbf{x}$ with $\mathbf{x} \in U_1 \subseteq W$, and

$$\varphi(\mathbf{u}) = a\mathbf{u}_1 + \theta(\mathbf{x}) = a\sigma(\mathbf{u}_1) + \sigma(\mathbf{x}) = \sigma(\mathbf{u}).$$

Step 2: $R \neq \{\mathbf{0}\}$. Choose $\mathbf{z} \in R$ with $\mathbf{z} \neq \mathbf{0}$ and a complement U_0 of $\operatorname{span}(\mathbf{z})$ in U, so that $U = \operatorname{span}(\mathbf{z}) \oplus U_0$ (Theorem 1.7.6). Since σ is an isometry of U onto U', it carries R onto $\operatorname{rad}(\beta|_{U'})$; write $\mathbf{z}' = \sigma(\mathbf{z})$ and $U_0' = \sigma(U_0)$, so that $U' = \operatorname{span}(\mathbf{z}') \oplus U_0'$ and $\mathbf{z}'$ lies in the radical of $\beta|_{U'}$. Note $q(\mathbf{z}) = 0$, because $\mathbf{z}$ pairs to zero with everything in U, in particular with itself; likewise $q(\mathbf{z}') = 0$.

> *Claim.* There is $\mathbf{w} \in V$ with $q(\mathbf{w}) = 0$, $\beta(\mathbf{z}, \mathbf{w}) = 1$ and $\beta(\mathbf{u}_0, \mathbf{w}) = 0$ for every $\mathbf{u}_0 \in U_0$.

> *Proof.* Consider the linear map $S\colon V \to U^*$ sending $\mathbf{v}$ to the restriction of $\beta(\cdot, \mathbf{v})$ to U. Its kernel is $U^{\perp_\beta}$, which has dimension $\dim V - \dim U$ by Lemma 13.7.1, since β is non-degenerate. By Rank–Nullity (Theorem 3.3.1), $\operatorname{rank} S = \dim U = \dim U^*$, so S is onto. Let $\psi_{\mathbf{z}} \in U^*$ be the functional with $\psi_{\mathbf{z}}(\mathbf{z}) = 1$ and $\psi_{\mathbf{z}}(U_0) = 0$, which exists because $U = \operatorname{span}(\mathbf{z}) \oplus U_0$. Pick $\mathbf{w}_0 \in V$ with $S(\mathbf{w}_0) = \psi_{\mathbf{z}}$, that is $\beta(\mathbf{z}, \mathbf{w}_0) = 1$ and $\beta(\mathbf{u}_0, \mathbf{w}_0) = 0$ for $\mathbf{u}_0 \in U_0$.
>
> Put $\mathbf{w} = \mathbf{w}_0 - \frac{1}{2} q(\mathbf{w}_0)\, \mathbf{z}$, which uses $\operatorname{char} F \neq 2$. Since $q(\mathbf{z}) = 0$ and $\beta(\mathbf{u}, \mathbf{z}) = 0$ for every $\mathbf{u} \in U$,
>
> $$\beta(\mathbf{z}, \mathbf{w}) = 1 - \tfrac{1}{2} q(\mathbf{w}_0) q(\mathbf{z}) = 1, \qquad \beta(\mathbf{u}_0, \mathbf{w}) = 0,$$
>
> and
>
> $$q(\mathbf{w}) = q(\mathbf{w}_0) - q(\mathbf{w}_0)\beta(\mathbf{w}_0, \mathbf{z}) + \tfrac{1}{4} q(\mathbf{w}_0)^2 q(\mathbf{z}) = 0,$$
>
> using $\beta(\mathbf{w}_0, \mathbf{z}) = \beta(\mathbf{z}, \mathbf{w}_0) = 1$.
>
> ∎

Apply the claim on both sides: it gives $\mathbf{w}$ for $(\mathbf{z}, U_0)$ and, by the same argument with $\mathbf{z}'$ and U_0', a vector $\mathbf{w}'$ with $q(\mathbf{w}') = 0$, $\beta(\mathbf{z}', \mathbf{w}') = 1$ and $\beta(U_0', \mathbf{w}') = 0$.

The vector $\mathbf{w}$ is not in U, since $\beta(\mathbf{z}, \mathbf{w}) = 1$ while $\beta(\mathbf{z}, \mathbf{u}) = 0$ for every $\mathbf{u} \in U$; likewise $\mathbf{w}' \notin U'$. So

$$\widetilde{U} = U \oplus F\mathbf{w}, \qquad \widetilde{U}' = U' \oplus F\mathbf{w}'$$

are subspaces of V of dimension $\dim U + 1$. Define $\widetilde{\sigma}(\mathbf{u} + c\mathbf{w}) = \sigma(\mathbf{u}) + c\mathbf{w}'$, a linear bijection $\widetilde{U} \to \widetilde{U}'$. It is an isometry: for $\mathbf{u} = a\mathbf{z} + \mathbf{u}_0 \in U$ we have

$$\beta(\mathbf{u}, \mathbf{w}) = a\beta(\mathbf{z}, \mathbf{w}) + \beta(\mathbf{u}_0, \mathbf{w}) = a,$$

and $\sigma(\mathbf{u}) = a\mathbf{z}' + \sigma(\mathbf{u}_0)$ with $\sigma(\mathbf{u}_0) \in U_0'$, so $\beta(\sigma\mathbf{u}, \mathbf{w}') = a$ as well. Hence, expanding by bilinearity and using $q(\mathbf{w}) = q(\mathbf{w}') = 0$,

$$\begin{aligned} \beta\big(\widetilde{\sigma}(\mathbf{u} + c\mathbf{w}),\, \widetilde{\sigma}(\mathbf{y} + d\mathbf{w})\big) &= \beta(\sigma\mathbf{u}, \sigma\mathbf{y}) + d\,\beta(\sigma\mathbf{u}, \mathbf{w}') + c\,\beta(\sigma\mathbf{y}, \mathbf{w}') \\ &= \beta(\mathbf{u}, \mathbf{y}) + d\,\beta(\mathbf{u}, \mathbf{w}) + c\,\beta(\mathbf{y}, \mathbf{w}) \\ &= \beta(\mathbf{u} + c\mathbf{w},\ \mathbf{y} + d\mathbf{w}). \end{aligned}$$

Claim. $\operatorname{rad}(\beta|_{\widetilde{U}}) = R \cap U_0$, and its dimension is $\dim R - 1$.

Proof. Let $\mathbf{x} = a\mathbf{z} + \mathbf{u}_0 + c\mathbf{w}$ lie in $\operatorname{rad}(\beta|_{\widetilde{U}})$, with $a, c \in F$ and $\mathbf{u}_0 \in U_0$. Pairing $\mathbf{x}$ with $\mathbf{w}$ gives $a\beta(\mathbf{z}, \mathbf{w}) + \beta(\mathbf{u}_0, \mathbf{w}) + c\,q(\mathbf{w}) = a$, so $a = 0$. Pairing $\mathbf{x}$ with $\mathbf{z}$ gives $\beta(\mathbf{u}_0, \mathbf{z}) + c\,\beta(\mathbf{w}, \mathbf{z}) = c$, since $\mathbf{z} \in R$ kills $\mathbf{u}_0$; so $c = 0$. Hence $\mathbf{x} = \mathbf{u}_0 \in U_0$, and $\mathbf{x}$ pairs to zero with all of $U \subseteq \widetilde{U}$, so $\mathbf{x} \in R \cap U_0$. Conversely a vector of $R \cap U_0$ pairs to zero with U and with $\mathbf{w}$, hence with $\widetilde{U}$.

For the dimension: every $\mathbf{r} \in R \subseteq U$ is $a\mathbf{z} + \mathbf{u}_0$, and $\mathbf{u}_0 = \mathbf{r} - a\mathbf{z} \in R$ because $\mathbf{z} \in R$; so $R = \operatorname{span}(\mathbf{z}) \oplus (R \cap U_0)$ and $\dim(R \cap U_0) = \dim R - 1$.

■

The pair attached to the triple $(V, \widetilde{U}, \widetilde{\sigma})$ is therefore $(\dim V, \dim R - 1)$, which precedes $(\dim V, \dim R)$ in the lexicographic order. By the induction hypothesis there is an isometry φ of V with $\varphi|_{\widetilde{U}} = \widetilde{\sigma}$. Since $U \subseteq \widetilde{U}$ and $\widetilde{\sigma}|_U = \sigma$, this φ extends σ.

Steps 0, 1 and 2 cover every case, so the induction is complete and the theorem is proved.

■

Three places earned their hypotheses. Non-degeneracy of β on V was used twice, once through Proposition 13.7.3 in Step 1 and once through the surjectivity of S in Step 2. Characteristic $\neq 2$ was used twice as well, in Lemma 13.4.1 and in the correction $\mathbf{w} = \mathbf{w}_0 - \frac{1}{2}q(\mathbf{w}_0)\mathbf{z}$, which is the same correction that built a hyperbolic pair in Lemma 13.7.4. And symmetry is everywhere: without it, "the" radical and "the" orthogonal complement would each split into a left and a right version.

13.8.4 Cancellation

The corollary is what the theorem is usually used for, and it is where a careless statement goes wrong. Witt cancellation removes a summand from an **orthogonal** decomposition of two spaces that are **already known to be isometric**, and what it produces is an isometry of the complements.

Corollary 13.8.4 — Witt's Cancellation Theorem

Let $\operatorname{char} F \neq 2$.

(a) Let β be a non-degenerate symmetric form on V, and let $U, U' \subseteq V$ be isometric subspaces. Then $U^{\perp_\beta} \cong U'^{\perp_\beta}$.

(b) Let (V, β) and (V', β') be finite-dimensional spaces with non-degenerate symmetric forms, and suppose
$$V = U \perp W, \qquad V' = U' \perp W'.$$
If $V \cong V'$ and $U \cong U'$, then $W \cong W'$.

Idea. For (a), extend the isometry $U \to U'$ to the whole of V and watch where the complement goes: an isometry of V carrying U onto U' has no choice but to carry $U^\perp$ onto $U'^\perp$. For (b), transport everything into the single space V along an isometry $V \to V'$, and apply (a).

Proof.

(a) Let $\sigma\colon U \to U'$ be an isometry. By Theorem 13.8.3 there is an isometry φ of V with $\varphi|_U = \sigma$; in particular $\varphi(U) = U'$. If $\mathbf{x} \in U^{\perp_\beta}$ and $\mathbf{u}' \in U'$, write $\mathbf{u}' = \varphi(\mathbf{u})$ with $\mathbf{u} \in U$; then
$$\beta(\mathbf{u}', \varphi\mathbf{x}) = \beta(\varphi\mathbf{u}, \varphi\mathbf{x}) = \beta(\mathbf{u}, \mathbf{x}) = 0,$$
so $\varphi(U^{\perp_\beta}) \subseteq U'^{\perp_\beta}$. Both subspaces have dimension $\dim V - \dim U$ by Lemma 13.7.1, using $\dim U = \dim U'$, and φ is injective, so the inclusion is an equality. Restricting φ gives an isometry $U^{\perp_\beta} \to U'^{\perp_\beta}$.

(b) First, $W = U^{\perp_\beta}$: the orthogonality in $V = U \perp W$ gives $W \subseteq U^{\perp_\beta}$, and both have dimension $\dim V - \dim U$, so they are equal (Theorem 1.6.8). Likewise $W' = U'^{\perp_{\beta'}}$.

Let $\psi\colon V \to V'$ be an isometry. Then $\psi^{-1}(U')$ is a subspace of V isometric to U', hence isometric to U. Moreover $\psi^{-1}\big(U'^{\perp_{\beta'}}\big) = \big(\psi^{-1}(U')\big)^{\perp_\beta}$, because ψ preserves the forms and is onto. Applying (a) inside V to the isometric subspaces U and $\psi^{-1}(U')$,
$$W = U^{\perp_\beta} \cong \big(\psi^{-1}(U')\big)^{\perp_\beta} = \psi^{-1}(W') \cong W',$$
the last isometry being the restriction of ψ. This proves the corollary.

■

Warning. **Cancellation needs the whole spaces to be isometric, and the sums to be orthogonal.** Neither hypothesis can be dropped.

Drop the first: inside $\mathbb{R}^2$ with $q = x_1^2 + x_2^2$ and inside $\mathbb{R}^2$ with $q' = x_1^2 - x_2^2$, the lines $\operatorname{span}(\mathbf{e}_1)$ are isometric, each carrying the form $\langle 1 \rangle$. Their complements are $\operatorname{span}(\mathbf{e}_2)$ with $q = x_2^2$ and $\operatorname{span}(\mathbf{e}_2)$ with $q' = -x_2^2$, which are **not** isometric: one is positive definite, the other negative definite. Isometric subspaces of **different** ambient spaces say nothing about complements.

Drop the second: in $\mathbb{R}^2$ with $q = x_1^2 - x_2^2$, both
$$V = \operatorname{span}(\mathbf{e}_1) \oplus \operatorname{span}(\mathbf{e}_1 + \mathbf{e}_2) \quad \text{and} \quad V = \operatorname{span}(\mathbf{e}_1) \oplus \operatorname{span}(\mathbf{e}_2)$$
are direct sums with the same first summand. The second summands carry $q(\mathbf{e}_1 + \mathbf{e}_2) = 0$ and $q(\mathbf{e}_2) = -1$, so they are not isometric. The first decomposition is not orthogonal,

since $\beta(\mathbf{e}_1, \mathbf{e}_1 + \mathbf{e}_2) = 1 \neq 0$, and that is exactly what breaks.

13.8.5 The Witt decomposition is unique

We can now close the question Section 7 left open.

Corollary 13.8.5 — The Anisotropic Part Is Determined

Let $\operatorname{char} F \neq 2$, let β be a non-degenerate symmetric form on a finite-dimensional V, and let

$$V = H_1 \perp \cdots \perp H_m \perp V_0 = H'_1 \perp \cdots \perp H'_{m'} \perp V'_0$$

be two decompositions as in Theorem 13.7.5. Then $m = m' = \operatorname{ind}(\beta)$ and $V_0 \cong V'_0$.

Proof. That $m = m' = \operatorname{ind}(\beta)$ is Proposition 13.7.6. Put $U = H_1 \perp \cdots \perp H_m$ and $U' = H'_1 \perp \cdots \perp H'_m$. Choosing a hyperbolic basis of each plane gives bases of U and of U' in which both Gram matrices are the same block diagonal matrix, namely m copies of $\left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$ down the diagonal. The linear bijection $U \to U'$ matching these bases in order is therefore an isometry.

Both V_0 and V'_0 are complements: $V_0 \subseteq U^{\perp_\beta}$ by orthogonality, and the dimensions agree, so $V_0 = U^{\perp_\beta}$ (Theorem 1.6.8), and likewise $V'_0 = U'^{\perp_\beta}$. By Corollary 13.8.4 (a), $V_0 \cong V'_0$. This proves the corollary.

■

So a non-degenerate symmetric form is completely described by two pieces of data: an integer, the Witt index, and an anisotropic form, determined up to isometry. Classifying all forms over a field F therefore reduces to classifying the **anisotropic** ones, which is where the arithmetic of F enters and where the subject stops being linear algebra. Over $\mathbb{R}$ the anisotropic forms are the definite ones, so the data $(\operatorname{ind}, V_0)$ is just the signature again. Over $\mathbb{C}$ the anisotropic forms have dimension 0 or 1, so the index and the parity of n are everything. Over $\mathbb{Q}$ the classification is a theorem of number theory and is not in this book.

13.8.6 Exercises

13.8.6.1 A. Check your understanding

Exercise A1.

(a) State Witt's extension theorem, with all its hypotheses.

(b) Define the reflection $\tau_{\mathbf{w}}$ and say which vectors it fixes.

(c) Determine whether the following statement is correct, and justify your answer: if $U \subseteq V$ and $U' \subseteq V'$ are isometric subspaces of non-degenerate spaces, then $U^\perp$ and $U'^\perp$ are isometric.

(d) Where is $\operatorname{char} F \neq 2$ used in the proof of Theorem 13.8.3?

(e) Two real non-degenerate forms of dimension 6 both have Witt index 2. Must they

be isometric?

Solution.

(a) Let $\operatorname{char} F \neq 2$, let β be a non-degenerate symmetric bilinear form on a finite-dimensional V over F, let $U, U' \subseteq V$ be subspaces and $\sigma\colon U \to U'$ an isometry for the restricted forms. Then σ extends to an isometry of V.

(b) $\tau_{\mathbf{w}}(\mathbf{v}) = \mathbf{v} - \big(2\beta(\mathbf{v},\mathbf{w})/q(\mathbf{w})\big)\mathbf{w}$, defined for anisotropic $\mathbf{w}$. It fixes every $\mathbf{v}$ with $\beta(\mathbf{v},\mathbf{w}) = 0$ and sends $\mathbf{w}$ to $-\mathbf{w}$.

(c) Incorrect. The warning after Corollary 13.8.4 gives the witness: the line $\operatorname{span}(\mathbf{e}_1)$ inside $(\mathbb{R}^2, x_1^2 + x_2^2)$ and inside $(\mathbb{R}^2, x_1^2 - x_2^2)$ are isometric, with complements of opposite definiteness. Cancellation requires the ambient spaces to be isometric too.

(d) Twice. In Step 1, through Lemma 13.4.1, which produces an anisotropic vector in a non-zero subspace where the form is not zero. In Step 2, through the correction $\mathbf{w} = \mathbf{w}_0 - \frac{1}{2}q(\mathbf{w}_0)\mathbf{z}$, which divides by 2.

(e) No. By Corollary 13.8.5 each is two hyperbolic planes orthogonal to an anisotropic part of dimension $6 - 4 = 2$, and over $\mathbb{R}$ an anisotropic form is definite, so that part has signature $(2,0)$ or $(0,2)$. The two possibilities give signatures $(4,2)$ and $(2,4)$ for the whole space, which are different, so the forms need not be isometric. What Corollary 13.8.5 says is that the anisotropic part is determined by the form, not that the index determines the form.

13.8.6.2 B. Practice

Exercise B1: Extend an isometry by hand.

Let $V = \mathbb{R}^3$ with $q(\mathbf{x}) = x_1^2 + x_2^2 - x_3^2$, let $U = \operatorname{span}(\mathbf{e}_1)$, $U' = \operatorname{span}(\mathbf{e}_2)$, and let $\sigma(\mathbf{e}_1) = \mathbf{e}_2$.

(a) Verify that σ is an isometry of U onto U'.

(b) Extend σ to an isometry of V, and write down its matrix in the standard basis.

(c) Determine $U^{\perp_\beta}$ and $U'^{\perp_\beta}$ and exhibit the isometry between them produced by your extension.

Solution.

(a) $\beta(a\mathbf{e}_1, b\mathbf{e}_1) = ab$ and $\beta(\sigma(a\mathbf{e}_1), \sigma(b\mathbf{e}_1)) = \beta(a\mathbf{e}_2, b\mathbf{e}_2) = ab$, and σ is a linear bijection $U \to U'$.

(b) Use the Quick check: $\mathbf{w} = \mathbf{e}_1 - \mathbf{e}_2$ has $q(\mathbf{w}) = 2$, and $\tau_{\mathbf{w}}(\mathbf{v}) = \mathbf{v} - \beta(\mathbf{v},\mathbf{w})\mathbf{w}$ sends $\mathbf{e}_1$ to $\mathbf{e}_2$. In coordinates $\beta(\mathbf{v},\mathbf{w}) = v_1 - v_2$, so

$$\tau_{\mathbf{w}}(\mathbf{v}) = (v_2,\ v_1,\ v_3), \qquad \mathbf{P} = \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix}.$$

This swaps the first two coordinates and indeed satisfies $\mathbf{P}^{\top}\operatorname{diag}(1,1,-1)\mathbf{P} = \operatorname{diag}(1,1,-1)$.

(c) $U^{\perp_\beta} = \{\mathbf{v} : v_1 = 0\} = \operatorname{span}(\mathbf{e}_2, \mathbf{e}_3)$ and $U'^{\perp_\beta} = \operatorname{span}(\mathbf{e}_1, \mathbf{e}_3)$. The extension maps

$\mathbf{e}_2 \mapsto \mathbf{e}_1$ and $\mathbf{e}_3 \mapsto \mathbf{e}_3$, an isometry between them; both carry the form $\operatorname{diag}(1,-1)$, as Corollary 13.8.4 (a) predicts.

Exercise B2: Cancel a hyperbolic plane.

Let H denote a hyperbolic plane over $\mathbb{R}$, and let A and B be non-degenerate real spaces with forms, with $\dim A = \dim B = 3$. Suppose $H \perp A \cong H \perp B$.

(a) Prove that $A \cong B$.

(b) If A has signature $(2,1)$, what is the signature of B?

(c) Does $A \perp B \cong A \perp B$ with $A \cong A$ allow us to conclude $B \cong B$? Say which part of Corollary 13.8.4 is being used and why the statement is not vacuous.

Solution.

(a) Put $V = H \perp A$ and $V' = H \perp B$, both non-degenerate. The two copies of H are isometric, and $V \cong V'$ by hypothesis, so Corollary 13.8.4 (b) gives $A \cong B$.

(b) By (a), $B \cong A$, so B has signature $(2,1)$ as well; isometric real spaces have equal signatures by Corollary 13.5.2.

(c) It uses (b) of Corollary 13.8.4 with $U = U' = A$ and $W = W' = B$; the conclusion $B \cong B$ is true but empty. The content of (b) appears only when the two decompositions are genuinely different, as in (a) above, where the hypothesis $V \cong V'$ is an assumption about the **whole** spaces and not about A and B.

Exercise B3: Reflections in an indefinite space.

In $\mathbb{R}^2$ with $q(\mathbf{x}) = x_1^2 - x_2^2$:

(a) Compute the matrix of $\tau_{\mathbf{e}_1}$ and of $\tau_{\mathbf{e}_2}$ in the standard basis, and check each satisfies $\mathbf{P}^{\top}\mathbf{A}\mathbf{P} = \mathbf{A}$ with $\mathbf{A} = \operatorname{diag}(1,-1)$.

(b) Explain why $\tau_{\mathbf{v}}$ is undefined for $\mathbf{v} = (1,1)$, and say what fails.

(c) Find an isometry carrying $(1,0)$ to $(-1,0)$ and one carrying $(2,\sqrt{3})$ to $(-2,\sqrt{3})$. *(Check the values of q first.)*

Solution.

(a) $q(\mathbf{e}_1) = 1$ and $\beta(\mathbf{v},\mathbf{e}_1) = v_1$, so $\tau_{\mathbf{e}_1}(\mathbf{v}) = \mathbf{v} - 2v_1\mathbf{e}_1 = (-v_1, v_2)$, with matrix $\operatorname{diag}(-1,1)$. Similarly $q(\mathbf{e}_2) = -1$ and $\beta(\mathbf{v},\mathbf{e}_2) = -v_2$, so the coefficient is $2(-v_2)/(-1) = 2v_2$ and $\tau_{\mathbf{e}_2}(\mathbf{v}) = \mathbf{v} - 2v_2\mathbf{e}_2 = (v_1, -v_2)$, with matrix $\operatorname{diag}(1,-1)$. Both matrices $\mathbf{P}$ are diagonal with entries ± 1, so $\mathbf{P}^{\top}\mathbf{A}\mathbf{P} = \mathbf{P}\mathbf{A}\mathbf{P} = \mathbf{A}$, as each sign is squared.

(b) $q(1,1) = 1 - 1 = 0$, so $(1,1)$ is isotropic and the denominator $q(\mathbf{w})$ in Definition 13.8.2 is zero. The formula divides by 0; there is no reflection in an isotropic vector.

(c) Both $(1,0)$ and $(-1,0)$ have $q = 1 \neq 0$. Here $\mathbf{u} - \mathbf{u}' = (2,0)$ with $q = 4 \neq 0$, so Case 1 of Lemma 13.8.2 applies: $\tau_{(2,0)} = \tau_{\mathbf{e}_1}$ works, and indeed $\tau_{\mathbf{e}_1}(1,0) = (-1,0)$.

For the second pair, $q(2,\sqrt{3}) = 4-3 = 1 = q(-2,\sqrt{3})$. Now $\mathbf{u}-\mathbf{u}' = (4,0)$, with $q = 16 \neq 0$, so $\tau_{\mathbf{e}_1}$ again works: it negates the first coordinate and fixes the second.

13.8.6.3 C. Going deeper

Exercise C1: Inertia from cancellation.

Work over $\mathbb{R}$ and let V be an n-dimensional space with a non-degenerate symmetric form.

(a) Prove that if $\mathbb{R}^{p,q}$ denotes $\mathbb{R}^{p+q}$ with the form $x_1^2+\cdots+x_p^2-x_{p+1}^2-\cdots-x_{p+q}^2$, then $\mathbb{R}^{p,q} \cong \mathbb{R}^{p',q'}$ forces $p = p'$ and $q = q'$, using only Corollary 13.8.4 and Proposition 13.7.7.

(b) Explain in one sentence how this compares with the proof of Theorem 13.5.1 in Section 5.

Solution.

(a) Suppose $\mathbb{R}^{p,q} \cong \mathbb{R}^{p',q'}$. Equal dimension gives $p+q = p'+q' = n$. By Proposition 13.7.7 (a) the Witt index is an isometry invariant, so $\min(p,q) = \min(p',q') = k$. By Corollary 13.8.5 each space is k hyperbolic planes orthogonal to an anisotropic part, and those anisotropic parts are isometric. The anisotropic part of $\mathbb{R}^{p,q}$ is positive definite of dimension $p-q$ when $p \geq q$ and negative definite of dimension $q-p$ when $q > p$. A positive definite form is never isometric to a negative definite one of the same dimension, since $q > 0$ on one and $q < 0$ on the other away from $\mathbf{0}$ — unless both dimensions are 0. So the two anisotropic parts have the same dimension and the same sign, giving $p-q = p'-q'$. With $p+q = p'+q'$ this forces $p = p'$ and $q = q'$.

(b) Section 5 proved this directly, by producing a positive subspace and a non-positive subspace whose dimensions are too large to intersect trivially; the route here instead invokes the whole Witt machinery, so it is longer but shows that inertia is the real instance of a statement that holds over every field of characteristic $\neq 2$.

Exercise C2: The isometry group acts transitively.

Let β be a non-degenerate symmetric form on V, with $\operatorname{char} F \neq 2$, and let G be the group of isometries of V.

(a) Prove that if $q(\mathbf{u}) = q(\mathbf{u}') \neq 0$ then some $\varphi \in G$ has $\varphi(\mathbf{u}) = \mathbf{u}'$.

(b) Prove that if $\mathbf{u}$ and $\mathbf{u}'$ are both isotropic and non-zero, then some $\varphi \in G$ has $\varphi(\mathbf{u}) = \mathbf{u}'$. *Hint: an isotropic line is a one-dimensional subspace on which the form is zero.*

(c) Deduce that G acts transitively on each "level set" $\{\mathbf{v} \neq \mathbf{0} : q(\mathbf{v}) = c\}$ for $c \neq 0$, and on the set of non-zero isotropic vectors.

Solution.

(a) This is Lemma 13.8.2, which already produces such an isometry as a product of at most two reflections. Alternatively, $\operatorname{span}(\mathbf{u}) \to \operatorname{span}(\mathbf{u}')$, $\mathbf{u} \mapsto \mathbf{u}'$, is an isometry of

one-dimensional subspaces because $q(\mathbf{u}) = q(\mathbf{u}')$, so Theorem 13.8.3 extends it.

(b) The map $\sigma\colon \operatorname{span}(\mathbf{u}) \to \operatorname{span}(\mathbf{u}')$ with $\sigma(a\mathbf{u}) = a\mathbf{u}'$ is a linear bijection, and

$$\beta(\sigma(a\mathbf{u}), \sigma(b\mathbf{u})) = ab\, q(\mathbf{u}') = 0 = ab\, q(\mathbf{u}) = \beta(a\mathbf{u}, b\mathbf{u}),$$

so it is an isometry of the restricted forms — both of which are zero. By Theorem 13.8.3 it extends to $\varphi \in G$. Note the restricted forms here are **degenerate**, which is exactly the case Step 2 of the proof was built for.

(c) Immediate from (a) and (b): any two members of such a set are carried to one another by some $\varphi \in G$. In particular, over $\mathbb{R}^{1,3}$ the isometry group moves any non-zero null vector to any other, which is the statement that the light cone has no distinguished direction.

Exercise C3: What extension does not say.

(a) Give an example of a non-degenerate (V, β) and subspaces U, U' of the **same dimension** that are not isometric, and say why Theorem 13.8.3 does not apply.

(b) Let β be non-degenerate on V and let $U \subseteq V$ be totally isotropic with $\dim U = \operatorname{ind}(\beta)$. Prove that any two such U are carried onto one another by an isometry of V.

(c) Deduce that all maximal totally isotropic subspaces of a non-degenerate space have the same dimension, and compare with Proposition 13.7.2.

Solution.

(a) Take $V = \mathbb{R}^2$ with $q = x_1^2 - x_2^2$, $U = \operatorname{span}(\mathbf{e}_1)$ and $U' = \operatorname{span}(\mathbf{e}_2)$. Both are lines, but q is positive on $U \setminus \{\mathbf{0}\}$ and negative on $U' \setminus \{\mathbf{0}\}$, so no linear bijection can preserve the form. Theorem 13.8.3 has nothing to extend: its hypothesis is that an isometry $U \to U'$ is **given**, and here none exists.

(b) Let U and U' be totally isotropic of the same dimension k. Any linear bijection $\sigma\colon U \to U'$ is an isometry, since both restricted forms are identically zero, so $\beta(\sigma\mathbf{u}, \sigma\mathbf{v}) = 0 = \beta(\mathbf{u}, \mathbf{v})$ for all $\mathbf{u}, \mathbf{v} \in U$. By Theorem 13.8.3, σ extends to an isometry φ of V, and $\varphi(U) = U'$.

(c) Let U be maximal among totally isotropic subspaces, and let U_1 be one of the largest dimension $m = \operatorname{ind}(\beta)$. If $\dim U < m$, choose any k-dimensional subspace $U_2 \subseteq U_1$ with $k = \dim U$; it is totally isotropic, so by (b) there is an isometry φ of V with $\varphi(U) = U_2$. Then $\varphi^{-1}(U_1)$ is totally isotropic of dimension $m > k$ and contains $\varphi^{-1}(U_2) = U$, contradicting maximality. So $\dim U = m$ for every maximal U. Proposition 13.7.2 says only $m \le n/2$; the present statement is sharper, since it says that no totally isotropic subspace can be maximal below the top dimension.

13.9 Alternating Forms and Darboux Bases

Almost every classification theorem so far in this chapter has carried the same asterisk — the exceptions being the crude invariants of Section 2, rank and the square class of the determinant, which need nothing of the field. Diagonalize a symmetric form: characteristic $\neq 2$. Split a

form into a symmetric and an alternating half: characteristic $\neq 2$. Recover a form from its quadratic form: characteristic $\neq 2$. This section has no asterisk. Alternating forms admit a complete classification over **every** field, with no hypothesis on the characteristic at all, and the classification is as clean as a classification gets: one congruence class for each even rank.

Throughout, F is an arbitrary field, V is a finite-dimensional vector space over F, and β is an **alternating** bilinear form on V (Definition 6.2.2), meaning $\beta(\mathbf{v},\mathbf{v}) = 0$ for **every** $\mathbf{v} \in V$. Two facts from Section 3 are used constantly. First, β is then skew-symmetric, $\beta(\mathbf{u},\mathbf{v}) = -\beta(\mathbf{v},\mathbf{u})$, by Theorem 13.3.3 (a) — and that direction needs no hypothesis on F. Second, by Proposition 13.3.2 (b) the matrix of β in any basis is skew-symmetric with **zero diagonal**, and we call such a matrix **alternating**. Symmetry of the situation is worth noting once: since $\beta(\mathbf{u},\mathbf{v}) = 0$ if and only if $\beta(\mathbf{v},\mathbf{u}) = 0$, "orthogonal" needs no left or right, and the radical $\operatorname{rad}(\beta)$ of Definition 13.1.3 is what one would want it to be from either side.

13.9.1 The two-dimensional model

A symmetric form has a one-dimensional model to build from: on a line $\operatorname{span}(\mathbf{v})$ it is $q(c\mathbf{v}) = c^2 q(\mathbf{v})$, a scalar multiple of the squaring function, and Section 4 assembled a general symmetric form out of such lines. An alternating form offers nothing on a line at all. For any $\mathbf{v}$ and any scalars c, d,

$$\beta(c\mathbf{v}, d\mathbf{v}) = cd\,\beta(\mathbf{v},\mathbf{v}) = 0,$$

so β restricted to any line is zero. The one-dimensional pieces are all identical and all trivial. The smallest place where an alternating form has something to say is a plane, and there is essentially only one thing it can say there.

Example. (Alternating Forms on a Plane)

Describe all alternating bilinear forms on F^2, and decide which are non-degenerate.

Solution. An alternating 2×2 matrix has zero diagonal and $a_{21} = -a_{12}$, so it is

$$\mathbf{A} = \begin{pmatrix} 0 & a \\ -a & 0 \end{pmatrix}$$

for a single scalar $a \in F$, and every such matrix is alternating. By Theorem 13.1.1 the corresponding form is $\beta(\mathbf{x},\mathbf{y}) = a(x_1 y_2 - x_2 y_1)$. Its determinant is a^2, so by Proposition 13.1.2 the form is non-degenerate exactly when $a \neq 0$.

When $a \neq 0$, replacing the basis vector $\mathbf{e}_2$ by $a^{-1}\mathbf{e}_2$ replaces a by 1. So up to a change of basis there are exactly **two** alternating forms on F^2: the zero form and the one with matrix $\left(\begin{smallmatrix} 0 & 1 \\ -1 & 0 \end{smallmatrix}\right)$, whatever the field.

That last matrix is the atom of the theory, and the pair of vectors producing it deserves a name. It is the alternating counterpart of the hyperbolic plane of Section 7: a two-dimensional space carrying a non-degenerate form on which the associated quadratic function vanishes identically. Here the vanishing is automatic, because *every* alternating form vanishes on the diagonal, so the whole content is in the pairing.

A hyperbolic pair is two vectors that pair to 1 *and to nothing else.*

Definition 13.9.1 — Hyperbolic Pair

Let β be an alternating form on V. A **hyperbolic pair** for β is an ordered pair $(\mathbf{u}, \mathbf{w})$ of vectors of V with

$$\beta(\mathbf{u}, \mathbf{w}) = 1.$$

Its **span** $H = \operatorname{span}(\mathbf{u}, \mathbf{w})$ is called a **hyperbolic plane** for β.

The definition looks as though it asks for one condition, but it quietly supplies three more. Alternation already gives $\beta(\mathbf{u}, \mathbf{u}) = \beta(\mathbf{w}, \mathbf{w}) = 0$, and skewness gives $\beta(\mathbf{w}, \mathbf{u}) = -1$. So the matrix of β restricted to H in the ordered basis $(\mathbf{u}, \mathbf{w})$ is exactly $\left(\begin{smallmatrix} 0 & 1 \\ -1 & 0 \end{smallmatrix}\right)$. Also, $\mathbf{u}$ and $\mathbf{w}$ are automatically linearly independent: if $\mathbf{w} = c\mathbf{u}$ then $\beta(\mathbf{u}, \mathbf{w}) = c\,\beta(\mathbf{u}, \mathbf{u}) = 0 \neq 1$, and $\mathbf{u} \neq \mathbf{0}$ for the same reason. So H really is a plane, $\dim H = 2$, and β restricted to H is non-degenerate.

Warning. **An alternating form is never diagonalizable, except when it is zero.** Section 4 found an orthogonal basis for every symmetric form in characteristic $\neq 2$; no such basis exists here. If $\mathcal{B}$ is any basis and $[\beta]_{\mathcal{B}}$ is diagonal, then its off-diagonal entries vanish by assumption and its diagonal entries vanish because β is alternating, so $[\beta]_{\mathcal{B}} = \mathbf{0}$ and $\beta = 0$. The standard form below is a block form, and it has to be: the 2×2 block is irreducible.

13.9.2 Splitting off a hyperbolic pair

The move that drives the whole section is the one Section 7 used for isotropic vectors: find a small non-degenerate piece, and cut the space along it. Here the small piece is a hyperbolic plane, and it can always be found as soon as β is not identically zero.

Lemma 13.9.1 — Peeling Off a Hyperbolic Plane

Let β be an alternating form on a finite-dimensional V, and suppose $\beta \neq 0$.

(a) There is a hyperbolic pair $(\mathbf{u}, \mathbf{w})$ for β.

(b) For any such pair, with $H = \operatorname{span}(\mathbf{u}, \mathbf{w})$ and

$$H^{\perp_\beta} = \{\, \mathbf{v} \in V : \beta(\mathbf{u}, \mathbf{v}) = \beta(\mathbf{w}, \mathbf{v}) = 0 \,\},$$

we have $V = H \oplus H^{\perp_\beta}$ and $\dim H^{\perp_\beta} = \dim V - 2$.

(c) $\operatorname{rad}(\beta) = \operatorname{rad}\big(\beta|_{H^{\perp_\beta}}\big)$. In particular, if β is non-degenerate then so is its restriction to $H^{\perp_\beta}$.

Idea. For (a), the hypothesis $\beta \neq 0$ hands us two vectors pairing to something non-zero; divide one of them by that scalar. For (b), the two conditions cutting out $H^{\perp_\beta}$ are two linear conditions, so the count should be $\dim V - 2$, and Rank–Nullity will say so once we check that the two conditions are independent — which is exactly what $\beta(\mathbf{u}, \mathbf{w}) = 1$ provides. Part (c) is the bookkeeping that lets the induction in the theorem keep its hypothesis.

Proof.

(a) Since $\beta \neq 0$ there are $\mathbf{u}_0, \mathbf{w}_0 \in V$ with $c := \beta(\mathbf{u}_0, \mathbf{w}_0) \neq 0$. Put $\mathbf{u} = \mathbf{u}_0$ and $\mathbf{w} = c^{-1}\mathbf{w}_0$, which is legitimate because $c \neq 0$ and F is a field. Then $\beta(\mathbf{u}, \mathbf{w}) = c^{-1}\beta(\mathbf{u}_0, \mathbf{w}_0) = 1$ by linearity in the second argument.

(b) Define $\varphi\colon V \to F^2$ by $\varphi(\mathbf{v}) = \big(\beta(\mathbf{u}, \mathbf{v}),\, \beta(\mathbf{w}, \mathbf{v})\big)$. It is linear, because β is linear in its second argument, and $\ker \varphi = H^{\perp_\beta}$ by the definition of $H^{\perp_\beta}$. It is surjective:

$$\varphi(\mathbf{w}) = (\beta(\mathbf{u}, \mathbf{w}), \beta(\mathbf{w}, \mathbf{w})) = (1, 0), \qquad \varphi(\mathbf{u}) = (0, -1),$$

using $\beta(\mathbf{w}, \mathbf{w}) = \beta(\mathbf{u}, \mathbf{u}) = 0$ and $\beta(\mathbf{w}, \mathbf{u}) = -1$, and these two values span F^2. Hence $\operatorname{rank} \varphi = 2$ and $\dim H^{\perp_\beta} = \dim V - 2$ by Rank–Nullity (Theorem 3.3.1). Next, $H \cap H^{\perp_\beta} = \{\mathbf{0}\}$. Let $\mathbf{v} = a\mathbf{u} + b\mathbf{w}$ lie in $H^{\perp_\beta}$. Then $0 = \beta(\mathbf{u}, \mathbf{v}) = a\beta(\mathbf{u}, \mathbf{u}) + b\beta(\mathbf{u}, \mathbf{w}) = b$, and $0 = \beta(\mathbf{w}, \mathbf{v}) = a\beta(\mathbf{w}, \mathbf{u}) = -a$, so $a = b = 0$. Hence the sum $H + H^{\perp_\beta}$ is direct (Theorem 1.7.4), and by Theorem 1.7.3 its dimension is $2 + (\dim V - 2) = \dim V$, so it is all of V (Theorem 1.6.8).

(c) ($\supseteq$) Let $\mathbf{v} \in H^{\perp_\beta}$ satisfy $\beta(\mathbf{z}, \mathbf{v}) = 0$ for every $\mathbf{z} \in H^{\perp_\beta}$. Any $\mathbf{y} \in V$ decomposes as $\mathbf{y} = \mathbf{h} + \mathbf{z}$ with $\mathbf{h} \in H$ and $\mathbf{z} \in H^{\perp_\beta}$ by (b), and $\beta(\mathbf{h}, \mathbf{v}) = -\beta(\mathbf{v}, \mathbf{h}) = 0$ because $\mathbf{v} \in H^{\perp_\beta}$ and $\mathbf{h}$ is a combination of $\mathbf{u}$ and $\mathbf{w}$. Hence $\beta(\mathbf{y}, \mathbf{v}) = 0$ for every $\mathbf{y} \in V$, so $\mathbf{v} \in \operatorname{rad}(\beta)$.

($\subseteq$) Let $\mathbf{v} \in \operatorname{rad}(\beta)$. Then in particular $\beta(\mathbf{u}, \mathbf{v}) = \beta(\mathbf{w}, \mathbf{v}) = 0$, so $\mathbf{v} \in H^{\perp_\beta}$, and $\beta(\mathbf{z}, \mathbf{v}) = 0$ for every $\mathbf{z}$ at all, so $\mathbf{v}$ lies in the radical of the restriction. This proves the lemma.

■

Notice what the proof did **not** use: it never divided by 2, never distinguished β from $-\beta$, and never needed a vector with $\beta(\mathbf{v}, \mathbf{v}) \neq 0$ — which is fortunate, since no such vector exists. Compare the corresponding step for symmetric forms, Lemma 13.4.1 in Section 4: there the whole difficulty was producing a vector on which the quadratic form did not vanish, and producing it cost the hypothesis $\operatorname{char} F \neq 2$. Here the quadratic form vanishes everywhere and we do not care.

13.9.3 The standard form

With the lemma in hand the classification is an induction that peels two dimensions at a time.

Theorem 13.9.2 — Standard Form of an Alternating Form

Let F be **any** field, let V be a vector space over F with $\dim V = n$, and let β be an alternating bilinear form on V. Then there are an integer $m \geq 0$ with $2m \leq n$ and a basis

$$\mathcal{B} = (\mathbf{u}_1, \dots, \mathbf{u}_m, \mathbf{w}_1, \dots, \mathbf{w}_m, \mathbf{z}_1, \dots, \mathbf{z}_{n-2m})$$

of V such that, for all i, j,

$$\beta(\mathbf{u}_i, \mathbf{w}_j) = \delta_{ij}, \qquad \beta(\mathbf{u}_i, \mathbf{u}_j) = \beta(\mathbf{w}_i, \mathbf{w}_j) = 0,$$

and $\beta(\mathbf{z}_k, \mathbf{v}) = 0$ for every k and every $\mathbf{v} \in V$. Equivalently, in this basis

$$[\beta]_{\mathcal{B}} = \mathbf{\Omega}_{2m} \oplus \mathbf{0}_{n-2m}, \qquad \mathbf{\Omega}_{2m} \coloneqq \begin{pmatrix} \mathbf{0} & \mathbf{I}_m \\ -\mathbf{I}_m & \mathbf{0} \end{pmatrix}. \tag{13.9.1}$$

In particular:

(a) every alternating $\mathbf{A} \in M_n(F)$ is congruent to $\mathbf{\Omega}_{2m} \oplus \mathbf{0}_{n-2m}$ for exactly one m;
(b) if β is non-degenerate then $n = 2m$ is **even** and $[\beta]_{\mathcal{B}} = \mathbf{\Omega}_n$.

Idea. Induction on n, two dimensions at a time. ① If $\beta = 0$, take $m = 0$ and any basis; this is the base case and also the case that stops the recursion. ② Otherwise Lemma 13.9.1 produces a hyperbolic pair $(\mathbf{u}_1, \mathbf{w}_1)$ and splits $V = H \oplus H^{\perp_\beta}$ with $\dim H^{\perp_\beta} = n - 2$; apply the induction hypothesis to β restricted to $H^{\perp_\beta}$, and put the pieces together. ③ Finally reorder the basis so that all the $\mathbf{u}$'s come before all the $\mathbf{w}$'s, which turns a string of 2×2 blocks into the one block matrix displayed. The radical, by part (c) of the lemma, is exactly what the last stage of the recursion leaves behind.

Proof. **Existence, by induction on $n = \dim V$.** For $n = 0$ and $n = 1$ every alternating form is zero: in dimension 1, $\beta(c\mathbf{v}, d\mathbf{v}) = cd\,\beta(\mathbf{v}, \mathbf{v}) = 0$. Take $m = 0$.

Let $n \geq 2$ and assume the statement for all spaces of dimension less than n.

Case 1: $\beta = 0$. Take $m = 0$ and any basis of V; every required equation reads $0 = 0$.

Case 2: $\beta \neq 0$. By Lemma 13.9.1 (a) there is a hyperbolic pair $(\mathbf{u}_1, \mathbf{w}_1)$, and by (b) we have $V = H \oplus W$ with $H = \operatorname{span}(\mathbf{u}_1, \mathbf{w}_1)$ and $W = H^{\perp_\beta}$ of dimension $n - 2$. The restriction $\beta|_W$ is again alternating, being a restriction of an alternating form, so the induction hypothesis applies to it: there is a basis

$$(\mathbf{u}_2, \dots, \mathbf{u}_m,\ \mathbf{w}_2, \dots, \mathbf{w}_m,\ \mathbf{z}_1, \dots, \mathbf{z}_{n-2m})$$

of W in which $\beta|_W(\mathbf{u}_i, \mathbf{w}_j) = \delta_{ij}$, all other pairings among the $\mathbf{u}$'s and $\mathbf{w}$'s vanish, and each $\mathbf{z}_k$ lies in $\operatorname{rad}(\beta|_W)$.

Putting $\mathbf{u}_1$ and $\mathbf{w}_1$ in front gives a basis of $V = H \oplus W$. The required equations hold: within H they are the definition of a hyperbolic pair together with alternation; within W they are the induction hypothesis; and across the two, every pairing of $\mathbf{u}_1$ or $\mathbf{w}_1$ with a vector of W vanishes because $W = H^{\perp_\beta}$ and β is skew-symmetric. Finally each $\mathbf{z}_k$ lies in $\operatorname{rad}(\beta|_W) = \operatorname{rad}(\beta)$ by Lemma 13.9.1 (c), which is the last assertion.

The matrix. Order the basis as $\mathcal{B} = (\mathbf{u}_1, \dots, \mathbf{u}_m, \mathbf{w}_1, \dots, \mathbf{w}_m, \mathbf{z}_1, \dots, \mathbf{z}_{n-2m})$. By Definition 13.1.2 the (i, j) entry of $[\beta]_{\mathcal{B}}$ is the pairing of the i-th and j-th basis vectors, and the equations above say precisely that the top-left $m \times m$ block and the $\mathbf{w}$-$\mathbf{w}$ block are $\mathbf{0}$, the $\mathbf{u}$-$\mathbf{w}$ block is $\mathbf{I}_m$, the $\mathbf{w}$-$\mathbf{u}$ block is $-\mathbf{I}_m$, and every row and column indexed by a $\mathbf{z}_k$ is zero. That is Eq. 13.9.1.

(a). Given alternating $\mathbf{A} \in M_n(F)$, let $\beta(\mathbf{x}, \mathbf{y}) = \mathbf{x}^{\top}\mathbf{A}\mathbf{y}$ on F^n; it is alternating by Proposition 13.3.2 (b). The basis just constructed gives $\mathbf{P}^{\top}\mathbf{A}\mathbf{P} = \mathbf{\Omega}_{2m} \oplus \mathbf{0}_{n-2m}$ with $\mathbf{P}$ the matrix whose columns are the basis vectors, by Theorem 13.2.1, so $\mathbf{A} \simeq \mathbf{\Omega}_{2m} \oplus \mathbf{0}_{n-2m}$. Uniqueness of m: congruence preserves rank (Theorem 13.2.3), and $\operatorname{rank}(\mathbf{\Omega}_{2m} \oplus \mathbf{0}_{n-2m}) = 2m$ because $\mathbf{\Omega}_{2m}$ is invertible, its square being $-\mathbf{I}_{2m}$. So $2m = \operatorname{rank}\mathbf{A}$ is determined by $\mathbf{A}$.

(b). If β is non-degenerate then $\operatorname{rad}(\beta) = \{\mathbf{0}\}$ by Definition 13.1.4, so there are no $\mathbf{z}_k$,

that is $n = 2m$. This proves the theorem.

■

Definition 13.9.2 — Symplectic Basis

A basis of V as in Theorem 13.9.2 is a **symplectic basis**, or a **Darboux basis**, for the alternating form β. A non-degenerate alternating form on a finite-dimensional space is called a **symplectic form**, and the pair (V, β) a **symplectic vector space**.

Now read the hypotheses of the theorem again, and notice what is missing. There is no "char $F \neq 2$", and there is no place one could be inserted, because no step of the proof divided by 2. Compare the statements this chapter has accumulated:

- Theorem 13.3.3: skew implies alternating only when char $F \neq 2$.
- Theorem 13.3.4: the splitting into halves exists only when char $F \neq 2$.
- Theorem 13.3.5: a symmetric form is recovered from its quadratic form only when char $F \neq 2$.
- Theorem 13.4.2: a symmetric form has an orthogonal basis only when char $F \neq 2$.
- Theorem 13.9.2: no hypothesis.

Over $\mathbb{F}_2$, where every one of the first four statements is false, the last one is true and gives a complete classification. The reason is visible in the proof: the symmetric theory needs a vector with $q(\mathbf{v}) \neq 0$, and that vector is manufactured by a polarization identity that divides by 2. The alternating theory needs a *pair* with $\beta(\mathbf{u}, \mathbf{w}) \neq 0$, and a pair is handed over by the assumption $\beta \neq 0$ itself, free of charge. Symmetric forms are hard in characteristic 2; alternating forms are not hard anywhere.

Quick check. Over $\mathbb{F}_2$ we have $-1 = 1$, so $\mathbf{\Omega}_{2m} = \left(\begin{smallmatrix} \mathbf{0} & \mathbf{I}_m \\ \mathbf{I}_m & \mathbf{0} \end{smallmatrix}\right)$, which is a **symmetric** matrix. Does that contradict the warning above, that an alternating form is never diagonalizable?

Solution. No. Over $\mathbb{F}_2$ every alternating matrix is symmetric, since skew-symmetric and symmetric are the same condition there (Theorem 13.3.3 and the warning after it). What distinguishes alternating from merely symmetric over $\mathbb{F}_2$ is the zero diagonal, and $\mathbf{\Omega}_{2m}$ does have a zero diagonal. The warning says a **diagonal** alternating matrix must be $\mathbf{0}$, and $\mathbf{\Omega}_{2m}$ is symmetric but not diagonal. Concretely, over $\mathbb{F}_2$ the matrix $\left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$ is the Gram matrix of the alternating form $\beta(\mathbf{x}, \mathbf{y}) = x_1 y_2 + x_2 y_1$, and no change of basis makes it diagonal.

13.9.4 Running the algorithm

The proof is an algorithm, and it is short enough to carry out by hand. Each round of the induction does three things: find a pair with $\beta(\mathbf{u}, \mathbf{w}) \neq 0$, rescale to make the value 1, and then correct every remaining basis vector so that it becomes orthogonal to both. The correction is a formula worth recording. If $\beta(\mathbf{u}, \mathbf{w}) = 1$, put

$$\mathbf{v}' \coloneqq \mathbf{v} - \beta(\mathbf{v}, \mathbf{w})\,\mathbf{u} + \beta(\mathbf{v}, \mathbf{u})\,\mathbf{w}. \tag{13.9.2}$$

Expanding and using $\beta(\mathbf{u},\mathbf{u}) = \beta(\mathbf{w},\mathbf{w}) = 0$, $\beta(\mathbf{u},\mathbf{w}) = 1$ and $\beta(\mathbf{w},\mathbf{u}) = -1$,

$$\beta(\mathbf{v}',\mathbf{u}) = \beta(\mathbf{v},\mathbf{u}) - \beta(\mathbf{v},\mathbf{w})\cdot 0 + \beta(\mathbf{v},\mathbf{u})\cdot(-1) = 0,$$
$$\beta(\mathbf{v}',\mathbf{w}) = \beta(\mathbf{v},\mathbf{w}) - \beta(\mathbf{v},\mathbf{w})\cdot 1 + \beta(\mathbf{v},\mathbf{u})\cdot 0 = 0,$$

so $\mathbf{v}' \in H^{\perp_\beta}$. It is the alternating analogue of subtracting a projection in Gram–Schmidt, with one difference: nothing is divided by a length, so it works over any field.

Example. (A Symplectic Basis for a 4×4 Form)

Let $\beta(\mathbf{x},\mathbf{y}) = \mathbf{x}^{\top}\mathbf{A}\mathbf{y}$ on $\mathbb{Q}^4$, where

$$\mathbf{A} = \begin{pmatrix} 0 & 1 & 2 & 3 \\ -1 & 0 & 1 & 1 \\ -2 & -1 & 0 & 0 \\ -3 & -1 & 0 & 0 \end{pmatrix}.$$

Find a symplectic basis, and the matrix $\mathbf{P}$ with $\mathbf{P}^{\top}\mathbf{A}\mathbf{P} = \mathbf{\Omega}_4$.

Solution. The matrix is skew-symmetric with zero diagonal, so β is alternating (Proposition 13.3.2 (b)).

Round 1. The entry $a_{12} = \beta(\mathbf{e}_1,\mathbf{e}_2) = 1$ is already 1, so $(\mathbf{u}_1,\mathbf{w}_1) = (\mathbf{e}_1,\mathbf{e}_2)$ is a hyperbolic pair and no rescaling is needed. Correct $\mathbf{e}_3$ and $\mathbf{e}_4$ by Eq. 13.9.2, reading the needed values off the matrix: $\beta(\mathbf{e}_3,\mathbf{e}_2) = a_{32} = -1$, $\beta(\mathbf{e}_3,\mathbf{e}_1) = a_{31} = -2$, $\beta(\mathbf{e}_4,\mathbf{e}_2) = a_{42} = -1$, $\beta(\mathbf{e}_4,\mathbf{e}_1) = a_{41} = -3$. So

$$\mathbf{v}_3 = \mathbf{e}_3 + \mathbf{e}_1 - 2\mathbf{e}_2 = (1,-2,1,0),$$
$$\mathbf{v}_4 = \mathbf{e}_4 + \mathbf{e}_1 - 3\mathbf{e}_2 = (1,-3,0,1).$$

Round 2. Both $\mathbf{v}_3$ and $\mathbf{v}_4$ pair to zero with $\mathbf{e}_1$ and $\mathbf{e}_2$, as the formula guarantees, so the recursion continues inside $\operatorname{span}(\mathbf{v}_3,\mathbf{v}_4)$. Compute $\mathbf{A}\mathbf{v}_4$ row by row with $\mathbf{v}_4 = (1,-3,0,1)$: row 1 gives $0-3+0+3 = 0$, row 2 gives $-1+0+0+1 = 0$, row 3 gives $-2+3+0+0 = 1$, row 4 gives $-3+3+0+0 = 0$. So $\mathbf{A}\mathbf{v}_4 = (0,0,1,0)^{\top}$, and

$$\beta(\mathbf{v}_3,\mathbf{v}_4) = \mathbf{v}_3^{\top}(\mathbf{A}\mathbf{v}_4) = 1\cdot 0 + (-2)\cdot 0 + 1\cdot 1 + 0\cdot 0 = 1.$$

The pair $(\mathbf{u}_2,\mathbf{w}_2) = (\mathbf{v}_3,\mathbf{v}_4)$ is therefore hyperbolic, and the recursion stops: the two remaining dimensions are used up.

The answer. The symplectic basis is $\mathcal{B} = (\mathbf{e}_1,\mathbf{v}_3,\mathbf{e}_2,\mathbf{v}_4)$, listing the $\mathbf{u}$'s first and then the $\mathbf{w}$'s. The matrix whose columns are these four vectors is

$$\mathbf{P} = \begin{pmatrix} 1 & 1 & 0 & 1 \\ 0 & -2 & 1 & -3 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}, \qquad \mathbf{P}^{\top}\mathbf{A}\mathbf{P} = \mathbf{\Omega}_4.$$

A check of two entries confirms the pattern: the $(1,3)$ entry of $\mathbf{P}^{\top}\mathbf{A}\mathbf{P}$ is $\beta(\mathbf{e}_1,\mathbf{e}_2) = 1$ and the $(2,4)$ entry is $\beta(\mathbf{v}_3,\mathbf{v}_4) = 1$, while the $(1,2)$ entry is $\beta(\mathbf{e}_1,\mathbf{v}_3) = a_{11} + a_{12}(-2) + a_{13} = 0 - 2 + 2 = 0$.

13.9.5 What the standard form classifies

The theorem is a classification, and it is worth reading off exactly what it classifies and how coarsely.

Corollary 13.9.3 — Alternating Matrices Are Classified by Rank

Let F be any field and let $\mathbf{A}, \mathbf{B} \in M_n(F)$ be alternating.

(a) $\operatorname{rank} \mathbf{A}$ is **even**.

(b) $\mathbf{A} \simeq \mathbf{B}$ if and only if $\operatorname{rank} \mathbf{A} = \operatorname{rank} \mathbf{B}$.

(c) There are exactly $\lfloor n/2 \rfloor + 1$ congruence classes of alternating matrices in $M_n(F)$, one for each even rank $0, 2, 4, \ldots$ up to n.

(d) If n is odd, every alternating $\mathbf{A} \in M_n(F)$ is singular.

Proof.

(a) By Theorem 13.9.2 (a), $\mathbf{A} \simeq \mathbf{\Omega}_{2m} \oplus \mathbf{0}_{n-2m}$ for some m, and congruence preserves rank (Theorem 13.2.3), so $\operatorname{rank} \mathbf{A} = 2m$.

(b) ($\Rightarrow$) is Theorem 13.2.3. ($\Leftarrow$) If $\operatorname{rank} \mathbf{A} = \operatorname{rank} \mathbf{B} = 2m$ then by (a) and Theorem 13.9.2 both are congruent to $\mathbf{\Omega}_{2m} \oplus \mathbf{0}_{n-2m}$, and congruence is an equivalence relation (Proposition 13.2.2), so $\mathbf{A} \simeq \mathbf{B}$.

(c) By (a) and (b) the classes are in bijection with the even integers $2m$ satisfying $0 \le 2m \le n$, and there are $\lfloor n/2 \rfloor + 1$ of those.

(d) By (a), $\operatorname{rank} \mathbf{A}$ is even and at most n; since n is odd, $\operatorname{rank} \mathbf{A} \le n - 1 < n$, so $\mathbf{A}$ is not invertible.

■

Part (d) deserves a second look, because there is a one-line proof of it that works only half the time. If $\mathbf{A}^{\top} = -\mathbf{A}$ with n odd, then $\det \mathbf{A} = \det(\mathbf{A}^{\top}) = \det(-\mathbf{A}) = (-1)^n \det \mathbf{A} = -\det \mathbf{A}$, so $(1+1)\det \mathbf{A} = 0$ and $\det \mathbf{A} = 0$ — provided $1 + 1 \neq 0$. In characteristic 2 that argument collapses, and it collapses for a real reason: over $\mathbb{F}_2$ the matrix $\operatorname{diag}(1, 0, 0)$ is skew-symmetric (because skew means symmetric there) and has odd rank 1. Part (d) survives because it is a statement about *alternating* matrices, and the standard form proves it without ever touching the determinant.

Warning. **"Skew-symmetric" is not enough.** Every statement in Corollary 13.9.3 is about alternating matrices: skew-symmetric **with zero diagonal**. Over $\mathbb{F}_2$, $\mathbf{I}_2$ is skew-symmetric and has rank 2, which is harmless; but $\operatorname{diag}(1, 0) \in M_2(\mathbb{F}_2)$ is skew-symmetric of rank 1, and $\mathbf{I}_3 \in M_3(\mathbb{F}_2)$ is skew-symmetric and invertible. Both would contradict the corollary if "skew-symmetric" could be substituted for "alternating". In characteristic $\neq 2$ the two words agree (Theorem 13.3.3 (b)) and the distinction can be forgotten; nowhere else.

13.9.6 The determinant, and the Pfaffian

Part (a) of Theorem 13.9.2 says that in even size an invertible alternating matrix is congruent to $\mathbf{\Omega}_n$. Congruence multiplies the determinant by a square (Theorem 13.2.5), so the determinant of an alternating matrix is heavily constrained.

Corollary 13.9.4 — The Determinant of an Alternating Matrix Is a Square

Let F be any field and let $\mathbf{A} \in M_n(F)$ be alternating. Then $\det \mathbf{A}$ is a square in F: there is $c \in F$ with $\det \mathbf{A} = c^2$.

Proof. If $\mathbf{A}$ is singular then $\det \mathbf{A} = 0 = 0^2$. So assume $\mathbf{A}$ is invertible. Then $\operatorname{rank} \mathbf{A} = n$ is even by Corollary 13.9.3 (a), say $n = 2m$, and Theorem 13.9.2 (a) supplies an invertible $\mathbf{P}$ with $\mathbf{P}^{\top}\mathbf{A}\mathbf{P} = \mathbf{\Omega}_{2m}$. Taking determinants and using Theorem 13.2.5,

$$\det \mathbf{\Omega}_{2m} = (\det \mathbf{P})^2 \det \mathbf{A}.$$

Now $\det \mathbf{\Omega}_{2m} = 1$. Indeed, performing the m row swaps $R_i \leftrightarrow R_{m+i}$ for $i = 1, \dots, m$ turns $\mathbf{\Omega}_{2m}$ into $(-\mathbf{I}_m) \oplus \mathbf{I}_m$, so by Theorem 6.5.1 (a) and Theorem 6.8.4,

$$(-1)^m \det \mathbf{\Omega}_{2m} = \det\big((-\mathbf{I}_m) \oplus \mathbf{I}_m\big) = (-1)^m,$$

and $(-1)^m$ is invertible, so $\det \mathbf{\Omega}_{2m} = 1$. Hence $\det \mathbf{A} = (\det \mathbf{P})^{-2} = \big((\det \mathbf{P})^{-1}\big)^2$, a square, since $\det \mathbf{P} \neq 0$. This proves the corollary. ∎

The corollary says a square root of $\det \mathbf{A}$ exists; it does not produce one. In fact there is a canonical choice. For every even n there is a polynomial Pf in the entries a_{ij} with $i < j$, with integer coefficients, called the **Pfaffian**, satisfying $\det \mathbf{A} = \operatorname{Pf}(\mathbf{A})^2$ for every alternating $\mathbf{A}$. Constructing it in general is a piece of multilinear algebra that we do not carry out, so we record only the name and the two smallest cases, both of which can be checked by expanding the determinant.

Example. (The Pfaffian in Sizes 2 and 4)

For $n = 2$,

$$\mathbf{A} = \begin{pmatrix} 0 & a \\ -a & 0 \end{pmatrix}, \qquad \det \mathbf{A} = a^2, \qquad \operatorname{Pf}(\mathbf{A}) = a.$$

For $n = 4$, write the six independent entries as $a = a_{12}$, $b = a_{13}$, $c = a_{14}$, $d = a_{23}$, $e = a_{24}$, $f = a_{34}$. Expanding the 4×4 determinant gives

$$\det \mathbf{A} = (af - be + cd)^2, \qquad \operatorname{Pf}(\mathbf{A}) = af - be + cd.$$

The three terms pair up $\{1,2\}\{3,4\}$, $\{1,3\}\{2,4\}$ and $\{1,4\}\{2,3\}$: the Pfaffian sums over the ways of splitting $\{1,2,3,4\}$ into two pairs, with a sign. For the matrix $\mathbf{A}$ of Example (A Symplectic Basis for a 4×4 Form) this reads $\operatorname{Pf}(\mathbf{A}) = 1 \cdot 0 - 2 \cdot 1 + 3 \cdot 1 = 1$, and indeed $\det \mathbf{A} = 1$.

Remark. The Pfaffian is not merely *a* square root: it is the one that behaves well under congruence, satisfying $\mathrm{Pf}(\mathbf{P}^{\top}\mathbf{A}\mathbf{P}) = \det(\mathbf{P})\,\mathrm{Pf}(\mathbf{A})$. That identity is the reason the Pfaffian matters. Section 10 records one of its consequences for the symplectic group, without proof and without leaning on it. We do not prove the identity either.

13.9.7 Symmetric against alternating

Put the two halves of the chapter side by side. Both are theories of a bilinear form under congruence; the answers could hardly be more different.

	Symmetric forms	Alternating forms
Field hypothesis	$\mathrm{char}\, F \neq 2$ for every theorem	none
Canonical form	diagonal, entries not canonical	$\mathbf{\Omega}_{2m} \oplus \mathbf{0}_{n-2m}$
Complete invariants	rank **and** more: over $\mathbb{R}$ the signature, over $\mathbb{Q}$ the discriminant and local data	rank alone
Classes in $M_n(\mathbb{R})$	$\frac{1}{2}(n+1)(n+2)$	$\lfloor n/2 \rfloor + 1$
Classes in $M_n(\mathbb{C})$	$n+1$	$\lfloor n/2 \rfloor + 1$
Classes in $M_n(\mathbb{Q})$	infinitely many already for $n = 1$	$\lfloor n/2 \rfloor + 1$
Possible ranks	every r with $0 \leq r \leq n$	even r only
Effect of the field	decisive	none

Two entries carry the point. Over $\mathbb{Q}$, the 1×1 symmetric matrices $[1], [2], [3], [5], \ldots$ are pairwise non-congruent, because congruence in size 1 multiplies by a non-zero square (Theorem 13.2.5) and distinct squarefree positive integers lie in distinct classes of $\mathbb{Q}^{\times}/(\mathbb{Q}^{\times})^2$. So the symmetric classification over $\mathbb{Q}$ is an infinite problem in number theory — Section 4 said as much. The alternating classification over $\mathbb{Q}$ has four classes in size 6, and the same four over $\mathbb{F}_2$, over $\mathbb{R}$, and over any field whatsoever.

The reason, one last time, is the two-dimensional model. A symmetric form on a line is $c \mapsto ac^2$, and rescaling changes a by a square, so the diagonal entry carries the field's arithmetic with it. An alternating form on a plane is $\left(\begin{smallmatrix} 0 & a \\ -a & 0 \end{smallmatrix}\right)$, and rescaling *one* of the two basis vectors changes a to ca for any $c \neq 0$ — an arbitrary non-zero scalar, not a square. There is nothing left for the field to remember.

13.9.8 Exercises

13.9.8.1 A. Check your understanding

Exercise A1.

(a) Define a hyperbolic pair for an alternating form, and say why its two vectors are automatically linearly independent.

(b) State Theorem 13.9.2, and say which hypothesis on F it needs.

(c) Determine whether the following is correct: every skew-symmetric matrix over every field has even rank. Justify your answer.

(d) Why can an alternating form never have a diagonal Gram matrix, unless the form is zero?

(e) How many congruence classes of alternating matrices are there in $M_5(\mathbb{R})$? In $M_5(\mathbb{F}_7)$?

Solution.

(a) A pair $(\mathbf{u}, \mathbf{w})$ with $\beta(\mathbf{u}, \mathbf{w}) = 1$ (Definition 13.9.1). If $\mathbf{w} = c\mathbf{u}$, then $\beta(\mathbf{u}, \mathbf{w}) = c\,\beta(\mathbf{u}, \mathbf{u}) = 0 \neq 1$, so $\mathbf{w} \notin \operatorname{span}(\mathbf{u})$; and $\mathbf{u} \neq \mathbf{0}$ since $\beta(\mathbf{0}, \mathbf{w}) = 0$. Two vectors, neither in the span of the other, are independent.

(b) Every alternating form on an n-dimensional V has a basis in which its matrix is $\mathbf{\Omega}_{2m} \oplus \mathbf{0}_{n-2m}$, with $2m = \operatorname{rank} \beta$; equivalently every alternating matrix is congruent to exactly one such matrix. **No** hypothesis on F is needed — in particular none on $\operatorname{char} F$.

(c) Incorrect. Over $\mathbb{F}_2$, $\operatorname{diag}(1, 0)$ is skew-symmetric, because $-1 = 1$ makes skew-symmetric and symmetric the same condition, and it has rank 1. The correct statement is about **alternating** matrices, Corollary 13.9.3 (a). In characteristic $\neq 2$ the two notions coincide (Theorem 13.3.3 (b)) and the statement is true.

(d) The off-diagonal entries of a diagonal matrix are 0 by definition, and the diagonal entries of the Gram matrix of an alternating form are $\beta(\mathbf{v}_i, \mathbf{v}_i) = 0$. So the whole matrix is $\mathbf{0}$, and then $\beta = 0$ by Theorem 13.1.1 (b).

(e) $\lfloor 5/2 \rfloor + 1 = 3$ in both cases, by Corollary 13.9.3 (c): the ranks $0, 2, 4$. The field makes no difference.

13.9.8.2 B. Practice

Exercise B1: A symplectic basis.

Let $\beta(\mathbf{x}, \mathbf{y}) = \mathbf{x}^\top \mathbf{B}\mathbf{y}$ on $\mathbb{Q}^4$, with

$$\mathbf{B} = \begin{pmatrix} 0 & 0 & 1 & 1 \\ 0 & 0 & 2 & 1 \\ -1 & -2 & 0 & 0 \\ -1 & -1 & 0 & 0 \end{pmatrix}.$$

Find a symplectic basis for β and an invertible $\mathbf{P} \in M_4(\mathbb{Q})$ with $\mathbf{P}^\top \mathbf{B}\mathbf{P} = \mathbf{\Omega}_4$.

Solution. $\mathbf{B}$ is skew-symmetric with zero diagonal, hence alternating (Proposition 13.3.2 (b)).

Round 1. Here $\beta(\mathbf{e}_1, \mathbf{e}_2) = 0$, so the first two standard basis vectors are **not** a hyperbolic pair; this is the step the worked example did not need. Look for any non-zero entry: $\beta(\mathbf{e}_1, \mathbf{e}_3) = 1$. Take $\mathbf{u}_1 = \mathbf{e}_1$, $\mathbf{w}_1 = \mathbf{e}_3$.

Correct the other two by Eq. 13.9.2, using $\beta(\mathbf{e}_2, \mathbf{e}_3) = 2$, $\beta(\mathbf{e}_2, \mathbf{e}_1) = 0$, $\beta(\mathbf{e}_4, \mathbf{e}_3) = 0$, $\beta(\mathbf{e}_4, \mathbf{e}_1) = -1$:

$$\mathbf{v}_2 = \mathbf{e}_2 - 2\mathbf{e}_1 + 0 \cdot \mathbf{e}_3 = (-2, 1, 0, 0),$$
$$\mathbf{v}_4 = \mathbf{e}_4 - 0 \cdot \mathbf{e}_1 - \mathbf{e}_3 = (0, 0, -1, 1).$$

Round 2. Compute $\mathbf{B}\mathbf{v}_4$ with $\mathbf{v}_4 = (0,0,-1,1)$: row 1 gives $-1+1=0$, row 2 gives $-2+1=-1$, rows 3 and 4 give 0. So $\mathbf{B}\mathbf{v}_4 = (0,-1,0,0)^\top$ and

$$\beta(\mathbf{v}_2,\mathbf{v}_4) = \mathbf{v}_2^\top(\mathbf{B}\mathbf{v}_4) = (-2)\cdot 0 + 1\cdot(-1) = -1.$$

This is non-zero but not 1, so rescale: replace $\mathbf{v}_4$ by $\mathbf{w}_2 := -\mathbf{v}_4 = (0,0,1,-1)$, giving $\beta(\mathbf{v}_2,\mathbf{w}_2) = 1$. Set $\mathbf{u}_2 = \mathbf{v}_2$.

The answer. The symplectic basis is $(\mathbf{u}_1,\mathbf{u}_2,\mathbf{w}_1,\mathbf{w}_2) = (\mathbf{e}_1,\ (-2,1,0,0),\ \mathbf{e}_3,\ (0,0,1,-1))$, so

$$\mathbf{P} = \begin{pmatrix} 1 & -2 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & -1 \end{pmatrix}, \qquad \mathbf{P}^\top\mathbf{B}\mathbf{P} = \mathbf{\Omega}_4.$$

$\mathbf{P}$ is invertible, being block upper triangular with invertible diagonal blocks, and $\det\mathbf{P} = -1 \neq 0$.

Exercise B2: Pfaffians and determinants.

For each matrix below, compute the Pfaffian using the formula of Example (The Pfaffian in Sizes 2 and 4), and verify that its square is the determinant.

$$\mathbf{A}_1 = \begin{pmatrix} 0 & 2 & 0 & 1 \\ -2 & 0 & 1 & 0 \\ 0 & -1 & 0 & 3 \\ -1 & 0 & -3 & 0 \end{pmatrix}, \qquad \mathbf{A}_2 = \begin{pmatrix} 0 & 1 & 1 & 1 \\ -1 & 0 & 1 & 1 \\ -1 & -1 & 0 & 1 \\ -1 & -1 & -1 & 0 \end{pmatrix}.$$

Hence write down, for each, an invertible matrix congruence class in the sense of Corollary 13.9.3.

Solution. For $\mathbf{A}_1$: $a=2$, $b=0$, $c=1$, $d=1$, $e=0$, $f=3$, so $\mathrm{Pf}(\mathbf{A}_1) = af - be + cd = 6 - 0 + 1 = 7$ and $\det\mathbf{A}_1 = 49$. Expanding the determinant along the first row confirms 49.

For $\mathbf{A}_2$: $a=b=c=d=e=f=1$, so $\mathrm{Pf}(\mathbf{A}_2) = 1-1+1 = 1$ and $\det\mathbf{A}_2 = 1$.

Both determinants are non-zero, so both matrices have rank 4, and by Corollary 13.9.3 (b) both lie in the single congruence class of invertible alternating matrices in $M_4(\mathbb{Q})$: each is congruent to $\mathbf{\Omega}_4$, and therefore $\mathbf{A}_1 \simeq \mathbf{A}_2$. Note that the two have different determinants, 49 and 1; congruence changes the determinant by a square (Theorem 13.2.5), and $49 = 7^2$.

Exercise B3: Determine which of the following.

Determine which of the following matrices are alternating, and for those that are, give the rank and the standard form $\mathbf{\Omega}_{2m} \oplus \mathbf{0}_{n-2m}$ it is congruent to. Justify your answer.

(a) $\left(\begin{smallmatrix} 0 & 5 \\ -5 & 0 \end{smallmatrix}\right)$ over $\mathbb{Q}$.
(b) $\left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$ over $\mathbb{Q}$.

(c) $\left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$ over $\mathbb{F}_2$.

(d) The 5×5 matrix with $a_{ij} = j - i$ over $\mathbb{Q}$.

Solution.

(a) Alternating: zero diagonal and $a_{21} = -a_{12}$. Its determinant is $25 \neq 0$, so the rank is 2 and it is congruent to $\mathbf{\Omega}_2$. (Explicitly, scaling the second basis vector by $1/5$ does it.)

(b) Not alternating. It is symmetric with $a_{12} = 1 \neq -1 = -a_{21}$, so it is not even skew-symmetric over $\mathbb{Q}$.

(c) Alternating. Over $\mathbb{F}_2$ we have $1 = -1$, so the matrix is skew-symmetric, and its diagonal is zero. Its determinant is $-1 = 1 \neq 0$, so the rank is 2 and it is congruent to $\mathbf{\Omega}_2 = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$ — it **is** $\mathbf{\Omega}_2$, since $-1 = 1$. Comparing (b) and (c): the same array of symbols is alternating over one field and not over another.

(d) Alternating: $a_{ii} = 0$ and $a_{ji} = i - j = -a_{ij}$. Its rank is even by Corollary 13.9.3 (a), and it is not zero, so the rank is 2 or 4. Every row is a combination of $(1, 2, 3, 4, 5)$ and $(1, 1, 1, 1, 1)$: indeed row i is $(j - i)_j = (1, 2, 3, 4, 5) - i(1, 1, 1, 1, 1)$. So the row space has dimension at most 2, and rows 1 and 2 are independent, giving rank exactly 2. Hence the matrix is congruent to $\mathbf{\Omega}_2 \oplus \mathbf{0}_3$. In particular it is singular, as Corollary 13.9.3 (d) requires for odd size.

13.9.8.3 C. Going deeper

Exercise C1: Lagrangian subspaces.

Let β be a symplectic form on V with $\dim V = 2m$ (Definition 13.9.2), and call a subspace $U \subseteq V$ **totally isotropic** if $\beta(\mathbf{u}, \mathbf{u}') = 0$ for all $\mathbf{u}, \mathbf{u}' \in U$.

(a) Prove that $\operatorname{span}(\mathbf{u}_1, \ldots, \mathbf{u}_m)$ is totally isotropic, for any symplectic basis.

(b) Prove that every totally isotropic subspace satisfies $\dim U \leq m$.

(c) Deduce that a symplectic form on a space of dimension $2m$ has a totally isotropic subspace of dimension exactly m, and no larger one. (These are the **Lagrangian** subspaces.)

Hint for (b): compare U with $U^{\perp_\beta}$ of Exercise (C2: Orthogonal complements for a form).

Solution.

(a) By Theorem 13.9.2, $\beta(\mathbf{u}_i, \mathbf{u}_j) = 0$ for all i, j. A general pair of elements of the span is $\sum_i c_i \mathbf{u}_i$ and $\sum_j d_j \mathbf{u}_j$, and bilinearity gives $\sum_{i,j} c_i d_j \beta(\mathbf{u}_i, \mathbf{u}_j) = 0$.

(b) Let U be totally isotropic. By definition $\beta(\mathbf{u}, \mathbf{v}) = 0$ for all $\mathbf{u} \in U$ and all $\mathbf{v} \in U$, so $U \subseteq U^{\perp_\beta}$. Since β is non-degenerate, $\dim U^{\perp_\beta} = 2m - \dim U$ by Exercise (C2: Orthogonal complements for a form) (b). Therefore

$$\dim U \leq 2m - \dim U,$$

that is $2 \dim U \leq 2m$. Both sides are integers, so $\dim U \leq m$. (No division by 2 inside the field occurs here: the inequality is between integers, not field elements,

so the argument is valid in every characteristic.)

(c) The subspace of (a) has dimension m, since the $\mathbf{u}_i$ are part of a basis, and it is totally isotropic; by (b) no totally isotropic subspace has dimension greater than m.

Exercise C2: The inverse of an alternating matrix.

Let F be any field.

(a) Prove that every alternating matrix of **odd** size over F is singular, without using determinants.

(b) Let $\mathbf{A} \in M_n(F)$ be alternating and invertible. Prove that $\mathbf{A}^{-1}$ is alternating.

Hint for (b): the adjugate. The (i,i) entry of $\operatorname{adj}\mathbf{A}$ *is a minor of* $\mathbf{A}$ *of size* $n-1$.

Solution.

(a) This is Corollary 13.9.3 (d): by Theorem 13.9.2 the rank is even, and an even number that is at most an odd n is at most $n-1$, so the matrix is not invertible. The proof of the standard form uses no determinants.

(b) Since $\mathbf{A}$ is invertible, Theorem 6.6.2 gives $\mathbf{A}^{-1} = (\det\mathbf{A})^{-1}\operatorname{adj}\mathbf{A}$. First, skewness: $(\mathbf{A}^{-1})^{\top} = (\mathbf{A}^{\top})^{-1} = (-\mathbf{A})^{-1} = -\mathbf{A}^{-1}$, using Theorem 0.9.5 and the fact that inversion turns $-\mathbf{A} = (-1)\mathbf{A}$ into $(-1)^{-1}\mathbf{A}^{-1} = -\mathbf{A}^{-1}$.

Now the diagonal. By Definition 6.6.2 the (i,i) entry of $\operatorname{adj}\mathbf{A}$ is the cofactor $C_{ii} = (-1)^{2i}M_{ii} = M_{ii}$, the determinant of the matrix obtained from $\mathbf{A}$ by deleting row i and column i. Deleting a row and the matching column of an alternating matrix leaves an alternating matrix, since the surviving entries keep their positions relative to the diagonal. Its size is $n-1$, and n is even by Corollary 13.9.3 (a) applied to the invertible $\mathbf{A}$; so $n-1$ is odd and $M_{ii} = 0$ by (a). Hence every diagonal entry of $\mathbf{A}^{-1}$ is 0, and with skewness this makes $\mathbf{A}^{-1}$ alternating.

Exercise C3: Counting over a finite field.

Let q be a power of an **odd** prime.

(a) How many alternating bilinear forms are there on $\mathbb{F}_q^{2m}$? How many symmetric ones?

(b) How many of the alternating forms on $\mathbb{F}_q^2$ are non-degenerate, and how many congruence classes do they fall into?

(c) How many of the symmetric forms on $\mathbb{F}_q^1$ are non-degenerate, and how many congruence classes do they fall into? *Hint: the squaring map* $\mathbb{F}_q^{\times} \to \mathbb{F}_q^{\times}$ *has kernel* $\{1,-1\}$.

(d) Explain in one or two sentences why the answers to (b) and (c) differ, in terms of what a change of basis can do to the single free parameter in each case.

Solution.

(a) By Theorem 13.1.1 (c), forms correspond bijectively to matrices, so we count ma-

trices. An alternating matrix of size $n = 2m$ is determined freely by its entries above the diagonal, of which there are $\binom{n}{2} = m(2m-1)$; so there are $q^{m(2m-1)}$ alternating forms. A symmetric matrix is determined freely by its entries on and above the diagonal, $\binom{n}{2} + n = m(2m+1)$ of them, giving $q^{m(2m+1)}$.

(b) The alternating forms on $\mathbb{F}_q^2$ have matrices $\left(\begin{smallmatrix} 0 & a \\ -a & 0 \end{smallmatrix}\right)$, so there are q of them, and the non-degenerate ones are those with $a \neq 0$, of which there are $q-1$. By Corollary 13.9.3 (b) all of these have rank 2 and so lie in a **single** congruence class.

(c) A symmetric form on $\mathbb{F}_q^1$ has matrix $[d]$ and is non-degenerate exactly when $d \neq 0$, so there are $q-1$ of them. Congruence in size 1 replaces d by $p^2 d$ with $p \neq 0$ (Definition 13.2.1), so the classes are the cosets of the subgroup of squares in $\mathbb{F}_q^\times$. The squaring homomorphism $\mathbb{F}_q^\times \to \mathbb{F}_q^\times$ has kernel $\{x : x^2 = 1\} = \{1, -1\}$, which has **two** elements because q is odd; so its image has index 2, and there are exactly **two** congruence classes. For $q = 5$, for instance, the squares are $\{1, 4\}$ and the non-squares $\{2, 3\}$, and $[1] \not\simeq [2]$.

(d) In the alternating case a change of basis may replace a by ca for **any** $c \neq 0$, because the two slots of $\beta(\mathbf{u}, \mathbf{w})$ hold different basis vectors and only one of them need be rescaled. In the symmetric case the parameter sits in $\beta(\mathbf{v}, \mathbf{v})$, where both slots hold the same vector, so rescaling changes d to $c^2 d$ — by a **square** only. The square class then survives as an invariant, and over $\mathbb{F}_q$ it has two values.

13.10 Groups Defined by Forms

Chapter 10 defined the orthogonal and unitary groups by a sentence: they consist of the operators that preserve the inner product. Read that sentence again and notice that positivity never appears in it. "Preserves $\langle \cdot, \cdot \rangle$" makes sense for any bilinear or Hermitian form at all, and it always produces a group. This section takes the definition apart and puts it back together over an arbitrary form, so that the four families of **classical groups** — orthogonal, indefinite orthogonal, unitary, symplectic — become four instances of one construction, chosen by the four kinds of form this chapter has classified.

Everything is recalled, not reproved. $\mathrm{O}(n)$, $\mathrm{SO}(n)$ and $\mathrm{U}(n)$ were defined in Chapter 10 (Definition 10.7.2, Definition 10.7.3), shown there to be groups with the expected determinants (Proposition 10.7.4), and classified element by element in the real case in Chapter 11 (Theorem 11.6.1). None of that is repeated. What is new here is the pattern behind it.

13.10.1 The isometry group of a form

An operator preserves a form when applying it to both arguments changes nothing. This is the same idea as an isometry of an inner product space (Definition 10.7.1), with the norm removed from the statement because a general form has no norm.

The isometry group of a form is the set of invertible changes of coordinates that the form cannot detect.

Definition 13.10.1 — Isometry Group of a Form

Let V be a finite-dimensional vector space over F and β a **non-degenerate** bilinear form on V (Definition 13.1.4). An operator $T \in \mathcal{L}(V)$ is an **isometry of** β if

$$\beta(T\mathbf{u}, T\mathbf{v}) = \beta(\mathbf{u}, \mathbf{v}) \qquad \text{for all } \mathbf{u}, \mathbf{v} \in V,$$

and the set of all of them is written $\mathrm{Isom}(\beta)$.

For a **non-singular** $\mathbf{A} \in M_n(F)$, the corresponding matrix group is

$$\mathrm{Isom}(\mathbf{A}) \coloneqq \{\, \mathbf{P} \in M_n(F) : \mathbf{P}^{\top}\mathbf{A}\mathbf{P} = \mathbf{A} \,\}.$$

When $F = \mathbb{C}$ and $\mathbf{A}^* = \mathbf{A}$ is non-singular Hermitian, $\mathrm{Isom}(\mathbf{A})$ means instead $\{\, \mathbf{P} : \mathbf{P}^*\mathbf{A}\mathbf{P} = \mathbf{A} \,\}$.

Read the clauses. The condition is required **for all** pairs, not just for a basis — though checking it on a basis is enough, since both sides are bilinear in $\mathbf{u}$ and in $\mathbf{v}$. The matrix condition $\mathbf{P}^{\top}\mathbf{A}\mathbf{P} = \mathbf{A}$ is the matrix condition of Theorem 13.2.1 with the new Gram matrix required to be the *old* one: an isometry is a change of basis that leaves the Gram matrix alone. And the two versions match, because if $\mathbf{A} = [\beta]_{\mathcal{B}}$ then $T \in \mathrm{Isom}(\beta)$ if and only if $[T]_{\mathcal{B}} \in \mathrm{Isom}(\mathbf{A})$, by Theorem 13.1.1 (a) applied twice.

Two clauses need defending. First, **non-degeneracy**. Without it the definition is worthless: for $\mathbf{A} = \mathbf{0}$ the condition $\mathbf{P}^{\top}\mathbf{0}\mathbf{P} = \mathbf{0}$ holds for every $\mathbf{P}$, including $\mathbf{P} = \mathbf{0}$, and the "group" is all of $M_n(F)$, which has no inverses. Second, the definition does **not** require $\mathbf{P}$ to be invertible. It does not have to: invertibility comes free, as the next result records, and this is exactly what non-degeneracy buys.

Theorem 13.10.1 — Isometry Groups Are Groups

Let $\mathbf{A} \in M_n(F)$ be non-singular. Then every $\mathbf{P} \in \mathrm{Isom}(\mathbf{A})$ is invertible, and $\mathrm{Isom}(\mathbf{A})$ is a subgroup of $\mathrm{GL}_n(F)$. The same holds for $\mathrm{Isom}(\beta)$ inside the group of invertible operators on V, and for the Hermitian version.

Proof. Let $\mathbf{P} \in \mathrm{Isom}(\mathbf{A})$. Taking determinants in $\mathbf{P}^{\top}\mathbf{A}\mathbf{P} = \mathbf{A}$ and using Theorem 6.5.4 and Theorem 6.4.5,

$$(\det \mathbf{P})^2 \det \mathbf{A} = \det \mathbf{A}.$$

Since $\mathbf{A}$ is non-singular, $\det \mathbf{A} \neq 0$ (Theorem 6.5.2), and canceling it in the field F gives $(\det \mathbf{P})^2 = 1$. Hence $\det \mathbf{P} \neq 0$ and $\mathbf{P}$ is invertible, again by Theorem 6.5.2.

Now the three subgroup checks. $\mathbf{I}_n^{\top}\mathbf{A}\mathbf{I}_n = \mathbf{A}$, so $\mathbf{I}_n \in \mathrm{Isom}(\mathbf{A})$. If $\mathbf{P}, \mathbf{Q} \in \mathrm{Isom}(\mathbf{A})$ then

$$(\mathbf{P}\mathbf{Q})^{\top}\mathbf{A}(\mathbf{P}\mathbf{Q}) = \mathbf{Q}^{\top}(\mathbf{P}^{\top}\mathbf{A}\mathbf{P})\mathbf{Q} = \mathbf{Q}^{\top}\mathbf{A}\mathbf{Q} = \mathbf{A},$$

using Theorem 0.9.5 for the first equality, so $\mathbf{P}\mathbf{Q} \in \mathrm{Isom}(\mathbf{A})$. And if $\mathbf{P} \in \mathrm{Isom}(\mathbf{A})$, multiply $\mathbf{P}^{\top}\mathbf{A}\mathbf{P} = \mathbf{A}$ on the left by $(\mathbf{P}^{\top})^{-1} = (\mathbf{P}^{-1})^{\top}$ and on the right by $\mathbf{P}^{-1}$, which is legitimate because $\mathbf{P}$ is invertible; this gives $\mathbf{A} = (\mathbf{P}^{-1})^{\top}\mathbf{A}\mathbf{P}^{-1}$, so $\mathbf{P}^{-1} \in \mathrm{Isom}(\mathbf{A})$. Associativity is inherited from $M_n(F)$.

For the Hermitian version replace $^{\top}$ by * throughout; the determinant step becomes $\overline{\det \mathbf{P}} \det \mathbf{P} \det \mathbf{A} = \det \mathbf{A}$, that is $|\det \mathbf{P}|^2 = 1$, which again forces $\det \mathbf{P} \neq 0$. The

operator version is the matrix version read through a basis. This proves the theorem. ∎

The proof is the one Chapter 10 gave for $\mathrm{O}(n)$ and $\mathrm{U}(n)$ in Proposition 10.7.4 (a), with $\mathbf{I}_n$ replaced by $\mathbf{A}$; nothing in it used what $\mathbf{A}$ was, only that it was non-singular. That is the whole point of the section: the group structure never depended on positivity, on symmetry, or on the field.

13.10.2 Congruent forms give conjugate groups

Before listing the families, one observation makes the list a classification rather than a list of unrelated examples. Congruent matrices have the "same" isometry group, in the strongest sense available.

Proposition 13.10.2 — Congruence Conjugates the Isometry Group

Let $\mathbf{A}, \mathbf{B} \in M_n(F)$ be non-singular with $\mathbf{B} = \mathbf{Q}^{\top}\mathbf{A}\mathbf{Q}$ for an invertible $\mathbf{Q}$ (Definition 13.2.1). Then

$$\mathrm{Isom}(\mathbf{B}) = \mathbf{Q}^{-1}\,\mathrm{Isom}(\mathbf{A})\,\mathbf{Q},$$

so the two groups are conjugate subgroups of $\mathrm{GL}_n(F)$; in particular they are isomorphic as groups, by $\mathbf{P} \mapsto \mathbf{Q}\mathbf{P}\mathbf{Q}^{-1}$.

Proof. Let $\mathbf{P} \in M_n(F)$. Substituting $\mathbf{B} = \mathbf{Q}^{\top}\mathbf{A}\mathbf{Q}$ and writing $\mathbf{R} = \mathbf{Q}\mathbf{P}\mathbf{Q}^{-1}$,

$$\begin{aligned} \mathbf{P}^{\top}\mathbf{B}\mathbf{P} = \mathbf{B} &\iff \mathbf{P}^{\top}\mathbf{Q}^{\top}\mathbf{A}\mathbf{Q}\mathbf{P} = \mathbf{Q}^{\top}\mathbf{A}\mathbf{Q} \\ &\iff (\mathbf{Q}\mathbf{P}\mathbf{Q}^{-1})^{\top}\mathbf{A}(\mathbf{Q}\mathbf{P}\mathbf{Q}^{-1}) = \mathbf{A}, \end{aligned}$$

where the second step multiplies on the left by $(\mathbf{Q}^{\top})^{-1}$ and on the right by $\mathbf{Q}^{-1}$ and uses Theorem 0.9.5; both operations are reversible because $\mathbf{Q}$ is invertible. So $\mathbf{P} \in \mathrm{Isom}(\mathbf{B})$ if and only if $\mathbf{R} = \mathbf{Q}\mathbf{P}\mathbf{Q}^{-1} \in \mathrm{Isom}(\mathbf{A})$, which is the claimed equality of sets. Conjugation by $\mathbf{Q}$ is an isomorphism of groups, being a bijection that respects products. ∎

So the isometry group depends only on the congruence class of the form, and this chapter has already listed the congruence classes. Over $\mathbb{R}$, Corollary 13.5.2 says a non-degenerate symmetric form is congruent to exactly one $\mathbf{I}_{n_+} \oplus (-\mathbf{I}_{n_-})$; over $\mathbb{C}$, Corollary 13.4.4 says a non-degenerate symmetric form is congruent to $\mathbf{I}_n$ and nothing else; and Theorem 13.9.2 says a symplectic form is congruent to $\boldsymbol{\Omega}_{2m}$ and nothing else. Each classification theorem of this chapter therefore doubles as a list of groups.

13.10.3 The four families

Definition 13.10.2 — The Indefinite Orthogonal and Symplectic Groups

For $p, q \geq 0$ with $p+q=n$, set $\mathbf{I}_{p,q} \coloneqq \mathbf{I}_p \oplus (-\mathbf{I}_q) \in M_n(\mathbb{R})$ and

$$\mathrm{O}(p,q) \coloneqq \mathrm{Isom}(\mathbf{I}_{p,q}) = \{\, \mathbf{P} \in M_n(\mathbb{R}) : \mathbf{P}^{\top}\mathbf{I}_{p,q}\mathbf{P} = \mathbf{I}_{p,q} \,\},$$

the **indefinite orthogonal group** of signature (p,q). For $m \geq 1$ and any field F, set

$$\mathrm{Sp}(2m,F) \coloneqq \mathrm{Isom}(\mathbf{\Omega}_{2m}) = \{\, \mathbf{P} \in M_{2m}(F) : \mathbf{P}^{\top}\mathbf{\Omega}_{2m}\mathbf{P} = \mathbf{\Omega}_{2m} \,\},$$

the **symplectic group**, where $\mathbf{\Omega}_{2m}$ is the standard alternating matrix of Eq. 13.9.1.

With Chapter 10's groups recalled, the four families line up as four choices of form.

Family	Form preserved	Kind of form	Section
$\mathrm{O}(n)$	$\mathbf{I}_n$ over $\mathbb{R}$	symmetric, positive definite	Ch 10 §07
$\mathrm{O}(p,q)$	$\mathbf{I}_{p,q}$ over $\mathbb{R}$	symmetric, signature (p,q)	§05
$\mathrm{U}(n)$	$\mathbf{I}_n$ over $\mathbb{C}$	Hermitian, positive definite	Ch 10 §07
$\mathrm{Sp}(2m,F)$	$\mathbf{\Omega}_{2m}$ over F	alternating, non-degenerate	§09

Two remarks on the list. $\mathrm{O}(n) = \mathrm{O}(n,0)$, so the ordinary orthogonal group is the extreme case of the indefinite one; and $\mathrm{O}(p,q)$ and $\mathrm{O}(q,p)$ are conjugate, because negating a form does not change which maps preserve it, and $-\mathbf{I}_{p,q} = (-\mathbf{I}_p) \oplus \mathbf{I}_q$ becomes $\mathbf{I}_{q,p}$ after a permutation of the coordinates, which is a congruence. There is no Sp for odd size: a non-degenerate alternating form exists only in even dimension (Theorem 13.9.2 (b)).

Example. (Members of Each Family)

Verify the following memberships, with $\mathbf{\Omega}_{2m}$ as above.

(a) $\left(\begin{smallmatrix} \cosh t & \sinh t \\ \sinh t & \cosh t \end{smallmatrix}\right) \in \mathrm{O}(1,1)$ for every $t \in \mathbb{R}$.

(b) $\left(\begin{smallmatrix} \mathbf{M} & \mathbf{0} \\ \mathbf{0} & (\mathbf{M}^{\top})^{-1} \end{smallmatrix}\right) \in \mathrm{Sp}(2m,F)$ for every invertible $\mathbf{M} \in M_m(F)$.

(c) $\left(\begin{smallmatrix} \mathbf{I}_m & \mathbf{S} \\ \mathbf{0} & \mathbf{I}_m \end{smallmatrix}\right) \in \mathrm{Sp}(2m,F)$ if and only if $\mathbf{S}^{\top} = \mathbf{S}$.

Solution.

(a) With $\mathbf{A} = \mathbf{I}_{1,1} = \mathrm{diag}(1,-1)$, $c = \cosh t$ and $s = \sinh t$,

$$\begin{pmatrix} c & s \\ s & c \end{pmatrix}\begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}\begin{pmatrix} c & s \\ s & c \end{pmatrix} = \begin{pmatrix} c^2 - s^2 & 0 \\ 0 & s^2 - c^2 \end{pmatrix} = \mathbf{I}_{1,1},$$

using $\cosh^2 t - \sinh^2 t = 1$ and the symmetry of the outer matrix.

(b) Write $\mathbf{P} = \mathbf{M} \oplus \mathbf{N}$ with $\mathbf{N} = (\mathbf{M}^{\top})^{-1}$. Multiplying the blocks,

$$\mathbf{P}^{\top}\mathbf{\Omega}_{2m}\mathbf{P} = \begin{pmatrix} \mathbf{M}^{\top} & \mathbf{0} \\ \mathbf{0} & \mathbf{N}^{\top} \end{pmatrix}\begin{pmatrix} \mathbf{0} & \mathbf{N} \\ -\mathbf{M} & \mathbf{0} \end{pmatrix} = \begin{pmatrix} \mathbf{0} & \mathbf{M}^{\top}\mathbf{N} \\ -\mathbf{N}^{\top}\mathbf{M} & \mathbf{0} \end{pmatrix},$$

which equals $\mathbf{\Omega}_{2m}$ exactly when $\mathbf{M}^{\top}\mathbf{N} = \mathbf{I}_m$, that is $\mathbf{N} = (\mathbf{M}^{\top})^{-1}$.

(c) With $\mathbf{P} = \left(\begin{smallmatrix} \mathbf{I}_m & \mathbf{S} \\ \mathbf{0} & \mathbf{I}_m \end{smallmatrix}\right)$,

$$\mathbf{P}^{\top}\mathbf{\Omega}_{2m}\mathbf{P} = \begin{pmatrix} \mathbf{I}_m & \mathbf{0} \\ \mathbf{S}^{\top} & \mathbf{I}_m \end{pmatrix}\begin{pmatrix} \mathbf{0} & \mathbf{I}_m \\ -\mathbf{I}_m & -\mathbf{S} \end{pmatrix} = \begin{pmatrix} \mathbf{0} & \mathbf{I}_m \\ -\mathbf{I}_m & \mathbf{S}^{\top} - \mathbf{S} \end{pmatrix},$$

which equals $\mathbf{\Omega}_{2m}$ exactly when $\mathbf{S}^{\top} = \mathbf{S}$. Such a $\mathbf{P}$ is a **symplectic shear**; part (c) is the first sign that symmetric matrices appear inside the symplectic group, and the dimension count below will make that precise.

13.10.4 Determinants

For the orthogonal family the determinant argument is already inside the proof of Theorem 13.10.1, and it costs nothing to state it over any field.

Theorem 13.10.3 — Determinants in the Classical Groups (a) Let F be any field and $\mathbf{A} \in M_n(F)$ non-singular. Then $\det \mathbf{P} = \pm 1$ for every $\mathbf{P} \in \mathrm{Isom}(\mathbf{A})$. In particular $\det \mathbf{P} = \pm 1$ for $\mathbf{P} \in \mathrm{O}(p, q)$, and both signs occur when $n \geq 1$.

(b) If $\mathbf{A} \in M_n(\mathbb{C})$ is Hermitian and non-singular, then $|\det \mathbf{P}| = 1$ for every $\mathbf{P} \in \mathrm{Isom}(\mathbf{A})$; in particular for $\mathbf{P} \in \mathrm{U}(n)$.

(c) $\mathrm{Sp}(2, F) = \mathrm{SL}_2(F)$. In particular every $\mathbf{P} \in \mathrm{Sp}(2, F)$ has $\det \mathbf{P} = 1$ exactly, and -1 does not occur.

Proof.

(a) The proof of Theorem 13.10.1 established $(\det \mathbf{P})^2 = 1$. The polynomial $x^2 - 1 = (x - 1)(x + 1)$ has at most two roots in a field (Corollary 5.1.4), and 1 and -1 are roots, so $\det \mathbf{P} \in \{1, -1\}$. For $\mathrm{O}(p, q)$, the identity has determinant 1; and $\mathbf{D} := \mathrm{diag}(-1, 1, \ldots, 1)$ satisfies $\mathbf{D}^{\top}\mathbf{I}_{p,q}\mathbf{D} = \mathbf{I}_{p,q}$, since $\mathbf{D}$ is diagonal and squaring its entries gives $\mathbf{I}_n$, while $\det \mathbf{D} = -1$.

(b) Also established in that proof: $|\det \mathbf{P}|^2 = 1$, and a non-negative real with square 1 is 1. This is Proposition 10.7.4 (b) for $\mathbf{A} = \mathbf{I}_n$.

(c) Write $\mathbf{J} = \mathbf{\Omega}_2 = \left(\begin{smallmatrix} 0 & 1 \\ -1 & 0 \end{smallmatrix}\right)$ and let $\mathbf{P} = \left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right)$ be arbitrary. Multiplying out,

$$\mathbf{P}^{\top}\mathbf{J}\mathbf{P} = \begin{pmatrix} a & c \\ b & d \end{pmatrix}\begin{pmatrix} c & d \\ -a & -b \end{pmatrix} = \begin{pmatrix} 0 & ad - bc \\ bc - ad & 0 \end{pmatrix} = (\det \mathbf{P})\,\mathbf{J}.$$

Since $\mathbf{J} \neq \mathbf{0}$, the equation $\mathbf{P}^{\top}\mathbf{J}\mathbf{P} = \mathbf{J}$ holds if and only if $\det \mathbf{P} = 1$. This proves the theorem.

■

Warning. **Every symplectic matrix has determinant $+1$, not ± 1.** The general argument of part (a) applies to $\mathbf{\Omega}_{2m}$ as well and gives only $(\det \mathbf{P})^2 = 1$, so it leaves -1 open. It is nevertheless true that $\mathrm{Sp}(2m, F) \subseteq \mathrm{SL}_{2m}(F)$ for every m, so -1 never occurs. Part (c) proves this for $m = 1$; **the general case is not proved in this book.** The clean route runs through the Pfaffian of Section 9 and its transformation rule $\mathrm{Pf}(\mathbf{P}^{\top}\mathbf{A}\mathbf{P}) = \det(\mathbf{P})\,\mathrm{Pf}(\mathbf{A})$: applied to $\mathbf{A} = \mathbf{\Omega}_{2m}$, whose Pfaffian is 1, it turns

> $\mathbf{P}^\top \boldsymbol{\Omega}_{2m} \mathbf{P} = \boldsymbol{\Omega}_{2m}$ directly into $\det \mathbf{P} = 1$. We stated that rule without proof, so we state its consequence without proof too. Do not use the statement as a step in an argument elsewhere in this book; treat it as information about the wider subject, like the fact that the general polynomial of degree five has no solution by radicals.

There is a consequence worth noticing. $\mathrm{O}(n)$ has the proper subgroup $\mathrm{SO}(n)$ cut out by $\det = 1$, and Chapter 11 made heavy use of it: rotations against reflections. The symplectic group has no such subgroup, because — by the fact just recorded, which this book does not prove — the determinant condition is already satisfied by everything in it. A symplectic form has no notion of reflection to detect.

13.10.5 Counting parameters

How big is each group? "Big" has an honest answer in this book only as a count, so here is the count, and here is what it does and does not mean.

The equation $\mathbf{P}^\top \mathbf{A} \mathbf{P} = \mathbf{A}$ is a system of scalar equations in the n^2 unknown entries of $\mathbf{P}$. If the system consisted of k independent equations we would expect the solutions to form a family described by $n^2 - k$ free parameters, and that number is what everybody calls the **dimension** of the group. The key observation is that the n^2 equations are far from independent, because the matrix $\mathbf{P}^\top \mathbf{A} \mathbf{P} - \mathbf{A}$ is not an arbitrary matrix: it has the same symmetry type as $\mathbf{A}$, by Proposition 13.2.4. So the equations repeat, and only the independent ones should be counted.

- If $\mathbf{A}$ is **symmetric**, then $\mathbf{P}^\top \mathbf{A} \mathbf{P} - \mathbf{A}$ is symmetric, and a symmetric $n \times n$ matrix has $\frac{1}{2}n(n+1)$ independent entries. Expected dimension: $n^2 - \frac{1}{2}n(n+1) = \frac{1}{2}n(n-1)$.
- If $\mathbf{A}$ is **alternating**, then $\mathbf{P}^\top \mathbf{A} \mathbf{P} - \mathbf{A}$ is alternating, and an alternating $n \times n$ matrix has $\frac{1}{2}n(n-1)$ independent entries. Expected dimension: $n^2 - \frac{1}{2}n(n-1) = \frac{1}{2}n(n+1)$.
- If $\mathbf{A}$ is **Hermitian** over $\mathbb{C}$, count real parameters: $\mathbf{P}$ has $2n^2$ of them, and a Hermitian matrix has n real diagonal entries and $\frac{1}{2}n(n-1)$ complex entries above the diagonal, in total n^2 real conditions. Expected real dimension: $2n^2 - n^2 = n^2$.

Group	Entries in $\mathbf{P}$	Independent conditions	Dimension
$\mathrm{O}(n)$, $\mathrm{O}(p,q)$, $p+q=n$	n^2	$\frac{1}{2}n(n+1)$	$\frac{1}{2}n(n-1)$
$\mathrm{U}(n)$ (real parameters)	$2n^2$	n^2	n^2
$\mathrm{Sp}(2m,\mathbb{R})$	$4m^2$	$m(2m-1)$	$m(2m+1)$

Small cases are a sanity check. $\mathrm{O}(2)$ comes out at dimension 1, and Chapter 10 found that its elements are described by a single angle. $\mathrm{O}(3)$ comes out at 3, matching the axis-and-angle description of Corollary 11.6.2: two parameters for the axis direction, one for the angle. $\mathrm{U}(1)$ comes out at 1, and $\mathrm{U}(1)$ is the unit circle in $\mathbb{C}$. And $\mathrm{Sp}(2,\mathbb{R}) = \mathrm{SL}_2(\mathbb{R})$ comes out at 3, which is right: four entries subject to the single equation $ad - bc = 1$.

Compare the orthogonal and symplectic rows of the table at $n = 2m$. The orthogonal group is smaller than the symplectic group of the same size, by exactly $\frac{1}{2}n(n+1) - \frac{1}{2}n(n-1) = n$. The gap is the gap between symmetric and alternating matrices, which is the n diagonal entries — the same diagonal that Section 3 found separating the two notions in the first place.

Warning. **This count is a heuristic, not a theorem of this book.** "Dimension" here means the number of free parameters one expects a solution set to have, and the step from "k independent-looking equations" to "$n^2 - k$ parameters" is not justified by anything proved above; for a non-linear system it can fail. Making it precise requires the notion of a smooth manifold and the implicit function theorem, which belong to analysis and differential geometry, not here. What is proved here is only the count of conditions. Every number in the table is nevertheless correct.

Quick check. The family $\mathrm{O}(p, q)$ is indexed by two integers, yet the table gives it a dimension depending only on $n = p + q$, not on how n splits. Does that mean $\mathrm{O}(3, 0)$ and $\mathrm{O}(2, 1)$ are the same group?

Solution. No. The count of conditions only sees that $\mathbf{I}_{p,q}$ is symmetric, not which symmetric matrix it is, so it cannot distinguish the two. They are genuinely different groups: $\mathrm{O}(3) = \mathrm{O}(3, 0)$ consists of matrices all of whose entries have absolute value at most 1, since its columns are unit vectors, whereas $\mathrm{O}(2, 1)$ contains matrices with arbitrarily large entries, as the next warning shows. Conjugate groups come from **congruent** forms (Proposition 13.10.2), and $\mathbf{I}_{3,0}$ and $\mathbf{I}_{2,1}$ are not congruent, because their signatures differ (Corollary 13.5.2).

13.10.6 Boundedness and its absence

Warning. $\mathrm{O}(p, q)$ **is not compact when** $p, q \geq 1$**, unlike** $\mathrm{O}(n)$**.** Compactness is a topological notion that this book does not develop, so the statement is **recorded here, not proved**. What can be seen without topology is the underlying reason, which is that the entries are unbounded. Take the hyperbolic plane $\mathbf{A} = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$, a non-degenerate symmetric real form of signature $(1, 1)$, hence congruent to $\mathbf{I}_{1,1}$. For every real $t \neq 0$,

$$\begin{pmatrix} t & 0 \\ 0 & t^{-1} \end{pmatrix}^{\top} \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} \begin{pmatrix} t & 0 \\ 0 & t^{-1} \end{pmatrix} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix},$$

so $\mathrm{diag}(t, t^{-1})$ lies in $\mathrm{Isom}(\mathbf{A})$, and its entries are unbounded as $t \to \infty$. By Proposition 13.10.2 the same unbounded family sits inside $\mathrm{O}(1, 1)$, and padding with an identity block puts it inside every $\mathrm{O}(p, q)$ with $p, q \geq 1$. By contrast every entry of a matrix in $\mathrm{O}(n)$ has absolute value at most 1, because each column is a unit vector for the Euclidean norm.

The same phenomenon shows up in $\mathrm{Sp}(2m, \mathbb{R})$, by Example (Members of Each Family) (b) with $\mathbf{M} = [t]$: the symplectic group is unbounded too. Only the two positive definite families, $\mathrm{O}(n)$ and $\mathrm{U}(n)$, are bounded, and positivity is exactly why — the form itself controls the size of the columns. Definiteness, which this chapter spent nine sections learning to do without, turns out to be what made Chapter 10's groups small.

Section 11 takes the indefinite case that physics uses, signature $(1, 3)$, and works out what its isometry group does to the geometry of spacetime.

13.10.7 Exercises

13.10.7.1 A. Check your understanding

Exercise A1.

(a) Define $\mathrm{Isom}(\mathbf{A})$ for a non-singular $\mathbf{A} \in M_n(F)$, and explain why its elements are automatically invertible.

(b) Which form does $\mathrm{O}(p,q)$ preserve, and which does $\mathrm{Sp}(2m,F)$ preserve?

(c) Determine whether the following is correct: if $\mathbf{A} \simeq \mathbf{B}$, then $\mathrm{Isom}(\mathbf{A}) = \mathrm{Isom}(\mathbf{B})$. Justify your answer.

(d) State what is known here about $\det \mathbf{P}$ for $\mathbf{P} \in \mathrm{Sp}(2m,F)$, distinguishing what is proved from what is only recorded.

(e) In the parameter count, what exactly does the word "dimension" mean, and what is not being claimed?

Solution.

(a) $\mathrm{Isom}(\mathbf{A}) = \{\mathbf{P} : \mathbf{P}^{\top}\mathbf{A}\mathbf{P} = \mathbf{A}\}$ (Definition 13.10.1). Taking determinants gives $(\det \mathbf{P})^2 \det \mathbf{A} = \det \mathbf{A}$, and $\det \mathbf{A} \neq 0$, so $(\det \mathbf{P})^2 = 1$ and $\det \mathbf{P} \neq 0$ (Theorem 13.10.1).

(b) $\mathrm{O}(p,q)$ preserves the real symmetric form with matrix $\mathbf{I}_{p,q} = \mathbf{I}_p \oplus (-\mathbf{I}_q)$, of signature (p,q). $\mathrm{Sp}(2m,F)$ preserves the standard alternating form with matrix $\mathbf{\Omega}_{2m}$ (Definition 13.10.2).

(c) Incorrect as stated: the two groups are **conjugate**, $\mathrm{Isom}(\mathbf{B}) = \mathbf{Q}^{-1}\,\mathrm{Isom}(\mathbf{A})\mathbf{Q}$, not equal (Proposition 13.10.2). For a witness take $\mathbf{A} = \mathbf{I}_2$ and $\mathbf{B} = \mathrm{diag}(1,4) = \mathbf{Q}^{\top}\mathbf{A}\mathbf{Q}$ with $\mathbf{Q} = \mathrm{diag}(1,2)$. Then $\left(\begin{smallmatrix} 0 & 1 \\ -1 & 0 \end{smallmatrix}\right) \in \mathrm{O}(2) = \mathrm{Isom}(\mathbf{A})$, but the corresponding element $\mathbf{Q}^{-1}\left(\begin{smallmatrix} 0 & 1 \\ -1 & 0 \end{smallmatrix}\right)\mathbf{Q} = \left(\begin{smallmatrix} 0 & 2 \\ -1/2 & 0 \end{smallmatrix}\right)$ of $\mathrm{Isom}(\mathbf{B})$ is not in $\mathrm{O}(2)$. What is always true is that the two groups are isomorphic.

(d) Proved here: $(\det \mathbf{P})^2 = 1$, hence $\det \mathbf{P} = \pm 1$, for every m (Theorem 13.10.3 (a)); and $\det \mathbf{P} = 1$ exactly, for $m = 1$, since $\mathrm{Sp}(2,F) = \mathrm{SL}_2(F)$ (part (c)). Recorded but not proved: $\det \mathbf{P} = 1$ for every m, which follows from the transformation rule of the Pfaffian.

(e) The number of free parameters expected in the solution set of $\mathbf{P}^{\top}\mathbf{A}\mathbf{P} = \mathbf{A}$, computed as n^2 minus the number of independent scalar conditions. It is not claimed that the solution set really is a family described by that many free parameters; that statement needs the implicit function theorem and is not proved here.

13.10.7.2 B. Practice

Exercise B1: Determine which of the following.

For each matrix, determine whether it lies in $\mathrm{O}(2)$, in $\mathrm{O}(1,1)$, in $\mathrm{Sp}(2,\mathbb{R})$ — where the relevant forms are $\mathbf{I}_2$, $\mathbf{I}_{1,1} = \mathrm{diag}(1,-1)$ and $\mathbf{\Omega}_2$ — listing all that apply. Justify each answer.

(a) $\left(\begin{smallmatrix} 1 & 0 \\ 0 & -1 \end{smallmatrix}\right)$.

(b) $\left(\begin{smallmatrix} 0 & -1 \\ 1 & 0 \end{smallmatrix}\right)$.

(c) $\begin{pmatrix} 3 & 0 \\ 0 & 1/3 \end{pmatrix}$.

(d) $\begin{pmatrix} 5/3 & 4/3 \\ 4/3 & 5/3 \end{pmatrix}$.

Solution. Throughout, membership in $\mathrm{Sp}(2,\mathbb{R})$ is decided by $\det \mathbf{P} = 1$ alone (Theorem 13.10.3 (c)), and membership in $\mathrm{O}(2)$ by orthonormality of the columns.

(a) $\mathrm{O}(2)$: yes, the columns are $\mathbf{e}_1$ and $-\mathbf{e}_2$, orthonormal. $\mathrm{O}(1,1)$: yes, $\mathbf{P}$ is diagonal with entries ± 1, so $\mathbf{P}^{\top}\mathbf{I}_{1,1}\mathbf{P} = \mathbf{I}_{1,1}$. $\mathrm{Sp}(2,\mathbb{R})$: no, $\det \mathbf{P} = -1$.

(b) $\mathrm{O}(2)$: yes, a rotation by $\pi/2$. $\mathrm{O}(1,1)$: no — $\mathbf{P}^{\top}\mathbf{I}_{1,1}\mathbf{P} = \left(\begin{smallmatrix} -1 & 0 \\ 0 & 1 \end{smallmatrix}\right) = -\mathbf{I}_{1,1} \neq \mathbf{I}_{1,1}$. $\mathrm{Sp}(2,\mathbb{R})$: yes, $\det \mathbf{P} = 1$.

(c) $\mathrm{O}(2)$: no, the first column has norm 3. $\mathrm{O}(1,1)$: no — for diagonal $\mathbf{P} = \mathrm{diag}(s,t)$ the condition is $\mathrm{diag}(s^2,-t^2) = \mathrm{diag}(1,-1)$, that is $s,t = \pm 1$, and $3 \neq \pm 1$. $\mathrm{Sp}(2,\mathbb{R})$: yes, $\det \mathbf{P} = 3 \cdot \frac{1}{3} = 1$.

(d) $\mathrm{O}(2)$: no, the first column has norm $\sqrt{25/9 + 16/9} = \sqrt{41}/3 \neq 1$. $\mathrm{O}(1,1)$: yes — this is $\left(\begin{smallmatrix} \cosh t & \sinh t \\ \sinh t & \cosh t \end{smallmatrix}\right)$ with $\cosh t = 5/3$, $\sinh t = 4/3$ and $(5/3)^2 - (4/3)^2 = 1$, so Example (Members of Each Family) (a) applies. $\mathrm{Sp}(2,\mathbb{R})$: yes, $\det \mathbf{P} = 25/9 - 16/9 = 1$.

Exercise B2: A symplectic matrix of size four.

Let $\mathbf{M} = \left(\begin{smallmatrix} 1 & 2 \\ 0 & 1 \end{smallmatrix}\right)$ and $\mathbf{S} = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$, and put

$$\mathbf{P}_1 = \begin{pmatrix} \mathbf{M} & \mathbf{0} \\ \mathbf{0} & (\mathbf{M}^{\top})^{-1} \end{pmatrix}, \qquad \mathbf{P}_2 = \begin{pmatrix} \mathbf{I}_2 & \mathbf{S} \\ \mathbf{0} & \mathbf{I}_2 \end{pmatrix}.$$

(a) Write out $\mathbf{P}_1$ explicitly and verify $\mathbf{P}_1 \in \mathrm{Sp}(4,\mathbb{Q})$ directly from the definition.

(b) Explain why $\mathbf{P}_1\mathbf{P}_2 \in \mathrm{Sp}(4,\mathbb{Q})$ without computing the product.

(c) Compute $\det \mathbf{P}_1$ and $\det \mathbf{P}_2$, and check them against Theorem 13.10.3.

Solution.

(a) $\mathbf{M}^{\top} = \left(\begin{smallmatrix} 1 & 0 \\ 2 & 1 \end{smallmatrix}\right)$, so $(\mathbf{M}^{\top})^{-1} = \left(\begin{smallmatrix} 1 & 0 \\ -2 & 1 \end{smallmatrix}\right)$ and

$$\mathbf{P}_1 = \begin{pmatrix} 1 & 2 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & -2 & 1 \end{pmatrix}.$$

By the block computation of Example (Members of Each Family) (b), $\mathbf{P}_1^{\top}\boldsymbol{\Omega}_4\mathbf{P}_1 = \left(\begin{smallmatrix} \mathbf{0} & \mathbf{M}^{\top}\mathbf{N} \\ -\mathbf{N}^{\top}\mathbf{M} & \mathbf{0} \end{smallmatrix}\right)$ with $\mathbf{N} = (\mathbf{M}^{\top})^{-1}$, and $\mathbf{M}^{\top}\mathbf{N} = \mathbf{M}^{\top}(\mathbf{M}^{\top})^{-1} = \mathbf{I}_2$. So $\mathbf{P}_1^{\top}\boldsymbol{\Omega}_4\mathbf{P}_1 = \boldsymbol{\Omega}_4$.

(b) $\mathbf{S}$ is symmetric, so $\mathbf{P}_2 \in \mathrm{Sp}(4,\mathbb{Q})$ by Example (Members of Each Family) (c). A product of two elements of a group is again in the group, and $\mathrm{Sp}(4,\mathbb{Q})$ is a group by Theorem 13.10.1.

(c) $\mathbf{P}_1 = \mathbf{M} \oplus (\mathbf{M}^\top)^{-1}$ is block diagonal, so by Theorem 6.8.4 and Corollary 6.5.6,

$$\det \mathbf{P}_1 = \det \mathbf{M} \, \det\big((\mathbf{M}^\top)^{-1}\big) = \det \mathbf{M} \, (\det \mathbf{M})^{-1} = 1,$$

using $\det \mathbf{M}^\top = \det \mathbf{M}$ (Theorem 6.4.5). And $\mathbf{P}_2$ is block upper triangular with both diagonal blocks equal to $\mathbf{I}_2$, so $\det \mathbf{P}_2 = 1$ by Theorem 6.8.4. Both equal $+1$, consistent with the recorded fact $\mathrm{Sp}(2m, F) \subseteq \mathrm{SL}_{2m}(F)$; part (a) of the theorem only guarantees ± 1.

Exercise B3: Counting parameters.

(a) Compute the expected dimensions of $\mathrm{O}(4)$, $\mathrm{O}(2,2)$, $\mathrm{U}(3)$ and $\mathrm{Sp}(4, \mathbb{R})$.

(b) For which n and m do $\mathrm{O}(n)$ and $\mathrm{Sp}(2m, \mathbb{R})$ have the same expected dimension? Solve the resulting equation.

(c) The group $\mathrm{SO}(n)$ is cut out of $\mathrm{O}(n)$ by the single equation $\det \mathbf{P} = 1$. Why does this **not** reduce the expected dimension by one?

Solution.

(a) $\mathrm{O}(4)$ and $\mathrm{O}(2,2)$ both have $n = 4$, so $\frac{1}{2} \cdot 4 \cdot 3 = 6$. $\mathrm{U}(3)$: $3^2 = 9$ real parameters. $\mathrm{Sp}(4, \mathbb{R})$: $m = 2$, so $m(2m+1) = 10$.

(b) The equation is $\frac{1}{2}n(n-1) = m(2m+1)$, that is $n(n-1) = (2m+1)(2m)$. Reading the right-hand side as $n(n-1)$ with $n = 2m+1$ shows that $n = 2m+1$ is a solution for **every** m, and it is the only one: $n \mapsto n(n-1)$ is strictly increasing for $n \geq 1$, so it takes each value at most once. Hence

$$\dim \mathrm{O}(2m+1) = \dim \mathrm{Sp}(2m, \mathbb{R}) = m(2m+1),$$

and no other pairing of the two families matches. The smallest case is $\mathrm{O}(3)$ and $\mathrm{Sp}(2, \mathbb{R}) = \mathrm{SL}_2(\mathbb{R})$, both of dimension 3.

(c) Because $\det \mathbf{P} = \pm 1$ already, by Theorem 13.10.3 (a). The condition $\det \mathbf{P} = 1$ does not shrink a continuum of possibilities to a smaller one; it selects one of two discrete alternatives. So $\mathrm{SO}(n)$ has the same expected dimension $\frac{1}{2}n(n-1)$ as $\mathrm{O}(n)$, and the two groups differ only in how many separate pieces they have — which is a topological statement of the kind this section does not prove.

13.10.7.3 C. Going deeper

Exercise C1: Isometries of a degenerate form.

Let $\mathbf{A} = \left(\begin{smallmatrix} 1 & 0 \\ 0 & 0 \end{smallmatrix}\right) \in M_2(\mathbb{R})$ and let $G = \{\, \mathbf{P} \in M_2(\mathbb{R}) : \mathbf{P}^\top \mathbf{A} \mathbf{P} = \mathbf{A} \,\}$, the set produced by dropping the non-degeneracy hypothesis from Definition 13.10.1.

(a) Determine G explicitly.

(b) Exhibit an element of G that is not invertible, and explain which step of the proof of Theorem 13.10.1 it defeats.

(c) Prove that the invertible elements of G do form a group.

Solution.

(a) Write $\mathbf{P} = \left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right)$. Then

$$\mathbf{P}^{\top}\mathbf{A}\mathbf{P} = \begin{pmatrix} a & c \\ b & d \end{pmatrix}\begin{pmatrix} a & b \\ 0 & 0 \end{pmatrix} = \begin{pmatrix} a^2 & ab \\ ab & b^2 \end{pmatrix},$$

so the condition is $a^2 = 1$, $ab = 0$, $b^2 = 0$. The last two say $b = 0$, and the first says $a = \pm 1$. Hence

$$G = \left\{ \begin{pmatrix} \pm 1 & 0 \\ c & d \end{pmatrix} : c, d \in \mathbb{R} \right\}.$$

(b) Take $c = d = 0$ and $a = 1$: the matrix $\left(\begin{smallmatrix} 1 & 0 \\ 0 & 0 \end{smallmatrix}\right)$ lies in G and has determinant 0. The step it defeats is the cancellation of $\det \mathbf{A}$ in $(\det \mathbf{P})^2 \det \mathbf{A} = \det \mathbf{A}$. Here $\det \mathbf{A} = 0$, the equation reads $0 = 0$, and it says nothing about $\det \mathbf{P}$.

(c) Let $G^{\times}$ be the set of invertible elements of G; from (a) these are the matrices above with $d \neq 0$. It contains $\mathbf{I}_2$. It is closed under products, since G is (the computation in Theorem 13.10.1 needs only $\mathbf{P}^{\top}\mathbf{A}\mathbf{P} = \mathbf{A}$ and $\mathbf{Q}^{\top}\mathbf{A}\mathbf{Q} = \mathbf{A}$, not invertibility) and a product of invertible matrices is invertible. And it is closed under inverses: if $\mathbf{P} \in G^{\times}$ then multiplying $\mathbf{P}^{\top}\mathbf{A}\mathbf{P} = \mathbf{A}$ by $(\mathbf{P}^{-1})^{\top}$ and $\mathbf{P}^{-1}$ gives $\mathbf{P}^{-1} \in G$, and $\mathbf{P}^{-1}$ is invertible. So $G^{\times}$ is a group — but it is *not* all of G, which is the reason Definition 13.10.1 assumes non-degeneracy rather than repairing the damage afterwards.

Exercise C2: The symplectic group of a two-dimensional form, revisited.

Let F be any field and let β be a non-degenerate alternating form on a two-dimensional vector space V over F.

(a) Prove that $\mathrm{Isom}(\beta) = \{\, T \in \mathcal{L}(V) : \det T = 1 \,\}$.

(b) Deduce that for $F = \mathbb{F}_2$ the group $\mathrm{Sp}(2, \mathbb{F}_2)$ has exactly 6 elements, and that $\mathrm{Sp}(2, \mathbb{F}_2) = \mathrm{GL}_2(\mathbb{F}_2)$.

(c) Is $\mathrm{Sp}(2, \mathbb{F}_3) = \mathrm{GL}_2(\mathbb{F}_3)$? Justify your answer by a count.

Hint for (b) and (c): count the invertible matrices over $\mathbb{F}_q$ by choosing the columns in turn.

Solution.

(a) Choose a symplectic basis $\mathcal{B}$ for β, which exists by Theorem 13.9.2 (b); then $[\beta]_{\mathcal{B}} = \mathbf{\Omega}_2$. By the correspondence after Definition 13.10.1, $T \in \mathrm{Isom}(\beta)$ if and only if $\mathbf{P} \coloneqq [T]_{\mathcal{B}}$ lies in $\mathrm{Isom}(\mathbf{\Omega}_2) = \mathrm{Sp}(2, F)$, which by Theorem 13.10.3 (c) says $\det \mathbf{P} = 1$. Finally $\det T = \det \mathbf{P}$ by Definition 6.5.1, since the determinant of an operator is that of its matrix in any basis.

(b) By (a), $\mathrm{Sp}(2, \mathbb{F}_2) = \mathrm{SL}_2(\mathbb{F}_2)$. Count $\mathrm{GL}_2(\mathbb{F}_2)$ first: the first column may be any of the $4 - 1 = 3$ non-zero vectors, and the second any of the $4 - 2 = 2$ vectors outside the span of the first, giving 6. Over $\mathbb{F}_2$ the only non-zero scalar is 1, so every invertible matrix has $\det = 1$; hence $\mathrm{SL}_2(\mathbb{F}_2) = \mathrm{GL}_2(\mathbb{F}_2)$ has 6 elements.

(c) No. The same count over $\mathbb{F}_3$ gives $|\mathrm{GL}_2(\mathbb{F}_3)| = (9-1)(9-3) = 48$. The determinant is a surjective homomorphism $\mathrm{GL}_2(\mathbb{F}_3) \to \mathbb{F}_3^{\times}$, whose target has 2 elements, and its fibers all have the same size; so $|\mathrm{SL}_2(\mathbb{F}_3)| = 24 \neq 48$. Concretely $\mathrm{diag}(1, -1)$ is

invertible with determinant $-1 \neq 1$, so it lies in $\mathrm{GL}_2(\mathbb{F}_3)$ and not in $\mathrm{Sp}(2, \mathbb{F}_3)$.

Exercise C3: Bounded and unbounded.

(a) Prove that every entry of a matrix $\mathbf{P} \in \mathrm{O}(n)$ satisfies $|p_{ij}| \leq 1$.

(b) Prove that for every $n \geq 2$ and every real M, the group $\mathrm{O}(n-1,1)$ contains a matrix with an entry larger than M.

(c) Explain in two sentences why (a) and (b) together make it plausible that $\mathrm{O}(n)$ is compact and $\mathrm{O}(n-1,1)$ is not, and say precisely what has and has not been proved.

Solution.

(a) The columns of $\mathbf{P} \in \mathrm{O}(n)$ are orthonormal in $\mathbb{R}^n$ (Theorem 10.7.3 (f)), so for each j we have $\sum_i p_{ij}^2 = 1$. Each term of a sum of non-negative reals is at most the sum, so $p_{ij}^2 \leq 1$ and $|p_{ij}| \leq 1$.

(b) Put $\mathbf{B}_t \coloneqq \left(\begin{smallmatrix} \cosh t & \sinh t \\ \sinh t & \cosh t \end{smallmatrix}\right)$, which lies in $\mathrm{O}(1,1)$ for every real t by Example (Members of Each Family) (a), and consider

$$\mathbf{P}_t \coloneqq \mathbf{I}_{n-2} \oplus \mathbf{B}_t \in M_n(\mathbb{R}).$$

(For $n = 2$ read $\mathbf{P}_t = \mathbf{B}_t$.) As a block diagonal matrix $\mathbf{I}_{n-1,1} = \mathbf{I}_{n-2} \oplus \mathbf{I}_{1,1}$, and each block of $\mathbf{P}_t$ preserves its own block of the form: $\mathbf{I}_{n-2}^{\top}\mathbf{I}_{n-2}\mathbf{I}_{n-2} = \mathbf{I}_{n-2}$, and $\mathbf{B}_t^{\top}\mathbf{I}_{1,1}\mathbf{B}_t = \mathbf{I}_{1,1}$ by Example (Members of Each Family) (a). Multiplying block by block gives $\mathbf{P}_t^{\top}\mathbf{I}_{n-1,1}\mathbf{P}_t = \mathbf{I}_{n-1,1}$, so $\mathbf{P}_t \in \mathrm{O}(n-1,1)$. Its (n,n) entry is $\cosh t = \frac{1}{2}(e^t + e^{-t}) \geq \frac{1}{2}e^t$, and e^t grows without bound, so some t makes this entry exceed the given M.

(c) A compact subset of $M_n(\mathbb{R}) \cong \mathbb{R}^{n^2}$ must be bounded, so (b) rules out compactness for $\mathrm{O}(n-1,1)$, while (a) supplies half of what $\mathrm{O}(n)$ would need. What has been **proved** here is only the statement about entries: $\mathrm{O}(n)$ is bounded and $\mathrm{O}(n-1,1)$ is not. That "bounded and closed implies compact" in $\mathbb{R}^{n^2}$, and that $\mathrm{O}(n)$ is closed, are theorems of analysis that this book does not prove, so the compactness claim itself remains recorded rather than established.

13.11 Minkowski Space

Sylvester's law of inertia says that a real symmetric form is nothing but a pair of counts, and that any two forms with the same counts are the same form in disguise. One pair of counts has a claim on our attention that none of the others has: the form of signature $(1,3)$ is the one the physical world appears to run on. This section does the linear algebra of that form. Everything in it is this chapter's machinery specialized, and the payoff is a picture — a cone dividing space into three regions — together with a classification theorem that is the hyperbolic twin of a circular one we already proved.

13.11.1 The form of special relativity

Fix $n_+ = 1$ and $n_- = 3$ in the canonical form of Corollary 13.5.2, and there is only one form to write down.

Definition 13.11.1 — Minkowski Space

Minkowski space $\mathbb{R}^{1,3}$ is the real vector space $\mathbb{R}^4$ equipped with the symmetric bilinear form

$$\eta(\mathbf{x}, \mathbf{y}) \coloneqq x_1y_1 - x_2y_2 - x_3y_3 - x_4y_4,$$

whose quadratic form is $q(\mathbf{x}) = x_1^2 - x_2^2 - x_3^2 - x_4^2$. The first coordinate is the **time** coordinate and the remaining three are the **space** coordinates. More generally, for $p, m \geq 0$, $\mathbb{R}^{p,m}$ is $\mathbb{R}^{p+m}$ with the form whose matrix in the standard basis is $\mathbf{I}_p \oplus (-\mathbf{I}_m)$.

In words: η is the dot product of $\mathbb{R}^4$ with three of its four signs reversed. Its matrix in the standard basis $\mathcal{E}$ is

$$[\eta]_{\mathcal{E}} = \operatorname{diag}(1, -1, -1, -1),$$

which is symmetric, so η is a symmetric form (Definition 13.3.1), and it is diagonal, so $\mathcal{E}$ is an orthogonal basis for η (Definition 13.4.1). Reading off the signs, the signature of η is $(1, 3)$ and its inertia is $(1, 3, 0)$ (Definition 13.5.1). The form is **non-degenerate**: $\eta(\mathbf{e}_1, \mathbf{x}) = x_1$ and $\eta(\mathbf{e}_j, \mathbf{x}) = -x_j$ for $j = 2, 3, 4$, so a vector paired to zero with everything has all four coordinates zero (Definition 13.1.4).

> *Warning.* **Two sign conventions are in use, and both are called "the" Minkowski form.** We take $(+, -, -, -)$, signature $(1, 3)$; many sources take $(-, +, +, +)$, signature $(3, 1)$, which is our $-\eta$. The two are not congruent — congruence preserves the signature (Theorem 13.5.1) — but every statement below transfers by reversing each inequality on q, because q changes sign. The one thing both conventions agree on is the set $\{q = 0\}$, which is why the picture of this section is convention-free. State your convention before computing, and never mix the two.

13.11.2 Timelike, spacelike and null

Nothing in this section is a new notion. Section 7 studied the vectors on which a form vanishes, and called them isotropic; over $\mathbb{R}$ a non-degenerate indefinite form has plenty of them, and the ones belonging to η have names of their own.

The form sorts non-zero vectors into three classes by the sign of q, and the middle class — where q vanishes — is exactly the isotropy of Section 7.

Definition 13.11.2 — Timelike, Spacelike, Null

Let $\mathbf{x} \in \mathbb{R}^{1,3}$ with $\mathbf{x} \neq \mathbf{0}$. Then $\mathbf{x}$ is

(a) **timelike** if $q(\mathbf{x}) > 0$;
(b) **null**, or **lightlike**, if $q(\mathbf{x}) = 0$;
(c) **spacelike** if $q(\mathbf{x}) < 0$.

The set $\{\mathbf{x} \in \mathbb{R}^{1,3} : q(\mathbf{x}) = 0\}$ is the **light cone**. A timelike $\mathbf{x}$ is **future-pointing** if $x_1 > 0$ and **past-pointing** if $x_1 < 0$.

The word **null** is a second name for something already defined: a null vector is precisely a non-zero **isotropic** vector for η in the sense of Definition 13.7.1, and the light cone is the isotropy locus of η together with $\mathbf{0}$. So "the light cone" is not new geometry; it is the locus Section 7 already forced us to take seriously, drawn for one particular form. Timelike and spacelike are then just names for the two sides that the isotropy locus separates.

The last clause of the definition is legitimate because a timelike vector cannot have $x_1 = 0$: if it did, then $q(\mathbf{x}) = -(x_2^2+x_3^2+x_4^2) \le 0$. So every timelike vector is future-pointing or past-pointing, and exactly one of the two.

Example. (Reading off the three types)

Classify $\mathbf{e}_1$, $\mathbf{e}_2$, $\mathbf{e}_1 + \mathbf{e}_2$ and $(2, 1, 1, 1)$ in $\mathbb{R}^{1,3}$, and decide which of them are isotropic.

Solution. $q(\mathbf{e}_1) = 1 > 0$, so $\mathbf{e}_1$ is timelike and future-pointing. $q(\mathbf{e}_2) = -1 < 0$, so $\mathbf{e}_2$ is spacelike. $q(\mathbf{e}_1 + \mathbf{e}_2) = 1 - 1 = 0$, so $\mathbf{e}_1 + \mathbf{e}_2$ is null, hence isotropic. Finally $q(2, 1, 1, 1) = 4 - 3 = 1 > 0$, timelike and future-pointing. Only $\mathbf{e}_1 + \mathbf{e}_2$ is isotropic; the other three are anisotropic.

Section 7's structure theorem applies verbatim. A non-zero isotropic vector sits in a hyperbolic plane, and here we can point to one: take $\mathbf{u} = \mathbf{e}_1+\mathbf{e}_2$ and $\mathbf{w} = \frac{1}{2}(\mathbf{e}_1-\mathbf{e}_2)$. Then $q(\mathbf{u}) = q(\mathbf{w}) = 0$ and

$$\eta(\mathbf{u}, \mathbf{w}) = \tfrac{1}{2}\big(1 - (-1)\big) = 1,$$

so the Gram matrix of $(\mathbf{u}, \mathbf{w})$ is $\left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$ and $\operatorname{span}(\mathbf{u}, \mathbf{w})$ is a hyperbolic plane (Definition 13.7.3). Splitting it off, Theorem 13.7.5 writes

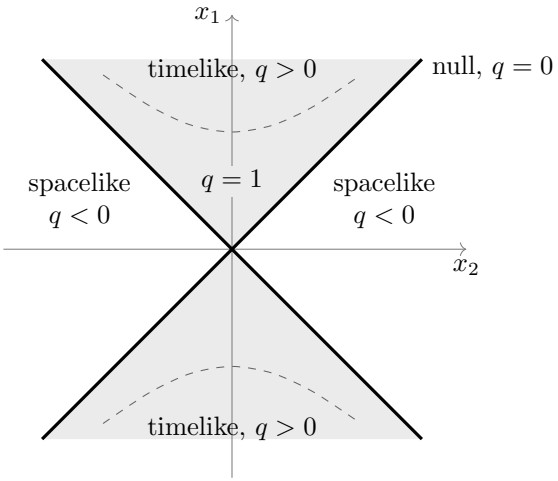
$$\mathbb{R}^{1,3} \;=\; H \perp W,$$

with H hyperbolic of signature $(1, 1)$ and W anisotropic of signature $(0, 2)$, that is, negative definite. Only one plane splits off, because the Witt index of a real form of signature (n_+, n_-) is $\min(n_+, n_-)$ (Proposition 13.7.7), which here is $\min(1, 3) = 1$.

Quick check. Is there a **plane** in $\mathbb{R}^{1,3}$ on which η vanishes identically?

Solution. No. Suppose $\mathbf{x} = (a, \mathbf{u})$ and $\mathbf{y} = (b, \mathbf{w})$ span such a plane, where $a, b \in \mathbb{R}$ and $\mathbf{u}, \mathbf{w} \in \mathbb{R}^3$. Then $q(\mathbf{x}) = q(\mathbf{y}) = 0$ gives $a^2 = \|\mathbf{u}\|^2$ and $b^2 = \|\mathbf{w}\|^2$, while $\eta(\mathbf{x}, \mathbf{y}) = 0$ gives $ab = \mathbf{u} \cdot \mathbf{w}$. Hence $|\mathbf{u} \cdot \mathbf{w}| = |a||b| = \|\mathbf{u}\|\|\mathbf{w}\|$, which is the equality case of Theorem 10.1.5, so $(\mathbf{u}, \mathbf{w})$ is dependent. If $\mathbf{u} = \mathbf{0}$ then $a = 0$ and $\mathbf{x} = \mathbf{0}$; otherwise $\mathbf{w} = \lambda\mathbf{u}$, so $b^2 = \lambda^2 a^2$ and $ab = \lambda a^2$, which force $b = \lambda a$ and $\mathbf{y} = \lambda\mathbf{x}$. Either way $(\mathbf{x}, \mathbf{y})$ is dependent, so no plane exists. Structurally this is the statement that the Witt index of $\mathbb{R}^{1,3}$ is $\min(1, 3) = 1$ (Proposition 13.7.7), since by Definition 13.7.4 no totally isotropic subspace has dimension larger than the index.

The picture is easiest to draw with one space coordinate instead of three, in $\mathbb{R}^{1,1}$, where the light cone degenerates to the two lines $x_2 = \pm x_1$.



The light cone $q = 0$ in the Minkowski plane separates the timelike vectors from the spacelike ones; the "unit sphere" $q = 1$ is the dashed hyperbola, and it is unbounded

Two features of the picture deserve to be said out loud. The shaded region is **not** connected: the future-pointing and past-pointing timelike vectors form two separate pieces, and no continuous path of timelike vectors joins them. That last claim is worth one line, since it is the only place in this section where a topological word is used. Suppose γ were a continuous path of timelike vectors from a future-pointing vector to a past-pointing one. Its first coordinate x_1 is a continuous real function that is positive at one end and negative at the other, so by the intermediate value theorem — an analysis input, quoted and not proved here, as in Section 6 — it vanishes somewhere along the path. But $x_1 = 0$ forces $q(\mathbf{x}) = -x_2^2 - x_3^2 - x_4^2 \leq 0$, so that point of the path is not timelike, a contradiction. And the level set $q = 1$, which plays the role the unit circle plays for the dot product, is unbounded. Both facts come straight from the mixed signs, and both are invisible to anyone whose intuition was trained on positive definite forms.

> *Warning.* **Orthogonality for η is not the perpendicularity you can see.** A null vector is η-orthogonal to *itself*, and the consequence is that Chapter 10's decomposition $V = U \oplus U^\perp$ fails. Take $U = \operatorname{span}\big((1,1,0,0)\big)$. Since $\eta\big((1,1,0,0),\mathbf{x}\big) = x_1 - x_2$, the η-orthogonal complement of U is the hyperplane $\{x_1 = x_2\}$, which **contains** U. So $U + U^\perp = U^\perp$ is three-dimensional, not four, and $U \cap U^\perp = U \neq \{\mathbf{0}\}$. Nothing has gone wrong; positivity was doing that work in Chapter 10, and it is gone.

13.11.3 Hyperbolic rotations

Now the isometries. The group attached to η is the isometry group of its matrix (Definition 13.10.1), which is $\mathrm{O}(1,3)$ in the notation of Definition 13.10.2: the matrices $\mathbf{P}$ with $\mathbf{P}^\top [\eta]_{\mathcal{E}} \mathbf{P} = [\eta]_{\mathcal{E}}$. Its elements are the **Lorentz transformations**. We classify them in dimension 2, where η becomes

$$\eta_2(\mathbf{x},\mathbf{y}) = x_1 y_1 - x_2 y_2, \qquad [\eta_2]_{\mathcal{E}} = \operatorname{diag}(1,-1).$$

The classification of $\mathrm{O}(2)$ in Theorem 10.7.5 rested on one geometric fact: a unit vector of the Euclidean plane is $(\cos\theta, \sin\theta)$ for exactly one $\theta \in [0, 2\pi)$. Replace the circle by the hyperbola and the same proof runs. We need the corresponding parametrization, and we take it from calculus:

$$\cosh t = \tfrac{1}{2}(e^t + e^{-t}), \qquad \sinh t = \tfrac{1}{2}(e^t - e^{-t}),$$
$$\cosh^2 t - \sinh^2 t = 1, \qquad \cosh t > 0,$$
$$\cosh(s+t) = \cosh s \cosh t + \sinh s \sinh t,$$
$$\sinh(s+t) = \sinh s \cosh t + \cosh s \sinh t,$$

and $\sinh\colon \mathbb{R} \to \mathbb{R}$ is a strictly increasing bijection. Those facts are the only analysis used in this section.

Definition 13.11.3 — Boost

For $t \in \mathbb{R}$, the **boost of rapidity** t is

$$\mathbf{B}_t := \begin{pmatrix} \cosh t & \sinh t \\ \sinh t & \cosh t \end{pmatrix} \in M_2(\mathbb{R}).$$

A boost is the hyperbolic analogue of the rotation $\mathbf{R}_\theta$ of Chapter 10: same shape, hyperbolic functions in place of circular ones, and no minus sign in the corner.

Theorem 13.11.1 — Classification of the Plane Lorentz Transformations

Let $\mathbf{P} \in \mathrm{O}(1,1)$, that is, $\mathbf{P} \in M_2(\mathbb{R})$ with $\mathbf{P}^{\top} \operatorname{diag}(1,-1)\mathbf{P} = \operatorname{diag}(1,-1)$. Then there are a unique $t \in \mathbb{R}$ and unique signs $\varepsilon, \mu \in \{1,-1\}$ with

$$\mathbf{P} = \begin{pmatrix} \varepsilon \cosh t & \mu \sinh t \\ \sinh t & \varepsilon\mu \cosh t \end{pmatrix},$$

and $\det \mathbf{P} = \mu$. Writing $\mathbf{D} = \operatorname{diag}(1,-1)$, this says

$$\mathrm{O}(1,1) = \{\, \mathbf{B}_t,\ \mathbf{B}_t\mathbf{D},\ -\mathbf{B}_t,\ -\mathbf{B}_t\mathbf{D} \ :\ t \in \mathbb{R} \,\},$$

a disjoint union of four families. Moreover $\mathbf{B}_s\mathbf{B}_t = \mathbf{B}_{s+t}$ for all s, t, so $\{\mathbf{B}_t : t \in \mathbb{R}\}$ is a subgroup of $\mathrm{O}(1,1)$ isomorphic to $(\mathbb{R}, +)$.

Idea. The congruence $\mathbf{P}^{\top}\mathbf{D}\mathbf{P} = \mathbf{D}$ says exactly that the two columns of $\mathbf{P}$ are an orthogonal basis for η_2 with q-values 1 and -1. So: parametrize the vectors with $q = 1$, which is the hyperbola; then the second column is forced, because the η_2-orthogonal complement of a non-isotropic vector is a line, and on that line only two vectors have $q = -1$. This is Theorem 10.7.5's proof with the circle replaced by the hyperbola.

Proof. Write $\mathbf{P} = \begin{pmatrix} a & c \\ b & d \end{pmatrix}$ with columns $\mathbf{p}_1 = (a,b)$ and $\mathbf{p}_2 = (c,d)$. The (i,j) entry of $\mathbf{P}^{\top}\mathbf{D}\mathbf{P}$ is $\eta_2(\mathbf{p}_i, \mathbf{p}_j)$, so the hypothesis says

$$q(\mathbf{p}_1) = 1, \qquad q(\mathbf{p}_2) = -1, \qquad \eta_2(\mathbf{p}_1, \mathbf{p}_2) = 0.$$

The first column. Since $\sinh$ is a bijection of $\mathbb{R}$, there is a unique $t \in \mathbb{R}$ with $b = \sinh t$. Then $a^2 = 1 + b^2 = 1 + \sinh^2 t = \cosh^2 t$, so $a = \varepsilon \cosh t$ for a unique sign ε, unique because $\cosh t > 0$.

The second column. The vector $\mathbf{z} = (\sinh t, \varepsilon \cosh t)$ satisfies $\eta_2(\mathbf{p}_1, \mathbf{z}) = \varepsilon \cosh t \sinh t - \sinh t\, \varepsilon \cosh t = 0$, and $\mathbf{z} \neq \mathbf{0}$ because $\varepsilon \cosh t \neq 0$. The set $\{\mathbf{y} : \eta_2(\mathbf{p}_1, \mathbf{y}) = 0\}$ is the null space of the non-zero row vector $(a, -b)$, hence a line, so it equals $\operatorname{span}(\mathbf{z})$. Therefore $\mathbf{p}_2 = \mu' \mathbf{z}$ for some $\mu' \in \mathbb{R}$, and $q(\mathbf{z}) = \sinh^2 t - \cosh^2 t = -1$ gives $-1 = q(\mathbf{p}_2) = (\mu')^2 q(\mathbf{z}) = -(\mu')^2$. Hence $\mu' = \mu$ is a sign, and it is determined by $\mathbf{P}$, since $d = \mu\varepsilon \cosh t$ and $\cosh t > 0$. This is the displayed matrix, and expanding,

$$\det \mathbf{P} = \mu\big(\varepsilon^2 \cosh^2 t - \sinh^2 t\big) = \mu.$$

The four families. For $\varepsilon = \mu = 1$ the matrix is $\mathbf{B}_t$; for $\varepsilon = 1, \mu = -1$ it is $\mathbf{B}_t\mathbf{D}$; for $\varepsilon = -1, \mu = 1$ it is $-\mathbf{B}_{-t}$; and for $\varepsilon = \mu = -1$ it is $-\mathbf{B}_{-t}\mathbf{D}$, each by multiplying out and using $\sinh(-t) = -\sinh t$, $\cosh(-t) = \cosh t$. As t runs over $\mathbb{R}$ so does $-t$, which gives the displayed set equality. The families are disjoint because ε is the sign of the $(1,1)$ entry and $\mu = \det \mathbf{P}$, and both are determined by $\mathbf{P}$.

The subgroup. By the addition formulas for cosh and sinh,

$$\mathbf{B}_s\mathbf{B}_t = \begin{pmatrix} \cosh(s+t) & \sinh(s+t) \\ \sinh(s+t) & \cosh(s+t) \end{pmatrix} = \mathbf{B}_{s+t}.$$

So $t \mapsto \mathbf{B}_t$ is a group homomorphism $(\mathbb{R}, +) \to \mathrm{O}(1,1)$; it is injective because sinh is, and its image is a subgroup by Definition 0.10.2. This proves the theorem.

■

The four families are sorted by two signs, and each sign has a reading. The determinant μ says whether the space coordinate is reversed, exactly as in O(2). The sign ε of the $(1,1)$ entry says whether the future cone is sent to the future cone: for $\mathbf{B}_t$ the image of $\mathbf{e}_1$ is $(\cosh t, \sinh t)$, with positive first coordinate, while $-\mathbf{B}_t$ sends it to $(-\cosh t, -\sinh t)$. So the identity component consists of the boosts alone, and the other three families are obtained from it by reversing space, time, or both.

13.11.4 Circular and hyperbolic, side by side

The comparison is the point of this section, so here it is in one table. In each column, the isometry group of the named form on $\mathbb{R}^2$.

	O(2): form $\mathbf{I}_2$	O(1,1): form $\operatorname{diag}(1,-1)$
level set $q = 1$	circle $x_1^2 + x_2^2 = 1$	hyperbola $x_1^2 - x_2^2 = 1$, two branches
canonical element	$\mathbf{R}_\theta = \left(\begin{smallmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{smallmatrix}\right)$	$\mathbf{B}_t = \left(\begin{smallmatrix} \cosh t & \sinh t \\ \sinh t & \cosh t \end{smallmatrix}\right)$
parameter	$\theta \in [0, 2\pi)$, periodic	$t \in \mathbb{R}$, unbounded
addition law	$\mathbf{R}_\alpha\mathbf{R}_\beta = \mathbf{R}_{\alpha+\beta}$	$\mathbf{B}_s\mathbf{B}_t = \mathbf{B}_{s+t}$
determinant $+1$ part	$\mathrm{SO}(2) = \{\mathbf{R}_\theta\}$	$\{\mathbf{B}_t\} \cup \{-\mathbf{B}_t\}$
determinant -1 part	reflections $\mathbf{M}_\theta$	$\{\mathbf{B}_t\mathbf{D}\} \cup \{-\mathbf{B}_t\mathbf{D}\}$
number of pieces	2	4
entries	all of modulus ≤ 1	unbounded

The two canonical forms differ in one place only: $\mathbf{R}_\theta$ carries a minus sign that $\mathbf{B}_t$ does not, and that single sign is the difference between $\cos^2 + \sin^2 = 1$ and $\cosh^2 - \sinh^2 = 1$. Everything else

in the table follows from it. In particular the last row is the unboundedness that Section 10 recorded when it observed, without proof, that $\mathrm{O}(p,q)$ is not compact for $p,q \geq 1$ while $\mathrm{O}(n)$ is.

> *Remark.* In the physical reading, $\tanh t$ is a velocity measured in units of the speed of light, and the additivity $\mathbf{B}_s\mathbf{B}_t = \mathbf{B}_{s+t}$ of rapidities becomes the relativistic law for adding velocities. Exercise (C1) derives the formula from the theorem. The book verifies the algebra and stops there.

13.11.5 The triangle inequality, reversed

For a timelike $\mathbf{x}$ the number $q(\mathbf{x})$ is positive, so it has a positive square root, and the analogy with a norm is irresistible. Write

$$\tau(\mathbf{x}) \coloneqq \sqrt{q(\mathbf{x})} \qquad (\mathbf{x} \text{ timelike}).$$

The analogy holds, but with every inequality upside down. First the tool.

Lemma 13.11.2 — Reversed Cauchy–Schwarz Inequality

Let $\mathbf{x}, \mathbf{y} \in \mathbb{R}^{1,3}$ be timelike and both future-pointing. Then

$$\eta(\mathbf{x},\mathbf{y}) \geq \tau(\mathbf{x})\tau(\mathbf{y}) > 0,$$

with equality if and only if $\mathbf{y} = \lambda\mathbf{x}$ for some $\lambda > 0$.

> *Idea.* Split each vector as a time coordinate plus a space part, $\mathbf{x} = (a, \mathbf{u})$. Timelike and future-pointing says $a > \|\mathbf{u}\| \geq 0$. Then $\eta(\mathbf{x},\mathbf{y}) = ab - \mathbf{u}\cdot\mathbf{w}$, and Theorem 10.1.5 bounds $\mathbf{u}\cdot\mathbf{w}$ by $\|\mathbf{u}\|\|\mathbf{w}\|$ — in the helpful direction, since it appears with a minus sign. What is left is to compare $ab - \|\mathbf{u}\|\|\mathbf{w}\|$ with $\tau(\mathbf{x})\tau(\mathbf{y})$, and squaring both sides turns the difference into a perfect square.

> *Proof.* Write $\mathbf{x} = (a,\mathbf{u})$ and $\mathbf{y} = (b,\mathbf{w})$ with $a, b \in \mathbb{R}$ and $\mathbf{u}, \mathbf{w} \in \mathbb{R}^3$, so that $q(\mathbf{x}) = a^2 - \|\mathbf{u}\|^2$ and $\eta(\mathbf{x},\mathbf{y}) = ab - \mathbf{u}\cdot\mathbf{w}$. Timelike gives $a^2 > \|\mathbf{u}\|^2$ and $b^2 > \|\mathbf{w}\|^2$, and future-pointing gives $a, b > 0$; hence $a > \|\mathbf{u}\| \geq 0$ and $b > \|\mathbf{w}\| \geq 0$, so $ab > \|\mathbf{u}\|\|\mathbf{w}\| \geq 0$. By Theorem 10.1.5 in $\mathbb{R}^3$,
>
> $$\eta(\mathbf{x},\mathbf{y}) = ab - \mathbf{u}\cdot\mathbf{w} \geq ab - \|\mathbf{u}\|\|\mathbf{w}\| > 0.$$
>
> Both sides of the inequality to be proved are now known positive, so it suffices to compare squares. Expanding,
>
> $$\begin{aligned} &\big(ab - \|\mathbf{u}\|\|\mathbf{w}\|\big)^2 - q(\mathbf{x})q(\mathbf{y}) \\ &\quad = a^2\|\mathbf{w}\|^2 + b^2\|\mathbf{u}\|^2 - 2ab\|\mathbf{u}\|\|\mathbf{w}\| \\ &\quad = \big(a\|\mathbf{w}\| - b\|\mathbf{u}\|\big)^2 \geq 0. \end{aligned}$$
>
> Therefore $ab - \|\mathbf{u}\|\|\mathbf{w}\| \geq \sqrt{q(\mathbf{x})q(\mathbf{y})} = \tau(\mathbf{x})\tau(\mathbf{y})$, and combining with the previous display gives $\eta(\mathbf{x},\mathbf{y}) \geq \tau(\mathbf{x})\tau(\mathbf{y}) > 0$.
>
> For the equality case, equality forces both steps to be equalities: $\mathbf{u}\cdot\mathbf{w} = \|\mathbf{u}\|\|\mathbf{w}\|$ and $a\|\mathbf{w}\| = b\|\mathbf{u}\|$. Suppose first $\mathbf{u} = \mathbf{0}$. Then $a\|\mathbf{w}\| = 0$ and $a > 0$, so $\mathbf{w} = \mathbf{0}$, and $\mathbf{y} = (b,\mathbf{0}) = (b/a)\mathbf{x}$ with $b/a > 0$. Suppose instead $\mathbf{u} \neq \mathbf{0}$. The equality case of

Theorem 10.1.5 makes $(\mathbf{u}, \mathbf{w})$ dependent, so $\mathbf{w} = \lambda\mathbf{u}$ with $\lambda \in \mathbb{R}$, and then $\mathbf{u} \cdot \mathbf{w} = \lambda\|\mathbf{u}\|^2 = \|\mathbf{u}\|\|\mathbf{w}\| = |\lambda|\|\mathbf{u}\|^2$ forces $\lambda \geq 0$. Now $a\|\mathbf{w}\| = b\|\mathbf{u}\|$ reads $a\lambda\|\mathbf{u}\| = b\|\mathbf{u}\|$, so $b = \lambda a$ and $\mathbf{y} = \lambda\mathbf{x}$; and $\lambda > 0$ because $b > 0$. Conversely, if $\mathbf{y} = \lambda\mathbf{x}$ with $\lambda > 0$ then $\eta(\mathbf{x}, \mathbf{y}) = \lambda q(\mathbf{x})$ and $\tau(\mathbf{x})\tau(\mathbf{y}) = \sqrt{\lambda^2 q(\mathbf{x})^2} = \lambda q(\mathbf{x})$, so equality holds. This proves the lemma.

■

Theorem 13.11.3 — Reversed Triangle Inequality

Let $\mathbf{x}, \mathbf{y} \in \mathbb{R}^{1,3}$ be timelike and both future-pointing. Then $\mathbf{x} + \mathbf{y}$ is timelike and future-pointing, and

$$\tau(\mathbf{x} + \mathbf{y}) \geq \tau(\mathbf{x}) + \tau(\mathbf{y}),$$

with equality if and only if $\mathbf{y}$ is a positive multiple of $\mathbf{x}$.

Proof. By Theorem 13.3.5, $q(\mathbf{x} + \mathbf{y}) = q(\mathbf{x}) + 2\eta(\mathbf{x}, \mathbf{y}) + q(\mathbf{y})$. By Lemma 13.11.2, $\eta(\mathbf{x}, \mathbf{y}) \geq \tau(\mathbf{x})\tau(\mathbf{y})$, so

$$q(\mathbf{x} + \mathbf{y}) \geq q(\mathbf{x}) + 2\tau(\mathbf{x})\tau(\mathbf{y}) + q(\mathbf{y}) = \big(\tau(\mathbf{x}) + \tau(\mathbf{y})\big)^2,$$

where the last step uses $q = \tau^2$ on timelike vectors. The right-hand side is positive, so $\mathbf{x} + \mathbf{y}$ is timelike; its first coordinate is a sum of two positive numbers, so it is future-pointing. Both sides of the last display are non-negative, so taking square roots preserves the inequality and gives $\tau(\mathbf{x} + \mathbf{y}) \geq \tau(\mathbf{x}) + \tau(\mathbf{y})$. Equality holds exactly when it holds in Lemma 13.11.2, that is, exactly when $\mathbf{y} = \lambda\mathbf{x}$ with $\lambda > 0$. This proves the theorem.

■

Remark. Compare Corollary 10.1.6, which gives $\|\mathbf{u}+\mathbf{v}\| \leq \|\mathbf{u}\|+\|\mathbf{v}\|$ in an inner product space, and Theorem 0.6.4, its ancestor in $\mathbb{C}$. Same shape, opposite direction: the reversal is produced by the single sign change in the form, and by nothing else.

Read as a statement about clocks, the reversed inequality says that a journey made in two straight legs accumulates *less* elapsed time than the single straight leg between the same endpoints, which is the algebra behind the twin paradox; whether that algebra describes the world is a question for physics, and this book answers only the algebra.

Quick check. Where exactly would the proof of Theorem 13.11.3 break if $\mathbf{x}$ were future-pointing and $\mathbf{y}$ past-pointing?

Solution. At Lemma 13.11.2, whose proof uses $a, b > 0$ to get $ab > \|\mathbf{u}\|\|\mathbf{w}\| \geq 0$. With $b < 0$ we have $ab < 0$, and $\eta(\mathbf{x}, \mathbf{y}) = ab - \mathbf{u} \cdot \mathbf{w}$ can be negative, so the chain collapses at its first step. The conclusion genuinely fails: take $\mathbf{x} = (1, 0, 0, 0)$ and $\mathbf{y} = (-1, 0, 0, 0)$, both timelike with $\tau = 1$, whose sum is $\mathbf{0}$ and is not timelike at all.

13.11.6 Exercises

13.11.6.1 A. Check your understanding

Exercise A1.

(a) State the sign convention used in this section, give the matrix of η in the standard basis, and say what its signature and inertia are.

(b) Define timelike, null and spacelike, and say which earlier notion the word "null" renames.

(c) True or false: the sum of two spacelike vectors is spacelike. Justify your answer.

(d) Write down $\det \mathbf{B}_t$ and $\mathbf{B}_t^{-1}$, and say which row of the comparison table each answer sits in.

(e) True or false: $\mathrm{O}(1,1)$ is abelian. Justify your answer.

Solution.

(a) The convention is $(+,-,-,-)$, so $[\eta]_{\mathcal{E}} = \mathrm{diag}(1,-1,-1,-1)$, with signature $(1,3)$ and inertia $(1,3,0)$ (Definition 13.5.1). The opposite convention $(-,+,+,+)$ uses $-\eta$ and has signature $(3,1)$.

(b) For $\mathbf{x} \neq \mathbf{0}$: timelike means $q(\mathbf{x}) > 0$, null means $q(\mathbf{x}) = 0$, spacelike means $q(\mathbf{x}) < 0$ (Definition 13.11.2). "Null" renames "non-zero isotropic vector" (Definition 13.7.1).

(c) False. Take $\mathbf{x} = (1,2,0,0)$ and $\mathbf{y} = (1,-2,0,0)$, with $q(\mathbf{x}) = q(\mathbf{y}) = 1 - 4 = -3 < 0$. Their sum is $(2,0,0,0)$, with $q = 4 > 0$, which is timelike.

(d) $\det \mathbf{B}_t = 1$ by Theorem 13.11.1 with $\mu = 1$, and $\mathbf{B}_t^{-1} = \mathbf{B}_{-t}$, since $\mathbf{B}_t\mathbf{B}_{-t} = \mathbf{B}_0 = \mathbf{I}_2$. The first sits in the "determinant $+1$ part" row, the second in the "addition law" row, which is what makes $t \mapsto \mathbf{B}_t$ a group homomorphism.

(e) False. $\mathbf{B}_1$ and $\mathbf{D} = \mathrm{diag}(1,-1)$ both lie in $\mathrm{O}(1,1)$, and $\mathbf{B}_1\mathbf{D}$ has $(1,2)$ entry $-\sinh 1$ while $\mathbf{D}\mathbf{B}_1$ has $(1,2)$ entry $\sinh 1$; these differ since $\sinh 1 \neq 0$.

13.11.6.2 B. Practice

Exercise B1.

Determine which of the following lie in $\mathrm{O}(1,1)$. For each one that does, give its rapidity t and the signs ε, μ of Theorem 13.11.1. Justify your answer.

$$\mathbf{A}_1 = \begin{pmatrix} 5/3 & 4/3 \\ 4/3 & 5/3 \end{pmatrix}, \quad \mathbf{A}_2 = \begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix}, \quad \mathbf{A}_3 = \begin{pmatrix} 5/3 & -4/3 \\ 4/3 & -5/3 \end{pmatrix}.$$

Solution. Write $\mathbf{D} = \mathrm{diag}(1,-1)$ and test $\mathbf{P}^{\top}\mathbf{D}\mathbf{P} = \mathbf{D}$ column by column, using $q(\mathbf{p}_1) = 1$, $q(\mathbf{p}_2) = -1$, $\eta_2(\mathbf{p}_1, \mathbf{p}_2) = 0$.

$\mathbf{A}_1$: $(5/3)^2 - (4/3)^2 = (25-16)/9 = 1$; $(4/3)^2 - (5/3)^2 = -1$; $(5/3)(4/3) - (4/3)(5/3) = 0$. So $\mathbf{A}_1 \in \mathrm{O}(1,1)$. Here $\sinh t = 4/3$ and $\cosh t = 5/3$, so $\varepsilon = \mu = 1$ and $\mathbf{A}_1 = \mathbf{B}_t$ with $t = \log 3$, since $\cosh(\log 3) = \frac{1}{2}(3 + \frac{1}{3}) = 5/3$ and $\sinh(\log 3) = \frac{1}{2}(3 - \frac{1}{3}) = 4/3$.

$\mathbf{A}_2$: $2^2 - 1^2 = 3 \neq 1$, so the first column already fails and $\mathbf{A}_2 \notin \mathrm{O}(1,1)$. (Indeed

$\mathbf{A}_2^{\top}\mathbf{D}\mathbf{A}_2 = \operatorname{diag}(3,-3) = 3\mathbf{D}$, so $\mathbf{A}_2$ scales the form rather than preserving it.)

$\mathbf{A}_3$: first column as for $\mathbf{A}_1$; second column $(-4/3)^2 - (-5/3)^2 = -1$; and $(5/3)(-4/3) - (4/3)(-5/3) = 0$. So $\mathbf{A}_3 \in \mathrm{O}(1,1)$, with $t = \log 3$, $\varepsilon = 1$ and $\mu = \det \mathbf{A}_3 = -25/9 + 16/9 = -1$; that is, $\mathbf{A}_3 = \mathbf{B}_{\log 3}\mathbf{D}$.

Exercise B2.

(a) Classify $\mathbf{x} = (3,1,2,2)$, $\mathbf{y} = (1,0,1,0)$ and $\mathbf{z} = (0,1,1,1)$ in $\mathbb{R}^{1,3}$ as timelike, null or spacelike.

(b) The vector $\mathbf{y}$ is null. Find a $\mathbf{w} \in \mathbb{R}^{1,3}$ such that $(\mathbf{y}, \mathbf{w})$ is a basis of a hyperbolic plane, that is, $q(\mathbf{w}) = 0$ and $\eta(\mathbf{y}, \mathbf{w}) = 1$.

Solution.

(a) $q(\mathbf{x}) = 9 - 1 - 4 - 4 = 0$, so $\mathbf{x}$ is null. $q(\mathbf{y}) = 1 - 0 - 1 - 0 = 0$, so $\mathbf{y}$ is null. $q(\mathbf{z}) = 0 - 1 - 1 - 1 = -3 < 0$, so $\mathbf{z}$ is spacelike.

(b) Try $\mathbf{w} = (c, 0, -c, 0)$, which has $q(\mathbf{w}) = c^2 - c^2 = 0$ for every c. Then $\eta(\mathbf{y}, \mathbf{w}) = 1 \cdot c - 1 \cdot (-c) = 2c$, so $c = \frac{1}{2}$ works: $\mathbf{w} = (\frac{1}{2}, 0, -\frac{1}{2}, 0)$. The Gram matrix of $(\mathbf{y}, \mathbf{w})$ is $\left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$, so $\operatorname{span}(\mathbf{y}, \mathbf{w})$ is a hyperbolic plane (Definition 13.7.3).

Exercise B3.

Let $\mathbf{x} = (5,3,0,0)$ and $\mathbf{y} = (13,12,0,0)$ in $\mathbb{R}^{1,3}$. Compute $\tau(\mathbf{x})$, $\tau(\mathbf{y})$, $\eta(\mathbf{x}, \mathbf{y})$ and $\tau(\mathbf{x}+\mathbf{y})$, and check Lemma 13.11.2 and Theorem 13.11.3 on this pair. Is either inequality an equality?

Solution. $q(\mathbf{x}) = 25 - 9 = 16$, so $\mathbf{x}$ is timelike and future-pointing with $\tau(\mathbf{x}) = 4$. $q(\mathbf{y}) = 169 - 144 = 25$, so $\tau(\mathbf{y}) = 5$. Next $\eta(\mathbf{x}, \mathbf{y}) = 5 \cdot 13 - 3 \cdot 12 = 65 - 36 = 29$, and $\tau(\mathbf{x})\tau(\mathbf{y}) = 20$, so $29 \geq 20$ as Lemma 13.11.2 requires. Finally $\mathbf{x} + \mathbf{y} = (18, 15, 0, 0)$ with $q = 324 - 225 = 99$, so $\tau(\mathbf{x} + \mathbf{y}) = \sqrt{99}$. Since $9^2 = 81 < 99$, we get $\tau(\mathbf{x} + \mathbf{y}) > 9 = \tau(\mathbf{x}) + \tau(\mathbf{y})$, as Theorem 13.11.3 requires. Neither is an equality, and indeed $\mathbf{y}$ is not a multiple of $\mathbf{x}$, since $13/5 \neq 12/3$.

13.11.6.3 C. Going deeper

Exercise C1.

For $t \in \mathbb{R}$ put $v(t) = \tanh t = \sinh t / \cosh t$.

(a) Prove that $v \colon \mathbb{R} \to (-1, 1)$ is a bijection, and that $\mathbf{B}_t \mathbf{e}_1$ is a positive multiple of $(1, v(t), 0, 0)$ read in $\mathbb{R}^{1,1}$.

(b) Hence deduce that $v(s+t) = \dfrac{v(s) + v(t)}{1 + v(s)v(t)}$, and say which part of Theorem 13.11.1 does the work.

Solution.

(a) Since $\cosh t > 0$ and $\cosh^2 t - \sinh^2 t = 1$, we have $|\sinh t| < \cosh t$, so $|v(t)| < 1$ and

v maps into $(-1,1)$. For injectivity and surjectivity, solve $v(t)=c$ with $|c|<1$: the equations $\sinh t = c\cosh t$ and $\cosh^2 t-\sinh^2 t=1$ give $\cosh^2 t(1-c^2)=1$, so $\cosh t=(1-c^2)^{-1/2}$, which is a legitimate value since it is ≥ 1, and then $\sinh t = c(1-c^2)^{-1/2}$ determines t uniquely because sinh is a bijection. So each c has exactly one preimage.
In $\mathbb{R}^{1,1}$, $\mathbf{B}_t\mathbf{e}_1=(\cosh t,\sinh t)=\cosh t\,(1,v(t))$, and $\cosh t>0$.

(b) By Theorem 13.11.1, $\mathbf{B}_s\mathbf{B}_t=\mathbf{B}_{s+t}$. Comparing entries,

$$v(s+t)=\frac{\sinh(s+t)}{\cosh(s+t)}=\frac{\sinh s\cosh t+\cosh s\sinh t}{\cosh s\cosh t+\sinh s\sinh t},$$

and dividing numerator and denominator by $\cosh s\cosh t>0$ gives $(v(s)+v(t))/(1+v(s)v(t))$. The work is done by the addition law $\mathbf{B}_s\mathbf{B}_t=\mathbf{B}_{s+t}$; the parametrization merely renames t as $v(t)$, and because v is a bijection onto $(-1,1)$ no information is lost in the renaming.

Exercise C2.

(a) Prove that $\{\mathbf{P}\mathbf{e}_1:\mathbf{P}\in \mathrm{O}(1,1)\}$ is the set of all $\mathbf{x}\in\mathbb{R}^{1,1}$ with $q(\mathbf{x})=1$, and that this set is unbounded.

(b) Deduce that no bound $|p_{ij}|\leq c$ holds for all $\mathbf{P}\in\mathrm{O}(1,1)$, and contrast this with $\mathrm{O}(2)$, where $|p_{ij}|\leq 1$ always. Which hypothesis of Chapter 10's $\mathrm{O}(2)$ theory is responsible?

Solution.

(a) ($\subseteq$) If $\mathbf{P}\in\mathrm{O}(1,1)$ then $q(\mathbf{P}\mathbf{e}_1)=(\mathbf{P}\mathbf{e}_1)^{\top}\mathbf{D}(\mathbf{P}\mathbf{e}_1)=\mathbf{e}_1^{\top}\mathbf{P}^{\top}\mathbf{D}\mathbf{P}\mathbf{e}_1=\mathbf{e}_1^{\top}\mathbf{D}\mathbf{e}_1=1$. ($\supseteq$) If $q(\mathbf{x})=1$, the proof of Theorem 13.11.1 shows $\mathbf{x}=(\varepsilon\cosh t,\sinh t)$ for some t and sign ε; then $\mathbf{x}$ is the first column of $\mathbf{B}_t$ when $\varepsilon=1$, and of $-\mathbf{B}_{-t}$ when $\varepsilon=-1$, and both lie in $\mathrm{O}(1,1)$. The set is unbounded because $\cosh t\to\infty$ as $t\to\infty$.

(b) The first column of $\mathbf{P}$ ranges over an unbounded set by (a), so its entries are unbounded, and no such c exists; this is the unboundedness Section 10 recorded, obtained here from the orbit rather than from a one-parameter family. In $\mathrm{O}(2)$ the columns are unit vectors for the Euclidean norm, so every entry has modulus at most 1 and the group sits inside a bounded region. The responsible hypothesis is **positive definiteness** of the form: it is what makes $q(\mathbf{x})=1$ a bounded set, namely the unit sphere. Once one sign is reversed, the level set is a hyperbola and nothing is bounded.

Exercise C3.

The Quick check above showed that $\mathbb{R}^{1,3}$ has no plane on which the form vanishes identically. Show that $\mathbb{R}^{2,2}$ does have one, by exhibiting two vectors that span it, and reconcile the two answers with Theorem 13.7.5.

Hint: pair each positive coordinate with a negative one.

Solution. In $\mathbb{R}^{2,2}$ the form is $\eta'(\mathbf{x},\mathbf{y})=x_1y_1+x_2y_2-x_3y_3-x_4y_4$. Put $\mathbf{u}=(1,0,1,0)$

and $\mathbf{w} = (0, 1, 0, 1)$. Then

$$q(\mathbf{u}) = 1 - 1 = 0, \quad q(\mathbf{w}) = 1 - 1 = 0, \quad \eta'(\mathbf{u}, \mathbf{w}) = 0,$$

the last because every term pairs a zero with something. The list $(\mathbf{u}, \mathbf{w})$ is independent, since a relation $a\mathbf{u} + b\mathbf{w} = \mathbf{0}$ reads $(a, b, a, b) = \mathbf{0}$. So $\operatorname{span}(\mathbf{u}, \mathbf{w})$ is a totally isotropic plane, and by bilinearity η' vanishes on all of it.

The reconciliation: by Definition 13.7.4 the Witt index bounds the dimension of a totally isotropic subspace, it counts the hyperbolic planes of Theorem 13.7.5, and over $\mathbb{R}$ it equals $\min(n_+, n_-)$ (Proposition 13.7.7). For $\mathbb{R}^{1,3}$ this is $\min(1, 3) = 1$, so totally isotropic subspaces are lines at most; for $\mathbb{R}^{2,2}$ it is $\min(2, 2) = 2$, so a totally isotropic plane is exactly what one should expect, and the two vectors above realize it. What differs is not the dimension 4 but how evenly the four signs are split.

13.12 A First Look at Clifford Algebras

The chapter ends with a construction rather than a classification. Everything so far has taken a quadratic form apart; this section asks instead for an algebra in which the form becomes a *square*, so that $q(\mathbf{v})$ is literally $\mathbf{v}$ times $\mathbf{v}$ for a multiplication we invent. The answer is a Clifford algebra, and two of the most familiar algebras in mathematics are its first two examples. This is an introduction only: we define the object, prove what the definition alone gives, work three cases out completely, and stop.

13.12.1 Making a form into a square

Take $V = \mathbb{R}^2$ with the negative definite form $q(\mathbf{x}) = -(x_1^2 + x_2^2)$, and suppose we had an associative multiplication on some larger space containing V, with an identity 1, in which every vector satisfies $\mathbf{v}^2 = q(\mathbf{v}) \cdot 1$. Write ϵ_1, ϵ_2 for the two standard basis vectors sitting inside that algebra. Expanding $\mathbf{v} = x_1\epsilon_1 + x_2\epsilon_2$ and using only bilinearity of the product,

$$\mathbf{v}^2 = x_1^2\epsilon_1^2 + x_1x_2(\epsilon_1\epsilon_2 + \epsilon_2\epsilon_1) + x_2^2\epsilon_2^2.$$

We want this to equal $-(x_1^2 + x_2^2) \cdot 1$ for **every** x_1, x_2. Taking $x_2 = 0$ forces $\epsilon_1^2 = -1$, and taking $x_1 = 0$ forces $\epsilon_2^2 = -1$. What is left is $x_1x_2(\epsilon_1\epsilon_2 + \epsilon_2\epsilon_1) = 0$ for all x_1, x_2, which forces

$$\epsilon_1\epsilon_2 = -\epsilon_2\epsilon_1.$$

So the two basis vectors must square to -1 and must **anticommute**. That last relation hands us a third square root of -1 we did not ask for, since $(\epsilon_1\epsilon_2)^2 = \epsilon_1\epsilon_2\epsilon_1\epsilon_2 = -\epsilon_1^2\epsilon_2^2 = -1$. Three anticommuting square roots of -1: those are Hamilton's quaternions. Run the same argument on a one-dimensional V with $q(x) = -x^2$ and the single relation $\epsilon_1^2 = -1$ produces $\mathbb{C}$.

A Clifford algebra is the smallest place where the vectors of V can be multiplied and each one squares to its own q-value.

13.12.2 Algebras

The objects above are algebras, a word the book has used informally and now needs precisely.

Definition 13.12.1 — Algebra over a Field

An **algebra over** F, or an F**-algebra**, is a vector space A over F together with a map $A \times A \to A$, written $(x, y) \mapsto xy$, which is

(A1) **bilinear**: linear in each argument with the other fixed;
(A2) **associative**: $(xy)z = x(yz)$ for all $x, y, z \in A$;
(A3) **unital**: there is an element $1_A \in A$ with $1_A x = x 1_A = x$ for every $x \in A$.

A **homomorphism of** F**-algebras** is an F-linear map $\varphi\colon A \to B$ with $\varphi(xy) = \varphi(x)\varphi(y)$ for all x, y and $\varphi(1_A) = 1_B$. An **isomorphism** is a bijective homomorphism.

Every algebra here is associative and unital, and we stop saying so. The examples are old friends: F itself; $M_n(F)$; $F[x]$; $\mathcal{L}(V)$ under composition; and $\mathbb{C}$ over $\mathbb{R}$, of dimension 2. A non-example by minimal change: $\mathbb{R}^3$ with the cross product is bilinear but fails (A2) and (A3), since $(\mathbf{e}_1 \times \mathbf{e}_1) \times \mathbf{e}_2 = \mathbf{0}$ while $\mathbf{e}_1 \times (\mathbf{e}_1 \times \mathbf{e}_2) = -\mathbf{e}_2$, and no vector acts as an identity.

One consequence of (A1) is used constantly below: a bilinear map is determined by its values on a basis, so two products agree, and a linear map is multiplicative, as soon as this is checked on basis elements.

13.12.3 The definition

Definition 13.12.2 — Clifford Algebra

Let F be a field with $\operatorname{char} F \neq 2$, let V be a finite-dimensional F-vector space, let β be a symmetric bilinear form on V and let $q(\mathbf{v}) = \beta(\mathbf{v}, \mathbf{v})$ be its quadratic form (Definition 13.3.2). A **Clifford algebra** of (V, q) is a pair (C, ι), where C is an F-algebra and $\iota\colon V \to C$ is a linear map, such that

(C1) $\iota(\mathbf{v})^2 = q(\mathbf{v}) 1_C$ for **every** $\mathbf{v} \in V$;
(C2) (**universal property**) for every F-algebra A and every linear map $f\colon V \to A$ with $f(\mathbf{v})^2 = q(\mathbf{v}) 1_A$ for every $\mathbf{v} \in V$, there is a **unique** algebra homomorphism $\bar{f}\colon C \to A$ with $\bar{f} \circ \iota = f$.

We write $\mathrm{Cl}(q)$, or $\mathrm{Cl}(V, q)$, for a Clifford algebra of (V, q), and $\mathrm{Cl}_{p,m}(\mathbb{R})$ when V is the space $\mathbb{R}^{p,m}$ of Definition 13.11.1, that is, $\mathbb{R}^{p+m}$ with the real form of signature (p, m).

Clause by clause. (C1) is the demand we started from: inside C every vector has a square, and that square is a *number* times the identity, not a vector. (C2) says C is the most economical algebra with that property. Any other algebra where the vectors square correctly receives a map from C, so C has no relations beyond those (C1) forces; and the map is unique, so C has no room to spare either. What is defined is the pair (C, ι), not C alone.

> *Remark.* The subscripts in $\mathrm{Cl}_{p,m}(\mathbb{R})$ are usually written p, q, but q already names the quadratic form here, so the second index is m.

Existence is deferred. The definition says what a Clifford algebra would be; it does not

produce one. The standard construction is not available yet: one takes the **tensor algebra** of V — the infinite-dimensional algebra whose elements are formal sums of strings of vectors, multiplied by concatenation — and divides out by the relations $\mathbf{v}\otimes\mathbf{v}-q(\mathbf{v})1$. Chapter 14 builds tensor algebras and carries this out, for every V and q at once. So everything below is of one of two kinds: a consequence of the definition, valid whenever a Clifford algebra exists, or an explicit algebra written down by hand, which proves existence in that case. We say which each time.

The first consequence is that "the" Clifford algebra is legitimate language.

Proposition 13.12.1 — Uniqueness of the Clifford Algebra

Let (C,ι) and (C',ι') both be Clifford algebras of (V,q). Then there is a unique algebra isomorphism $\varphi\colon C\to C'$ with $\varphi\circ\iota=\iota'$.

Idea. Each one's universal property produces a map to the other. The two composites are self-maps that do nothing to ι, and the uniqueness clause says the only such self-map is the identity.

Proof. Since (C',ι') satisfies (C1), the universal property (C2) of C, applied with $A=C'$ and $f=\iota'$, gives an algebra homomorphism $\varphi\colon C\to C'$ with $\varphi\iota=\iota'$. Symmetrically, (C2) for C' gives $\psi\colon C'\to C$ with $\psi\iota'=\iota$. Then $\psi\varphi\colon C\to C$ is an algebra homomorphism with $\psi\varphi\iota=\psi\iota'=\iota$. The identity id_C is another one. By the uniqueness clause of (C2) for C, applied with $A=C$ and $f=\iota$, the two coincide: $\psi\varphi=\mathrm{id}_C$. Swapping the roles of C and C' gives $\varphi\psi=\mathrm{id}_{C'}$. Hence φ is an isomorphism, and it is unique because (C2) already delivers it uniquely. This proves the proposition. ∎

Next, the identity that does all the computing.

Lemma 13.12.2 — The Anticommutation Relation

Let (C,ι) be a Clifford algebra of (V,q). Then for all $\mathbf{u},\mathbf{v}\in V$,

$$\iota(\mathbf{u})\iota(\mathbf{v})+\iota(\mathbf{v})\iota(\mathbf{u})=2\beta(\mathbf{u},\mathbf{v})1_C.$$

In particular $\iota(\mathbf{u})$ and $\iota(\mathbf{v})$ anticommute whenever $\beta(\mathbf{u},\mathbf{v})=0$.

Proof. By (C1) applied to $\mathbf{u}+\mathbf{v}$, and then bilinearity of the product together with linearity of ι,

$$q(\mathbf{u}+\mathbf{v})1_C=\iota(\mathbf{u}+\mathbf{v})^2=\iota(\mathbf{u})^2+\iota(\mathbf{u})\iota(\mathbf{v})+\iota(\mathbf{v})\iota(\mathbf{u})+\iota(\mathbf{v})^2.$$

By Theorem 13.3.5, $q(\mathbf{u}+\mathbf{v})=q(\mathbf{u})+2\beta(\mathbf{u},\mathbf{v})+q(\mathbf{v})$, and by (C1) again $\iota(\mathbf{u})^2=q(\mathbf{u})1_C$ and $\iota(\mathbf{v})^2=q(\mathbf{v})1_C$. Canceling those two terms from both sides leaves the stated identity. The last sentence is the case $\beta(\mathbf{u},\mathbf{v})=0$. ∎

So an **orthogonal** basis for β becomes a list of pairwise anticommuting elements of C, each with a scalar square. That is the whole computational content of a Clifford algebra, and Theorem 13.4.2 guarantees such a basis exists whenever $\operatorname{char} F \neq 2$ — which is where the characteristic hypothesis in Definition 13.12.2 earns its place, since Theorem 13.3.5 needs it too.

13.12.4 Three algebras, worked out

Example. (The zero space)

Let $V = \{\mathbf{0}\}$, so $q = 0$ and $n = 0$. Show that (F, ι) with $\iota = 0$ is a Clifford algebra of (V, q), so that $\mathrm{Cl}(0) = F$.

Solution. (C1): the only vector is $\mathbf{0}$, and $\iota(\mathbf{0})^2 = 0 = q(\mathbf{0})1_F$.

(C2): let A be an F-algebra and $f\colon V \to A$ linear, necessarily $f = 0$, so the condition on f reads $0 = 0$. Define $\bar{f}\colon F \to A$ by $\bar{f}(a) = a1_A$: it is linear, sends 1 to 1_A, and is multiplicative because $\bar{f}(ab) = (ab)1_A = (a1_A)(b1_A)$ by bilinearity of the product and $1_A 1_A = 1_A$; and $\bar{f}\iota = 0 = f$. It is unique, since any algebra homomorphism $\varphi\colon F \to A$ is linear with $\varphi(1) = 1_A$, hence $\varphi(a) = a1_A$.

So $\mathrm{Cl}(0) = F$, of dimension $1 = 2^0$: the construction adds nothing when there is nothing to add.

Example. (The complex numbers)

Let $V = \mathbb{R}$ with $q(x) = -x^2$, the form of signature $(0, 1)$. Show that $\mathbb{C}$, with $\iota\colon \mathbb{R} \to \mathbb{C}$ given by $\iota(x) = xi$, is a Clifford algebra of (V, q), so that $\mathrm{Cl}_{0,1}(\mathbb{R}) = \mathbb{C}$.

Solution. Here $\mathbb{C}$ is an algebra over $\mathbb{R}$ of dimension 2, with basis $(1, i)$.

(C1): $\iota(x)^2 = (xi)^2 = x^2 i^2 = -x^2 = q(x) \cdot 1$.

(C2): let A be a real algebra and $f\colon \mathbb{R} \to A$ linear with $f(x)^2 = -x^2 1_A$. Put $u = f(1)$, so $f(x) = xu$ by linearity and $u^2 = -1_A$. Define $\bar{f}\colon \mathbb{C} \to A$ by $\bar{f}(a + bi) = a1_A + bu$, which is $\mathbb{R}$-linear and sends 1 to 1_A. To see it is multiplicative, note that $(z, w) \mapsto \bar{f}(zw)$ and $(z, w) \mapsto \bar{f}(z)\bar{f}(w)$ are both $\mathbb{R}$-bilinear, so it suffices to compare them on the basis $(1, i)$: the pairs involving 1 are immediate, and $\bar{f}(i \cdot i) = \bar{f}(-1) = -1_A = u^2 = \bar{f}(i)\bar{f}(i)$. Finally $\bar{f}\iota(x) = \bar{f}(xi) = xu = f(x)$. For uniqueness, an algebra homomorphism φ with $\varphi\iota = f$ has $\varphi(1) = 1_A$ and $\varphi(i) = \varphi(\iota(1)) = f(1) = u$, and $(1, i)$ spans $\mathbb{C}$, so $\varphi = \bar{f}$.

So $\mathrm{Cl}_{0,1}(\mathbb{R}) = \mathbb{C}$, of dimension $2 = 2^1$. Read this backwards: $\mathbb{C}$ is not primarily "$\mathbb{R}$ with a square root of -1 attached", it is the smallest algebra in which the number x squares to $-x^2$.

For the two-dimensional case we need the quaternions, and we need them to be associative. The cheapest way to get associativity is to find them inside a matrix algebra, where it is free.

Definition 13.12.3 — The Quaternions

Inside $M_2(\mathbb{C})$, regarded as an algebra over $\mathbb{R}$, put

$$\mathbf{i} = \begin{pmatrix} i & 0 \\ 0 & -i \end{pmatrix}, \quad \mathbf{j} = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}, \quad \mathbf{k} = \begin{pmatrix} 0 & i \\ i & 0 \end{pmatrix}.$$

The **quaternions** $\mathbb{H}$ are the real span of $\mathbf{I}_2, \mathbf{i}, \mathbf{j}, \mathbf{k}$ in $M_2(\mathbb{C})$.

The three matrices carry Hamilton's names and are written bold lowercase, as basis vectors of $\mathbb{H}$; the plain i in their entries is the complex unit, which is a different object from the matrix $\mathbf{i}$. Multiplying them out gives

$$\mathbf{i}^2 = \mathbf{j}^2 = \mathbf{k}^2 = -\mathbf{I}_2, \qquad \mathbf{ij} = \mathbf{k} = -\mathbf{ji},$$

and then $\mathbf{jk} = \mathbf{i} = -\mathbf{kj}$ and $\mathbf{ki} = \mathbf{j} = -\mathbf{ik}$. A real combination $a\mathbf{I}_2 + b\mathbf{i} + c\mathbf{j} + d\mathbf{k}$ is the matrix with rows $(a+bi,\ c+di)$ and $(-c+di,\ a-bi)$, which vanishes only when $a = b = c = d = 0$; so $\dim_{\mathbb{R}} \mathbb{H} = 4$. The relations show the span is closed under multiplication, so $\mathbb{H}$ is a real subalgebra of $M_2(\mathbb{C})$ — and it is associative for free, because matrix multiplication is.

Example. (The quaternions)

Let $V = \mathbb{R}^2$ with $q(\mathbf{x}) = -(x_1^2 + x_2^2)$, the form of signature $(0, 2)$. Show that $\mathbb{H}$, with $\iota(\mathbf{x}) = x_1\mathbf{i} + x_2\mathbf{j}$, is a Clifford algebra of (V, q), so that $\mathrm{Cl}_{0,2}(\mathbb{R}) = \mathbb{H}$.

Solution. (C1): using $\mathbf{ij} + \mathbf{ji} = \mathbf{0}$ and $\mathbf{i}^2 = \mathbf{j}^2 = -\mathbf{I}_2$,

$$\iota(\mathbf{x})^2 = x_1^2\mathbf{i}^2 + x_1x_2(\mathbf{ij} + \mathbf{ji}) + x_2^2\mathbf{j}^2 = -(x_1^2 + x_2^2)\mathbf{I}_2,$$

which is $q(\mathbf{x})1_{\mathbb{H}}$.

(C2): let A be a real algebra and $f\colon \mathbb{R}^2 \to A$ linear with $f(\mathbf{x})^2 = q(\mathbf{x})1_A$. Put $u = f(\mathbf{e}_1)$ and $w = f(\mathbf{e}_2)$, so $u^2 = w^2 = -1_A$, and by Lemma 13.12.2 — or directly, by expanding $f(\mathbf{e}_1 + \mathbf{e}_2)^2 = -2 \cdot 1_A$ — we get $uw + wu = 0$, that is, $wu = -uw$. Define the linear map

$$\bar{f}(a\mathbf{I}_2 + b\mathbf{i} + c\mathbf{j} + d\mathbf{k}) = a1_A + bu + cw + d\,uw,$$

which is well defined because $(\mathbf{I}_2, \mathbf{i}, \mathbf{j}, \mathbf{k})$ is a basis of $\mathbb{H}$, and sends $1_{\mathbb{H}} = \mathbf{I}_2$ to 1_A. Both $(z, z') \mapsto \bar{f}(zz')$ and $(z, z') \mapsto \bar{f}(z)\bar{f}(z')$ are $\mathbb{R}$-bilinear, so multiplicativity need only be checked on the basis. The pairs involving $\mathbf{I}_2$ are immediate, and the remaining nine are

$$\begin{aligned}
\mathbf{ii} = -\mathbf{I}_2 &\mapsto -1_A = u^2, & \mathbf{jj} = -\mathbf{I}_2 &\mapsto -1_A = w^2,\\
\mathbf{ij} = \mathbf{k} &\mapsto uw, & \mathbf{ji} = -\mathbf{k} &\mapsto -uw = wu,\\
\mathbf{ik} = -\mathbf{j} &\mapsto -w = u(uw), & \mathbf{ki} = \mathbf{j} &\mapsto w = (uw)u,\\
\mathbf{jk} = \mathbf{i} &\mapsto u = w(uw), & \mathbf{kj} = -\mathbf{i} &\mapsto -u = (uw)w,\\
\mathbf{kk} = -\mathbf{I}_2 &\mapsto -1_A = (uw)^2.
\end{aligned}$$

Each right-hand claim is one line of algebra in A, using associativity, $wu = -uw$ and $u^2 = w^2 = -1_A$. For instance $(uw)u = u(wu) = -u(uw) = -u^2w = w$, and $(uw)^2 = u(wu)w = -u^2w^2 = -1_A$.

Finally $\bar{f}\iota(\mathbf{x}) = x_1u + x_2w = f(\mathbf{x})$. For uniqueness, an algebra homomorphism φ with $\varphi\iota = f$ is forced on $\mathbf{I}_2$, on $\mathbf{i} = \iota(\mathbf{e}_1)$ and on $\mathbf{j} = \iota(\mathbf{e}_2)$, hence on $\mathbf{k} = \mathbf{ij}$, and these four span $\mathbb{H}$.

So $\mathrm{Cl}_{0,2}(\mathbb{R}) = \mathbb{H}$, of dimension $4 = 2^2$.

Warning. **A Clifford algebra is not commutative, and a product of two vectors is not a vector.** In $\mathrm{Cl}_{0,2}(\mathbb{R}) = \mathbb{H}$ the image $\iota(\mathbb{R}^2) = \mathrm{span}(\mathbf{i}, \mathbf{j})$ is a plane, and $\mathbf{ij} = \mathbf{k}$ lies outside it; worse, $\mathbf{ij} = -\mathbf{ji}$, so the order matters. Two habits have to go: that multiplying two elements of V keeps you in V, and that $xy = yx$. Beyond the scalars $F \cdot 1_C$, nothing may be assumed to commute.

13.12.5 How big is it

The three examples all came out with $\dim = 2^n$. Half of that is a theorem we can prove.

Proposition 13.12.3 — The Clifford Algebra Is Spanned by Sorted Products

Let (C, ι) be a Clifford algebra of (V, q), where $\dim V = n$ and $\mathrm{char}\, F \neq 2$, and let $(\mathbf{e}_1, \dots, \mathbf{e}_n)$ be an orthogonal basis of V for β. Then C is spanned over F by the 2^n products

$$\iota(\mathbf{e}_{i_1})\iota(\mathbf{e}_{i_2}) \cdots \iota(\mathbf{e}_{i_k}), \qquad 1 \le i_1 < i_2 < \cdots < i_k \le n,$$

one for each subset $\{i_1, \dots, i_k\}$ of $\{1, \dots, n\}$, the empty product being 1_C. In particular $\dim_F C \le 2^n$.

Idea. Two steps. ① Show that C is generated as an algebra by 1_C and $\iota(V)$ — this is not automatic, and it is where the *uniqueness* half of the universal property does its work. ② Sort: any product of basis vectors can be put in increasing order by swapping neighbors at the cost of a sign (Lemma 13.12.2), and a repeated neighbor collapses to a scalar (C1).

Proof. An orthogonal basis exists by Theorem 13.4.2, since $\mathrm{char}\, F \neq 2$. Write $d_i = q(\mathbf{e}_i)$.

Step 1: C is generated by 1_C and $\iota(V)$. Let $C' \subseteq C$ be the set of all F-linear combinations of 1_C and of finite products $\iota(\mathbf{v}_1) \cdots \iota(\mathbf{v}_m)$ with $\mathbf{v}_1, \dots, \mathbf{v}_m \in V$. It is a subspace closed under multiplication and contains 1_C, hence is itself an F-algebra, and ι followed by the change of codomain gives a linear map $\iota' \colon V \to C'$ satisfying (C1). By the universal property of C, applied with $A = C'$ and $f = \iota'$, there is an algebra homomorphism $g \colon C \to C'$ with $g\iota = \iota'$. Let $j \colon C' \to C$ be the inclusion, an algebra homomorphism. Then $jg \colon C \to C$ is an algebra homomorphism with $jg\iota = \iota$, and so is id_C; by the uniqueness clause of (C2), applied with $A = C$ and $f = \iota$, we get $jg = \mathrm{id}_C$. Hence j is surjective, so $C' = C$.

Step 2: sorting. By Step 1 and linearity of ι, C is spanned by 1_C together with the products $\iota(\mathbf{e}_{j_1}) \cdots \iota(\mathbf{e}_{j_m})$ over all finite index strings $(j_1, \dots, j_m)$. Fix such a product and induct on the pair $\big(m, \mathrm{inv}(j_1, \dots, j_m)\big)$, ordered lexicographically, where inv counts the pairs $r < s$ with $j_r > j_s$. If the string is strictly increasing, the product is on the list and we are done. Otherwise some neighboring pair has $j_r \ge j_{r+1}$. If $j_r = j_{r+1}$, then (C1) replaces $\iota(\mathbf{e}_{j_r})^2$ by the scalar d_{j_r}, producing a scalar multiple of a product of length $m - 2$. If $j_r > j_{r+1}$, then Lemma 13.12.2 with $\beta(\mathbf{e}_{j_r}, \mathbf{e}_{j_{r+1}}) = 0$ lets us swap the two factors at the cost of a sign, producing a product of the same length with one fewer

inversion. Either way the induction applies, and the product is a scalar multiple of a listed one.

There are 2^n subsets of $\{1, \dots, n\}$, so the spanning list has 2^n members and $\dim_F C \le 2^n$. This proves the proposition.

■

Quick check. Where exactly does Proposition 13.12.3 use the word **unique** in (C2), and what would go wrong without it?

Solution. In Step 1, at the sentence "by the uniqueness clause of (C2) … we get $jg = \mathrm{id}_C$". Existence alone gives an algebra homomorphism $jg\colon C \to C$ fixing ι, but nothing then makes it the identity, and the argument cannot conclude that j is surjective. The conclusion really would be false. Take $V = \mathbb{R}$ with $q(x) = -x^2$, let $A = \mathbb{C} \times \mathbb{C}$ with componentwise multiplication, and set $\iota(x) = (xi, xi)$. Then $\iota(x)^2 = q(x)1_A$, so (C1) holds, and so does the existence half of (C2): the first projection, followed by the homomorphism $\mathbb{C} \to B$ built in Example (The complex numbers), does the job for every target B. But A is **not** spanned by 1_A and products of vectors, since every such product lies in the diagonal $\{(z, z)\}$, of dimension 2. What fails is uniqueness — the second projection is a second map — and that is the clause the proof needs.

The other half of the count is a different matter.

Theorem 13.12.4 — Dimension of a Clifford Algebra

Let $\mathrm{char}\, F \neq 2$, let $\dim V = n$, and let (C, ι) be a Clifford algebra of (V, q). Then the 2^n sorted products of Proposition 13.12.3 form a **basis** of C, so $\dim_F C = 2^n$. In particular ι is injective.

What is proved here, and what is not. The inequality $\dim_F C \le 2^n$ is Proposition 13.12.3, proved in full. The reverse inequality — that the 2^n sorted products are linearly independent — is **not proved in this section**, and it cannot be, because the definition alone does not even produce an algebra: independence and existence have to be established together, by constructing one algebra of dimension exactly 2^n that satisfies (C1) and (C2). Chapter 14 does that, from the tensor algebra. What this section does establish is the theorem in the three cases above: $n = 0$ with $\dim = 1$, $n = 1$ with $\dim = 2$, and the case $q = -x_1^2 - x_2^2$ of $n = 2$ with $\dim = 4$, each by writing the algebra down and checking (C1) and (C2) by hand. For $n \ge 3$, read the statement above as quoted from Chapter 14 and not as proved here.

Granting the theorem, the subsets of $\{1, \dots, n\}$ indexing the basis are the first sign that $\mathrm{Cl}(q)$ is assembled from the exterior powers $\Lambda^k V$, one for each k. Chapter 14 constructs both and makes that precise.

13.12.6 What Clifford algebras are for

One computation shows where the subject goes. Recall from Section 10 that the isometries of q form a group (Definition 13.10.1). Inside $\mathrm{Cl}(q)$, some of them are conjugations.

Proposition 13.12.5 — Reflections Are Conjugations

Let (C, ι) be a Clifford algebra of (V, q) and let $\mathbf{u} \in V$ with $q(\mathbf{u}) \neq 0$. Then $\iota(\mathbf{u})$ is invertible in C, with inverse $q(\mathbf{u})^{-1}\iota(\mathbf{u})$, and for every $\mathbf{v} \in V$,

$$-\iota(\mathbf{u})\iota(\mathbf{v})\iota(\mathbf{u})^{-1} = \iota\big(s_{\mathbf{u}}(\mathbf{v})\big), \qquad s_{\mathbf{u}}(\mathbf{v}) \coloneqq \mathbf{v} - \frac{2\beta(\mathbf{u},\mathbf{v})}{q(\mathbf{u})}\,\mathbf{u}.$$

The map $s_{\mathbf{u}}$ fixes $\{\mathbf{v} : \beta(\mathbf{u},\mathbf{v}) = 0\}$ pointwise, sends $\mathbf{u}$ to $-\mathbf{u}$, and satisfies $q(s_{\mathbf{u}}(\mathbf{v})) = q(\mathbf{v})$.

Proof. By (C1), $\iota(\mathbf{u})^2 = q(\mathbf{u})1_C$ with $q(\mathbf{u}) \neq 0$, so $\iota(\mathbf{u})\big(q(\mathbf{u})^{-1}\iota(\mathbf{u})\big) = 1_C$ and likewise on the other side. By Lemma 13.12.2, $\iota(\mathbf{u})\iota(\mathbf{v}) = 2\beta(\mathbf{u},\mathbf{v})1_C - \iota(\mathbf{v})\iota(\mathbf{u})$, so multiplying on the right by $\iota(\mathbf{u})$,

$$\iota(\mathbf{u})\iota(\mathbf{v})\iota(\mathbf{u}) = 2\beta(\mathbf{u},\mathbf{v})\iota(\mathbf{u}) - q(\mathbf{u})\iota(\mathbf{v}).$$

Dividing by $q(\mathbf{u})$ and negating gives $-\iota(\mathbf{u})\iota(\mathbf{v})\iota(\mathbf{u})^{-1} = \iota(\mathbf{v}) - \frac{2\beta(\mathbf{u},\mathbf{v})}{q(\mathbf{u})}\iota(\mathbf{u})$, which is $\iota(s_{\mathbf{u}}(\mathbf{v}))$ by linearity of ι. If $\beta(\mathbf{u},\mathbf{v}) = 0$ then $s_{\mathbf{u}}(\mathbf{v}) = \mathbf{v}$; and $s_{\mathbf{u}}(\mathbf{u}) = \mathbf{u} - 2\mathbf{u} = -\mathbf{u}$. Finally, writing $c = 2\beta(\mathbf{u},\mathbf{v})/q(\mathbf{u})$,

$$q(\mathbf{v} - c\mathbf{u}) = q(\mathbf{v}) - 2c\beta(\mathbf{u},\mathbf{v}) + c^2 q(\mathbf{u}) = q(\mathbf{v}),$$

since $c^2 q(\mathbf{u}) = c \cdot 2\beta(\mathbf{u},\mathbf{v})$. This proves the proposition. ∎

So the reflection in a hyperplane, the basic isometry of a quadratic form, is carried out inside $\mathrm{Cl}(q)$ by conjugating with a single vector. Composing such conjugations reaches more isometries, and the invertible elements of $\mathrm{Cl}(q)$ acting on V this way form a group mapping onto the isometry group of q — two-to-one, since $\iota(\mathbf{u})$ and $-\iota(\mathbf{u})$ conjugate alike. That double covering is where **spinors** live: objects the covering group acts on and the isometry group does not, because going once around a rotation returns them with a sign. This book will not build them. What it will do is Chapter 14: construct tensor algebras, construct $\mathrm{Cl}(q)$ from one, and prove Theorem 13.12.4. Nothing later depends on this section, and the chapter ends here.

13.12.7 Exercises

13.12.7.1 A. Check your understanding

Exercise A1.

(a) State the definition of an F-algebra, and give one example of dimension 1 and one of dimension 4.

(b) State the universal property (C2), with every quantifier.

(c) What is $\mathrm{Cl}(0)$ when $V = \{\mathbf{0}\}$, and what is its dimension?

(d) True or false: $\mathrm{Cl}_{0,2}(\mathbb{R})$ is commutative. Justify your answer.

(e) What does this book prove about $\dim \mathrm{Cl}(q)$ when $\dim V = 3$, and what does it

only quote?

Solution.

(a) A vector space over F with a bilinear, associative, unital multiplication (Definition 13.12.1). Dimension 1: F itself. Dimension 4: $M_2(F)$, or $\mathbb{H}$ over $\mathbb{R}$.

(b) For every F-algebra A and every linear $f\colon V \to A$ such that $f(\mathbf{v})^2 = q(\mathbf{v})1_A$ for every $\mathbf{v} \in V$, there exists a unique algebra homomorphism $\bar{f}\colon C \to A$ such that $\bar{f} \circ \iota = f$.

(c) $\mathrm{Cl}(0) = F$, of dimension $1 = 2^0$ (Example (The zero space)).

(d) False. It is $\mathbb{H}$ by Example (The quaternions), and $\mathbf{ij} = \mathbf{k} \neq -\mathbf{k} = \mathbf{ji}$.

(e) It proves $\dim \mathrm{Cl}(q) \leq 2^3 = 8$, by Proposition 13.12.3. The equality $\dim \mathrm{Cl}(q) = 8$, and indeed the existence of $\mathrm{Cl}(q)$ at all, is quoted from Chapter 14.

13.12.7.2 B. Practice

Exercise B1: The split case.

Let $V = \mathbb{R}$ with $q(x) = x^2$, the form of signature $(1, 0)$. Let $A = \mathbb{R} \times \mathbb{R}$ with componentwise addition and multiplication, and $\iota\colon \mathbb{R} \to A$, $\iota(x) = (x, -x)$. Prove that (A, ι) is a Clifford algebra of (V, q), and state its dimension.

Solution. A is a real algebra of dimension 2 with identity $1_A = (1, 1)$, and $\big(1_A, \iota(1)\big) = \big((1, 1), (1, -1)\big)$ is a basis, since $a(1, 1) + b(1, -1) = (a + b, a - b)$ vanishes only for $a = b = 0$.

(C1): $\iota(x)^2 = (x^2, x^2) = q(x)1_A$.

(C2): let B be a real algebra and $f\colon \mathbb{R} \to B$ linear with $f(x)^2 = x^2 1_B$. Put $u = f(1)$, so $f(x) = xu$ and $u^2 = 1_B$. Define $\bar{f}(a, b) = \frac{a+b}{2}1_B + \frac{a-b}{2}u$, which is linear and sends 1_A to 1_B and $\iota(1)$ to u. By bilinearity, multiplicativity need only be checked on that basis: the pairs involving 1_A are immediate, and $\iota(1)^2 = 1_A \mapsto 1_B = u^2$. Also $\bar{f}\iota(x) = xu = f(x)$, and any such homomorphism is forced on 1_A and $\iota(1)$, which span A.

So $\mathrm{Cl}_{1,0}(\mathbb{R}) = \mathbb{R} \times \mathbb{R}$, of dimension $2 = 2^1$. Comparing with Example (The complex numbers): the same one-dimensional V with the opposite sign of q gives $\mathbb{C}$ instead, so the Clifford algebra sees the sign of the form, not just its rank.

Exercise B2.

Work in $\mathrm{Cl}_{0,2}(\mathbb{R}) = \mathbb{H}$, with $\iota(\mathbf{x}) = x_1\mathbf{i} + x_2\mathbf{j}$. Let $\mathbf{u} = (1, 2)$ and $\mathbf{v} = (3, -1)$.

(a) Compute $\iota(\mathbf{u})\iota(\mathbf{v})$ and $\iota(\mathbf{v})\iota(\mathbf{u})$, and verify Lemma 13.12.2 on this pair.

(b) Compute $q(\mathbf{u})$, verify $\iota(\mathbf{u})^2 = q(\mathbf{u})1_{\mathbb{H}}$, and write down $\iota(\mathbf{u})^{-1}$.

Solution.

(a) Using $\mathbf{i}^2 = \mathbf{j}^2 = -1$ and $\mathbf{ij} = \mathbf{k} = -\mathbf{ji}$, and writing 1 for $\mathbf{I}_2$,

$$\iota(\mathbf{u})\iota(\mathbf{v}) = (\mathbf{i}+2\mathbf{j})(3\mathbf{i}-\mathbf{j}) = -3-\mathbf{k}-6\mathbf{k}+2 = -1-7\mathbf{k},$$
$$\iota(\mathbf{v})\iota(\mathbf{u}) = (3\mathbf{i}-\mathbf{j})(\mathbf{i}+2\mathbf{j}) = -3+6\mathbf{k}+\mathbf{k}+2 = -1+7\mathbf{k}.$$

Their sum is -2. On the other side, $\beta(\mathbf{u},\mathbf{v}) = -(1\cdot 3 + 2\cdot(-1)) = -1$, so $2\beta(\mathbf{u},\mathbf{v})1_{\mathbb{H}} = -2$. The two agree.

(b) $q(\mathbf{u}) = -(1+4) = -5$. And $\iota(\mathbf{u})^2 = (\mathbf{i}+2\mathbf{j})^2 = -1+2\mathbf{k}-2\mathbf{k}-4 = -5$, as required. Hence $\iota(\mathbf{u})^{-1} = q(\mathbf{u})^{-1}\iota(\mathbf{u}) = -\frac{1}{5}(\mathbf{i}+2\mathbf{j})$ by Proposition 13.12.5.

Exercise B3.

In $\mathbb{R}^{0,2}$ let $\mathbf{u} = \mathbf{e}_1$ and $\mathbf{v} = \mathbf{e}_1 + \mathbf{e}_2$. Compute the reflection $s_{\mathbf{u}}(\mathbf{v})$ directly from the formula in Proposition 13.12.5, then compute $-\iota(\mathbf{u})\iota(\mathbf{v})\iota(\mathbf{u})^{-1}$ inside $\mathbb{H}$, and check that the two agree.

Solution. Here $\beta(\mathbf{x},\mathbf{y}) = -(x_1y_1 + x_2y_2)$, so $\beta(\mathbf{u},\mathbf{v}) = -1$ and $q(\mathbf{u}) = -1$. The formula gives

$$s_{\mathbf{u}}(\mathbf{v}) = \mathbf{v} - \frac{2(-1)}{-1}\mathbf{u} = \mathbf{v} - 2\mathbf{u} = -\mathbf{e}_1 + \mathbf{e}_2.$$

In $\mathbb{H}$: $\iota(\mathbf{u}) = \mathbf{i}$, $\iota(\mathbf{v}) = \mathbf{i}+\mathbf{j}$, and $\iota(\mathbf{u})^{-1} = q(\mathbf{u})^{-1}\mathbf{i} = -\mathbf{i}$. Hence

$$-\mathbf{i}(\mathbf{i}+\mathbf{j})(-\mathbf{i}) = \mathbf{i}(\mathbf{i}+\mathbf{j})\mathbf{i} = (-1+\mathbf{k})\mathbf{i} = -\mathbf{i}+\mathbf{ki} = -\mathbf{i}+\mathbf{j},$$

using $\mathbf{ki} = \mathbf{j}$. That is $\iota(-\mathbf{e}_1+\mathbf{e}_2)$, which agrees with $\iota(s_{\mathbf{u}}(\mathbf{v}))$. Geometrically $s_{\mathbf{u}}$ negates the $\mathbf{e}_1$ coordinate and fixes the $\mathbf{e}_2$ one, which is what the answer shows.

13.12.7.3 C. Going deeper

Exercise C1: A Clifford algebra of matrices.

In $M_2(\mathbb{R})$ put $\mathbf{E}_1 = \left(\begin{smallmatrix}1&0\\0&-1\end{smallmatrix}\right)$ and $\mathbf{E}_2 = \left(\begin{smallmatrix}0&1\\-1&0\end{smallmatrix}\right)$, and let $V = \mathbb{R}^2$ carry the form $q(\mathbf{x}) = x_1^2 - x_2^2$ of signature $(1,1)$, with $f(\mathbf{x}) = x_1\mathbf{E}_1 + x_2\mathbf{E}_2$.

(a) Prove that $f(\mathbf{x})^2 = q(\mathbf{x})\mathbf{I}_2$ for every $\mathbf{x}$, and that $(\mathbf{I}_2, \mathbf{E}_1, \mathbf{E}_2, \mathbf{E}_1\mathbf{E}_2)$ is a basis of $M_2(\mathbb{R})$.

(b) Assume a Clifford algebra (C,ι) of (V,q) exists. Deduce that $C \cong M_2(\mathbb{R})$, and hence that $\dim C = 4$.

Hint for (b): the homomorphism the universal property hands you has a surjective image; then count.

Solution.

(a) A direct multiplication gives $\mathbf{E}_1^2 = \mathbf{I}_2$, $\mathbf{E}_2^2 = -\mathbf{I}_2$ and

$$\mathbf{E}_1\mathbf{E}_2 = \begin{pmatrix}0&1\\1&0\end{pmatrix} = -\mathbf{E}_2\mathbf{E}_1,$$

so $\mathbf{E}_1\mathbf{E}_2 + \mathbf{E}_2\mathbf{E}_1 = \mathbf{0}$ and

$$f(\mathbf{x})^2 = x_1^2\mathbf{E}_1^2 + x_1x_2(\mathbf{E}_1\mathbf{E}_2 + \mathbf{E}_2\mathbf{E}_1) + x_2^2\mathbf{E}_2^2 = (x_1^2 - x_2^2)\mathbf{I}_2.$$

For the basis: $a\mathbf{I}_2 + b\mathbf{E}_1 + c\mathbf{E}_2 + d\mathbf{E}_1\mathbf{E}_2$ is the matrix with rows $(a+b,\ c+d)$ and $(-c+d,\ a-b)$, and setting all four entries to zero forces $a = b = c = d = 0$. Four independent vectors in the 4-dimensional space $M_2(\mathbb{R})$ form a basis.

(b) By (a) and the universal property (C2) with $A = M_2(\mathbb{R})$, there is an algebra homomorphism $\bar{f}\colon C \to M_2(\mathbb{R})$ with $\bar{f}\iota = f$. Its image is a subalgebra containing $\mathbf{I}_2$, $\mathbf{E}_1 = f(\mathbf{e}_1)$ and $\mathbf{E}_2 = f(\mathbf{e}_2)$, hence also $\mathbf{E}_1\mathbf{E}_2$; by (a) those four span $M_2(\mathbb{R})$, so $\bar{f}$ is surjective and $\dim C \geq 4$. On the other hand $\dim C \leq 2^2 = 4$ by Proposition 13.12.3. Therefore $\dim C = 4$ and $\bar{f}$ is a surjective linear map between spaces of equal finite dimension, hence bijective, hence an algebra isomorphism. So $\mathrm{Cl}_{1,1}(\mathbb{R}) \cong M_2(\mathbb{R})$.

Exercise C2: Why characteristic 2 is excluded.

Explain why Definition 13.12.2 assumes $\mathrm{char}\, F \neq 2$, by naming the first statement of this section that fails without it and saying what replaces the missing input.

Solution. The first casualty is Lemma 13.12.2, whose proof cites Theorem 13.3.5 for $q(\mathbf{u}+\mathbf{v}) = q(\mathbf{u}) + 2\beta(\mathbf{u},\mathbf{v}) + q(\mathbf{v})$ — and that identity is how β is recovered from q, by a division by 2 that is unavailable in characteristic 2. Without it, the relation $\iota(\mathbf{u})\iota(\mathbf{v}) + \iota(\mathbf{v})\iota(\mathbf{u}) = 2\beta(\mathbf{u},\mathbf{v})1_C$ collapses to $\iota(\mathbf{u})\iota(\mathbf{v}) + \iota(\mathbf{v})\iota(\mathbf{u}) = 0$ and carries no information about the form at all. Proposition 13.12.3 then loses its sorting step in the form given, and Theorem 13.4.2, which supplied the orthogonal basis, has the same hypothesis.

What is missing is a definition. In characteristic 2 a quadratic form is not the same data as a symmetric bilinear form — Section 3 warned exactly this — so a quadratic form must be defined in its own right, as a function $q\colon V \to F$ with $q(a\mathbf{v}) = a^2q(\mathbf{v})$ whose associated $\beta(\mathbf{u},\mathbf{v}) = q(\mathbf{u}+\mathbf{v}) - q(\mathbf{u}) - q(\mathbf{v})$ is bilinear. Clifford algebras are defined in that setting too, by the same (C1) and (C2), but this book does not define quadratic forms there and so does not go on.

Chapter 14

Tensors and Exterior Algebra

Three times already this book has built an object out of one construction and then walked past the construction without naming it. Chapter 6 characterized the determinant as the **unique** alternating n-linear form sending the standard basis to 1 (Theorem 6.4.2), and got a number out of a function of n vectors. Chapter 7 defined the Kronecker product $\mathbf{A} \otimes \mathbf{B}$ by writing $\mathbf{A}$ with its entries replaced by blocks, borrowed the symbol $\otimes$, and admitted that the symbol was borrowed from something it had not yet met. Chapter 13 defined a Clifford algebra by saying what maps out of it must look like, proved that at most one such algebra exists, and then could not produce one: the construction needed an algebra of "formal sums of strings of vectors", and no such algebra had been built. The missing object is the same in all three places. It is the **tensor product**, and this chapter builds it.

The problem it solves is stated in one line. A bilinear map $\beta\colon V \times W \to Z$ is not a linear map, so nothing from Chapters 3 to 5 applies to it: it has no matrix, no kernel, no rank, and $\beta(2\mathbf{v}, 2\mathbf{w})$ is $4\beta(\mathbf{v}, \mathbf{w})$ rather than $2\beta(\mathbf{v}, \mathbf{w})$. Multilinearity is everywhere in the book — the determinant, the dot product, matrix multiplication, every bilinear form of Chapter 13 — and each time we have had to develop it by hand, because the general theory of linear maps was unavailable. The tensor product ends that. It manufactures a single space $V \otimes W$ and a single bilinear map $(\mathbf{v}, \mathbf{w}) \mapsto \mathbf{v} \otimes \mathbf{w}$ into it, through which **every** bilinear map out of $V \times W$ factors, uniquely, as a linear map. Bilinear maps on $V \times W$ become linear maps on $V \otimes W$. From there the whole chapter is bookkeeping: repeat the construction k times to get the tensor algebra, then divide it by the relation $\mathbf{v} \otimes \mathbf{w} = \mathbf{w} \otimes \mathbf{v}$ to get symmetric powers, or by the relation $\mathbf{v} \otimes \mathbf{v} = 0$ to get exterior powers, where the determinant reappears as an induced map and the Clifford algebra finally gets built.

The method of this chapter is new, and §02 is where it is learned. Until now every object in the book was defined by a formula or by a construction: the determinant by the Leibniz sum, the quotient by cosets, the Jordan form by an algorithm. From here on we define objects by what maps out of them look like — a **universal property** — and the order of business inverts. First we say what the object must do; then we prove that any two objects doing it are isomorphic by a *unique* isomorphism, so that "the" object is legitimate; and only then do we build one, to know that the definition is not empty. Chapter 13 §12 already ran this argument once, for Clifford algebras (Proposition 13.12.1), without saying that it was a pattern. It is a pattern. Sections 02, 06, 07, 08 and 10 each execute it in exactly the same three moves, on five different objects. Theorem 14.2.1 in §02 is the template, written out at full length; the four later repetitions are compressed, and they are compressed on purpose, so that the reader who has absorbed the template recognizes it rather than rereads it. It is worth learning here because it

is the only way to define these objects that does not depend on a choice of basis, and because a proof from a universal property is usually three lines long where a proof from a construction is a page.

The field is a general F throughout. Where a statement genuinely needs $\operatorname{char} F = 0$ or $\operatorname{char} F \neq 2$ — and some do, in §§07, 08 and 10 — the hypothesis is stated and its job is named, as Chapter 13 did. Everything else holds over every field.

What you need. From Chapter 3, quotient spaces and their universal property, which is the engine of every construction here (Definition 3.9.3, Lemma 3.9.3, Theorem 3.9.4, Theorem 3.9.10, Theorem 3.9.5, Theorem 3.9.7), together with the space of linear maps and its dimension (Definition 3.4.1, Theorem 3.4.1, Theorem 3.6.4), the matrix of a map (Definition 3.6.1, Theorem 3.6.1), products of spaces (Definition 3.9.1, Theorem 3.9.1), rank (Definition 3.3.2, Theorem 3.3.1) and the trace (Definition 3.10.2, Theorem 3.7.5). From Chapter 1, bases in any dimension and the freedom to prescribe a linear map on one (Definition 1.5.1, Theorem 1.6.4, Theorem 1.8.2, Theorem 3.1.6, Theorem 1.2.1). From Chapter 4, duality, used constantly: Definition 4.1.2, Definition 4.1.1, Theorem 4.1.3, Theorem 4.1.5, Definition 4.4.1, Theorem 4.4.2, Theorem 4.4.6. From Chapter 6, multilinearity and alternation, which §01 extends rather than redefines (Definition 6.2.1, Definition 6.2.2, Definition 6.2.3, Theorem 6.2.1, Theorem 6.2.2), and the determinant with its Leibniz formula and multiplicativity (Definition 6.4.1, Theorem 6.4.3, Theorem 6.4.2, Theorem 6.5.4, Theorem 6.4.5, Theorem 6.6.1, Theorem 6.7.1). From Chapter 7, the Kronecker product, whose two open promises §03 pays (Definition 7.4.1, Theorem 7.4.1, Theorem 7.4.3, Definition 7.4.2, Theorem 7.4.4). From Chapter 12, the singular value decomposition, which §11 turns out to be reading in another language (Theorem 12.8.1). From Chapter 13, algebras, forms and the Clifford algebra whose existence §10 supplies (Definition 13.12.1, Definition 13.1.1, Definition 13.3.2, Definition 13.3.1, Definition 13.12.2, Proposition 13.12.1, Proposition 13.12.3, Theorem 13.12.4). From Chapter 5, the polynomial ring, which §07 identifies with a symmetric algebra (Definition 0.8.2).

14.0.1 Roadmap

- **Multilinear maps.** Chapter 6's multilinear forms, extended from $V^k \to F$ to $V_1 \times \cdots \times V_k \to W$; the space they form, its dimension $\dim W \cdot \prod_i \dim V_i$, and the problem that they are not linear maps.
- **The tensor product.** The universal property, uniqueness up to unique isomorphism, the construction as a free space modulo the bilinearity relations, the basis $(\mathbf{v}_i \otimes \mathbf{w}_j)$, and three warnings about what a tensor is not.
- **Tensor products of maps.** $S \otimes T$ built from the universal property; its matrix is exactly the Kronecker product of Chapter 7, which settles two debts; and the identification $V^* \otimes W \cong \mathcal{L}(V, W)$ that everything later uses.
- **Contraction.** Evaluation $V^* \otimes V \to F$, extended to mixed tensors, and the discovery that under the previous identification it is the trace — the basis-free definition of trace the book has wanted since Chapter 3.
- **Index notation.** Components, upper and lower indices, the summation convention, the transformation law derived rather than asserted, and the older definition of a tensor proved equivalent to ours.
- **The tensor algebra.** $T(V) = \bigoplus_k V^{\otimes k}$: graded, associative, non-commutative, infinite-dimensional, and free. Its universal property is what the next three sections quotient.
- **Symmetric powers.** $\operatorname{Sym}^k V$ by killing $\mathbf{v} \otimes \mathbf{w} - \mathbf{w} \otimes \mathbf{v}$; a basis indexed by non-decreasing tuples; the symmetric algebra is the polynomial ring of Chapter 5; and what goes wrong in characteristic p.

- **Exterior powers.** $\Lambda^k V$ by killing $\mathbf{v} \otimes \mathbf{v}$ — the characteristic-free choice, exactly Chapter 13's distinction between alternating and skew. A basis indexed by increasing tuples, $\dim \Lambda^k V = \binom{n}{k}$, and the test that $\mathbf{v}_1 \wedge \cdots \wedge \mathbf{v}_k \neq 0$ exactly when the list is independent.
- **The determinant, again.** $\Lambda^n V$ is a line, and $\Lambda^n T$ is multiplication by $\det T$. Multiplicativity becomes a one-line consequence, Laplace expansion falls out of Λ^k, and the coordinates of a wedge are the minors.
- **Grassmann and Clifford.** The exterior algebra ΛV, of dimension 2^n; elements of $\Lambda^2 V$ that are not decomposable; and $\mathrm{Cl}(q) = T(V)/\langle \mathbf{v} \otimes \mathbf{v} - q(\mathbf{v})1 \rangle$, which constructs the Clifford algebra of Chapter 13 and proves its dimension is 2^n.
- **Tensors in quantum mechanics.** Composite systems as tensor products, entanglement as failure of simplicity, and the Schmidt decomposition, which is the singular value decomposition of Chapter 12 wearing different notation.

14.0.2 Named moves

- **Define by universal property, then build a model.** State what maps out of the object must look like. Prove that any two objects with that property are isomorphic by a unique isomorphism, using nothing but the property itself. Then construct one object, so that the definition has content. The uniqueness proof is always the same four lines: each object's property produces a map to the other, each composite is a self-map fixing the structure map, and the uniqueness clause says the identity is the only such self-map.
- **A quotient kills exactly the relations you want.** To impose relations on a space, take the free object, take the subspace spanned by the relations written as "left side minus right side", and divide. A map respecting the relations kills that subspace, so it factors through the quotient. This chapter does it three times: tensor, symmetric, exterior.
- **To define a map out of a quotient, define it upstairs first.** Never define a map on cosets, or on simple tensors, by a formula and hope it is well defined. Define it on the free object, where a map may be prescribed arbitrarily on a basis, check that it kills the relations, and let the universal property hand you the induced map.
- **Count a basis by counting index tuples.** Every dimension formula in this chapter comes from counting tuples: all k-tuples for $V^{\otimes k}$, giving n^k; non-decreasing ones for $\mathrm{Sym}^k V$, giving $\binom{n+k-1}{k}$; strictly increasing ones for $\Lambda^k V$, giving $\binom{n}{k}$. Spanning is a rewriting argument, independence is a supply of linear functionals, and the count is combinatorics.

14.1 Multilinear Maps

Chapter 6 needed functions of several vectors that were linear in each vector separately, and called them multilinear forms (Definition 6.2.1). Every one of them landed in the field F: the determinant, the signed area, a product of functionals. This chapter needs the same idea with the output allowed to be any vector space, because three of the most familiar operations in the book — matrix multiplication, composition of linear maps, the cross product — are linear in each argument and return something that is not a scalar. So we begin by extending Chapter 6's definition, count how many such maps there are, and then state the problem that the rest of the chapter exists to solve: a multilinear map is **not** a linear map, so none of the machinery of Chapters 3 to 5 is available to it.

Throughout, F is a field, $k \geq 1$ is an integer, and all vector spaces are over F. From the third

subsection on, every space named is finite-dimensional.

14.1.1 From forms to maps

Here are three operations the book has used constantly.

- **Matrix multiplication.** For fixed sizes, $(\mathbf{A}, \mathbf{B}) \mapsto \mathbf{AB}$ satisfies $(\mathbf{A}+\mathbf{A}')\mathbf{B} = \mathbf{AB}+\mathbf{A}'\mathbf{B}$ and $\mathbf{A}(\mathbf{B}+\mathbf{B}') = \mathbf{AB}+\mathbf{AB}'$, and scalars pull out of either factor.
- **Composition of linear maps.** $(S, T) \mapsto ST$ satisfies the same four rules.
- **The cross product** on $\mathbb{R}^3$, which is linear in each factor and returns a vector.

Each is linear in one argument while the other is held fixed. Each therefore looks exactly like Definition 6.2.1 with $k = 2$ — except that the value is a matrix, a linear map or a vector, not a scalar. Chapter 6 had no reason to allow that, because it was building the determinant. We do, so we widen the definition. Nothing about Chapter 6's statements changes; a multilinear **form** will simply be the special case where the target is F, and we will keep using Definition 6.2.1 by that name whenever the target really is F.

A multilinear map is a function of several vectors that is linear in each one while the others are held fixed, with values in a vector space rather than in the field.

Definition 14.1.1 — Multilinear Map

Let $V_1, \dots, V_k$ and W be vector spaces over the **same** field F, with $k \geq 1$. A function

$$\beta \colon V_1 \times V_2 \times \cdots \times V_k \to W$$

is **k-linear**, or a **multilinear map**, if **for every** position $i \in \{1, \dots, k\}$ and **every** choice of fixed vectors $\mathbf{v}_j \in V_j$ for the positions $j \neq i$, the function

$$V_i \to W, \qquad \mathbf{x} \mapsto \beta(\mathbf{v}_1, \dots, \mathbf{v}_{i-1}, \mathbf{x}, \mathbf{v}_{i+1}, \dots, \mathbf{v}_k),$$

is linear. A 2-linear map is called **bilinear**.

When $V_1 = \cdots = V_k = V$ we say β is k-linear **on** V; when in addition $W = F$, the definition is word for word Definition 6.2.1, and we call β a multilinear **form**.

In words, clause by clause. **Same field:** all $k+1$ spaces are over one F, since otherwise "linear" would mean different things in different slots. **For every position:** the condition is imposed k separate times, once per slot. **Every choice of fixed vectors:** the other $k-1$ arguments are frozen at arbitrary values, not at convenient ones. **Is linear:** written out, for all $\mathbf{x}, \mathbf{y} \in V_i$ and all $c \in F$,

$$\beta(\dots, \mathbf{x}+\mathbf{y}, \dots) = \beta(\dots, \mathbf{x}, \dots) + \beta(\dots, \mathbf{y}, \dots),$$
$$\beta(\dots, c\mathbf{x}, \dots) = c\,\beta(\dots, \mathbf{x}, \dots),$$

where the dots stand for the same frozen vectors on both sides. The spaces $V_1, \dots, V_k$ are allowed to be different from each other and from W; nothing forces k to be related to any dimension.

Two consequences are free. Putting $c = 0$ in slot i gives $\beta(\dots, \mathbf{0}, \dots) = \mathbf{0}$: a multilinear map kills any tuple with a zero entry. And by induction on the number of terms, expanding one slot

at a time,

$$\beta\Big(\sum_{i_1} a_{i_1}\mathbf{x}_{i_1},\ \ldots,\ \sum_{i_k} a_{i_k}\mathbf{y}_{i_k}\Big) = \sum_{i_1,\ldots,i_k} a_{i_1}\cdots a_{i_k}\,\beta(\mathbf{x}_{i_1},\ldots,\mathbf{y}_{i_k}),$$

a sum over all tuples of indices, one index per slot. This identity is the whole of the section: it says that a multilinear map is determined by its values on tuples drawn from spanning sets, and that the number of such tuples is a product, not a sum.

Example. (Seven functions of several vectors)

Decide which of the following are multilinear, and with which k.

(a) Any linear map $T\colon V \to W$, viewed as a function of one vector.

(b) Scalar multiplication $F \times V \to V$, $(c, \mathbf{v}) \mapsto c\mathbf{v}$, with F regarded as a vector space over itself.

(c) Matrix multiplication $M_{m\times n}(F) \times M_{n\times p}(F) \to M_{m\times p}(F)$, $(\mathbf{A}, \mathbf{B}) \mapsto \mathbf{AB}$.

(d) Composition $\mathcal{L}(W, Z) \times \mathcal{L}(V, W) \to \mathcal{L}(V, Z)$, $(S, T) \mapsto ST$.

(e) The determinant $(F^n)^n \to F$ sending $(\mathbf{a}_1, \ldots, \mathbf{a}_n)$ to $\det \mathbf{A}$, where $\mathbf{A}$ has columns $\mathbf{a}_1, \ldots, \mathbf{a}_n$.

(f) The evaluation pairing $V^* \times V \to F$, $(\varphi, \mathbf{v}) \mapsto \varphi(\mathbf{v})$.

(g) The cross product $\mathbb{R}^3 \times \mathbb{R}^3 \to \mathbb{R}^3$.

Solution.

(a) With $k = 1$ there is one position and no other argument to freeze, so the condition reads: $\mathbf{x} \mapsto T\mathbf{x}$ is linear. That is the hypothesis. So a 1-linear map is **exactly** a linear map (Definition 3.1.1), and Definition 14.1.1 generalizes it.

(b) Fix $\mathbf{v}$. Then $c \mapsto c\mathbf{v}$ is linear by (VS6) and (VS7) of Definition 1.1.1, which give $(a + b)\mathbf{v} = a\mathbf{v} + b\mathbf{v}$ and $a(c\mathbf{v}) = (ac)\mathbf{v}$. Fix c. Then $\mathbf{v} \mapsto c\mathbf{v}$ is linear by (VS5) and (VS7), the second of which gives $c(a\mathbf{v}) = (ca)\mathbf{v} = (ac)\mathbf{v} = a(c\mathbf{v})$, using that F is commutative. So scalar multiplication is bilinear. It is the smallest interesting example, and it shows that the two input spaces need not be equal.

(c) Fix $\mathbf{B}$. Then $\mathbf{A} \mapsto \mathbf{AB}$ is linear, since $(\mathbf{A}+\mathbf{A}')\mathbf{B} = \mathbf{AB}+\mathbf{A}'\mathbf{B}$ and $(c\mathbf{A})\mathbf{B} = c(\mathbf{AB})$ by Theorem 0.9.4. Fixing $\mathbf{A}$ gives the other slot. So matrix multiplication is bilinear, with three different spaces in play when m, n, p differ.

(d) Same check, with Theorem 3.4.2 (a) supplying linearity of ST and Theorem 3.4.2 (d) supplying the two slots. Bilinear.

(e) The determinant is n-linear in the columns, and alternating, by Theorem 6.4.3. It is the standard example of a multilinear form with k equal to the dimension. Here $k = n$ is forced by the shape of a square matrix, not by the definition.

(f) Fix $\mathbf{v}$. Then $\varphi \mapsto \varphi(\mathbf{v})$ is linear because the operations on V^* are pointwise (Definition 4.1.2). Fix φ. Then $\mathbf{v} \mapsto \varphi(\mathbf{v})$ is linear because φ is a linear functional. Bilinear. This one-line example is the source of the contraction operation of a later section.

(g) The cross product of Chapter 6 has components $a_2b_3 - a_3b_2$ and its two cousins, each bilinear as in Example (Alternating Forms) (b). A vector of bilinear functions is bilinear, since linearity in a slot may be checked coordinate by coordinate. So it is bilinear, with values in $\mathbb{R}^3$ — an example that genuinely needs Definition 14.1.1 rather than Definition 6.2.1.

Non-example, by minimal change. Keep $k = 2$, keep $V_1 = V_2 = W = F$, and change multiplication to addition: $\sigma(a, b) = a + b$. Freeze $b = 1$. The resulting function $a \mapsto a + 1$ sends 0 to 1, so it is not linear (Theorem 3.1.1), and the clause "is linear" fails in the first slot. What still works is that σ is linear as a function on the product space $F \times F$ of Definition 3.9.1. That is precisely the distinction the next subsection is about.

Why this definition. One could try to define a "map of several variables" by asking for linearity in all slots at once, that is, by asking for a linear map on $V_1 \times \cdots \times V_k$. The result would be a different and much poorer notion: it would exclude multiplication, composition, the determinant and every inner product, and would include only sums of linear maps applied to the separate slots. Freezing all but one slot is what keeps products in the theory. The name says the same thing: *multi*, once per slot; *linear*, in that slot alone.

14.1.2 Multilinear is not linear

The product $V \times W$ is itself a vector space, with $(\mathbf{v}, \mathbf{w}) + (\mathbf{v}', \mathbf{w}') = (\mathbf{v} + \mathbf{v}', \mathbf{w} + \mathbf{w}')$ and $c(\mathbf{v}, \mathbf{w}) = (c\mathbf{v}, c\mathbf{w})$ (Definition 3.9.1). So a function $\beta\colon V \times W \to Z$ has two different conditions it might satisfy, and they are stated on the same domain. They are not the same condition, and confusing them is the standard first error with tensors.

Side by side, for $\beta\colon V \times W \to Z$:

- **Linear on the product** means $\beta\big((\mathbf{v}, \mathbf{w}) + (\mathbf{v}', \mathbf{w}')\big) = \beta(\mathbf{v}, \mathbf{w}) + \beta(\mathbf{v}', \mathbf{w}')$ and $\beta(c\mathbf{v}, c\mathbf{w}) = c\,\beta(\mathbf{v}, \mathbf{w})$. Both slots move together.
- **Bilinear** means $\beta(\mathbf{v} + \mathbf{v}', \mathbf{w}) = \beta(\mathbf{v}, \mathbf{w}) + \beta(\mathbf{v}', \mathbf{w})$, and the same in the second slot with the first frozen. One slot moves at a time.

Warning. **Do not add in both slots at once.** For a bilinear β, the correct expansion has **four** terms:

$$\beta(\mathbf{v} + \mathbf{v}', \mathbf{w} + \mathbf{w}') = \beta(\mathbf{v}, \mathbf{w}) + \beta(\mathbf{v}, \mathbf{w}') + \beta(\mathbf{v}', \mathbf{w}) + \beta(\mathbf{v}', \mathbf{w}').$$

Concretely, with $\beta(a, b) = ab$ on $F \times F$: $\beta(1 + 1, 1 + 1) = 4$, not $\beta(1, 1) + \beta(1, 1) = 2$. Scaling is worse: $\beta(c\mathbf{v}, c\mathbf{w}) = c^2\beta(\mathbf{v}, \mathbf{w})$, so a bilinear map scales by the **square**. Pull out scalars one slot at a time, always.

Quick check. Is $\beta(\mathbf{x}, \mathbf{y}) = x_1y_1 + x_2$ a bilinear map $F^2 \times F^2 \to F$?

Solution. No. Freeze $\mathbf{y}$. Then $\mathbf{x} \mapsto y_1x_1 + x_2$ is a linear functional, so the first slot is fine. Freeze $\mathbf{x} = \mathbf{e}_2$. Then $\mathbf{y} \mapsto 0 \cdot y_1 + 1 = 1$ is the constant function 1, which sends $\mathbf{0}$ to 1 and so is not linear. The clause that fails is "is linear" at position $i = 2$. The extra summand x_2 does not involve $\mathbf{y}$ at all, and a bilinear map must vanish whenever an argument is $\mathbf{0}$.

14.1.3 Values on basis tuples

A linear map may be prescribed arbitrarily on a basis and is determined by those values (Theorem 3.1.6). The corresponding statement for multilinear maps replaces "basis vectors" by "tuples of basis vectors, one from each slot", and the proof is the expansion identity above read in both directions.

Theorem 14.1.1 — Multilinear Maps from Values on Basis Tuples

Let $V_1, \dots, V_k$ be finite-dimensional, with ordered bases $\mathcal{B}_i = (\mathbf{v}_1^{(i)}, \dots, \mathbf{v}_{n_i}^{(i)})$ for $i = 1, \dots, k$, and let W be any vector space over F. For every family of vectors

$$\mathbf{w}_{i_1 i_2 \dots i_k} \in W, \qquad 1 \le i_1 \le n_1, \ \dots, \ 1 \le i_k \le n_k,$$

there is **exactly one** k-linear map $\beta \colon V_1 \times \cdots \times V_k \to W$ with $\beta(\mathbf{v}_{i_1}^{(1)}, \dots, \mathbf{v}_{i_k}^{(k)}) = \mathbf{w}_{i_1 \dots i_k}$ for every tuple of indices.

Idea. Uniqueness is the expansion identity: write each argument in its basis, expand one slot at a time, and every value of β is a combination of the prescribed ones. For existence we need a formula, and the coefficients in that expansion are exactly the coordinates, which Theorem 4.1.3 supplies as linear functionals. So multiply the right functionals together and use them as coefficients.

Proof. Uniqueness. Let β and β' be k-linear with the same values on all basis tuples, and let $\mathbf{x}_i \in V_i$. Write $\mathbf{x}_i = \sum_j a_j^{(i)} \mathbf{v}_j^{(i)}$. Expanding each slot in turn by Definition 14.1.1,

$$\beta(\mathbf{x}_1, \dots, \mathbf{x}_k) = \sum_{i_1, \dots, i_k} a_{i_1}^{(1)} \cdots a_{i_k}^{(k)} \, \mathbf{w}_{i_1 \dots i_k},$$

and the same computation applies to β'. Hence $\beta = \beta'$.

Existence. For each i, let $(\varphi_1^{(i)}, \dots, \varphi_{n_i}^{(i)})$ be the basis of V_i^* dual to $\mathcal{B}_i$, so that $\varphi_a^{(i)}(\mathbf{v}_b^{(i)}) = \delta_{ab}$ and $\varphi_j^{(i)}(\mathbf{x})$ is the j-th coordinate of $\mathbf{x}$ (Theorem 4.1.3). Define

$$\beta(\mathbf{x}_1, \dots, \mathbf{x}_k) \coloneqq \sum_{i_1, \dots, i_k} \varphi_{i_1}^{(1)}(\mathbf{x}_1) \cdots \varphi_{i_k}^{(k)}(\mathbf{x}_k) \, \mathbf{w}_{i_1 \dots i_k},$$

a finite sum of vectors of W, so a well-defined element of W.

It is k-linear: freeze every slot but the m-th. Each summand is then the vector $\mathbf{w}_{i_1 \dots i_k}$ multiplied by a fixed scalar times $\varphi_{i_m}^{(m)}(\mathbf{x}_m)$, and $\varphi_{i_m}^{(m)}$ is linear; a finite sum of linear functions of $\mathbf{x}_m$, each scaled by a fixed vector, is linear in $\mathbf{x}_m$. This holds for every m, which is the condition of Definition 14.1.1.

Its values are the prescribed ones: at $\mathbf{x}_i = \mathbf{v}_{j_i}^{(i)}$ the coefficient $\varphi_{i_1}^{(1)}(\mathbf{v}_{j_1}^{(1)}) \cdots \varphi_{i_k}^{(k)}(\mathbf{v}_{j_k}^{(k)})$ is 1 when $i_1 = j_1, \dots, i_k = j_k$ and 0 otherwise, so only the term $\mathbf{w}_{j_1 \dots j_k}$ survives. This proves the theorem.

■

So a multilinear map is "nothing but" a family of vectors of W indexed by tuples of basis indices, exactly as a linear map is nothing but a family indexed by single basis indices. The count of tuples is where the product in the next theorem comes from.

14.1.4 The space of multilinear maps

Two multilinear maps with the same slots and the same target can be added and scaled pointwise, and the results are again multilinear. That makes them a vector space, and we name it before counting it.

Definition 14.1.2 — The Space of Multilinear Maps

Let $V_1, \dots, V_k$ and W be vector spaces over F. Write

$$\mathcal{M}(V_1, \dots, V_k; W)$$

for the set of all k-linear maps $V_1 \times \cdots \times V_k \to W$, with the **pointwise** operations

$$(\beta + \gamma)(\mathbf{x}_1, \dots, \mathbf{x}_k) \coloneqq \beta(\mathbf{x}_1, \dots, \mathbf{x}_k) + \gamma(\mathbf{x}_1, \dots, \mathbf{x}_k),$$

and $(c\beta)(\mathbf{x}_1, \dots, \mathbf{x}_k) \coloneqq c\,\beta(\mathbf{x}_1, \dots, \mathbf{x}_k)$. The semicolon separates the inputs from the output.

Well-definedness. The set of *all* functions $V_1 \times \cdots \times V_k \to W$ is a vector space under the pointwise operations, by the argument of Example (The Standard Vector Spaces) (d) with F replaced by W: two functions are equal when they agree at every point, so each axiom is checked one point at a time and reduces to the corresponding axiom in W. Inside it, $\mathcal{M}(V_1, \dots, V_k; W)$ passes Theorem 1.2.1. The zero function is k-linear, since freezing slots leaves the zero map. If β, γ are k-linear and $c \in F$, then freezing all slots but the m-th turns $\beta + \gamma$ and $c\beta$ into a sum and a scalar multiple of linear maps $V_m \to W$, which are linear by Theorem 3.4.1. So $\mathcal{M}(V_1, \dots, V_k; W)$ is a subspace, hence a vector space.

Two special cases are old friends. For $k = 1$, $\mathcal{M}(V; W) = \mathcal{L}(V, W)$ by Example (Seven functions of several vectors) (a). For $W = F$, the elements are the multilinear forms of Definition 6.2.1; Chapter 6 wrote the space of alternating n-linear forms on F^n and proved it one-dimensional (Corollary 6.4.4), which is a subspace of $\mathcal{M}(F^n, \dots, F^n; F)$.

Theorem 14.1.2 — Dimension of the Space of Multilinear Maps

Let $V_1, \dots, V_k$ and W be finite-dimensional, with $\dim V_i = n_i$ and $\dim W = m$. Then $\mathcal{M}(V_1, \dots, V_k; W)$ is finite-dimensional, of dimension

$$\dim \mathcal{M}(V_1, \dots, V_k; W) = (\dim W) \prod_{i=1}^{k} \dim V_i = m\, n_1 n_2 \cdots n_k. \tag{14.1.1}$$

Explicitly, fix bases $\mathcal{B}_i$ of V_i with dual bases $(\varphi_j^{(i)})$, and a basis $(\mathbf{w}_1, \dots, \mathbf{w}_m)$ of W. For a tuple $I = (i_1, \dots, i_k)$ and an index r, let

$$E_I^r(\mathbf{x}_1, \dots, \mathbf{x}_k) \coloneqq \varphi_{i_1}^{(1)}(\mathbf{x}_1) \cdots \varphi_{i_k}^{(k)}(\mathbf{x}_k)\, \mathbf{w}_r.$$

The $m\, n_1 \cdots n_k$ maps E_I^r form a basis of $\mathcal{M}(V_1, \dots, V_k; W)$.

Idea. Theorem 14.1.1 says a multilinear map is the same thing as a list of vectors of W, one per index tuple. So count the lists: there are $n_1 \cdots n_k$ tuples and each entry needs m coordinates. The maps E_I^r are the maps whose list has a single $\mathbf{w}_r$ in position I and zeros elsewhere, which is why they should be the basis.

Proof. Each E_I^r is k-linear by the existence half of Theorem 14.1.1, being the map prescribed to take the value $\mathbf{w}_r$ at the basis tuple $(\mathbf{v}_{i_1}^{(1)}, \dots, \mathbf{v}_{i_k}^{(k)})$ and $\mathbf{0}$ at every other basis tuple.

Spanning. Let $\beta \in \mathcal{M}(V_1, \dots, V_k; W)$. For each tuple I write its value on the corresponding basis tuple in the basis of W:

$$\beta(\mathbf{v}_{i_1}^{(1)}, \dots, \mathbf{v}_{i_k}^{(k)}) = \sum_{r=1}^{m} c_{I,r}\, \mathbf{w}_r,$$

which is possible, and with unique coefficients, since $(\mathbf{w}_1, \dots, \mathbf{w}_m)$ is a basis. The map $\sum_{I,r} c_{I,r} E_I^r$ is k-linear and takes exactly these values on the basis tuples. By the uniqueness half of Theorem 14.1.1 it equals β.

Independence. Suppose $\sum_{I,r} c_{I,r} E_I^r = 0$, the zero map. Evaluate at a basis tuple indexed by J. By the displayed formula for E_I^r, the coefficient $\varphi_{i_1}^{(1)}(\mathbf{v}_{j_1}^{(1)}) \cdots \varphi_{i_k}^{(k)}(\mathbf{v}_{j_k}^{(k)})$ is 1 for $I = J$ and 0 otherwise, so the value is $\sum_r c_{J,r} \mathbf{w}_r = \mathbf{0}$. Since $(\mathbf{w}_r)$ is independent, $c_{J,r} = 0$ for every r. As J was arbitrary, every coefficient vanishes.

Hence the E_I^r form a basis. There are $n_1 n_2 \cdots n_k$ index tuples I and m choices of r, so the count is $m\, n_1 \cdots n_k$, which is Eq. 14.1.1. This proves the theorem.

■

Aftermath. Two sanity checks. With $k = 1$, Eq. 14.1.1 reads $\dim \mathcal{L}(V, W) = (\dim W)(\dim V)$, which is Theorem 3.6.4. With $W = F$ and $k = 2$, it reads $\dim \mathcal{M}(V_1, V_2; F) = n_1 n_2$, which is the count of $n_1 \times n_2$ matrices — and indeed Chapter 13 recorded a bilinear form on a single space by its Gram matrix (Definition 13.1.2). The n_i enter as a **product**, once per slot, and that is the number to remember.

Example. (Counting bilinear maps)

(a) Find $\dim \mathcal{M}(F^2, F^3; F^2)$.

(b) Find $\dim \mathcal{M}(F^3, F^3, F^3; F)$, and the dimension of the subspace of alternating forms inside it when $F = \mathbb{R}$.

(c) Write the bilinear map $\beta\colon F^2 \times F^2 \to F^2$, $\beta(\mathbf{x}, \mathbf{y}) = (x_1 y_1,\ x_1 y_2 + x_2 y_1)$, in the basis of Theorem 14.1.2 for the standard bases.

Solution.

(a) $\dim W \cdot \dim V_1 \cdot \dim V_2 = 2 \cdot 2 \cdot 3 = 12$.

(b) $1 \cdot 3 \cdot 3 \cdot 3 = 27$. The alternating ones form a subspace of dimension 1 by Corollary 6.4.4, spanned by the determinant. So alternation is a very strong condition: it cuts 27 down to 1.

(c) Here $m = n_1 = n_2 = 2$, so there are $2 \cdot 2 \cdot 2 = 8$ basis maps $E_{(i,j)}^r$, and $E_{(i,j)}^r(\mathbf{x}, \mathbf{y}) =$

$x_i y_j \mathbf{e}_r$. Evaluate β on the four basis pairs:

$$\beta(\mathbf{e}_1, \mathbf{e}_1) = (1,0) = \mathbf{e}_1, \quad \beta(\mathbf{e}_1, \mathbf{e}_2) = (0,1) = \mathbf{e}_2,$$
$$\beta(\mathbf{e}_2, \mathbf{e}_1) = (0,1) = \mathbf{e}_2, \quad \beta(\mathbf{e}_2, \mathbf{e}_2) = (0,0) = \mathbf{0}.$$

By the spanning argument, $\beta = E^1_{(1,1)} + E^2_{(1,2)} + E^2_{(2,1)}$, with the other five coefficients zero. Reading the formula back, $\beta(\mathbf{x}, \mathbf{y}) = x_1 y_1 \mathbf{e}_1 + x_1 y_2 \mathbf{e}_2 + x_2 y_1 \mathbf{e}_2$, which is the given map.

Quick check. What does Eq. 14.1.1 give for $\mathcal{M}(V_1, V_2; W)$ when $V_2 = \{\mathbf{0}\}$? Does the answer make sense?

Solution. It gives $(\dim W) \cdot (\dim V_1) \cdot 0 = 0$, so the space is $\{0\}$. That is right: a bilinear map must satisfy $\beta(\mathbf{v}, \mathbf{0}) = \mathbf{0}$, and $\mathbf{0}$ is the only vector of V_2, so the only bilinear map is the zero map. The degenerate case is worth checking because it is where a formula with a product behaves differently from one with a sum.

14.1.5 The problem this chapter solves

We now have a good supply of multilinear maps and we know how many there are. What we do not have is any way to *work* with them. Consider what Chapters 3 to 5 give a linear map $T\colon V \to W$: a matrix, a kernel, an image, a rank, Rank–Nullity, a dual map, a determinant when $V = W$, eigenvalues, a Jordan form. A bilinear map $\beta\colon V \times W \to Z$ has none of these. It has no matrix, because Definition 3.6.1 applies to linear maps. It has no kernel that is a subspace: the set where β vanishes contains $(\mathbf{v}, \mathbf{0})$ and $(\mathbf{0}, \mathbf{w})$ for all $\mathbf{v}, \mathbf{w}$ but usually not their sum. It is not an element of $\mathcal{L}(V \times W, Z)$, as the previous subsection insisted. Every fact we know about it has had to be proved by hand, one slot at a time.

The wish is therefore easy to state. **We want to replace multilinearity by linearity.** Concretely, for two spaces V and W we want a single vector space — call it X for now — and a single bilinear map $\tau\colon V \times W \to X$, so universal that every bilinear map out of $V \times W$ is τ followed by a **linear** map. If that works, then bilinear maps $V \times W \to Z$ correspond to linear maps $X \to Z$, and the entire toolkit of Chapters 3 to 5 applies to the latter.

Before building anything, we can predict the size of X, and the prediction is a good reason to believe the object exists. Suppose such an X and τ existed, and suppose the correspondence "β on $V \times W \leftrightarrow$ linear map on X" is a bijection for every target Z. Take $Z = F$. Then Eq. 14.1.1 gives

$$\dim \mathcal{M}(V, W; F) = 1 \cdot \dim V \cdot \dim W,$$

while Theorem 3.6.4 gives $\dim \mathcal{L}(X, F) = \dim X$. A bijection that respects addition and scalars forces these to agree, so

$$\dim X = (\dim V)(\dim W).$$

The product of the dimensions, not the sum. This already rules out the naive guess $X = V \times W$, whose dimension is $\dim V + \dim W$ by Theorem 3.9.1, and it tells us what to aim for. The next section constructs X, calls it $V \otimes W$, and proves that its dimension is exactly this product.

One more remark before we go. The prediction used only the case $Z = F$, but the same count works for every Z: Eq. 14.1.1 gives $\dim Z \cdot \dim V \cdot \dim W$ on one side and $\dim Z \cdot \dim X$ on the other, and the two agree precisely when $\dim X = (\dim V)(\dim W)$. When the next section

produces a basis of $V \otimes W$ indexed by pairs (i, j) of basis indices, that is the same count seen a second time, and the agreement is not a coincidence — it is the universal property, counted.

14.1.6 Exercises

14.1.6.1 A. Check your understanding

Exercise A1.

(a) Define what it means for $\beta\colon V_1 \times \cdots \times V_k \to W$ to be k-linear, with every quantifier.

(b) State the difference between "β is bilinear" and "β is linear on the product space $V \times W$", and give a function that is one but not the other.

(c) Write out $\beta(\mathbf{u} + \mathbf{u}', \mathbf{v} + \mathbf{v}')$ for a bilinear β. How many terms are there?

(d) State $\dim \mathcal{M}(V_1, \ldots, V_k; W)$ in terms of the dimensions of the spaces involved.

(e) True or false: every bilinear map $\beta\colon V \times W \to Z$ satisfies $\beta(\mathbf{v}, \mathbf{0}) = \mathbf{0}$. Justify your answer.

(f) What is a 1-linear map? What is a k-linear map with $W = F$ called?

Solution.

(a) It is k-linear if for **every** position i and **every** choice of fixed $\mathbf{v}_j \in V_j$ with $j \neq i$, the function $\mathbf{x} \mapsto \beta(\mathbf{v}_1, \ldots, \mathbf{x}, \ldots, \mathbf{v}_k)$ with $\mathbf{x}$ in position i is a linear map $V_i \to W$ (Definition 14.1.1). All spaces are over the same field.

(b) Bilinear means linear in each slot with the other **frozen**; linear on the product means linear when both slots move **together**. The multiplication $\beta(a, b) = ab$ on $F \times F$ is bilinear but not linear on the product, since $\beta(2 \cdot (1, 1)) = 4 \neq 2\beta(1, 1)$. The sum $\sigma(a, b) = a + b$ is linear on the product but not bilinear, since $a \mapsto a + 1$ is not linear.

(c) $\beta(\mathbf{u}, \mathbf{v}) + \beta(\mathbf{u}, \mathbf{v}') + \beta(\mathbf{u}', \mathbf{v}) + \beta(\mathbf{u}', \mathbf{v}')$: four terms.

(d) $(\dim W) \prod_{i=1}^{k} \dim V_i$ (Eq. 14.1.1).

(e) True. Freeze $\mathbf{v}$; the map $\mathbf{y} \mapsto \beta(\mathbf{v}, \mathbf{y})$ is linear, and a linear map sends $\mathbf{0}$ to $\mathbf{0}$ by Theorem 3.1.1.

(f) A 1-linear map is exactly a linear map. A k-linear map into F is a multilinear form (Definition 6.2.1).

14.1.6.2 B. Practice

Exercise B1: Determine which are multilinear.

Determine which of the following are multilinear maps. For those that are, say what k is; for those that are not, name the clause that fails and give a concrete witness. Justify your answer.

(a) $\beta\colon M_n(F) \times M_n(F) \to M_n(F)$, $\beta(\mathbf{A}, \mathbf{B}) = \mathbf{AB} - \mathbf{BA}$.

(b) $\beta\colon \mathbb{R}^2 \times \mathbb{R}^2 \to \mathbb{R}$, $\beta(\mathbf{x}, \mathbf{y}) = x_1 y_2 - x_2 y_1 + 1$.

(c) $\beta\colon F^n \times F^n \to M_n(F)$, $\beta(\mathbf{x}, \mathbf{y}) = \mathbf{x}\mathbf{y}^\top$.

(d) $\beta\colon M_n(F)\times M_n(F)\to F$, $\beta(\mathbf{A},\mathbf{B})=\det(\mathbf{AB})$, for $n\geq 2$.
(e) $\beta\colon V^*\times V^*\times V\times V\to F$, $\beta(\varphi,\psi,\mathbf{u},\mathbf{v})=\varphi(\mathbf{u})\psi(\mathbf{v})$.

Solution.

(a) Bilinear, $k=2$. This is the commutator $[\mathbf{A},\mathbf{B}]$ of Definition 7.5.1. Freeze $\mathbf{B}$: then $\mathbf{A}\mapsto\mathbf{AB}-\mathbf{BA}$ is a difference of two linear maps of $\mathbf{A}$, hence linear (Theorem 3.4.1). Freezing $\mathbf{A}$ is the same computation.
(b) Not multilinear. Freeze $\mathbf{y}=\mathbf{0}$; then $\mathbf{x}\mapsto 1$ is constant, so it sends $\mathbf{0}$ to 1 and the clause "is linear" fails at position 1. Removing the $+1$ leaves the signed area, which is bilinear.
(c) Bilinear, $k=2$. The (i,j) entry of $\mathbf{xy}^\top$ is x_iy_j. Freeze $\mathbf{y}$: each entry is a linear functional of $\mathbf{x}$ and the entries are the coordinates of the output in the basis of matrix units, so $\mathbf{x}\mapsto\mathbf{xy}^\top$ is linear. Symmetrically in $\mathbf{y}$. This map will reappear as the model of the tensor product of two coordinate spaces.
(d) Not multilinear for $n\geq 2$. By Theorem 6.5.4, $\beta(\mathbf{A},\mathbf{B})=\det\mathbf{A}\det\mathbf{B}$. Freeze $\mathbf{B}=\mathbf{I}_n$; then $\mathbf{A}\mapsto\det\mathbf{A}$ is not linear, since $\det(c\mathbf{A})=c^n\det\mathbf{A}$ and $n\geq 2$. Concretely with $n=2$, $\det(2\mathbf{I}_2)=4\neq 2\det\mathbf{I}_2=2$. The failing clause is again "is linear".
(e) 4-linear. Freeze three of the four arguments; in each case what remains is one of $\varphi\mapsto\varphi(\mathbf{u})\cdot\psi(\mathbf{v})$, $\psi\mapsto\psi(\mathbf{v})\cdot\varphi(\mathbf{u})$, $\mathbf{u}\mapsto\varphi(\mathbf{u})\cdot\psi(\mathbf{v})$, $\mathbf{v}\mapsto\psi(\mathbf{v})\cdot\varphi(\mathbf{u})$, each a fixed scalar times a linear functional, hence linear. Note that the four slots do **not** all lie in the same space, which Definition 14.1.1 allows and Definition 6.2.1 does not.

Exercise B2: Dimension counts.

Compute the dimension of each space. The field is F throughout.

(a) $\mathcal{M}(F^4,F^5;F^3)$.
(b) $\mathcal{M}(F^2,F^2,F^2;F^2)$.
(c) $\mathcal{M}(M_2(F),F^3;F)$.
(d) $\mathcal{M}(F^n;W)$ for $\dim W=m$, and the space $\mathcal{L}(F^n,W)$. Compare.

Solution.

(a) $3\cdot 4\cdot 5=60$ by Eq. 14.1.1.
(b) $2\cdot 2\cdot 2\cdot 2=16$.
(c) $\dim M_2(F)=4$, so $1\cdot 4\cdot 3=12$.
(d) Both are mn. With $k=1$ the two spaces are equal, by Example (Seven functions of several vectors) (a), and Eq. 14.1.1 reduces to Theorem 3.6.4. The formula is consistent with what Chapter 3 already proved.

Exercise B3: Expanding in the basis.

Let $\beta\colon F^2\times F^3\to F^2$ be given by

$$\beta(\mathbf{x},\mathbf{y})=(x_1y_1-2x_2y_3,\ x_1y_2+x_2y_1).$$

(a) Verify that β is bilinear.

(b) Compute the six values $\beta(\mathbf{e}_i, \mathbf{f}_j)$, where $(\mathbf{e}_1, \mathbf{e}_2)$ and $(\mathbf{f}_1, \mathbf{f}_2, \mathbf{f}_3)$ are the standard bases.

(c) Write β in the basis $\{E^r_{(i,j)}\}$ of Theorem 14.1.2, and say how many of the 12 coefficients are non-zero.

Solution.

(a) Freeze $\mathbf{y}$. Each output coordinate is a fixed linear combination of x_1 and x_2, hence a linear functional of $\mathbf{x}$ (Theorem 4.1.1), and a map into F^2 whose coordinates are linear is linear. Freeze $\mathbf{x}$: each output coordinate is a fixed linear combination of y_1, y_2, y_3, and the same argument applies. So β is bilinear.

(b) Substituting the standard basis vectors:

$$\begin{aligned} &\beta(\mathbf{e}_1, \mathbf{f}_1) = (1,0), \quad \beta(\mathbf{e}_1, \mathbf{f}_2) = (0,1), \quad \beta(\mathbf{e}_1, \mathbf{f}_3) = (0,0), \\ &\beta(\mathbf{e}_2, \mathbf{f}_1) = (0,1), \quad \beta(\mathbf{e}_2, \mathbf{f}_2) = (0,0), \quad \beta(\mathbf{e}_2, \mathbf{f}_3) = (-2,0). \end{aligned}$$

(c) Reading the coordinates off, $c_{(1,1),1} = 1$, $c_{(1,2),2} = 1$, $c_{(2,1),2} = 1$ and $c_{(2,3),1} = -2$, all others zero. Hence

$$\beta = E^1_{(1,1)} + E^2_{(1,2)} + E^2_{(2,1)} - 2\,E^1_{(2,3)},$$

so 4 of the $2 \cdot 2 \cdot 3 = 12$ coefficients are non-zero.

14.1.6.3 C. Going deeper

Exercise C1: Bilinear forms on coordinate spaces are matrices.

Let $m, n \geq 1$.

(a) Prove that for every bilinear $\beta\colon F^m \times F^n \to F$ there is a **unique** $\mathbf{A} \in M_{m\times n}(F)$ with $\beta(\mathbf{x}, \mathbf{y}) = \mathbf{x}^\top \mathbf{A}\mathbf{y}$ for all $\mathbf{x}, \mathbf{y}$.

(b) Hence deduce that $\dim \mathcal{M}(F^m, F^n; F) = mn$, and check that this agrees with Eq. 14.1.1.

Hint for (a): the entries of $\mathbf{A}$ can only be the values of β on pairs of standard basis vectors.

Solution.

(a) *Existence.* Put $a_{ij} := \beta(\mathbf{e}_i, \mathbf{f}_j)$, where $(\mathbf{e}_i)$ and $(\mathbf{f}_j)$ are the standard bases of F^m and F^n, and let $\mathbf{A} = (a_{ij})$. For $\mathbf{x} = \sum_i x_i \mathbf{e}_i$ and $\mathbf{y} = \sum_j y_j \mathbf{f}_j$, expanding one slot at a time by Definition 14.1.1 gives

$$\beta(\mathbf{x}, \mathbf{y}) = \sum_{i,j} x_i y_j\, \beta(\mathbf{e}_i, \mathbf{f}_j) = \sum_{i,j} x_i a_{ij} y_j = \mathbf{x}^\top \mathbf{A}\mathbf{y}.$$

Uniqueness. If $\mathbf{x}^\top \mathbf{A}\mathbf{y} = \mathbf{x}^\top \mathbf{A}'\mathbf{y}$ for all $\mathbf{x}, \mathbf{y}$, take $\mathbf{x} = \mathbf{e}_i$ and $\mathbf{y} = \mathbf{f}_j$: the left side is a_{ij} and the right side is a'_{ij}. Hence $\mathbf{A} = \mathbf{A}'$.

(b) By (a) the map $\mathcal{M}(F^m, F^n; F) \to M_{m\times n}(F)$, $\beta \mapsto \mathbf{A}$, is a bijection, and it is linear because the entries $\beta(\mathbf{e}_i, \mathbf{f}_j)$ depend linearly on β by the definition of the pointwise

operations. So it is an isomorphism, and $\dim \mathcal{M}(F^m, F^n; F) = \dim M_{m\times n}(F) = mn$ by Theorem 3.5.4. Eq. 14.1.1 gives $1 \cdot m \cdot n = mn$, the same value.

Exercise C2: Linear and bilinear at once.

Let V, W, Z be vector spaces over F and let $\beta\colon V \times W \to Z$ be a function.

(a) Prove that if β is **both** bilinear and linear as a map on the product space $V \times W$, then β is the zero map.

(b) Give an example, with $V = W = Z = F$, of a non-zero bilinear map and a non-zero linear map on the product, and say which property each one fails.

(c) Does (a) still hold when $V = \{\mathbf{0}\}$? Explain what the statement says in that case.

Solution.

(a) Let $\mathbf{v} \in V$ and $\mathbf{w} \in W$. In the product space, $(\mathbf{v}, \mathbf{w}) = (\mathbf{v}, \mathbf{0}) + (\mathbf{0}, \mathbf{w})$. Since β is linear on the product,

$$\beta(\mathbf{v}, \mathbf{w}) = \beta(\mathbf{v}, \mathbf{0}) + \beta(\mathbf{0}, \mathbf{w}).$$

Since β is bilinear, freezing the first slot at $\mathbf{v}$ makes $\mathbf{y} \mapsto \beta(\mathbf{v}, \mathbf{y})$ linear, so $\beta(\mathbf{v}, \mathbf{0}) = \mathbf{0}$ by Theorem 3.1.1; freezing the second slot at $\mathbf{w}$ gives $\beta(\mathbf{0}, \mathbf{w}) = \mathbf{0}$ likewise. Therefore $\beta(\mathbf{v}, \mathbf{w}) = \mathbf{0}$ for all $\mathbf{v}, \mathbf{w}$, that is, $\beta = 0$.

(b) The product $\mu(a, b) = ab$ is bilinear and fails linearity on the product, since $\mu(2 \cdot (1, 1)) = 4 \neq 2\mu(1, 1)$. The sum $\sigma(a, b) = a + b$ is linear on the product and fails bilinearity, since $\sigma(0, 1) = 1 \neq 0$ while a bilinear map must vanish when a slot is $\mathbf{0}$.

(c) Yes, but it says nothing: if $V = \{\mathbf{0}\}$ then $\mathbf{v} = \mathbf{0}$ always, and the only function $\{\mathbf{0}\} \times W \to Z$ that is bilinear is already the zero map, since $\beta(\mathbf{0}, \mathbf{w}) = \mathbf{0}$. The content of (a) appears only when both V and W are non-zero and $Z \neq \{\mathbf{0}\}$.

Exercise C3: Counting over a finite field.

Work over $\mathbb{F}_2$, the field with two elements.

(a) How many bilinear maps $\mathbb{F}_2^2 \times \mathbb{F}_2^2 \to \mathbb{F}_2$ are there? How many trilinear maps $\mathbb{F}_2^2 \times \mathbb{F}_2^2 \times \mathbb{F}_2^2 \to \mathbb{F}_2$?

(b) How many of the bilinear maps in (a) are symmetric, that is, satisfy $\beta(\mathbf{x}, \mathbf{y}) = \beta(\mathbf{y}, \mathbf{x})$ for all $\mathbf{x}, \mathbf{y}$? How many are alternating in the sense of Definition 6.2.2?

(c) Is every alternating bilinear form on $\mathbb{F}_2^2$ symmetric? Is every symmetric one alternating?

Solution.

(a) By Eq. 14.1.1, $\dim \mathcal{M}(\mathbb{F}_2^2, \mathbb{F}_2^2; \mathbb{F}_2) = 1 \cdot 2 \cdot 2 = 4$. A vector space of dimension d over $\mathbb{F}_2$ has exactly 2^d elements, since each of the d coordinates is 0 or 1. So there are $2^4 = 16$ bilinear maps. For three slots the dimension is $2^3 = 8$, giving $2^8 = 256$ trilinear maps.

(b) By Exercise (C1: Bilinear forms on coordinate spaces are matrices) a bilinear form on $\mathbb{F}_2^2$ is $\mathbf{x}^\top \mathbf{A}\mathbf{y}$ for a unique $\mathbf{A} \in M_2(\mathbb{F}_2)$, and β is symmetric exactly when

$\mathbf{A} = \mathbf{A}^\top$ (compare the values at $(\mathbf{e}_i, \mathbf{e}_j)$ and $(\mathbf{e}_j, \mathbf{e}_i)$). A symmetric 2×2 matrix is determined by a_{11}, a_{12}, a_{22}, so there are $2^3 = 8$ symmetric ones. Alternating means $\beta(\mathbf{x}, \mathbf{x}) = 0$ for all $\mathbf{x}$, which forces $a_{11} = \beta(\mathbf{e}_1, \mathbf{e}_1) = 0$, $a_{22} = 0$, and then $\beta(\mathbf{e}_1 + \mathbf{e}_2, \mathbf{e}_1 + \mathbf{e}_2) = a_{12} + a_{21} = 0$. Over $\mathbb{F}_2$ that says $a_{21} = a_{12}$, so $\mathbf{A} = \left(\begin{smallmatrix} 0 & a \\ a & 0 \end{smallmatrix}\right)$ and there are 2 alternating forms: the zero form and the signed area.

(c) Both alternating forms found in (b) have symmetric matrices, so yes, every alternating form here is symmetric — which is Theorem 13.3.3 in characteristic 2, where $-1 = 1$. The converse fails: the dot product $\beta(\mathbf{x}, \mathbf{y}) = x_1 y_1 + x_2 y_2$ is symmetric, and $\beta(\mathbf{e}_1, \mathbf{e}_1) = 1 \neq 0$, so it is not alternating. Of the 8 symmetric forms only 2 are alternating.

14.2 The Tensor Product

The previous section ended with a wish: a space through which every bilinear map out of $V \times W$ becomes a **linear** map. This section grants it. The object is called the tensor product, and building it is the main technical work of the chapter — but the way we go about it matters more than the object itself, because the same three moves recur four more times, for the tensor algebra, the symmetric powers, the exterior powers and the Clifford algebra.

The three moves are: **state what the object must do**, in the form of a property of the maps out of it; **prove that any two objects doing it are isomorphic by a unique isomorphism**, using nothing but that property; and only then **construct one**, to know that the definition is not empty. The middle move is what licenses the word "the". Theorem 14.2.1 below is written out at full length and is the template for the rest of the chapter, so it is worth reading twice.

Throughout, F is a field and all vector spaces are over F. No finite-dimensionality is assumed until we reach bases, where it is stated.

14.2.1 What the object has to do

Here is the goal, stated before its terms are defined. We want a space X and a bilinear map $\tau\colon V \times W \to X$ such that *every bilinear map β out of $V \times W$ can be pushed through τ, and what comes out the other side is linear.* Two demands hide in that sentence. There must be **at least one** way to push β through, or the property is useless; and **at most one**, or we cannot recover β from its linear shadow. So we ask for existence and uniqueness together.

A tensor product is the most efficient bilinear map out of $V \times W$: every other one is it, followed by a single linear map.

Definition 14.2.1 — Tensor Product

Let V and W be vector spaces over F. A **tensor product of V and W** is a pair (X, τ), where X is a vector space over F and $\tau\colon V \times W \to X$ is a bilinear map, satisfying:

(T1) (**universal property**) **For every** vector space Z over F and **every** bilinear map $\beta\colon V \times W \to Z$, there is a **unique** linear map $\bar{\beta}\colon X \to Z$ with $\bar{\beta} \circ \tau = \beta$.

In words, clause by clause. **For every Z:** the property is a demand about *all* targets at once, not about one favorite target. **Every bilinear β:** the arbitrary bilinear map is the input; nothing is assumed about it beyond Definition 14.1.1 with $k = 2$. **There is a unique linear $\bar{\beta}$:** exactly one, so both existence and uniqueness are being asserted. **With $\bar{\beta} \circ \tau = \beta$:** this is an equality of functions on $V \times W$, namely $\bar{\beta}(\tau(\mathbf{v}, \mathbf{w})) = \beta(\mathbf{v}, \mathbf{w})$ for all $\mathbf{v}, \mathbf{w}$. We say β **factors through** τ, and picture it as a triangle: the two routes from $V \times W$ to Z, one direct and one through X, give the same answer.

Notice what the definition does **not** say. It says nothing about the elements of X, nothing about a formula, and nothing about a basis: it is a statement purely about maps. That is deliberate, since a definition naming elements would depend on a construction, and there are several.

> *Warning.* **The definition does not say that every element of X has the form $\tau(\mathbf{v}, \mathbf{w})$.** It says that the values $\tau(\mathbf{v}, \mathbf{w})$ are enough to *determine* a linear map on X — which, as we prove below, means they span X, not that they exhaust it. Sums of them are generally not of that form. This is the single most common misreading of the tensor product, and we return to it with a proof at the end of the section.

14.2.2 Any two tensor products are the same

Before building anything, we settle the word "the". If two pairs both satisfy (T1), each one's property produces a map to the other, and the composites have no choice but to be identities. This is the argument Chapter 13 used for the Clifford algebra (Proposition 13.12.1), and it is the argument we will use in four more sections.

Theorem 14.2.1 — Uniqueness of the Tensor Product

Let V and W be vector spaces over F, and let (X, τ) and (X', τ') both be tensor products of V and W. Then there is a **unique** isomorphism $\varphi \colon X \to X'$ with $\varphi \circ \tau = \tau'$.

Idea. Three steps. ① Each pair's universal property, applied with the *other* pair's bilinear map as input, produces a linear map; so we get $\varphi \colon X \to X'$ and $\psi \colon X' \to X$ at once, for free. ② Compose them. The composite $\psi\varphi$ is a linear self-map of X that does nothing to τ — and so is the identity. ③ The uniqueness half of (T1), applied with $Z = X$ and $\beta = \tau$, says there is only **one** linear self-map doing nothing to τ. So the two coincide. The uniqueness half is the engine; without it the argument produces two maps and no reason for them to be inverse.

Proof. **Step 1.** The map $\tau' \colon V \times W \to X'$ is bilinear. Apply (T1) for (X, τ) with $Z = X'$ and $\beta = \tau'$: there is a unique linear $\varphi \colon X \to X'$ with $\varphi \circ \tau = \tau'$. Symmetrically, applying (T1) for (X', τ') with $Z = X$ and $\beta = \tau$ gives a unique linear $\psi \colon X' \to X$ with $\psi \circ \tau' = \tau$.

Step 2. The composite $\psi\varphi \colon X \to X$ is linear (Theorem 3.4.2 (a)), and

$$(\psi\varphi) \circ \tau = \psi \circ (\varphi \circ \tau) = \psi \circ \tau' = \tau.$$

The identity id_X is also linear and satisfies $\mathrm{id}_X \circ \tau = \tau$.

Step 3. Apply (T1) for (X, τ) with $Z = X$ and $\beta = \tau$, which is bilinear by hypothesis. It says there is **exactly one** linear map $X \to X$ whose composite with τ is τ. Both

$\psi\varphi$ and id_X are such maps. Hence $\psi\varphi = \mathrm{id}_X$. Swapping the roles of (X, τ) and (X', τ') gives $\varphi\psi = \mathrm{id}_{X'}$.

So φ has a two-sided inverse and is a bijection, hence an isomorphism (Theorem 3.5.1). It is the unique isomorphism with $\varphi \circ \tau = \tau'$, because (T1) already produced it as the unique **linear** map with that property, and an isomorphism is in particular linear. This proves the theorem.

■

Aftermath, and the template. Read the proof again with the names removed. It says: *an object defined by a universal property is determined up to a unique isomorphism compatible with its structure map, because each object's property hands you a comparison map, and the uniqueness clause forces the composites to be identities.* Nothing in it used bilinearity, or vector spaces, or two factors. Sections 06, 07, 08 and 10 define the tensor algebra, the symmetric power, the exterior power and the Clifford algebra by universal properties of exactly this shape, and each time the uniqueness proof is these three steps with different letters. When you meet them, do not reread the argument; recognize it.

Because of Theorem 14.2.1 we may now speak of **the** tensor product and fix notation.

Definition 14.2.2 — Notation for Tensors

When a tensor product of V and W exists, we write it $V \otimes W$, write $\mathbf{v} \otimes \mathbf{w}$ for $\tau(\mathbf{v}, \mathbf{w})$, and call an element of the form $\mathbf{v} \otimes \mathbf{w}$ a **simple tensor** (also called a *pure* or *decomposable* tensor). The defining property then reads: every bilinear $\beta\colon V \times W \to Z$ has a unique linear $\bar{\beta}\colon V \otimes W \to Z$ with $\bar{\beta}(\mathbf{v} \otimes \mathbf{w}) = \beta(\mathbf{v}, \mathbf{w})$.

Bilinearity of τ, rewritten in this notation, gives the rules we compute with:

$$\begin{aligned}(\mathbf{v} + \mathbf{v}') \otimes \mathbf{w} &= \mathbf{v} \otimes \mathbf{w} + \mathbf{v}' \otimes \mathbf{w},\\ \mathbf{v} \otimes (\mathbf{w} + \mathbf{w}') &= \mathbf{v} \otimes \mathbf{w} + \mathbf{v} \otimes \mathbf{w}',\\ (c\mathbf{v}) \otimes \mathbf{w} &= c(\mathbf{v} \otimes \mathbf{w}) = \mathbf{v} \otimes (c\mathbf{w}).\end{aligned}$$

The third line is the one to remember: **a scalar moves freely across the $\otimes$ sign.** That is the whole reason $\mathbf{v} \otimes \mathbf{w}$ does not determine $\mathbf{v}$ and $\mathbf{w}$.

14.2.3 Building one: a free space modulo relations

Uniqueness is worthless if nothing satisfies (T1), so we construct a tensor product. The strategy is the one named in the chapter introduction: *take a space in which the symbols $\mathbf{v} \otimes \mathbf{w}$ are completely unrelated, then divide out exactly the relations bilinearity demands.* Both halves need a tool.

The first tool is a space with a basis indexed by an arbitrary set. It is the space of finitely supported functions, which Chapter 1 met for $S = \mathbb{N}$ (Exercise (B1: Finitely Supported Sequences)).

Definition 14.2.3 — Free Vector Space on a Set

Let S be a set and F a field. The **free vector space on S over F** is

$$F^{(S)} := \{\, f\colon S \to F \;:\; f(s) = 0 \text{ for all but finitely many } s \,\},$$

a subset of the space F^S of all functions $S \to F$ (Example (The Standard Vector Spaces) (d)), with the pointwise operations. For $s \in S$, let $\delta_s \in F^{(S)}$ be the function with $\delta_s(s) = 1$ and $\delta_s(t) = 0$ for $t \neq s$.

Lemma 14.2.2 — Universal Property of the Free Vector Space

Let S be a set and F a field.

(a) $F^{(S)}$ is a subspace of F^S, and $\{\delta_s : s \in S\}$ is a basis of it.

(b) For **every** vector space Z over F and **every** function $g\colon S \to Z$ — no structure on g is assumed, since S is only a set — there is **exactly one** linear map $\bar{g}\colon F^{(S)} \to Z$ with $\bar{g}(\delta_s) = g(s)$ for all $s \in S$.

Proof.

(a) We use Theorem 1.2.1. The zero function vanishes everywhere, so it lies in $F^{(S)}$. If $f, h \in F^{(S)}$ vanish outside the finite sets A and B, then $f + h$ vanishes outside $A \cup B$, which is finite, and cf vanishes outside A. So $F^{(S)}$ is a subspace.
Each δ_s lies in $F^{(S)}$. *Spanning:* if $f \in F^{(S)}$ is non-zero exactly on the finite set $\{s_1, \dots, s_r\}$, then f and $\sum_i f(s_i)\delta_{s_i}$ take the same value at every point of S, hence are equal. *Independence:* if $\sum_i a_i \delta_{s_i} = 0$ for distinct $s_1, \dots, s_r$, evaluate at s_j to get $a_j = 0$. By Definition 1.5.1, $\{\delta_s\}$ is a basis, possibly infinite in the sense of Theorem 1.8.2.

(b) Immediate from (a) and Theorem 3.1.6, which prescribes a linear map arbitrarily on a basis, in one and only one way.

■

In words: **a function on a set becomes a linear map on the free space, for free.** That is the point of the construction, and the whole of it: $F^{(S)}$ imposes no relations among the δ_s, so nothing can obstruct a prescription.

The second tool is the quotient. Chapter 3 recorded exactly the statement we need: a linear map that kills a subspace U passes, in exactly one way, to a linear map on V/U (Theorem 3.9.10 (a)). We use it in the form "to define a map out of a quotient, define it upstairs and check it kills the relations".

Theorem 14.2.3 — Existence of the Tensor Product

For every pair of vector spaces V, W over F, a tensor product (X, τ) of V and W exists.

Idea. Write down the symbols $\mathbf{v} \otimes \mathbf{w}$ as a basis of a huge space P, one basis vector for each **pair** of vectors — so at this stage $\mathbf{v} \otimes \mathbf{w}$ has no properties at all. The four bilinearity rules are then four families of elements of P that we want to be zero, so divide by the subspace they span. A bilinear β becomes a linear map on P by Lemma 14.2.2, kills each relation because it is bilinear, and therefore passes to the quotient by Theorem 3.9.10. Uniqueness of the induced map is spanning: the cosets of the basis vectors span the quotient.

Proof. Let $S = V \times W$, regarded as a **set**, and let $P = F^{(S)}$ be the free vector space on it (Definition 14.2.3), with basis $\{\delta_{(\mathbf{v},\mathbf{w})}\}$. Let $R \subseteq P$ be the span of all elements of the four forms

$$\delta_{(\mathbf{v}+\mathbf{v}',\,\mathbf{w})} - \delta_{(\mathbf{v},\mathbf{w})} - \delta_{(\mathbf{v}',\mathbf{w})}, \qquad \delta_{(\mathbf{v},\,\mathbf{w}+\mathbf{w}')} - \delta_{(\mathbf{v},\mathbf{w})} - \delta_{(\mathbf{v},\mathbf{w}')},$$
$$\delta_{(c\mathbf{v},\,\mathbf{w})} - c\,\delta_{(\mathbf{v},\mathbf{w})}, \qquad \delta_{(\mathbf{v},\,c\mathbf{w})} - c\,\delta_{(\mathbf{v},\mathbf{w})},$$

taken over all $\mathbf{v}, \mathbf{v}' \in V$, all $\mathbf{w}, \mathbf{w}' \in W$ and all $c \in F$. A span is a subspace, so R is one. Put

$$X \coloneqq P/R, \qquad \tau(\mathbf{v}, \mathbf{w}) \coloneqq \pi\big(\delta_{(\mathbf{v},\mathbf{w})}\big),$$

where $\pi\colon P \to P/R$ is the quotient map, which is linear with kernel R (Theorem 3.9.4).

τ is bilinear. The element $\delta_{(\mathbf{v}+\mathbf{v}',\mathbf{w})} - \delta_{(\mathbf{v},\mathbf{w})} - \delta_{(\mathbf{v}',\mathbf{w})}$ lies in $R = \ker \pi$, so applying π and using its linearity gives $\tau(\mathbf{v}+\mathbf{v}', \mathbf{w}) - \tau(\mathbf{v}, \mathbf{w}) - \tau(\mathbf{v}', \mathbf{w}) = \mathbf{0}$. The other three families give, in the same way, additivity in the second slot and the two scalar rules. These are the clauses of Definition 14.1.1 for $k = 2$.

(T1), existence. Let Z be a vector space and $\beta\colon V \times W \to Z$ bilinear. Regarding β as a **function** on the set S, Lemma 14.2.2 (b) gives a unique linear $b\colon P \to Z$ with $b(\delta_{(\mathbf{v},\mathbf{w})}) = \beta(\mathbf{v}, \mathbf{w})$. It kills every generator of R: for instance

$$b\big(\delta_{(\mathbf{v}+\mathbf{v}',\mathbf{w})} - \delta_{(\mathbf{v},\mathbf{w})} - \delta_{(\mathbf{v}',\mathbf{w})}\big) = \beta(\mathbf{v}+\mathbf{v}', \mathbf{w}) - \beta(\mathbf{v}, \mathbf{w}) - \beta(\mathbf{v}', \mathbf{w}) = \mathbf{0}$$

because β is linear in its first slot, and the other three families vanish by the other three clauses of bilinearity. Since b is linear and vanishes on a spanning set of R, it vanishes on R (Theorem 3.1.4); that is, $R \subseteq \ker b$. By Theorem 3.9.10 (a) there is exactly one linear $\bar{\beta}\colon X \to Z$ with $\bar{\beta} \circ \pi = b$, and then

$$\bar{\beta}(\tau(\mathbf{v}, \mathbf{w})) = \bar{\beta}\big(\pi(\delta_{(\mathbf{v},\mathbf{w})})\big) = b\big(\delta_{(\mathbf{v},\mathbf{w})}\big) = \beta(\mathbf{v}, \mathbf{w}),$$

so $\bar{\beta} \circ \tau = \beta$.

(T1), uniqueness. Suppose $L\colon X \to Z$ is linear with $L \circ \tau = \beta$. Since π is surjective and the $\delta_{(\mathbf{v},\mathbf{w})}$ span P, the elements $\tau(\mathbf{v}, \mathbf{w}) = \pi(\delta_{(\mathbf{v},\mathbf{w})})$ span X. On each of them, L and $\bar{\beta}$ agree, both giving $\beta(\mathbf{v}, \mathbf{w})$. Two linear maps that agree on a spanning set agree everywhere, by Theorem 3.1.4. Hence $L = \bar{\beta}$.

So (X, τ) satisfies (T1), which proves the theorem. ∎

Aftermath. The construction is ugly and the object is not. That is normal for a universal property: the model is a scaffolding, and after this proof we never open it again. Every later fact about $V \otimes W$ in this book is derived from (T1), never from cosets of formal sums — which is also why the identification $F^m \otimes F^n \cong M_{m\times n}(F)$ below is legitimate as an alternative model,

and much more pleasant to compute in.

One property is worth extracting at once, because we will use it constantly and because it is the second appearance of the self-map trick.

Proposition 14.2.4 — Simple Tensors Span

Let $(V \otimes W, \tau)$ be a tensor product. Then $V \otimes W = \operatorname{span}\{\, \mathbf{v} \otimes \mathbf{w} : \mathbf{v} \in V,\ \mathbf{w} \in W \,\}$.

Proof. Let $Y = \operatorname{span}\{\mathbf{v}\otimes\mathbf{w}\}$, a subspace of $V\otimes W$, and let $j\colon Y \to V\otimes W$ be the inclusion, which is linear. Restricting the codomain of τ gives a bilinear map $\tau_Y\colon V \times W \to Y$, $(\mathbf{v}, \mathbf{w}) \mapsto \mathbf{v} \otimes \mathbf{w}$; it is bilinear because τ is and because Y is a subspace, so the identities hold already in Y. By (T1) with $Z = Y$ there is a linear $L\colon V\otimes W \to Y$ with $L\circ\tau = \tau_Y$. Then jL is a linear self-map of $V \otimes W$ with $jL\tau = j\tau_Y = \tau$, and so is id. By the uniqueness clause of (T1) with $Z = V \otimes W$ and $\beta = \tau$, we get $jL = \mathrm{id}$. Hence j is surjective, so $Y = V \otimes W$.

■

Remark. That proof used no basis, no construction and no finite dimension — only (T1). It is the same three lines as Step 1 of Proposition 13.12.3's proof in Chapter 13, where the generated subalgebra was shown to be everything. Once you see "a subobject that receives the structure map must be the whole thing", you can reuse it verbatim.

14.2.4 A basis and a dimension

Now we can count. The prediction at the end of the previous section was $\dim(V \otimes W) = (\dim V)(\dim W)$, and here it is, with a basis attached.

Theorem 14.2.5 — Basis of a Tensor Product

Let V and W be finite-dimensional, with bases $(\mathbf{v}_1, \dots, \mathbf{v}_n)$ of V and $(\mathbf{w}_1, \dots, \mathbf{w}_m)$ of W. Then the nm simple tensors

$$\mathbf{v}_i \otimes \mathbf{w}_j, \qquad 1 \le i \le n, \quad 1 \le j \le m,$$

form a basis of $V \otimes W$. In particular $\dim(V \otimes W) = (\dim V)(\dim W)$.

Idea. Spanning is bilinearity: expand both slots of a simple tensor and use Proposition 14.2.4. Independence needs linear functionals on $V \otimes W$ that pick out one coefficient — and (T1) manufactures functionals out of bilinear forms, while Theorem 4.1.3 supplies all the bilinear forms we could want, namely $(\mathbf{x}, \mathbf{y}) \mapsto \varphi_p(\mathbf{x})\psi_q(\mathbf{y})$.

Proof. Spanning. By Proposition 14.2.4 it suffices to write each simple tensor in terms of the listed ones. Let $\mathbf{v} = \sum_i a_i \mathbf{v}_i$ and $\mathbf{w} = \sum_j b_j \mathbf{w}_j$. Expanding one slot at a time by

the rules following Definition 14.2.2,

$$\mathbf{v}\otimes\mathbf{w}=\Big(\sum_i a_i\mathbf{v}_i\Big)\otimes\Big(\sum_j b_j\mathbf{w}_j\Big)=\sum_{i,j}a_ib_j\,(\mathbf{v}_i\otimes\mathbf{w}_j).$$

Independence. Let $(\varphi_1,\dots,\varphi_n)$ and $(\psi_1,\dots,\psi_m)$ be the bases of V^* and W^* dual to the given ones, so $\varphi_p(\mathbf{v}_i)=\delta_{pi}$ and $\psi_q(\mathbf{w}_j)=\delta_{qj}$ (Theorem 4.1.3). Fix p and q. The function

$$\beta_{pq}\colon V\times W\to F,\qquad \beta_{pq}(\mathbf{x},\mathbf{y})=\varphi_p(\mathbf{x})\,\psi_q(\mathbf{y}),$$

is bilinear: freezing $\mathbf{y}$ leaves $\psi_q(\mathbf{y})\varphi_p$, a scalar multiple of a linear functional, and symmetrically. By (T1) there is a linear $f_{pq}\colon V\otimes W\to F$ with $f_{pq}(\mathbf{x}\otimes\mathbf{y})=\varphi_p(\mathbf{x})\psi_q(\mathbf{y})$; in particular $f_{pq}(\mathbf{v}_i\otimes\mathbf{w}_j)=\delta_{pi}\delta_{qj}$.

Now suppose $\sum_{i,j}c_{ij}\,(\mathbf{v}_i\otimes\mathbf{w}_j)=\mathbf{0}$. Apply f_{pq}. By linearity the left side becomes $\sum_{i,j}c_{ij}\delta_{pi}\delta_{qj}=c_{pq}$, and the right side is 0. Hence $c_{pq}=0$. Since p and q were arbitrary, all coefficients vanish.

So the nm listed tensors form a basis, and $\dim(V\otimes W)=nm$. This proves the theorem. ∎

Aftermath: the count agrees. In Theorem 14.1.2 we found $\dim\mathcal{M}(V,W;Z)=(\dim Z)(\dim V)(\dim W)$, and we argued that a universal object X would have to satisfy $\dim\mathcal{L}(X,Z)=\dim\mathcal{M}(V,W;Z)$, forcing $\dim X=(\dim V)(\dim W)$. Theorem 14.2.5 delivers exactly that number, and the agreement is not a coincidence — it is the universal property, counted. Here is the statement behind it.

Corollary 14.2.6 — Bilinear Maps Are Linear Maps on the Tensor Product

Let V,W,Z be vector spaces over F. The map

$$\Xi\colon\mathcal{L}(V\otimes W,Z)\to\mathcal{M}(V,W;Z),\qquad L\mapsto L\circ\tau,$$

is an isomorphism of vector spaces. When V, W and Z are finite-dimensional, both sides have dimension $(\dim Z)(\dim V)(\dim W)$.

Proof. Ξ lands where claimed: $L\circ\tau$ is bilinear, since freezing one slot of τ gives a linear map and composing with the linear L keeps it linear (Theorem 3.4.2 (a)). It is linear in L by Theorem 3.4.2 (d), which gives $(L_1+L_2)\circ\tau=L_1\tau+L_2\tau$ and $(cL)\circ\tau=c(L\tau)$. It is surjective by the existence half of (T1) and injective by the uniqueness half: if $L\tau=0$, then both L and the zero map are linear maps composing with τ to give the zero bilinear map, so $L=0$, and Theorem 3.2.3 applies. The dimension count is Theorem 14.1.2 on one side and Theorem 3.6.4 together with Theorem 14.2.5 on the other. ∎

Quick check. What is $V\otimes W$ when $W=F$, viewed as a one-dimensional space over itself? What is it when $W=\{\mathbf{0}\}$?

Solution. For $W = F$: $\dim(V \otimes F) = (\dim V) \cdot 1 = \dim V$ by Theorem 14.2.5, and indeed $\mathbf{v} \mapsto \mathbf{v} \otimes 1$ is an isomorphism $V \to V \otimes F$, since it carries a basis $(\mathbf{v}_i)$ to the basis $(\mathbf{v}_i \otimes 1)$. For $W = \{\mathbf{0}\}$: the dimension is 0, so $V \otimes \{\mathbf{0}\} = \{\mathbf{0}\}$. Both are the degenerate cases one should be able to predict from the product formula, and both come out right.

14.2.5 Coordinates: the tensor product of coordinate spaces

An abstract object is easier to trust once it has a concrete model. For coordinate spaces there is a very good one: $F^m \otimes F^n$ is the space of $m \times n$ matrices, with the simple tensor $\mathbf{x} \otimes \mathbf{y}$ corresponding to the outer product $\mathbf{x}\mathbf{y}^\top$.

Theorem 14.2.7 — $F^m \otimes F^n \cong M_{m\times n}(F)$

Let $m, n \geq 1$. There is a unique linear map

$$\Theta\colon F^m \otimes F^n \to M_{m\times n}(F), \qquad \Theta(\mathbf{x} \otimes \mathbf{y}) = \mathbf{x}\mathbf{y}^\top,$$

and it is an isomorphism, carrying $\mathbf{e}_i \otimes \mathbf{f}_j$ to the matrix unit $\mathbf{E}_{ij}$. Under Θ, the simple tensors correspond exactly to the matrices of rank at most 1.

Proof. The map $(\mathbf{x}, \mathbf{y}) \mapsto \mathbf{x}\mathbf{y}^\top$ is bilinear: its (i, j) entry is $x_i y_j$, and with $\mathbf{y}$ frozen, $(\mathbf{x} + \mathbf{x}')\mathbf{y}^\top = \mathbf{x}\mathbf{y}^\top + \mathbf{x}'\mathbf{y}^\top$ and $(c\mathbf{x})\mathbf{y}^\top = c(\mathbf{x}\mathbf{y}^\top)$ by Theorem 0.9.4 (2) and (4); freezing $\mathbf{x}$ is the same computation (Exercise (B1: Determine which are multilinear) (c)). By (T1) there is a unique linear Θ with $\Theta(\mathbf{x} \otimes \mathbf{y}) = \mathbf{x}\mathbf{y}^\top$. On standard basis vectors, $\mathbf{e}_i\mathbf{f}_j^\top$ has a single 1 in position (i, j), so $\Theta(\mathbf{e}_i \otimes \mathbf{f}_j) = \mathbf{E}_{ij}$.

By Theorem 14.2.5 the mn tensors $\mathbf{e}_i \otimes \mathbf{f}_j$ form a basis of $F^m \otimes F^n$, and the mn matrix units form a basis of $M_{m\times n}(F)$ (Example (Standard Bases) (c)). By Theorem 3.1.5 there is a linear $\Psi\colon M_{m\times n}(F) \to F^m \otimes F^n$ with $\Psi(\mathbf{E}_{ij}) = \mathbf{e}_i \otimes \mathbf{f}_j$. Then $\Psi\Theta$ and $\Theta\Psi$ are linear maps fixing a basis, hence are the identities by the uniqueness half of Theorem 3.1.5. So Θ is an isomorphism.

For the last claim, a non-zero $\mathbf{x}\mathbf{y}^\top$ is a product of an $m \times 1$ and a $1 \times n$ matrix, so it has rank 1 by Proposition 3.8.2; and $\mathbf{x}\mathbf{y}^\top = \mathbf{0}$ when $\mathbf{x} = \mathbf{0}$ or $\mathbf{y} = \mathbf{0}$, of rank 0. Conversely, a matrix $\mathbf{A}$ of rank 1 factors as $\mathbf{A} = \mathbf{x}\mathbf{y}^\top$ with $\mathbf{x} \in F^m$ and $\mathbf{y}^\top \in M_{1\times n}(F)$, again by Proposition 3.8.2, and the zero matrix is $\mathbf{0} \otimes \mathbf{0}$. This proves the theorem. ∎

Example. (Computing in $F^2 \otimes F^3$)

Work in $F^2 \otimes F^3$ with standard bases $(\mathbf{e}_1, \mathbf{e}_2)$ and $(\mathbf{f}_1, \mathbf{f}_2, \mathbf{f}_3)$.

(a) Expand $(\mathbf{e}_1 + 2\mathbf{e}_2) \otimes (3\mathbf{f}_1 - \mathbf{f}_2)$ in the basis of Theorem 14.2.5, and write the corresponding matrix.

(b) Decide whether $t = \mathbf{e}_1 \otimes \mathbf{f}_1 + 2\,\mathbf{e}_1 \otimes \mathbf{f}_2 + 3\,\mathbf{e}_2 \otimes \mathbf{f}_1 + 6\,\mathbf{e}_2 \otimes \mathbf{f}_2$ is a simple tensor, and if so write it as one.

(c) Decide whether $u = \mathbf{e}_1 \otimes \mathbf{f}_1 + \mathbf{e}_2 \otimes \mathbf{f}_2$ is a simple tensor.

Solution.

(a) Expanding one slot at a time,

$$(\mathbf{e}_1 + 2\mathbf{e}_2) \otimes (3\mathbf{f}_1 - \mathbf{f}_2) = 3\,\mathbf{e}_1 \otimes \mathbf{f}_1 - \mathbf{e}_1 \otimes \mathbf{f}_2 + 6\,\mathbf{e}_2 \otimes \mathbf{f}_1 - 2\,\mathbf{e}_2 \otimes \mathbf{f}_2.$$

The coefficient of $\mathbf{e}_i \otimes \mathbf{f}_j$ is the (i,j) entry of the matrix, so Θ sends it to

$$\begin{pmatrix} 3 & -1 & 0 \\ 6 & -2 & 0 \end{pmatrix} = \begin{pmatrix} 1 \\ 2 \end{pmatrix} \begin{pmatrix} 3 & -1 & 0 \end{pmatrix},$$

which is the outer product predicted by Theorem 14.2.7.

(b) The coefficients give $\Theta(t) = \left(\begin{smallmatrix} 1 & 2 & 0 \\ 3 & 6 & 0 \end{smallmatrix}\right)$. Its second row is 3 times its first, so every 2×2 minor vanishes and the rank is 1 (Theorem 6.7.1). By Theorem 14.2.7, t is simple. Factoring, $\Theta(t) = (1,3)^{\top}(1,2,0)$, so

$$t = (\mathbf{e}_1 + 3\mathbf{e}_2) \otimes (\mathbf{f}_1 + 2\mathbf{f}_2),$$

which expands back to t.

(c) Here $\Theta(u) = \left(\begin{smallmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \end{smallmatrix}\right)$, whose first two columns are independent, so its rank is 2. By Theorem 14.2.7, u is **not** simple. No amount of rewriting will turn it into a single $\mathbf{v} \otimes \mathbf{w}$.

14.2.6 Three things a tensor is not

Part (c) above is not a curiosity; it is the central negative fact about tensor products, and the first of three misreadings worth naming before they happen.

14.2.6.1 Not every tensor is simple

Example. (A tensor that is not simple)

In $F^2 \otimes F^2$, the element $u = \mathbf{e}_1 \otimes \mathbf{e}_1 + \mathbf{e}_2 \otimes \mathbf{e}_2$ is not a simple tensor, for any field F.

Idea. Two routes, and both are worth having. The quick one: $\Theta(u) = \mathbf{I}_2$, of rank 2, while simple tensors have rank at most 1. The portable one: suppose $u = \mathbf{v} \otimes \mathbf{w}$, hit it with the four coordinate functionals f_{pq} built in the proof of Theorem 14.2.5, and read off four scalar equations that cannot all hold.

Proof. Suppose $u = \mathbf{v} \otimes \mathbf{w}$ for some $\mathbf{v}, \mathbf{w} \in F^2$. Let (φ_1, φ_2) be the basis of $(F^2)^*$ dual to $(\mathbf{e}_1, \mathbf{e}_2)$, and for $p, q \in \{1,2\}$ let $f_{pq} \colon F^2 \otimes F^2 \to F$ be the linear map with $f_{pq}(\mathbf{x} \otimes \mathbf{y}) = \varphi_p(\mathbf{x})\varphi_q(\mathbf{y})$, supplied by (T1) as in the proof of Theorem 14.2.5. Applying f_{pq} to both sides of $u = \mathbf{v} \otimes \mathbf{w}$ gives

$$v_p w_q = f_{pq}(u) = \delta_{p1}\delta_{q1} + \delta_{p2}\delta_{q2},$$

that is, $v_1 w_1 = 1$, $v_2 w_2 = 1$, $v_1 w_2 = 0$ and $v_2 w_1 = 0$. From $v_1 w_1 = 1$ we get $v_1 \neq 0$, so $v_1 w_2 = 0$ forces $w_2 = 0$ — and then $v_2 w_2 = 0 \neq 1$. This contradiction shows that no

such $\mathbf{v}, \mathbf{w}$ exist, so u is not simple.

■

Warning. **A general element of $V \otimes W$ is a *sum* of simple tensors, not a simple tensor.** Proposition 14.2.4 says the simple tensors span; Example (A tensor that is not simple) says they do not exhaust. A statement proved only for simple tensors is therefore proved for nothing until you extend it by linearity — which is legitimate precisely when the statement is about a linear map, and illegitimate when it is about, say, ranks or products. Whenever you want to define something on $V \otimes W$, do not write "define it on $\mathbf{v} \otimes \mathbf{w}$ and extend": use (T1), which is that move done correctly.

The smallest number of simple tensors needed to write a given tensor is a genuine invariant, and for coordinate spaces Theorem 14.2.7 identifies it: it is the rank of the corresponding matrix. So "not simple" means "rank at least 2". A later section meets the same failure for elements of $\Lambda^2 V$ that are not wedges of two vectors, and the closing section meets it again under the name *entanglement*.

14.2.6.2 A simple tensor vanishes only for an obvious reason

Proposition 14.2.8 — When a Simple Tensor Is Zero

Let V and W be finite-dimensional, $\mathbf{v} \in V$ and $\mathbf{w} \in W$. Then $\mathbf{v} \otimes \mathbf{w} = \mathbf{0}$ if and only if $\mathbf{v} = \mathbf{0}$ or $\mathbf{w} = \mathbf{0}$.

Proof. ($\Leftarrow$) If $\mathbf{v} = \mathbf{0}$, then $\mathbf{v} \otimes \mathbf{w} = (0 \cdot \mathbf{0}) \otimes \mathbf{w} = 0(\mathbf{0} \otimes \mathbf{w}) = \mathbf{0}$, using that a scalar passes across $\otimes$. The case $\mathbf{w} = \mathbf{0}$ is the same with the slots swapped.

($\Rightarrow$) Suppose $\mathbf{v} \neq \mathbf{0}$ and $\mathbf{w} \neq \mathbf{0}$. By Theorem 4.1.5 (a) there are $\varphi \in V^*$ and $\psi \in W^*$ with $\varphi(\mathbf{v}) = 1$ and $\psi(\mathbf{w}) = 1$. The map $(\mathbf{x}, \mathbf{y}) \mapsto \varphi(\mathbf{x})\psi(\mathbf{y})$ is bilinear, so (T1) gives a linear $f \colon V \otimes W \to F$ with $f(\mathbf{x} \otimes \mathbf{y}) = \varphi(\mathbf{x})\psi(\mathbf{y})$. Then $f(\mathbf{v} \otimes \mathbf{w}) = 1 \neq 0$, while $f(\mathbf{0}) = 0$. Hence $\mathbf{v} \otimes \mathbf{w} \neq \mathbf{0}$. This proves the proposition.

■

Warning. **A product of non-zero things can be zero in many algebraic settings, but not here.** It is tempting to expect $V \otimes W$ to behave like a ring with zero divisors, so that some $\mathbf{v} \otimes \mathbf{w}$ vanishes accidentally. It does not: Proposition 14.2.8 says the only way to get $\mathbf{0}$ is to feed in $\mathbf{0}$. The zero divisors appear one level later — in the algebras of the following sections, where products of non-zero *sums* of simple tensors can vanish.

14.2.6.3 A simple tensor does not remember its factors

Proposition 14.2.9 — When Two Simple Tensors Agree

Let V and W be finite-dimensional, and let $\mathbf{v}, \mathbf{v}' \in V$ and $\mathbf{w}, \mathbf{w}' \in W$ with $\mathbf{v} \otimes \mathbf{w} \neq \mathbf{0}$. Then

$$\mathbf{v} \otimes \mathbf{w} = \mathbf{v}' \otimes \mathbf{w}'$$

if and only if there is a scalar $c \neq 0$ with $\mathbf{v}' = c\mathbf{v}$ and $\mathbf{w}' = c^{-1}\mathbf{w}$.

Idea. The "if" half is the scalar rule. For "only if", the danger is that $\mathbf{v}'$ points somewhere new. Suppose it does; then $(\mathbf{v}, \mathbf{v}')$ is independent, so there is a functional killing $\mathbf{v}$ and not $\mathbf{v}'$, and the corresponding f on $V \otimes W$ separates the two sides.

Proof. ($\Leftarrow$) If $\mathbf{v}' = c\mathbf{v}$ and $\mathbf{w}' = c^{-1}\mathbf{w}$, then $\mathbf{v}' \otimes \mathbf{w}' = (c\mathbf{v}) \otimes (c^{-1}\mathbf{w}) = cc^{-1}(\mathbf{v} \otimes \mathbf{w}) = \mathbf{v} \otimes \mathbf{w}$, moving each scalar across $\otimes$.

($\Rightarrow$) Suppose $\mathbf{v} \otimes \mathbf{w} = \mathbf{v}' \otimes \mathbf{w}' \neq \mathbf{0}$. By Proposition 14.2.8 all four vectors are non-zero. Suppose, for a contradiction, that $\mathbf{v}' \notin \operatorname{span}(\mathbf{v})$. Then $(\mathbf{v}, \mathbf{v}')$ is linearly independent, so it extends to a basis of V (Theorem 1.6.5), and the dual basis (Theorem 4.1.3) provides $\varphi \in V^*$ with $\varphi(\mathbf{v}) = 0$ and $\varphi(\mathbf{v}') = 1$. Since $\mathbf{w}' \neq \mathbf{0}$, Theorem 4.1.5 (a) provides $\psi \in W^*$ with $\psi(\mathbf{w}') = 1$. By (T1) there is a linear $f\colon V \otimes W \to F$ with $f(\mathbf{x} \otimes \mathbf{y}) = \varphi(\mathbf{x})\psi(\mathbf{y})$. Evaluating both sides of $\mathbf{v} \otimes \mathbf{w} = \mathbf{v}' \otimes \mathbf{w}'$,

$$0 = \varphi(\mathbf{v})\psi(\mathbf{w}) = f(\mathbf{v} \otimes \mathbf{w}) = f(\mathbf{v}' \otimes \mathbf{w}') = \varphi(\mathbf{v}')\psi(\mathbf{w}') = 1,$$

which is absurd. Hence $\mathbf{v}' = c\mathbf{v}$ for some $c \in F$, and $c \neq 0$ because $\mathbf{v}' \neq \mathbf{0}$.

Then $\mathbf{v} \otimes \mathbf{w} = (c\mathbf{v}) \otimes \mathbf{w}' = \mathbf{v} \otimes (c\mathbf{w}')$, so $\mathbf{v} \otimes (\mathbf{w} - c\mathbf{w}') = \mathbf{0}$ by bilinearity. Since $\mathbf{v} \neq \mathbf{0}$, Proposition 14.2.8 forces $\mathbf{w} - c\mathbf{w}' = \mathbf{0}$, that is, $\mathbf{w}' = c^{-1}\mathbf{w}$. This proves the proposition. ∎

Warning. **$\mathbf{v} \otimes \mathbf{w} = \mathbf{v}' \otimes \mathbf{w}'$ does not mean $\mathbf{v} = \mathbf{v}'$ and $\mathbf{w} = \mathbf{w}'$.** Already $2\mathbf{v} \otimes \mathbf{w} = \mathbf{v} \otimes 2\mathbf{w}$, with different factors on the two sides. So "the first factor of a simple tensor" is **not** a well-defined function: writing $t = \mathbf{v} \otimes \mathbf{w}$ and then speaking of "the $\mathbf{v}$ of t" is an error. What Proposition 14.2.9 salvages is that the *lines* $\operatorname{span}(\mathbf{v})$ and $\operatorname{span}(\mathbf{w})$ are determined, which is exactly the information carried by a rank-one matrix: its column space and its row space.

Quick check. In $\mathbb{R}^2 \otimes \mathbb{R}^2$, is $\mathbf{e}_1 \otimes \mathbf{e}_2 + \mathbf{e}_2 \otimes \mathbf{e}_1$ a simple tensor?

Solution. No. Its matrix under Θ is $\left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$, of determinant $-1 \neq 0$, hence of rank 2 (Theorem 6.5.2). By Theorem 14.2.7 a simple tensor would have rank at most 1. Note how little the symmetry of the expression helps: being a sum of two simple tensors is the generic situation, not a special one.

14.2.7 Exercises

14.2.7.1 A. Check your understanding

Exercise A1.

(a) State the universal property (T1) of the tensor product, with every quantifier.

(b) What does Theorem 14.2.1 assert, and which clause of (T1) makes the composites identities?

(c) Give $\dim(V \otimes W)$ in terms of $\dim V$ and $\dim W$, and a basis.

(d) True or false: every element of $V \otimes W$ is of the form $\mathbf{v} \otimes \mathbf{w}$. Justify your answer.

(e) True or false: if $\mathbf{v} \otimes \mathbf{w} = \mathbf{0}$ then $\mathbf{v} = \mathbf{0}$. Justify your answer.

(f) Explain in one sentence why the tensor product is **not** defined by a formula for its elements.

Solution.

(a) A pair (X, τ) with $\tau\colon V \times W \to X$ bilinear such that for **every** vector space Z and **every** bilinear $\beta\colon V \times W \to Z$ there is a **unique** linear $\bar{\beta}\colon X \to Z$ with $\bar{\beta} \circ \tau = \beta$ (Definition 14.2.1).

(b) That any two tensor products of V and W are isomorphic by a unique isomorphism commuting with the two structure maps. The **uniqueness** clause: it says there is only one linear self-map $X \to X$ composing with τ to give τ, and since both $\psi\varphi$ and id_X are such maps, they are equal.

(c) $(\dim V)(\dim W)$, with basis $(\mathbf{v}_i \otimes \mathbf{w}_j)$ for bases $(\mathbf{v}_i)$ of V and $(\mathbf{w}_j)$ of W (Theorem 14.2.5).

(d) False. In $F^2 \otimes F^2$, $\mathbf{e}_1 \otimes \mathbf{e}_1 + \mathbf{e}_2 \otimes \mathbf{e}_2$ is not simple (Example (A tensor that is not simple)).

(e) False as stated: it says $\mathbf{v} = \mathbf{0}$ **or** $\mathbf{w} = \mathbf{0}$ (Proposition 14.2.8). For instance $\mathbf{v} \otimes \mathbf{0} = \mathbf{0}$ for every $\mathbf{v}$.

(f) Because a formula would require choosing a construction, and the object is characterized by what maps out of it do, not by what its elements look like; different constructions give different-looking elements and the same space up to a unique isomorphism.

14.2.7.2 B. Practice

Exercise B1: Simple or not.

For each element of $F^3 \otimes F^3$ below, determine whether it is a simple tensor. If it is, write it as $\mathbf{v} \otimes \mathbf{w}$; if it is not, justify your answer. Use the standard basis $(\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3)$ in both factors.

(a) $t_1 = \mathbf{e}_1 \otimes \mathbf{e}_2 - 2\,\mathbf{e}_1 \otimes \mathbf{e}_3 + 3\,\mathbf{e}_3 \otimes \mathbf{e}_2 - 6\,\mathbf{e}_3 \otimes \mathbf{e}_3$.

(b) $t_2 = \mathbf{e}_1 \otimes \mathbf{e}_1 + \mathbf{e}_2 \otimes \mathbf{e}_2 + \mathbf{e}_3 \otimes \mathbf{e}_3$.

(c) $t_3 = \mathbf{e}_1 \otimes \mathbf{e}_2 + \mathbf{e}_2 \otimes \mathbf{e}_1$.

(d) $t_4 = \mathbf{0}$.

Solution. Throughout we use Theorem 14.2.7: t is simple exactly when the matrix $\Theta(t)$, whose (i, j) entry is the coefficient of $\mathbf{e}_i \otimes \mathbf{e}_j$, has rank at most 1.

(a) $\Theta(t_1) = \left(\begin{smallmatrix} 0 & 1 & -2 \\ 0 & 0 & 0 \\ 0 & 3 & -6 \end{smallmatrix}\right)$. Row 3 is 3 times row 1 and row 2 is zero, so the rank is 1. Factoring, $\Theta(t_1) = (1, 0, 3)^{\top}(0, 1, -2)$, so

$$t_1 = (\mathbf{e}_1 + 3\mathbf{e}_3) \otimes (\mathbf{e}_2 - 2\mathbf{e}_3),$$

which expands to the four given terms.

(b) $\Theta(t_2) = \mathbf{I}_3$, of rank 3. Not simple. This is Example (A tensor that is not simple) one size larger.

(c) $\Theta(t_3)$ has 1 in positions $(1, 2)$ and $(2, 1)$ and zeros elsewhere. Its top-left 2×2

minor is $0 \cdot 0 - 1 \cdot 1 = -1 \neq 0$, so its rank is 2 (Theorem 6.7.1). Not simple.

(d) $\Theta(t_4) = \mathbf{0}$, of rank $0 \leq 1$. So t_4 is simple, and indeed $\mathbf{0} = \mathbf{0} \otimes \mathbf{0}$. The degenerate case is simple for a boring reason, and it is worth keeping in the statement of Theorem 14.2.7.

Exercise B2: Inducing maps from bilinear maps.

In each case, a bilinear map is given. Use (T1) to produce the induced linear map on the tensor product, and compute the requested value.

(a) $\beta\colon F^2 \times F^2 \to F$, $\beta(\mathbf{x}, \mathbf{y}) = x_1y_1 + x_2y_2$. Compute $\bar{\beta}(\mathbf{e}_1 \otimes \mathbf{e}_1 + \mathbf{e}_2 \otimes \mathbf{e}_2)$.

(b) $\beta\colon F^n \times F^n \to M_n(F)$, $\beta(\mathbf{x}, \mathbf{y}) = \mathbf{x}\mathbf{y}^{\top} - \mathbf{y}\mathbf{x}^{\top}$. Compute $\bar{\beta}(\mathbf{v} \otimes \mathbf{v})$ for any $\mathbf{v}$.

(c) $\beta\colon V^* \times V \to F$, $\beta(\varphi, \mathbf{v}) = \varphi(\mathbf{v})$, for V finite-dimensional. Compute $\bar{\beta}(\varphi_1 \otimes \mathbf{v}_1 + \varphi_2 \otimes \mathbf{v}_2)$ for a basis $(\mathbf{v}_i)$ with dual basis (φ_i), assuming $\dim V \geq 2$.

Solution.

(a) β is the dot product, bilinear by Example (Six two-slot functions) (a). By (T1) there is a unique linear $\bar{\beta}$ with $\bar{\beta}(\mathbf{x} \otimes \mathbf{y}) = x_1y_1 + x_2y_2$. By linearity,

$$\bar{\beta}(\mathbf{e}_1 \otimes \mathbf{e}_1 + \mathbf{e}_2 \otimes \mathbf{e}_2) = \bar{\beta}(\mathbf{e}_1 \otimes \mathbf{e}_1) + \bar{\beta}(\mathbf{e}_2 \otimes \mathbf{e}_2) = 1 + 1 = 2.$$

(b) Each entry of $\mathbf{x}\mathbf{y}^{\top} - \mathbf{y}\mathbf{x}^{\top}$ is $x_iy_j - y_ix_j$, linear in each slot, so β is bilinear and (T1) applies. Then $\bar{\beta}(\mathbf{v} \otimes \mathbf{v}) = \mathbf{v}\mathbf{v}^{\top} - \mathbf{v}\mathbf{v}^{\top} = \mathbf{0}$ for every $\mathbf{v}$, so the induced map kills every "diagonal" simple tensor without being zero: $\bar{\beta}(\mathbf{e}_1 \otimes \mathbf{e}_2) = \mathbf{E}_{12} - \mathbf{E}_{21} \neq \mathbf{0}$ for $n \geq 2$.

(c) The evaluation pairing is bilinear by Example (Seven functions of several vectors) (f), so $\bar{\beta}\colon V^* \otimes V \to F$ exists with $\bar{\beta}(\varphi \otimes \mathbf{v}) = \varphi(\mathbf{v})$. Hence

$$\bar{\beta}(\varphi_1 \otimes \mathbf{v}_1 + \varphi_2 \otimes \mathbf{v}_2) = \varphi_1(\mathbf{v}_1) + \varphi_2(\mathbf{v}_2) = 1 + 1 = 2.$$

This map is the contraction, and the answer 2 is a first glimpse of a later section: it is the trace of a rank-two projection.

Exercise B3: Dimensions and bases.

Let V, W and U be finite-dimensional over F, with $\dim V = 3$, $\dim W = 4$ and $\dim U = 2$.

(a) Find $\dim(V \otimes W)$ and $\dim\big((V \otimes W) \otimes U\big)$.

(b) Find $\dim \mathcal{L}(V \otimes W, U)$ and $\dim \mathcal{M}(V, W; U)$, and explain why they agree.

(c) Let $V = F^3$ with basis $(\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3)$ and $W = F^4$ with basis $(\mathbf{f}_1, \dots, \mathbf{f}_4)$. Write down a basis of $V \otimes W$ and say which basis vector corresponds to the matrix unit $\mathbf{E}_{23}$ under Θ.

Solution.

(a) $\dim(V \otimes W) = 3 \cdot 4 = 12$ by Theorem 14.2.5, and then $\dim((V \otimes W) \otimes U) = 12 \cdot 2 = 24$, applying the theorem again to the pair $(V \otimes W, U)$.

(b) $\dim \mathcal{L}(V \otimes W, U) = (\dim U)\dim(V \otimes W) = 2 \cdot 12 = 24$ by Theorem 3.6.4, and $\dim \mathcal{M}(V, W; U) = 2 \cdot 3 \cdot 4 = 24$ by Eq. 14.1.1. They agree because Corollary 14.2.6 exhibits an isomorphism between the two spaces; the equality of numbers is that isomorphism, counted.

(c) The 12 tensors $\mathbf{e}_i \otimes \mathbf{f}_j$ with $1 \le i \le 3$ and $1 \le j \le 4$. Since $\Theta(\mathbf{e}_i \otimes \mathbf{f}_j) = \mathbf{E}_{ij}$, the basis vector corresponding to $\mathbf{E}_{23}$ is $\mathbf{e}_2 \otimes \mathbf{f}_3$.

14.2.7.3 C. Going deeper

Exercise C1: The tensor product is commutative, up to a unique isomorphism.

Let V and W be vector spaces over F.

(a) Prove that there is a unique linear map $\sigma\colon V \otimes W \to W \otimes V$ with $\sigma(\mathbf{v} \otimes \mathbf{w}) = \mathbf{w} \otimes \mathbf{v}$ for all $\mathbf{v}, \mathbf{w}$, and that it is an isomorphism.

(b) Deduce that $\sigma^2 = \mathrm{id}$ when $V = W$, where σ^2 means σ applied twice to $V \otimes V$.

(c) Explain why the argument in (a) never mentions a basis, and why that matters.

Hint for (a): the map $(\mathbf{v}, \mathbf{w}) \mapsto \mathbf{w} \otimes \mathbf{v}$ is bilinear; then build the inverse the same way and use the uniqueness clause of (T1).

Solution.

(a) The map $V \times W \to W \otimes V$, $(\mathbf{v}, \mathbf{w}) \mapsto \mathbf{w} \otimes \mathbf{v}$, is bilinear, because $\otimes$ is bilinear and swapping the slots exchanges the two clauses of Definition 14.1.1. By (T1) for $V \otimes W$ there is a unique linear σ with $\sigma(\mathbf{v} \otimes \mathbf{w}) = \mathbf{w} \otimes \mathbf{v}$. Symmetrically, (T1) for $W \otimes V$ gives a unique linear $\sigma'\colon W \otimes V \to V \otimes W$ with $\sigma'(\mathbf{w} \otimes \mathbf{v}) = \mathbf{v} \otimes \mathbf{w}$. Then $\sigma'\sigma$ is a linear self-map of $V \otimes W$ with $(\sigma'\sigma)(\mathbf{v} \otimes \mathbf{w}) = \mathbf{v} \otimes \mathbf{w}$, and so is the identity; by the uniqueness clause of (T1) applied with $Z = V \otimes W$ and $\beta = \tau$, the two agree, so $\sigma'\sigma = \mathrm{id}$. Symmetrically $\sigma\sigma' = \mathrm{id}$. Hence σ is an isomorphism (Theorem 3.5.1).

(b) With $V = W$, part (a) gives $\sigma' = \sigma$, since both are the unique linear map sending $\mathbf{v} \otimes \mathbf{w}$ to $\mathbf{w} \otimes \mathbf{v}$. Hence $\sigma^2 = \sigma'\sigma = \mathrm{id}$.

(c) Every step used only (T1) and the bilinearity of $\otimes$. So the argument works for infinite-dimensional spaces, where Theorem 14.2.5 is unavailable, and it produces a **canonical** isomorphism, whereas a basis-dependent construction would give one isomorphism per basis and no reason to prefer any of them.

Exercise C2: Recovering the factors from a simple tensor.

Let V and W be finite-dimensional and let $t = \mathbf{v} \otimes \mathbf{w} \neq \mathbf{0}$.

(a) Prove that the subspace $\mathrm{span}(\mathbf{v}) \subseteq V$ depends only on t, not on the chosen factorization.

(b) Prove the corresponding statement for $\mathrm{span}(\mathbf{w}) \subseteq W$.

(c) For $V = F^m$ and $W = F^n$, identify these two subspaces in terms of the matrix

$\Theta(t)$ of Theorem 14.2.7, and say why (a) and (b) are then statements you already knew.

Solution.

(a) Suppose $t = \mathbf{v} \otimes \mathbf{w} = \mathbf{v}' \otimes \mathbf{w}'$ with $t \neq \mathbf{0}$. By Proposition 14.2.9 there is $c \neq 0$ with $\mathbf{v}' = c\mathbf{v}$. A non-zero scalar multiple spans the same subspace, so $\operatorname{span}(\mathbf{v}') = \operatorname{span}(\mathbf{v})$. Hence the line is determined by t alone.

(b) The same proposition gives $\mathbf{w}' = c^{-1}\mathbf{w}$ with $c^{-1} \neq 0$, so $\operatorname{span}(\mathbf{w}') = \operatorname{span}(\mathbf{w})$.

(c) Under Θ, t corresponds to $\mathbf{A} = \mathbf{v}\mathbf{w}^{\top}$, a matrix of rank 1 (Theorem 14.2.7). Every column of $\mathbf{A}$ is a scalar multiple of $\mathbf{v}$, and $\mathbf{A}$ is non-zero, so $\operatorname{col}(\mathbf{A}) = \operatorname{span}(\mathbf{v})$; every row is a multiple of $\mathbf{w}^{\top}$, so $\operatorname{row}(\mathbf{A}) = \operatorname{span}(\mathbf{w}^{\top})$. Thus (a) and (b) say that a matrix has a well-defined column space and row space, which Chapter 3 established long ago. The tensor language adds nothing here except the reason the statement looks surprising: it is surprising only if one expects $\mathbf{v}$ itself, rather than its line, to be recoverable.

14.3 Tensor Products of Maps

Section 02 built the space $V \otimes W$. A construction on spaces is worth little until it acts on maps as well: the philosophy of the whole book has been objects first, then the maps between them. So given $S\colon V \to V'$ and $T\colon W \to W'$, we want a single map $V \otimes W \to V' \otimes W'$ built from the two. This section builds it, computes its matrix, and discovers that the matrix is the Kronecker product of Chapter 7 — which pays both of the debts that Chapter 7 §04 left open. It ends with the identification $V^* \otimes W \cong \mathcal{L}(V, W)$, which every later section of the chapter uses.

14.3.1 A map on each factor gives a map on the product

The definition writes itself, and that is the danger. We want a map that sends $\mathbf{v}\otimes\mathbf{w}$ to $S\mathbf{v}\otimes T\mathbf{w}$, so the temptation is to write

> "Define $(S \otimes T)(\mathbf{v} \otimes \mathbf{w}) := S\mathbf{v} \otimes T\mathbf{w}$, and extend linearly."

Nothing in that sentence is a definition. Simple tensors span $V \otimes W$ (Proposition 14.2.4), but they do not exhaust it, and worse, the expression of an element as a combination of them is wildly non-unique: $\mathbf{v} \otimes \mathbf{w} = (2\mathbf{v}) \otimes (\frac{1}{2}\mathbf{w})$, and $\mathbf{v} \otimes \mathbf{w} + \mathbf{v} \otimes \mathbf{w}' = \mathbf{v} \otimes (\mathbf{w} + \mathbf{w}')$. A formula prescribed on simple tensors may therefore assign two different values to one element, and then it defines nothing at all. Here is a formula that really does fail. Try to define $g\colon V \otimes W \to V$ by $g(\mathbf{v} \otimes \mathbf{w}) := \mathbf{v}$. Taking $\mathbf{w} = \mathbf{0}$ gives $\mathbf{v} \otimes \mathbf{0} = \mathbf{0}$ (Proposition 14.2.8), so g would have to send $\mathbf{0}$ to every $\mathbf{v}$ at once.

To build a map out of $V \otimes W$, never write a formula on simple tensors: write down a bilinear map and let the universal property produce the linear one.

That is the discipline of this chapter, and applied here it costs three lines.

Theorem 14.3.1 — Tensor Product of Two Linear Maps

Let V, V', W, W' be vector spaces over F, and let $S \in \mathcal{L}(V, V')$ and $T \in \mathcal{L}(W, W')$. Then there is **exactly one** linear map

$$f : V \otimes W \to V' \otimes W'$$

with $f(\mathbf{v} \otimes \mathbf{w}) = S\mathbf{v} \otimes T\mathbf{w}$ for **all** $\mathbf{v} \in V$ and $\mathbf{w} \in W$.

Idea. The assignment $(\mathbf{v}, \mathbf{w}) \mapsto S\mathbf{v} \otimes T\mathbf{w}$ is bilinear, because S and T are linear and $\otimes$ is bilinear in its two slots. A bilinear map out of $V \times W$ is exactly what the universal property consumes, and what it returns is a unique linear map out of $V \otimes W$. There is nothing else to check.

Proof. Define $\beta : V \times W \to V' \otimes W'$ by $\beta(\mathbf{v}, \mathbf{w}) := S\mathbf{v} \otimes T\mathbf{w}$. Fix $\mathbf{w} \in W$. The map $\mathbf{v} \mapsto S\mathbf{v} \otimes T\mathbf{w}$ is the composite of S, which is linear, with the map $\mathbf{u} \mapsto \mathbf{u} \otimes T\mathbf{w}$, which is linear because the map $\otimes : V' \times W' \to V' \otimes W'$ of Definition 14.2.1 is bilinear, hence linear in its first slot with the second slot held fixed. A composite of linear maps is linear (Theorem 3.4.2), so β is linear in its first argument. Fixing $\mathbf{v}$ instead and swapping the roles of the two slots gives linearity in the second. Hence β is bilinear.

By the universal property in Definition 14.2.1 there is a unique linear $f : V \otimes W \to V' \otimes W'$ with $f(\mathbf{v} \otimes \mathbf{w}) = \beta(\mathbf{v}, \mathbf{w}) = S\mathbf{v} \otimes T\mathbf{w}$ for all $\mathbf{v}, \mathbf{w}$. This proves both existence and uniqueness.

■

Uniqueness is what licenses a name.

Definition 14.3.1 — Tensor product of linear maps

Let $S \in \mathcal{L}(V, V')$ and $T \in \mathcal{L}(W, W')$. The **tensor product** of S and T is the unique linear map

$$S \otimes T : V \otimes W \to V' \otimes W'$$

of Theorem 14.3.1, characterized by

$$(S \otimes T)(\mathbf{v} \otimes \mathbf{w}) = S\mathbf{v} \otimes T\mathbf{w} \quad (\mathbf{v} \in V,\ \mathbf{w} \in W).$$

The symbol $\otimes$ now has three jobs — a space, a vector, a map — and they agree: $S \otimes T$ applied to $\mathbf{v} \otimes \mathbf{w}$ is $S\mathbf{v} \otimes T\mathbf{w}$, which is the only thing the notation could mean.

Examples.

1. **The identity.** $\mathrm{id}_V \otimes \mathrm{id}_W$ sends $\mathbf{v} \otimes \mathbf{w}$ to $\mathbf{v} \otimes \mathbf{w}$, and so does $\mathrm{id}_{V \otimes W}$. Both are linear and both are the factorization of the same bilinear map, so $\mathrm{id}_V \otimes \mathrm{id}_W = \mathrm{id}_{V \otimes W}$ by the uniqueness clause. Degenerate, and used in almost every proof below.
2. **Acting on one slot.** $S \otimes \mathrm{id}_W$ sends $\mathbf{v} \otimes \mathbf{w}$ to $S\mathbf{v} \otimes \mathbf{w}$: it does S in the first slot and leaves the second alone. If $V = W = F[x]$ and $S = D$ is differentiation, $D \otimes \mathrm{id}$ is "differentiate the first factor".
3. **Scalars.** For $c, d \in F$, $(c\,\mathrm{id}_V) \otimes (d\,\mathrm{id}_W)$ sends $\mathbf{v} \otimes \mathbf{w}$ to $c\mathbf{v} \otimes d\mathbf{w} = cd\,(\mathbf{v} \otimes \mathbf{w})$, so it is

$cd\ \mathrm{id}_{V\otimes W}$. In particular a scalar may be moved from one slot to the other, which is the map-level shadow of $c\mathbf{v}\otimes\mathbf{w}=\mathbf{v}\otimes c\mathbf{w}$.

4. **Zero.** If $S=0$, then $(S\otimes T)(\mathbf{v}\otimes\mathbf{w})=\mathbf{0}\otimes T\mathbf{w}=\mathbf{0}$, so $S\otimes T=0$. The converse also holds; see Exercise (C1: When a tensor product of maps vanishes).

Non-example by minimal change. Keep S and T linear, but try to send $\mathbf{v}\otimes\mathbf{w}$ to $S\mathbf{v}\otimes T\mathbf{w}+\mathbf{v}\otimes\mathbf{w}$. This one *is* legitimate: the assignment $(\mathbf{v},\mathbf{w})\mapsto S\mathbf{v}\otimes T\mathbf{w}+\mathbf{v}\otimes\mathbf{w}$ is a sum of two bilinear maps, hence bilinear, and the universal property applies. What is not legitimate is $(\mathbf{v},\mathbf{w})\mapsto S\mathbf{v}\otimes T\mathbf{w}+\mathbf{u}_0$ for a fixed non-zero $\mathbf{u}_0\in V'\otimes W'$: the added constant destroys linearity in each slot, so no linear map on $V\otimes W$ does this, and indeed the prescription contradicts itself at $\mathbf{w}=\mathbf{0}$. The exact clause that fails is bilinearity, and it fails for the same reason as in the map g above.

We will lean repeatedly on the following consequence of the uniqueness clause. It replaces the phrase "and extend linearly", which we are not allowed to use.

Lemma 14.3.2 — Simple Tensors Determine a Map

Let Z be a vector space over F and let $f,g\colon V\otimes W\to Z$ be linear. If $f(\mathbf{v}\otimes\mathbf{w})=g(\mathbf{v}\otimes\mathbf{w})$ for all $\mathbf{v}\in V$ and $\mathbf{w}\in W$, then $f=g$.

Proof. Put $\beta(\mathbf{v},\mathbf{w}):=f(\mathbf{v}\otimes\mathbf{w})$. Since $\otimes$ is bilinear and f is linear, β is bilinear. By hypothesis $\beta(\mathbf{v},\mathbf{w})=g(\mathbf{v}\otimes\mathbf{w})$ as well, so f and g are both linear maps factoring β through $\otimes$. The universal property of Definition 14.2.1 says there is only one such map. Hence $f=g$. ∎

No finite-dimensionality is needed, and no basis is chosen. With it, the algebra of $\otimes$ on maps is a formality.

Proposition 14.3.3 — Algebra of Tensor Products of Maps

Let $S,S_1,S_2\in\mathcal{L}(V,V')$, $T,T_1,T_2\in\mathcal{L}(W,W')$ and $c\in F$. Let also $R\in\mathcal{L}(V',V'')$ and $U\in\mathcal{L}(W',W'')$. Then:

(a) $(S_1+S_2)\otimes T=S_1\otimes T+S_2\otimes T$ and $S\otimes(T_1+T_2)=S\otimes T_1+S\otimes T_2$;
(b) $(cS)\otimes T=c(S\otimes T)=S\otimes(cT)$;
(c) $(R\otimes U)(S\otimes T)=RS\otimes UT$;
(d) $\mathrm{id}_V\otimes\mathrm{id}_W=\mathrm{id}_{V\otimes W}$.

Proof. In each part both sides are linear maps out of $V\otimes W$, so by Lemma 14.3.2 it suffices to compare their values at a simple tensor $\mathbf{v}\otimes\mathbf{w}$.

(a) The left side gives $(S_1+S_2)\mathbf{v}\otimes T\mathbf{w}=(S_1\mathbf{v}+S_2\mathbf{v})\otimes T\mathbf{w}$, which equals $S_1\mathbf{v}\otimes T\mathbf{w}+S_2\mathbf{v}\otimes T\mathbf{w}$ because $\otimes$ is additive in its first slot. That is the value of the right side. The second identity is the same argument in the other slot.

(b) $(cS)\mathbf{v}\otimes T\mathbf{w}=(cS\mathbf{v})\otimes T\mathbf{w}=c(S\mathbf{v}\otimes T\mathbf{w})=S\mathbf{v}\otimes(cT\mathbf{w})$, where both outer equalities use bilinearity of $\otimes$.

(c) $(R\otimes U)\big((S\otimes T)(\mathbf{v}\otimes\mathbf{w})\big) = (R\otimes U)(S\mathbf{v}\otimes T\mathbf{w}) = RS\mathbf{v}\otimes UT\mathbf{w}$, which is the value of $RS\otimes UT$.

(d) Done in Example 1.

■

Part (c) is the statement that $\otimes$ respects composition: it is *functoriality*, and we will see in a moment that it is the mixed product rule of Theorem 7.4.1 in disguise.

Two more structural facts are needed before §04 can speak of tensors with several slots. The first extends the universal property from two factors to any number, and the second says that the brackets do not matter.

For $k \geq 2$ define the iterated tensor product by

$$V_1 \otimes \cdots \otimes V_k \coloneqq (V_1 \otimes \cdots \otimes V_{k-1}) \otimes V_k,$$

starting from V_1 itself when $k = 1$, and write $\mathbf{v}_1 \otimes \cdots \otimes \mathbf{v}_k$ for $(\mathbf{v}_1 \otimes \cdots \otimes \mathbf{v}_{k-1}) \otimes \mathbf{v}_k$. Multilinear maps of k arguments were defined in Definition 14.1.1.

Lemma 14.3.4 — Universal Property for k Factors

Let $V_1, \ldots, V_k$ and Z be vector spaces over F, and let $\beta\colon V_1 \times \cdots \times V_k \to Z$ be multilinear. Then there is **exactly one** linear map

$$\bar{\beta}\colon V_1 \otimes \cdots \otimes V_k \to Z$$

with $\bar{\beta}(\mathbf{v}_1 \otimes \cdots \otimes \mathbf{v}_k) = \beta(\mathbf{v}_1, \ldots, \mathbf{v}_k)$ for all $\mathbf{v}_1, \ldots, \mathbf{v}_k$. Moreover the tensors $\mathbf{v}_1 \otimes \cdots \otimes \mathbf{v}_k$ span $V_1 \otimes \cdots \otimes V_k$.

Idea. Induction on k, freezing the last argument. With $\mathbf{v}_k$ held fixed, β is multilinear in the first $k-1$ arguments, so the inductive hypothesis converts it into a linear map on $X = V_1 \otimes \cdots \otimes V_{k-1}$. Letting $\mathbf{v}_k$ move again gives a bilinear map on $X \times V_k$, and (T1) finishes. The spanning claim is the same induction.

Proof. For $k = 1$ take $\bar{\beta} = \beta$, which is linear, and the claim is trivial; for $k = 2$ the statement is Definition 14.2.1 together with Proposition 14.2.4. Let $k \geq 3$ and assume the lemma for $k-1$. Put $X \coloneqq V_1 \otimes \cdots \otimes V_{k-1}$.

Fix $\mathbf{v}_k \in V_k$. The map $(\mathbf{v}_1, \ldots, \mathbf{v}_{k-1}) \mapsto \beta(\mathbf{v}_1, \ldots, \mathbf{v}_k)$ is multilinear, so the inductive hypothesis gives a unique linear $g_{\mathbf{v}_k}\colon X \to Z$ with $g_{\mathbf{v}_k}(\mathbf{v}_1 \otimes \cdots \otimes \mathbf{v}_{k-1}) = \beta(\mathbf{v}_1, \ldots, \mathbf{v}_k)$.

The map $X \times V_k \to Z$, $(x, \mathbf{v}_k) \mapsto g_{\mathbf{v}_k}(x)$, is bilinear. It is linear in x because each $g_{\mathbf{v}_k}$ is. For linearity in $\mathbf{v}_k$, fix $\mathbf{v}_k, \mathbf{v}_k' \in V_k$ and $c \in F$: the linear maps $g_{\mathbf{v}_k + c\mathbf{v}_k'}$ and $g_{\mathbf{v}_k} + c\, g_{\mathbf{v}_k'}$ agree at every $\mathbf{v}_1 \otimes \cdots \otimes \mathbf{v}_{k-1}$, because β is linear in its last argument, and those tensors span X by the inductive hypothesis; so the two maps are equal.

By Definition 14.2.1 there is a unique linear $\bar{\beta}$ on $X \otimes V_k = V_1 \otimes \cdots \otimes V_k$ with $\bar{\beta}(x \otimes \mathbf{v}_k) = g_{\mathbf{v}_k}(x)$; taking $x = \mathbf{v}_1 \otimes \cdots \otimes \mathbf{v}_{k-1}$ gives $\bar{\beta}(\mathbf{v}_1 \otimes \cdots \otimes \mathbf{v}_k) = \beta(\mathbf{v}_1, \ldots, \mathbf{v}_k)$.

Finally, $X \otimes V_k$ is spanned by the simple tensors $x \otimes \mathbf{v}_k$ (Proposition 14.2.4), each x is a combination of $\mathbf{v}_1 \otimes \cdots \otimes \mathbf{v}_{k-1}$ by the inductive hypothesis, and $\otimes$ is linear in its first slot; so the k-fold tensors span. A linear map is determined by its values on a spanning

set, which gives uniqueness of $\bar{\beta}$.

■

Proposition 14.3.5 — Associativity of the Tensor Product

Let U, V, W be vector spaces over F. There is a unique isomorphism

$$\alpha\colon (U \otimes V) \otimes W \to U \otimes (V \otimes W)$$

with $\alpha\big((\mathbf{u} \otimes \mathbf{v}) \otimes \mathbf{w}\big) = \mathbf{u} \otimes (\mathbf{v} \otimes \mathbf{w})$ for all $\mathbf{u}, \mathbf{v}, \mathbf{w}$.

Proof. The map $(\mathbf{u}, \mathbf{v}, \mathbf{w}) \mapsto \mathbf{u} \otimes (\mathbf{v} \otimes \mathbf{w})$ is trilinear, since $\otimes$ is bilinear in each of its two uses. By Lemma 14.3.4 with $k = 3$ there is a unique linear α on $(U \otimes V) \otimes W$ with the stated values. Symmetrically, freezing the *first* argument instead and running the two-factor property twice produces a linear $\alpha'\colon U \otimes (V \otimes W) \to (U \otimes V) \otimes W$ with $\alpha'(\mathbf{u} \otimes (\mathbf{v} \otimes \mathbf{w})) = (\mathbf{u} \otimes \mathbf{v}) \otimes \mathbf{w}$. The composite $\alpha'\alpha$ fixes every $(\mathbf{u} \otimes \mathbf{v}) \otimes \mathbf{w}$, and those span by Lemma 14.3.4, so $\alpha'\alpha = \mathrm{id}$; symmetrically $\alpha\alpha' = \mathrm{id}$. Hence α is an isomorphism.

■

From now on we drop the brackets and write $U \otimes V \otimes W$, with $\mathbf{u} \otimes \mathbf{v} \otimes \mathbf{w}$ for the element that both ways of bracketing name, and likewise for any number of factors.

14.3.2 The matrix of a tensor product of maps

Now we compute. A matrix needs **ordered** bases, and $V \otimes W$ has a basis indexed by *pairs* (i, k), so the whole content of the computation is which order we put the pairs in.

Order the basis $\mathbf{v}_i \otimes \mathbf{w}_k$ by dictionary order on the pair (i, k): the index of the first factor changes slowly, the index of the second factor runs fastest.

Definition 14.3.2 — The product basis, ordered

Let $\mathcal{B} = (\mathbf{v}_1, \dots, \mathbf{v}_n)$ be an ordered basis of V and $\mathcal{C} = (\mathbf{w}_1, \dots, \mathbf{w}_q)$ an ordered basis of W. Write $\mathcal{B} \otimes \mathcal{C}$ for the basis $(\mathbf{v}_i \otimes \mathbf{w}_k)$ of $V \otimes W$ given by Theorem 14.2.5, **ordered** so that $\mathbf{v}_i \otimes \mathbf{w}_k$ occupies position

$$(i-1)q + k \qquad (1 \le i \le n,\ 1 \le k \le q),$$

that is, in the order

$$\mathbf{v}_1 \otimes \mathbf{w}_1,\ \dots,\ \mathbf{v}_1 \otimes \mathbf{w}_q,\ \mathbf{v}_2 \otimes \mathbf{w}_1,\ \dots,\ \mathbf{v}_n \otimes \mathbf{w}_q.$$

Division with remainder writes every position $1, \dots, nq$ as $(i-1)q + k$ for exactly one pair, so this really is an ordering of the whole basis. It is the dictionary order on pairs, and it is the same rule that Chapter 7 used to label the rows and columns of a Kronecker product in the formula $(*)$ after Definition 7.4.1. That is not a coincidence, and the next theorem says why.

Theorem 14.3.6 — The Kronecker Product Is the Matrix of a Tensor Product of Maps

Let V, V', W, W' be finite-dimensional vector spaces over F with ordered bases

$$\mathcal{B} = (\mathbf{v}_1, \dots, \mathbf{v}_n) \text{ of } V, \qquad \mathcal{B}' = (\mathbf{v}'_1, \dots, \mathbf{v}'_m) \text{ of } V',$$
$$\mathcal{C} = (\mathbf{w}_1, \dots, \mathbf{w}_q) \text{ of } W, \qquad \mathcal{C}' = (\mathbf{w}'_1, \dots, \mathbf{w}'_p) \text{ of } W'.$$

Let $S \in \mathcal{L}(V, V')$ and $T \in \mathcal{L}(W, W')$. Then, with the orderings of Definition 14.3.2 on both sides,

$$[S \otimes T]^{\mathcal{B}' \otimes \mathcal{C}'}_{\mathcal{B} \otimes \mathcal{C}} = [S]^{\mathcal{B}'}_{\mathcal{B}} \otimes [T]^{\mathcal{C}'}_{\mathcal{C}},$$

the Kronecker product of Definition 7.4.1.

Idea. A matrix is read off column by column, and column (j, l) of the left side holds the coordinates of $(S \otimes T)(\mathbf{v}_j \otimes \mathbf{w}_l) = S\mathbf{v}_j \otimes T\mathbf{w}_l$. Expanding $S\mathbf{v}_j$ and $T\mathbf{w}_l$ in their bases and multiplying out by bilinearity produces the coefficient $a_{ij}b_{kl}$ on $\mathbf{v}'_i \otimes \mathbf{w}'_k$ — a product of one entry of each matrix. The entry formula $(*)$ of Chapter 7 says the Kronecker product puts exactly that number in exactly that place, provided the pairs are read in dictionary order. So the theorem is the entry formula and bilinearity, nothing more.

Proof. Write $\mathbf{A} = (a_{ij}) = [S]^{\mathcal{B}'}_{\mathcal{B}} \in M_{m \times n}(F)$ and $\mathbf{B} = (b_{kl}) = [T]^{\mathcal{C}'}_{\mathcal{C}} \in M_{p \times q}(F)$, so that by Definition 3.6.1

$$S\mathbf{v}_j = \sum_{i=1}^{m} a_{ij}\mathbf{v}'_i, \qquad T\mathbf{w}_l = \sum_{k=1}^{p} b_{kl}\mathbf{w}'_k.$$

Fix j and l. Using Definition 14.3.1 and then bilinearity of $\otimes$ in each slot,

$$\begin{aligned}(S \otimes T)(\mathbf{v}_j \otimes \mathbf{w}_l) &= S\mathbf{v}_j \otimes T\mathbf{w}_l \\ &= \Big(\sum_i a_{ij}\mathbf{v}'_i\Big) \otimes \Big(\sum_k b_{kl}\mathbf{w}'_k\Big) \\ &= \sum_{i=1}^{m}\sum_{k=1}^{p} a_{ij}b_{kl}\,(\mathbf{v}'_i \otimes \mathbf{w}'_k).\end{aligned}$$

By Definition 14.3.2, $\mathbf{v}_j \otimes \mathbf{w}_l$ is the basis vector in position $(j-1)q + l$ of $\mathcal{B} \otimes \mathcal{C}$, and $\mathbf{v}'_i \otimes \mathbf{w}'_k$ is the basis vector in position $(i-1)p + k$ of $\mathcal{B}' \otimes \mathcal{C}'$. So the displayed expansion says that the entry of $[S \otimes T]^{\mathcal{B}' \otimes \mathcal{C}'}_{\mathcal{B} \otimes \mathcal{C}}$ in row $(i-1)p + k$ and column $(j-1)q + l$ is $a_{ij}b_{kl}$.

By the entry formula $(*)$ accompanying Definition 7.4.1, that is exactly the entry of $\mathbf{A} \otimes \mathbf{B}$ in the same position. Every row index of an $mp \times nq$ matrix is $(i-1)p + k$ for exactly one pair (i, k), and every column index is $(j-1)q + l$ for exactly one pair (j, l), so the two matrices agree in every position. This proves the theorem. ∎

The ordering is the whole content, so it is worth being exact about it. Suppose we had ordered the product basis the other way, putting $\mathbf{v}_i \otimes \mathbf{w}_k$ in position $(k-1)n + i$, so that the *second* index changes slowly. Running the proof again, the entry in row $(k-1)m + i$ and column $(l-1)n + j$ is still $a_{ij}b_{kl}$, which by $(*)$ is the entry of $\mathbf{B} \otimes \mathbf{A}$ in that position. So the

other ordering gives

$$[T]_{\mathcal{C}}^{\mathcal{C}'} \otimes [S]_{\mathcal{B}}^{\mathcal{B}'},$$

the Kronecker product with the factors **swapped** — not the transpose, and not the same matrix. For square factors the two answers are related exactly as Proposition 7.4.2 says, by conjugating with the permutation matrix that relabels dictionary order into its reverse — which is precisely the change-of-coordinates matrix between the two orderings of the product basis. In the rectangular setting of Theorem 14.3.6 the relation is not a conjugation at all: the row and column relabelings are different permutations, so $\mathbf{B} \otimes \mathbf{A} = \mathbf{P}_{\sigma}^{\top}(\mathbf{A} \otimes \mathbf{B})\mathbf{P}_{\tau}$ with two matrices, as Chapter 7 notes just after that proposition's proof.

Warning. **Do not reverse the two factors of the basis ordering.** The theorem needs the index of the **first** tensor factor to be the slow one, matching Chapter 7's dictionary order in $(*)$. With the fast and slow indices exchanged the matrix of $S \otimes T$ is $[T] \otimes [S]$. For $\mathbf{A} = \begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix}$ and $\mathbf{B} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$ these two differ in the $(1,2)$ entry, which is $a_{11}b_{12} = 1$ in the first and $b_{11}a_{12} = 0$ in the second (the non-example after Definition 7.4.1).

Chapter 7's two promises, paid. At Definition 7.4.1, Chapter 7 wrote that the symbol $\otimes$ "anticipates the tensor product of Chapter 14, of which this is the matrix version". Theorem 14.3.6 is that statement, made precise and proved: the Kronecker product of two matrices is the matrix of the tensor product of the two maps they represent, taken in the product bases. At the end of the same section, Chapter 7 wrote that the Kronecker product is "the coordinate shadow of a basis-free construction: the tensor product of linear maps, in Chapter 14, whose matrix in suitable bases is exactly $\mathbf{A} \otimes \mathbf{B}$", and promised that "the dictionary order in $(*)$ will reappear there as an ordering of a basis $\mathbf{v}_i \otimes \mathbf{w}_k$". The suitable bases are $\mathcal{B} \otimes \mathcal{C}$ and $\mathcal{B}' \otimes \mathcal{C}'$; the dictionary order has reappeared, as Definition 14.3.2; and the shadow is cast by $S \otimes T$. The second promise gets a sharper payment at the end of this section, where the vec identity turns out to be this same theorem applied to a space of matrices.

Example. (Computing with a tensor product of maps)

Let $S\colon F^2 \to F^2$ and $T\colon F^3 \to F^2$ have matrices, in the standard bases,

$$\mathbf{A} = \begin{pmatrix} 2 & 1 \\ 0 & 3 \end{pmatrix}, \qquad \mathbf{B} = \begin{pmatrix} 1 & 0 & -1 \\ 2 & 1 & 0 \end{pmatrix}.$$

Compute $(S \otimes T)(\mathbf{e}_1 \otimes \mathbf{f}_2 + \mathbf{e}_2 \otimes \mathbf{f}_3)$ directly from Definition 14.3.1, and again from the matrix of Theorem 14.3.6. Here $(\mathbf{e}_1, \mathbf{e}_2)$ is the standard basis of F^2 and $(\mathbf{f}_1, \mathbf{f}_2, \mathbf{f}_3)$ that of F^3.

Solution. **Directly.** Columns of $\mathbf{A}$ and $\mathbf{B}$ give $S\mathbf{e}_1 = 2\mathbf{e}_1$, $S\mathbf{e}_2 = \mathbf{e}_1 + 3\mathbf{e}_2$, $T\mathbf{f}_2 = \mathbf{e}_2$ and $T\mathbf{f}_3 = -\mathbf{e}_1$. Hence

$$\begin{aligned}(S \otimes T)(\mathbf{e}_1 \otimes \mathbf{f}_2 + \mathbf{e}_2 \otimes \mathbf{f}_3) &= 2\mathbf{e}_1 \otimes \mathbf{e}_2 + (\mathbf{e}_1 + 3\mathbf{e}_2) \otimes (-\mathbf{e}_1) \\ &= -\,\mathbf{e}_1 \otimes \mathbf{e}_1 + 2\,\mathbf{e}_1 \otimes \mathbf{e}_2 - 3\,\mathbf{e}_2 \otimes \mathbf{e}_1,\end{aligned}$$

using bilinearity of $\otimes$ in both slots.

By matrix. The domain basis, ordered as in Definition 14.3.2, is $(\mathbf{e}_1 \otimes \mathbf{f}_1, \mathbf{e}_1 \otimes \mathbf{f}_2, \mathbf{e}_1 \otimes \mathbf{f}_3, \mathbf{e}_2 \otimes \mathbf{f}_1, \mathbf{e}_2 \otimes \mathbf{f}_2, \mathbf{e}_2 \otimes \mathbf{f}_3)$, so the input has coordinate column $(0, 1, 0, 0, 0, 1)$. By The-

orem 14.3.6 the matrix of $S \otimes T$ is

$$\mathbf{A} \otimes \mathbf{B} = \begin{pmatrix} 2 & 0 & -2 & 1 & 0 & -1 \\ 4 & 2 & 0 & 2 & 1 & 0 \\ 0 & 0 & 0 & 3 & 0 & -3 \\ 0 & 0 & 0 & 6 & 3 & 0 \end{pmatrix},$$

and multiplying it by that column gives $(-1, 2, -3, 0)$. In the codomain basis $(\mathbf{e}_1 \otimes \mathbf{e}_1, \mathbf{e}_1 \otimes \mathbf{e}_2, \mathbf{e}_2 \otimes \mathbf{e}_1, \mathbf{e}_2 \otimes \mathbf{e}_2)$ this is the same element as before.

14.3.3 What Chapter 7 was computing

Every property of the Kronecker product proved by entry-chasing in Chapter 7 is now a property of maps, and several of them become one-liners. We record the three that the rest of the chapter uses.

The mixed product rule comes first, because it is the one Chapter 7 called "the engine of everything that follows".

Corollary 14.3.7 — The Mixed Product Rule Is Functoriality

Let $\mathbf{A} \in M_{m\times n}(F)$, $\mathbf{C} \in M_{n\times t}(F)$, $\mathbf{B} \in M_{p\times q}(F)$ and $\mathbf{D} \in M_{q\times u}(F)$. Then

$$(\mathbf{A} \otimes \mathbf{B})(\mathbf{C} \otimes \mathbf{D}) = (\mathbf{AC}) \otimes (\mathbf{BD}).$$

Proof. Let S, R, T, U be the linear maps with matrices $\mathbf{A}, \mathbf{C}, \mathbf{B}, \mathbf{D}$ in the standard bases of the relevant spaces F^k. By Theorem 14.3.6, with all product bases ordered as in Definition 14.3.2, $\mathbf{A} \otimes \mathbf{B}$ and $\mathbf{C} \otimes \mathbf{D}$ are the matrices of $S \otimes T$ and $R \otimes U$. By Theorem 3.6.2 the product of the matrices is the matrix of the composite $(S \otimes T)(R \otimes U)$, which is $SR \otimes TU$ by Proposition 14.3.3 (c). Applying Theorem 14.3.6 once more, and Theorem 3.6.2 again to each factor, the matrix of $SR \otimes TU$ is $(\mathbf{AC}) \otimes (\mathbf{BD})$. ∎

This is Theorem 7.4.1 (c), which Chapter 7 proved by partitioning both matrices into conformable blocks and multiplying blockwise. The proof above says what the identity *means*: doing two things one after the other in each slot separately is the same as doing them one after the other in both slots at once. In the same way, the bilinearity of Theorem 7.4.1 (a) is parts (a) and (b) of Proposition 14.3.3, its associativity (b) is Proposition 14.3.5, and its inverse rule (e) is parts (c) and (d) together with invertibility of a composite.

Next, the numerical invariants.

Corollary 14.3.8 — Rank, Determinant and Trace of a Tensor Product of Maps

Let V, V', W, W' be finite-dimensional over F, $S \in \mathcal{L}(V, V')$, $T \in \mathcal{L}(W, W')$. Then

$$\operatorname{rank}(S \otimes T) = \operatorname{rank} S \cdot \operatorname{rank} T.$$

If moreover $V = V'$ and $W = W'$, with $n = \dim V \geq 1$ and $m = \dim W \geq 1$, then

$$\det(S \otimes T) = (\det S)^m (\det T)^n, \qquad \operatorname{tr}(S \otimes T) = \operatorname{tr} S \cdot \operatorname{tr} T.$$

Idea. For the rank, choose bases adapted to the two kernels: then $S \otimes T$ kills most product basis vectors and sends the remaining $\operatorname{rank} S \cdot \operatorname{rank} T$ of them to independent vectors. For the determinant, split $S \otimes T = (S \otimes \mathrm{id})(\mathrm{id} \otimes T)$. The factor $\mathrm{id}_V \otimes T$ preserves each of the n subspaces $\mathbf{v}_i \otimes W$ and acts on each as T; the factor $S \otimes \mathrm{id}_W$ preserves each of the m subspaces $V \otimes \mathbf{w}_k$ and acts as S. So each factor is block diagonal with repeated blocks, and the exponents count the *other* space's dimension, which is where the exponents come from. The trace we take from the matrix.

Proof. **Rank.** Let $r = \operatorname{rank} S$ and $s = \operatorname{rank} T$. Choose a basis $(\mathbf{v}_1, \dots, \mathbf{v}_n)$ of V whose last $n - r$ vectors form a basis of $\ker S$; this is possible by Theorem 1.8.2 applied to a basis of $\ker S$, after reordering. Then $S\mathbf{v}_1, \dots, S\mathbf{v}_r$ span $\operatorname{im} S$ by Theorem 3.2.4, and being $r = \operatorname{rank} S$ spanning vectors of an r-dimensional space they form a basis of $\operatorname{im} S$ (Theorem 1.6.4). Choose a basis $(\mathbf{w}_1, \dots, \mathbf{w}_m)$ of W the same way, so that $T\mathbf{w}_1, \dots, T\mathbf{w}_s$ is a basis of $\operatorname{im} T$ and $T\mathbf{w}_l = \mathbf{0}$ for $l > s$.

By Theorem 3.2.4, $\operatorname{im}(S \otimes T)$ is spanned by the vectors $S\mathbf{v}_j \otimes T\mathbf{w}_l$, and those with $j > r$ or $l > s$ are $\mathbf{0}$. Extend $(S\mathbf{v}_1, \dots, S\mathbf{v}_r)$ to a basis of V' and $(T\mathbf{w}_1, \dots, T\mathbf{w}_s)$ to a basis of W' (Theorem 1.8.2). By Theorem 14.2.5 the products of these basis vectors form a basis of $V' \otimes W'$; in particular the rs vectors $S\mathbf{v}_j \otimes T\mathbf{w}_l$ with $j \leq r$, $l \leq s$ are linearly independent. They therefore form a basis of $\operatorname{im}(S \otimes T)$, and $\operatorname{rank}(S \otimes T) = rs$.

Determinant. By Proposition 14.3.3 (c) and (d),

$$S \otimes T = (S \otimes \mathrm{id}_W)(\mathrm{id}_V \otimes T),$$

so $\det(S \otimes T) = \det(S \otimes \mathrm{id}_W) \det(\mathrm{id}_V \otimes T)$ by Theorem 6.5.8. Fix bases $\mathcal{B}$ of V and $\mathcal{C}$ of W and use the ordering of Definition 14.3.2. For each i, the subspace $\mathbf{v}_i \otimes W := \operatorname{span}(\mathbf{v}_i \otimes \mathbf{w}_1, \dots, \mathbf{v}_i \otimes \mathbf{w}_m)$ is carried into itself by $\mathrm{id}_V \otimes T$, which acts on it as T does on W; and $V \otimes W$ is the direct sum of these n subspaces, because their bases together form the basis $\mathcal{B} \otimes \mathcal{C}$. Consecutive blocks of the ordering are exactly these subspaces, so

$$[\mathrm{id}_V \otimes T]^{\mathcal{B}\otimes\mathcal{C}}_{\mathcal{B}\otimes\mathcal{C}} = \underbrace{[T]^{\mathcal{C}}_{\mathcal{C}} \oplus \cdots \oplus [T]^{\mathcal{C}}_{\mathcal{C}}}_{n \text{ blocks}},$$

whose determinant is $(\det T)^n$ by Theorem 7.1.4 (d) and induction on the number of blocks. The same argument for $S \otimes \mathrm{id}_W$, using instead the m subspaces $V \otimes \mathbf{w}_k$, gives $\det(S \otimes \mathrm{id}_W) = (\det S)^m$. (This time the relevant basis vectors are not consecutive in the ordering of Definition 14.3.2, so reorder the basis to make them so; matrices of one operator in two bases are similar, by Theorem 3.7.3, hence have the same determinant, by Corollary 6.5.7.) Multiplying the two gives the formula.

Trace. By Theorem 14.3.6 the matrix of $S \otimes T$ in $\mathcal{B} \otimes \mathcal{C}$ is $[S]^{\mathcal{B}}_{\mathcal{B}} \otimes [T]^{\mathcal{C}}_{\mathcal{C}}$, so by Definition 3.10.2 and Theorem 7.4.3 (b), $\operatorname{tr}(S \otimes T) = \operatorname{tr} S \cdot \operatorname{tr} T$.

■

These are parts (a), (c) and (b) of Theorem 7.4.3, transported to operators. Two remarks on what has changed. First, the exponents in the determinant formula are no longer something to memorize: $\det S$ appears to the power $\dim W$ because $S \otimes \mathrm{id}_W$ runs S once on each of the $\dim W$

copies of V inside $V \otimes W$. Second, the proof of the trace formula above is still a computation in a basis. There is a genuinely basis-free reason, and §04 gives it. The determinant, too, has a basis-free explanation, which has to wait for the top exterior power in §09.

Warning. **Most operators on $V \otimes W$ are not of the form $S \otimes T$.** The operators that are of this form are heavily constrained: by Corollary 14.3.8 their rank is a product rs with $r \le \dim V$ and $s \le \dim W$. Take $V = W = F^2$, so $\dim(V \otimes W) = 4$, and let P be any operator on $V \otimes W$ of rank 3, for instance the projection onto the span of the first three basis vectors of Definition 14.3.2. Then $3 = rs$ with $r, s \in \{0, 1, 2\}$ is impossible, so $P \neq S \otimes T$ for every S and T. The maps $S \otimes T$ do **span** $\mathcal{L}(V \otimes W)$, which is a different and weaker statement; this is the same distinction as between simple tensors and general tensors in §02.

Quick check. Let $S \in \mathcal{L}(V)$ and $T \in \mathcal{L}(W)$ with $\dim V = 3$ and $\dim W = 2$, and suppose $\det S = 2$ and $\det T = -1$. What are $\det(S \otimes T)$ and $\det(T \otimes S)$, where the second is an operator on $W \otimes V$?

Solution. By Corollary 14.3.8, $\det(S \otimes T) = (\det S)^{\dim W}(\det T)^{\dim V} = 2^2(-1)^3 = -4$. For $T \otimes S$ the roles swap, giving $(\det T)^{\dim V}(\det S)^{\dim W} = (-1)^3 2^2 = -4$ as well. The two agree, as they must: a determinant is a product of scalars, and the exponent always belongs to the *other* factor's dimension. The tempting wrong answer, $(\det S)^3(\det T)^2 = 8$, puts each map's own dimension in its exponent.

14.3.4 Maps as tensors

We come to the identification that the rest of the chapter runs on. A functional $\varphi \in V^*$ and a vector $\mathbf{w} \in W$ together determine a linear map $V \to W$: measure with φ, then scale $\mathbf{w}$ by the answer. That recipe is bilinear in $(\varphi, \mathbf{w})$, which is now a reflex: it must come from a linear map on $V^* \otimes W$.

Theorem 14.3.9 — Tensors Are Maps

Let V and W be **finite-dimensional** vector spaces over F. There is a unique linear map

$$\Theta \colon V^* \otimes W \to \mathcal{L}(V, W), \qquad \Theta(\varphi \otimes \mathbf{w})(\mathbf{v}) = \varphi(\mathbf{v})\,\mathbf{w},$$

and it is an isomorphism. Moreover, for $R \in \mathcal{L}(V_0, V)$ and $U \in \mathcal{L}(W, W_0)$ with V_0, W_0 finite-dimensional,

$$\Theta\big((R' \otimes U)(\xi)\big) = U\,\Theta(\xi)\,R \qquad (\xi \in V^* \otimes W),$$

where $R' \colon V^* \to V_0^*$ is the dual map of Definition 4.4.1 and the Θ on the left is the one for the pair (V_0, W_0).

Idea. Existence is the universal property again. For bijectivity, count: both sides have dimension $\dim V \cdot \dim W$, so it is enough to see that Θ carries a basis onto a basis. It carries $\varphi_j \otimes \mathbf{w}_i$ to the map whose matrix is the matrix unit $\mathbf{E}_{ij}$, and the matrix units are a basis. The last formula is the statement that Θ turns the tensor product of maps into composition on the two sides; it is checked on simple tensors.

Proof. **Existence and uniqueness.** For fixed φ and $\mathbf{w}$, the assignment $\mathbf{v} \mapsto \varphi(\mathbf{v})\mathbf{w}$ is linear, so it is an element $\varphi \cdot \mathbf{w}$ of $\mathcal{L}(V, W)$. The map $(\varphi, \mathbf{w}) \mapsto \varphi \cdot \mathbf{w}$ is bilinear: for every $\mathbf{v}$,

$$(\varphi + \psi)(\mathbf{v})\mathbf{w} = \varphi(\mathbf{v})\mathbf{w} + \psi(\mathbf{v})\mathbf{w},$$
$$\varphi(\mathbf{v})(\mathbf{w} + \mathbf{w}') = \varphi(\mathbf{v})\mathbf{w} + \varphi(\mathbf{v})\mathbf{w}',$$
$$(c\varphi)(\mathbf{v})\mathbf{w} = c\,\varphi(\mathbf{v})\mathbf{w} = \varphi(\mathbf{v})(c\mathbf{w}),$$

and two maps agreeing at every $\mathbf{v}$ are equal. By Definition 14.2.1 there is a unique linear Θ with $\Theta(\varphi \otimes \mathbf{w}) = \varphi \cdot \mathbf{w}$.

Bijectivity. Let $\mathcal{B} = (\mathbf{v}_1, \dots, \mathbf{v}_n)$ be a basis of V with dual basis $\mathcal{B}^* = (\varphi_1, \dots, \varphi_n)$ (Definition 4.1.3), and $\mathcal{C} = (\mathbf{w}_1, \dots, \mathbf{w}_m)$ a basis of W. By Theorem 14.2.5 the products $\varphi_j \otimes \mathbf{w}_i$ form a basis of $V^* \otimes W$, of size nm. Now $\Theta(\varphi_j \otimes \mathbf{w}_i)$ sends $\mathbf{v}_k$ to $\varphi_j(\mathbf{v}_k)\mathbf{w}_i = \delta_{jk}\mathbf{w}_i$, so it sends $\mathbf{v}_j$ to $\mathbf{w}_i$ and every other basis vector to $\mathbf{0}$. By Definition 3.6.1 its matrix is the matrix unit $\mathbf{E}_{ij}$. The matrix units form a basis of $M_{m\times n}(F)$ (Example (Standard Bases)) and $T \mapsto [T]_{\mathcal{B}}^{\mathcal{C}}$ is an isomorphism (Theorem 3.6.4), so the nm maps $\Theta(\varphi_j \otimes \mathbf{w}_i)$ form a basis of $\mathcal{L}(V, W)$.

Hence $\operatorname{im}\Theta$ contains a basis of $\mathcal{L}(V, W)$, so Θ is surjective (Theorem 3.2.4). Since $\dim(V^* \otimes W) = nm = \dim \mathcal{L}(V, W)$, Theorem 3.3.1 gives $\operatorname{nullity}\Theta = 0$, so Θ is injective (Theorem 3.2.3). Therefore Θ is an isomorphism.

Naturality. Both $\xi \mapsto \Theta((R' \otimes U)\xi)$ and $\xi \mapsto U\,\Theta(\xi)\,R$ are linear in ξ, so by Lemma 14.3.2 it suffices to check them at $\xi = \varphi \otimes \mathbf{w}$. On the left, $(R' \otimes U)(\varphi \otimes \mathbf{w}) = R'\varphi \otimes U\mathbf{w}$, and for $\mathbf{v} \in V_0$,

$$\Theta(R'\varphi \otimes U\mathbf{w})(\mathbf{v}) = (R'\varphi)(\mathbf{v})\,U\mathbf{w} = \varphi(R\mathbf{v})\,U\mathbf{w},$$

using Definition 4.4.1. On the right, $\big(U\,\Theta(\varphi \otimes \mathbf{w})\,R\big)(\mathbf{v}) = U\big(\varphi(R\mathbf{v})\mathbf{w}\big) = \varphi(R\mathbf{v})\,U\mathbf{w}$ by linearity of U. The two agree.

■

Warning. **Finite dimension is a hypothesis, not decoration.** The map Θ is defined and injective for any V and W, but it is surjective only onto the maps of finite rank: $\Theta(\sum_{t=1}^{N} \varphi_t \otimes \mathbf{w}_t)$ has image inside $\operatorname{span}(\mathbf{w}_1, \dots, \mathbf{w}_N)$, so its rank is at most N. On $V = W = F[x]$, the identity map has infinite rank and is therefore not $\Theta(\xi)$ for any $\xi \in V^* \otimes V$. Everything below uses the finite-dimensional statement.

The letter Θ is deliberate: taking $V = F^n$ and $W = F^m$ and using the dual basis to identify $(F^n)^*$ with F^n, this Θ is the isomorphism $F^m \otimes F^n \cong M_{m\times n}(F)$ of Theorem 14.2.7, with the two factors written in the order that makes the source a space of *maps* rather than of matrices. Section 02's model was the special case; this is the general statement.

Two uses of the theorem, immediately. First, it names the matrix units: under Θ, the map with matrix $\mathbf{E}_{ij}$ *is* the tensor $\varphi_j \otimes \mathbf{w}_i$, so a matrix is a sum $\sum_{i,j} a_{ij}\,\varphi_j \otimes \mathbf{w}_i$. Note the index order — the functional carries the column index, the vector the row index — and compare it with Chapter 7's vectorization, which stacks columns.

Second, the naturality formula is the vec identity.

Example. (The vec identity, read as a tensor product of maps)

Let $\mathbf{A} \in M_{k\times m}(F)$ and $\mathbf{B} \in M_{n\times l}(F)$, and let

$$\Psi\colon M_{m\times n}(F) \to M_{k\times l}(F), \qquad \mathbf{X} \mapsto \mathbf{AXB},$$

which is linear. Identify $M_{m\times n}(F)$ with $\mathcal{L}(F^n, F^m)$ and $M_{k\times l}(F)$ with $\mathcal{L}(F^l, F^k)$. Explain why Theorem 7.4.4, $\operatorname{vec}(\mathbf{AXB}) = (\mathbf{B}^\top \otimes \mathbf{A})\operatorname{vec}\mathbf{X}$, is Theorem 14.3.6 applied to Ψ.

Solution. Let $R\colon F^l \to F^n$ and $U\colon F^m \to F^k$ be the maps with matrices $\mathbf{B}$ and $\mathbf{A}$ in the standard bases. Under the identification, Ψ becomes the map $\mathcal{L}(F^n, F^m) \to \mathcal{L}(F^l, F^k)$ sending T to UTR, so by the naturality clause of Theorem 14.3.9 it corresponds, through Θ, to

$$R' \otimes U\colon (F^n)^* \otimes F^m \to (F^l)^* \otimes F^k.$$

Order the basis of $(F^n)^* \otimes F^m$ as in Definition 14.3.2, using the dual standard basis $(\varphi_1, \dots, \varphi_n)$ first and the standard basis $(\mathbf{e}_1, \dots, \mathbf{e}_m)$ second. Then $\varphi_j \otimes \mathbf{e}_i$ sits in position $(j-1)m + i$, and $\Theta(\varphi_j \otimes \mathbf{e}_i) = \mathbf{E}_{ij}$. By Definition 7.4.2, $\operatorname{vec}\mathbf{E}_{ij} = \mathbf{e}_{(j-1)m+i}$. So vec **is** the coordinate map of this ordered basis: the dictionary order with the *column* index slow is exactly the order in which vectorization stacks the columns.

Now apply Theorem 14.3.6. The matrix of R' in the dual standard bases is $\mathbf{B}^\top$, because the matrix of a dual map is the transpose (Theorem 4.4.2), and the matrix of U is $\mathbf{A}$. Hence the matrix of $R' \otimes U$ in the product bases above is $\mathbf{B}^\top \otimes \mathbf{A}$. Reading that equality of matrices through the coordinate map vec gives $\operatorname{vec}(\mathbf{AXB}) = (\mathbf{B}^\top \otimes \mathbf{A})\operatorname{vec}\mathbf{X}$, which is Theorem 7.4.4.

For a numerical check, take $\mathbf{A} = \begin{pmatrix} 1 & 2 \\ 0 & 1 \end{pmatrix}$ and $\mathbf{B} = \begin{pmatrix} 3 & 0 \\ 1 & -1 \end{pmatrix}$. Writing the four images $\mathbf{AE}_{ij}\mathbf{B}$ in the order $\mathbf{E}_{11}, \mathbf{E}_{21}, \mathbf{E}_{12}, \mathbf{E}_{22}$ and stacking the four columns $\operatorname{vec}(\mathbf{AE}_{ij}\mathbf{B})$ side by side gives

$$\begin{pmatrix} 3 & 6 & 1 & 2 \\ 0 & 3 & 0 & 1 \\ 0 & 0 & -1 & -2 \\ 0 & 0 & 0 & -1 \end{pmatrix},$$

which is $\mathbf{B}^\top \otimes \mathbf{A}$ written out.

So the transpose in the vec identity, which Chapter 7 had to warn readers not to get wrong, is not a bookkeeping accident: it is there because Ψ multiplies $\mathbf{X}$ on the right by $\mathbf{B}$, and right multiplication is *precomposition*, which reverses arrows. The dual map is what reverses them, and the matrix of a dual map is a transpose. That is the sharper form of Chapter 7's second promise, and it is why the wrong guesses $\mathbf{A} \otimes \mathbf{B}^\top$ and $\mathbf{B} \otimes \mathbf{A}$ are wrong.

14.3.5 Exercises

14.3.5.1 A. Check your understanding

Exercise A1.

(a) State the defining property of $S \otimes T$, and say why writing "$(S \otimes T)(\mathbf{v} \otimes \mathbf{w}) = S\mathbf{v} \otimes T\mathbf{w}$, extended linearly" is not by itself a definition.

(b) Let $\dim V = 3$, $\dim W = 4$, $\dim V' = 2$, $\dim W' = 5$. What are the sizes of $[S]_{\mathcal{B}}^{\mathcal{B}'}$, $[T]_{\mathcal{C}}^{\mathcal{C}'}$ and $[S \otimes T]_{\mathcal{B}\otimes\mathcal{C}}^{\mathcal{B}'\otimes\mathcal{C}'}$?

(c) In the ordering of Definition 14.3.2 with $\dim V = 3$ and $\dim W = 4$, which basis vector of $V \otimes W$ sits in position 7?

(d) True or false: every operator on $V \otimes W$ is of the form $S \otimes T$. Justify your answer.

(e) State Theorem 14.3.9, including its hypothesis, and say what $\Theta(\varphi \otimes \mathbf{w})$ does to a vector $\mathbf{v}$.

Solution.

(a) $S \otimes T$ is the **unique** linear map $V \otimes W \to V' \otimes W'$ with $(S \otimes T)(\mathbf{v} \otimes \mathbf{w}) = S\mathbf{v} \otimes T\mathbf{w}$ for all $\mathbf{v}, \mathbf{w}$ (Definition 14.3.1). The quoted phrase is not a definition because a general element of $V \otimes W$ is a sum of simple tensors in many different ways, so a prescription on simple tensors may be inconsistent; $\mathbf{v} \otimes \mathbf{0} = \mathbf{0}$ already forces consistency conditions. What makes it work is that $(\mathbf{v}, \mathbf{w}) \mapsto S\mathbf{v} \otimes T\mathbf{w}$ is bilinear, so Definition 14.2.1 supplies the map.

(b) 2×3, 5×4, and 10×12 (Theorem 14.3.6: an $m \times n$ and a $p \times q$ matrix give an $mp \times nq$ one).

(c) With $q = 4$, position $7 = (i-1) \cdot 4 + k$ forces $i = 2$, $k = 3$. So it is $\mathbf{v}_2 \otimes \mathbf{w}_3$.

(d) False. By Corollary 14.3.8, $\operatorname{rank}(S \otimes T) = \operatorname{rank} S \cdot \operatorname{rank} T$. With $\dim V = \dim W = 2$, an operator of rank 3 on the 4-dimensional space $V \otimes W$ cannot have its rank factored as a product of two integers each at most 2.

(e) For V, W **finite-dimensional**, there is a unique linear $\Theta\colon V^* \otimes W \to \mathcal{L}(V, W)$ with $\Theta(\varphi \otimes \mathbf{w})(\mathbf{v}) = \varphi(\mathbf{v})\mathbf{w}$, and it is an isomorphism. So $\Theta(\varphi \otimes \mathbf{w})$ measures $\mathbf{v}$ with φ and scales $\mathbf{w}$ by the result.

14.3.5.2 B. Practice

Exercise B1: A tensor product of maps, two ways.

Let $S\colon \mathbb{Q}^2 \to \mathbb{Q}^2$ and $T\colon \mathbb{Q}^2 \to \mathbb{Q}^3$ have matrices, in the standard bases,

$$\mathbf{A} = \begin{pmatrix} 1 & -1 \\ 2 & 0 \end{pmatrix}, \qquad \mathbf{B} = \begin{pmatrix} 1 & 0 \\ 0 & 2 \\ -1 & 1 \end{pmatrix}.$$

(a) Write down $[S \otimes T]_{\mathcal{B}\otimes\mathcal{C}}^{\mathcal{B}'\otimes\mathcal{C}'}$ for the standard bases, ordered as in Definition 14.3.2.

(b) Compute $(S \otimes T)(\mathbf{e}_1 \otimes \mathbf{e}_2 - \mathbf{e}_2 \otimes \mathbf{e}_1)$ directly from Definition 14.3.1.

(c) Check (b) against (a) by multiplying the matrix by the coordinate column of the input.

Solution.

(a) By Theorem 14.3.6 the matrix is $\mathbf{A} \otimes \mathbf{B}$, of size 6×4:

$$\mathbf{A} \otimes \mathbf{B} = \begin{pmatrix} 1 & 0 & -1 & 0 \\ 0 & 2 & 0 & -2 \\ -1 & 1 & 1 & -1 \\ 2 & 0 & 0 & 0 \\ 0 & 4 & 0 & 0 \\ -2 & 2 & 0 & 0 \end{pmatrix}.$$

(b) The columns of $\mathbf{A}$ give $S\mathbf{e}_1 = \mathbf{e}_1 + 2\mathbf{e}_2$ and $S\mathbf{e}_2 = -\mathbf{e}_1$; the columns of $\mathbf{B}$ give $T\mathbf{e}_1 = \mathbf{f}_1 - \mathbf{f}_3$ and $T\mathbf{e}_2 = 2\mathbf{f}_2 + \mathbf{f}_3$, where $(\mathbf{f}_1, \mathbf{f}_2, \mathbf{f}_3)$ is the standard basis of $\mathbb{Q}^3$. Hence

$$\begin{aligned}(S \otimes T)(\mathbf{e}_1 \otimes \mathbf{e}_2 - \mathbf{e}_2 \otimes \mathbf{e}_1) \\ = (\mathbf{e}_1 + 2\mathbf{e}_2) \otimes (2\mathbf{f}_2 + \mathbf{f}_3) - (-\mathbf{e}_1) \otimes (\mathbf{f}_1 - \mathbf{f}_3) \\ = \mathbf{e}_1 \otimes \mathbf{f}_1 + 2\,\mathbf{e}_1 \otimes \mathbf{f}_2 + 4\,\mathbf{e}_2 \otimes \mathbf{f}_2 + 2\,\mathbf{e}_2 \otimes \mathbf{f}_3,\end{aligned}$$

where the $\mathbf{e}_1 \otimes \mathbf{f}_3$ terms cancel: $+1$ from the first product and -1 from the second.

(c) The input has coordinates $(0, 1, -1, 0)$ in the basis $(\mathbf{e}_1 \otimes \mathbf{e}_1, \mathbf{e}_1 \otimes \mathbf{e}_2, \mathbf{e}_2 \otimes \mathbf{e}_1, \mathbf{e}_2 \otimes \mathbf{e}_2)$. Multiplying gives $(1, 2, 0, 0, 4, 2)$, which in the basis $(\mathbf{e}_1 \otimes \mathbf{f}_1, \mathbf{e}_1 \otimes \mathbf{f}_2, \mathbf{e}_1 \otimes \mathbf{f}_3, \mathbf{e}_2 \otimes \mathbf{f}_1, \mathbf{e}_2 \otimes \mathbf{f}_2, \mathbf{e}_2 \otimes \mathbf{f}_3)$ is exactly the answer to (b).

Exercise B2: Invariants without multiplying matrices.

Let $S \in \mathcal{L}(V)$ and $T \in \mathcal{L}(W)$ over $\mathbb{R}$, with $\dim V = 4$, $\dim W = 3$, $\operatorname{rank} S = 2$, $\operatorname{rank} T = 3$, $\operatorname{tr} S = 5$, $\operatorname{tr} T = -2$, $\det T = 6$.

(a) Find $\operatorname{rank}(S \otimes T)$ and $\operatorname{nullity}(S \otimes T)$.

(b) Find $\operatorname{tr}(S \otimes T)$.

(c) Find $\det(S \otimes T)$. Justify the value from the ranks alone.

(d) Find $\operatorname{tr}(S \otimes \mathrm{id}_W)$ and $\operatorname{tr}(\mathrm{id}_V \otimes T)$, and check that their product is **not** $\operatorname{tr}(S \otimes T)$ in general by comparing with (b).

Solution.

(a) By Corollary 14.3.8, $\operatorname{rank}(S \otimes T) = 2 \cdot 3 = 6$. Since $\dim(V \otimes W) = 12$ by Theorem 14.2.5, Theorem 3.3.1 gives $\operatorname{nullity}(S \otimes T) = 12 - 6 = 6$.

(b) $\operatorname{tr}(S \otimes T) = 5 \cdot (-2) = -10$.

(c) $\operatorname{rank} S = 2 < 4 = \dim V$, so S is not invertible and $\det S = 0$ by Theorem 2.4.4 and Definition 6.5.1. Hence $\det(S \otimes T) = 0^3 \cdot 6^4 = 0$. Directly: $\operatorname{rank}(S \otimes T) = 6 < 12$, so $S \otimes T$ is not invertible.

(d) $\operatorname{tr}(S \otimes \mathrm{id}_W) = \operatorname{tr} S \cdot \operatorname{tr} \mathrm{id}_W = 5 \cdot 3 = 15$ and $\operatorname{tr}(\mathrm{id}_V \otimes T) = 4 \cdot (-2) = -8$, using $\operatorname{tr} \mathrm{id} = (\dim) \cdot 1$ from Theorem 3.10.3. Their product is $-120 \neq -10$. There is no contradiction: $S \otimes T$ is the *composite* of the two, and the trace of a composite is not the product of the traces.

Exercise B3: Which statements hold?.

Let V, W be finite-dimensional over F. Determine which of the following hold for **all** $S, S_1, S_2 \in \mathcal{L}(V)$ and $T \in \mathcal{L}(W)$. Justify your answer.

(a) $(S_1S_2)\otimes T = (S_1\otimes T)(S_2\otimes T)$.
(b) $(S_1S_2)\otimes T^2 = (S_1\otimes T)(S_2\otimes T)$.
(c) $S\otimes T = 0$ implies $S = 0$ or $T = 0$.
(d) $S\otimes \mathrm{id}_W$ and $\mathrm{id}_V\otimes T$ commute.
(e) If S and T are invertible, so is $S\otimes T$, with inverse $S^{-1}\otimes T^{-1}$.

Solution.

(a) Fails. By Proposition 14.3.3 (c) the right side is $S_1S_2\otimes T^2$, and with $S_1 = S_2 = \mathrm{id}_V$ and $T = 2\,\mathrm{id}_W$ over $\mathbb{Q}$ the two sides are 2 id and 4 id on $V\otimes W$, by Example 3 after Definition 14.3.1.
(b) Holds: it is exactly Proposition 14.3.3 (c).
(c) Holds. If $S\neq 0$ and $T\neq 0$, then $\operatorname{rank} S\geq 1$ and $\operatorname{rank} T\geq 1$, so $\operatorname{rank}(S\otimes T)\geq 1$ by Corollary 14.3.8, and $S\otimes T\neq 0$.
(d) Holds. By Proposition 14.3.3 (c) and (d), both composites equal $S\otimes T$.
(e) Holds. By Proposition 14.3.3 (c) and (d), $(S\otimes T)(S^{-1}\otimes T^{-1}) = \mathrm{id}_V\otimes\mathrm{id}_W = \mathrm{id}_{V\otimes W}$, and likewise in the other order.

14.3.5.3 C. Going deeper

Exercise C1: When a tensor product of maps vanishes.

Let V, V', W, W' be finite-dimensional over F, $S\in\mathcal{L}(V,V')$ and $T\in\mathcal{L}(W,W')$.

(a) Prove that $S\otimes T = 0$ if and only if $S = 0$ or $T = 0$.
(b) Prove that $\ker(S\otimes\mathrm{id}_W) = \ker S\otimes W$, meaning the span of all $\mathbf{v}\otimes\mathbf{w}$ with $\mathbf{v}\in\ker S$.
(c) Deduce $\operatorname{nullity}(S\otimes\mathrm{id}_W) = \operatorname{nullity} S\cdot\dim W$, and check it against Corollary 14.3.8.

Solution.

(a) ($\Leftarrow$) If $S = 0$, then $(S\otimes T)(\mathbf{v}\otimes\mathbf{w}) = \mathbf{0}\otimes T\mathbf{w} = \mathbf{0}$ for all $\mathbf{v},\mathbf{w}$, so $S\otimes T = 0$ by Lemma 14.3.2. Likewise if $T = 0$. ($\Rightarrow$) Suppose $S\neq 0$ and $T\neq 0$. Then $\operatorname{rank} S\geq 1$ and $\operatorname{rank} T\geq 1$, so $\operatorname{rank}(S\otimes T) = \operatorname{rank} S\cdot\operatorname{rank} T\geq 1$ by Corollary 14.3.8, and $S\otimes T\neq 0$.
(b) ($\supseteq$) For $\mathbf{v}\in\ker S$ and $\mathbf{w}\in W$, $(S\otimes\mathrm{id}_W)(\mathbf{v}\otimes\mathbf{w}) = \mathbf{0}\otimes\mathbf{w} = \mathbf{0}$; a kernel is a subspace (Theorem 3.2.1), so it contains the span of these elements. ($\subseteq$) Choose a basis $(\mathbf{v}_1,\dots,\mathbf{v}_n)$ of V whose last $n-r$ vectors span $\ker S$, where $r = \operatorname{rank} S$, and such that $S\mathbf{v}_1,\dots,S\mathbf{v}_r$ are independent (as in the proof of Corollary 14.3.8). Let $(\mathbf{w}_1,\dots,\mathbf{w}_q)$ be a basis of W and let $z = \sum_{j,l} c_{jl}\,\mathbf{v}_j\otimes\mathbf{w}_l$ lie in the kernel. Then

$$\mathbf{0} = (S\otimes\mathrm{id}_W)(z) = \sum_{j\leq r}\sum_{l} c_{jl}\,S\mathbf{v}_j\otimes\mathbf{w}_l,$$

and the vectors $S\mathbf{v}_j\otimes\mathbf{w}_l$ with $j\leq r$ are linearly independent by Theorem 14.2.5, after extending $(S\mathbf{v}_1,\dots,S\mathbf{v}_r)$ to a basis of V'. Hence $c_{jl} = 0$ for all $j\leq r$, so z is a combination of the $\mathbf{v}_j\otimes\mathbf{w}_l$ with $j > r$, all of which lie in $\ker S\otimes W$.
(c) By (b) and Theorem 14.2.5 applied to $\ker S$ and W, $\operatorname{nullity}(S\otimes\mathrm{id}_W) = \dim\ker S\cdot\dim W = \operatorname{nullity} S\cdot\dim W$. Consistency: Corollary 14.3.8 gives $\operatorname{rank}(S\otimes\mathrm{id}_W) =$

rank $S \cdot \dim W$, and adding the two gives $(\operatorname{rank} S + \operatorname{nullity} S)\dim W = \dim V \cdot \dim W = \dim(V \otimes W)$, as Theorem 3.3.1 requires.

Exercise C2: Rank-one maps and simple tensors.

Let V, W be finite-dimensional over F and let Θ be the isomorphism of Theorem 14.3.9.

(a) Prove that $\Theta(\xi)$ has rank at most 1 if and only if ξ is a simple tensor $\varphi \otimes \mathbf{w}$.

(b) Deduce that "not every tensor is simple" (§02) says exactly that not every linear map has rank at most 1, and identify the tensor corresponding to id_V in a basis.

(c) Let $\dim V = \dim W = 2$. Exhibit $\xi \in V^* \otimes W$ that is not simple, by exhibiting a map of rank 2.

Solution.

(a) ($\Leftarrow$) $\Theta(\varphi \otimes \mathbf{w})$ sends every $\mathbf{v}$ into $\operatorname{span}(\mathbf{w})$, so its image has dimension at most 1. ($\Rightarrow$) Suppose $R := \Theta(\xi)$ has rank at most 1. If $R = 0$, then $\xi = 0 = 0 \otimes \mathbf{0}$ since Θ is injective. Otherwise $\operatorname{im} R = \operatorname{span}(\mathbf{w})$ for some $\mathbf{w} \neq \mathbf{0}$, so for each $\mathbf{v}$ there is a unique scalar $\varphi(\mathbf{v})$ with $R\mathbf{v} = \varphi(\mathbf{v})\mathbf{w}$; uniqueness and linearity of R make φ linear, so $\varphi \in V^*$. Then $R = \Theta(\varphi \otimes \mathbf{w})$, and $\xi = \varphi \otimes \mathbf{w}$ because Θ is injective.

(b) By (a) and bijectivity of Θ, the non-simple tensors in $V^* \otimes W$ correspond exactly to the maps of rank at least 2. Taking $W = V$ with basis $\mathcal{B} = (\mathbf{v}_1, \dots, \mathbf{v}_n)$ and dual basis $(\varphi_1, \dots, \varphi_n)$, the matrix of id_V is $\mathbf{I}_n = \sum_i \mathbf{E}_{ii}$, so $\mathrm{id}_V = \Theta\big(\sum_{i=1}^{n} \varphi_i \otimes \mathbf{v}_i\big)$. For $n \geq 2$ this has rank $n \geq 2$, hence is not simple. For $n = 2$ it is the witness $\varphi_1 \otimes \mathbf{v}_1 + \varphi_2 \otimes \mathbf{v}_2$, which is Example (A tensor that is not simple) read through Θ.

(c) Take $\xi = \varphi_1 \otimes \mathbf{w}_1 + \varphi_2 \otimes \mathbf{w}_2$ for bases $(\mathbf{v}_1, \mathbf{v}_2)$ of V and $(\mathbf{w}_1, \mathbf{w}_2)$ of W. Then $\Theta(\xi)$ sends $\mathbf{v}_1 \mapsto \mathbf{w}_1$ and $\mathbf{v}_2 \mapsto \mathbf{w}_2$, so it has rank 2, and by (a) ξ is not simple.

Exercise C3: Reproving the swap.

Let V and W be finite-dimensional over F with ordered bases $\mathcal{B}$ and $\mathcal{C}$.

(a) Prove that there is a unique isomorphism $\tau\colon V \otimes W \to W \otimes V$ with $\tau(\mathbf{v} \otimes \mathbf{w}) = \mathbf{w} \otimes \mathbf{v}$.

(b) Prove that $\tau(S \otimes T) = (T \otimes S)\tau$ for all $S \in \mathcal{L}(V)$, $T \in \mathcal{L}(W)$.

(c) Deduce Proposition 7.4.2: for $\mathbf{A} \in M_n(F)$ and $\mathbf{B} \in M_m(F)$ there is a permutation matrix $\mathbf{P}$ with $\mathbf{B} \otimes \mathbf{A} = \mathbf{P}^{-1}(\mathbf{A} \otimes \mathbf{B})\mathbf{P}$, and identify $\mathbf{P}$.

Hint for (c): think of τ as renaming basis vectors rather than as moving them.

Solution.

(a) The map $(\mathbf{v}, \mathbf{w}) \mapsto \mathbf{w} \otimes \mathbf{v}$ is bilinear, so Definition 14.2.1 gives a unique linear τ with $\tau(\mathbf{v} \otimes \mathbf{w}) = \mathbf{w} \otimes \mathbf{v}$. The same construction with the roles swapped gives $\sigma\colon W \otimes V \to V \otimes W$ with $\sigma(\mathbf{w} \otimes \mathbf{v}) = \mathbf{v} \otimes \mathbf{w}$. Then $\sigma\tau$ fixes every simple tensor, so $\sigma\tau = \mathrm{id}$ by Lemma 14.3.2, and likewise $\tau\sigma = \mathrm{id}$. Hence τ is an isomorphism.

(b) Both sides are linear maps out of $V \otimes W$, so by Lemma 14.3.2 compare at $\mathbf{v} \otimes \mathbf{w}$: the left gives $\tau(S\mathbf{v} \otimes T\mathbf{w}) = T\mathbf{w} \otimes S\mathbf{v}$, and the right gives $(T \otimes S)(\mathbf{w} \otimes \mathbf{v}) = T\mathbf{w} \otimes S\mathbf{v}$.

(c) Let S, T be the operators on F^n, F^m with matrices $\mathbf{A}, \mathbf{B}$. Both $\mathcal{B}\otimes\mathcal{C}$ and $\tau^{-1}(\mathcal{C}\otimes\mathcal{B})$ are orderings of the same basis of $F^n \otimes F^m$, differing by the permutation σ that sends position $(k-1)n+i$ to position $(i-1)m+k$ — the direction matters, since σ is not an involution unless $n = m$ — and let $\mathbf{P}$ be its matrix, which is exactly the $\mathbf{P}_\sigma$ built in the proof of Proposition 7.4.2.

14.4 Contraction and the Trace

Chapter 3 defined the trace of an operator by choosing a basis, writing down the matrix, and adding the diagonal entries; it then proved that the answer does not depend on the choice (Definition 3.10.2). That is a correct definition and an unsatisfying one. It says how to compute the number, not what the number is, and the independence of the basis arrives afterwards, as a theorem about similar matrices. Section 03 offers a way out. An operator on V is an element of $V^* \otimes V$ (Theorem 14.3.9), and on $V^* \otimes V$ there is one obvious scalar-valued map that uses no basis at all: apply the functional to the vector. This section builds that map, proves that it is the trace, and extends it to tensors with many slots.

14.4.1 Evaluation, made linear

The dual space was invented so that its elements could eat vectors. The eating is a function of two arguments,

$$V^* \times V \to F, \qquad (\varphi, \mathbf{v}) \mapsto \varphi(\mathbf{v}),$$

and it is bilinear: linear in $\mathbf{v}$ because φ is a linear map, and linear in φ because that is how V^* is added and scaled (Definition 4.1.2). A bilinear map is exactly what the tensor product converts into a linear one, and by now this should be a reflex.

Contraction is the evaluation pairing, turned into a single linear map by the tensor product.

Definition 14.4.1 — Contraction

Let V be a vector space over F. The **contraction** of V is the unique linear map

$$C\colon V^* \otimes V \to F, \qquad C(\varphi \otimes \mathbf{v}) = \varphi(\mathbf{v}) \quad (\varphi \in V^*,\ \mathbf{v} \in V).$$

Well-definedness. The pairing $(\varphi, \mathbf{v}) \mapsto \varphi(\mathbf{v})$ is bilinear, so Definition 14.2.1 supplies exactly one linear map on $V^* \otimes V$ taking those values. Nothing else is chosen: no basis, no finite dimension, no extra structure on V.

Examples.

1. **In coordinates.** Let $\dim V = n$, let $\mathcal{B} = (\mathbf{v}_1, \dots, \mathbf{v}_n)$ be a basis and $\mathcal{B}^* = (\varphi^1, \dots, \varphi^n)$ its dual basis (Definition 4.1.3), so $\varphi^j(\mathbf{v}_i) = \delta^j_i$. A general $\xi \in V^* \otimes V$ is $\xi = \sum_{i,j} a_{ij}\, \varphi^j \otimes \mathbf{v}_i$ by Theorem 14.2.5, and
$$C(\xi) = \sum_{i,j} a_{ij}\, \varphi^j(\mathbf{v}_i) = \sum_{i=1}^{n} a_{ii}.$$
The contraction sums the coefficients whose two indices agree. That is a diagonal sum, which is the first hint of what is coming.

2. **The smallest case.** If $\dim V = 1$, pick $\mathbf{v} \neq \mathbf{0}$ and let φ be dual to it. Every element of $V^* \otimes V$ is $a\,\varphi \otimes \mathbf{v}$, and $C(a\,\varphi \otimes \mathbf{v}) = a$. So C is the isomorphism $V^* \otimes V \cong F$. Degenerate, and worth seeing: the contraction is the only thing that can happen here.
3. **A functional times a vector, in F^n.** With $V = F^n$, $\varphi = \mathbf{y}^\top$ and $\mathbf{v} = \mathbf{x}$, $C(\varphi \otimes \mathbf{v}) = \mathbf{y}^\top \mathbf{x}$, the dot product. Chapter 10's inner product on $\mathbb{R}^n$ is this contraction composed with the identification of $\mathbb{R}^n$ with its dual — which is extra structure, and is why the dot product is not a contraction of $V \otimes V$.

Non-example by minimal change. Replace $\varphi(\mathbf{v})$ by $\varphi(\mathbf{v})^2$. The assignment $(\varphi, \mathbf{v}) \mapsto \varphi(\mathbf{v})^2$ is not bilinear — doubling $\mathbf{v}$ multiplies it by 4 — so no linear map on $V^* \otimes V$ agrees with it, and Definition 14.2.1 does not apply. The exact clause that fails is linearity in each slot.

Why one upper slot and one lower slot. Contraction needs a functional *and* a vector: the functional supplies the mouth. There is no analogous map $V \otimes V \to F$.

> *Warning.* **There is no canonical contraction of two vectors.** A linear map $V \otimes V \to F$ is the same thing as a bilinear form on V (Definition 14.2.1 with $Z = F$), and Chapter 13 spent a chapter on the fact that a vector space carries *many* bilinear forms and prefers none of them. Each basis of V supplies one, $(\mathbf{v}, \mathbf{w}) \mapsto \sum_i \varphi^i(\mathbf{v})\varphi^i(\mathbf{w})$, and different bases supply different ones: on $\mathbb{R}^2$ the standard basis gives the dot product, while $((1,0),(1,1))$ gives a form under which $(1,0)$ and $(0,1)$ are not orthogonal. Only the pairing between V^* and V is free of charge.

14.4.2 Contraction is the trace

We can now say what the trace is.

Theorem 14.4.1 — The Trace Is a Contraction

Let V be a finite-dimensional vector space over F, and let

$$\Theta \colon V^* \otimes V \to \mathcal{L}(V)$$

be the isomorphism of Theorem 14.3.9. Then

$$\operatorname{tr}\big(\Theta(\xi)\big) = C(\xi) \qquad \text{for every } \xi \in V^* \otimes V,$$

that is, $\operatorname{tr} = C \circ \Theta^{-1}$ as maps $\mathcal{L}(V) \to F$.

> *Idea.* Both sides are linear in ξ, so by Lemma 14.3.2 it is enough to check simple tensors. And $\Theta(\varphi \otimes \mathbf{v})$ is the rank-at-most-one map $\mathbf{u} \mapsto \varphi(\mathbf{u})\mathbf{v}$, whose trace can be read off from a single well-chosen basis: put $\mathbf{v}$ first.

> *Proof.* Both $\xi \mapsto \operatorname{tr}(\Theta(\xi))$ and $\xi \mapsto C(\xi)$ are linear, being composites of linear maps (Theorem 3.10.3 for the first). By Lemma 14.3.2 it suffices to prove $\operatorname{tr}(\Theta(\varphi \otimes \mathbf{v})) = \varphi(\mathbf{v})$ for all $\varphi \in V^*$, $\mathbf{v} \in V$.
>
> Write $R \coloneqq \Theta(\varphi \otimes \mathbf{v})$, so $R\mathbf{u} = \varphi(\mathbf{u})\mathbf{v}$ for every $\mathbf{u}$. If $\mathbf{v} = \mathbf{0}$, then $R = 0$ and $\varphi(\mathbf{v}) = 0$, so both sides vanish. Otherwise $(\mathbf{v})$ is a linearly independent list, so by Theorem 1.8.2

it extends to a basis $\mathcal{B} = (\mathbf{u}_1, \dots, \mathbf{u}_n)$ of V with $\mathbf{u}_1 = \mathbf{v}$. For each j,

$$R\mathbf{u}_j = \varphi(\mathbf{u}_j)\,\mathbf{v} = \varphi(\mathbf{u}_j)\,\mathbf{u}_1,$$

so column j of $[R]_{\mathcal{B}}^{\mathcal{B}}$ has $\varphi(\mathbf{u}_j)$ in row 1 and zeros below it (Definition 3.6.1). Hence the only non-zero diagonal entry is the one in position $(1,1)$, equal to $\varphi(\mathbf{u}_1) = \varphi(\mathbf{v})$. By Definition 3.10.2, $\operatorname{tr} R = \varphi(\mathbf{v})$, as required.

■

What has changed. Chapter 3's definition named a basis and then had to prove that the answer survived a change of basis, using Theorem 3.7.5. Here nothing was named. The map C was manufactured by the universal property out of the evaluation pairing, which exists before any basis does, and Θ was manufactured the same way. So basis-independence is not a theorem about $C \circ \Theta^{-1}$; there is no basis in the construction to be independent of. Chapter 3's theorem is still true, and it is what makes the two descriptions agree — but it is now an observation about a *computation* of the trace, not part of its definition. The single basis used in the proof above was a convenience for reading off one number, not a choice the answer could depend on.

Two consequences come free. First, the trace of a rank-one map.

Corollary 14.4.2 — Trace of a Rank-One Map

Let V be finite-dimensional, $\varphi \in V^*$ and $\mathbf{v} \in V$, and let $R \in \mathcal{L}(V)$ be $R\mathbf{u} = \varphi(\mathbf{u})\mathbf{v}$. Then $\operatorname{tr} R = \varphi(\mathbf{v})$. In particular, with a basis $\mathcal{B}$ and its dual basis, $\mathrm{id}_V = \Theta\big(\sum_i \varphi^i \otimes \mathbf{v}_i\big)$ and $\operatorname{tr} \mathrm{id}_V = \sum_i \varphi^i(\mathbf{v}_i) = n \cdot 1$.

Proof. The first claim was proved inside Theorem 14.4.1. For the second, $\Theta(\sum_i \varphi^i \otimes \mathbf{v}_i)$ sends $\mathbf{v}_j$ to $\sum_i \varphi^i(\mathbf{v}_j)\mathbf{v}_i = \mathbf{v}_j$, so it is id_V (Theorem 3.1.5); applying C gives $\sum_i \varphi^i(\mathbf{v}_i) = \sum_i 1 = n \cdot 1$.

■

Second, the promise made in §03: the trace of a tensor product of maps multiplies, and now we can see why. The key is that a functional on $V \otimes W$ is built from one on each factor.

Proposition 14.4.3 — The Dual of a Tensor Product

Let V and W be finite-dimensional over F. There is a unique linear map

$$\kappa \colon V^* \otimes W^* \to (V \otimes W)^*, \qquad \kappa(\varphi \otimes \psi)(\mathbf{v} \otimes \mathbf{w}) = \varphi(\mathbf{v})\,\psi(\mathbf{w}),$$

and it is an isomorphism.

Proof. For fixed φ, ψ, the map $(\mathbf{v}, \mathbf{w}) \mapsto \varphi(\mathbf{v})\psi(\mathbf{w})$ is bilinear, so Definition 14.2.1 produces a unique functional $\varphi \cdot \psi \in (V \otimes W)^*$ with the stated values. The assignment $(\varphi, \psi) \mapsto \varphi \cdot \psi$ is itself bilinear, since two functionals agreeing on all simple tensors are equal (Lemma 14.3.2), so Definition 14.2.1 gives the unique linear κ.

Let $\mathcal{B} = (\mathbf{v}_1, \dots, \mathbf{v}_n)$ and $\mathcal{C} = (\mathbf{w}_1, \dots, \mathbf{w}_m)$ be bases with dual bases (φ^i) and (ψ^j). Then $\kappa(\varphi^i \otimes \psi^j)(\mathbf{v}_k \otimes \mathbf{w}_l) = \delta^i_k \delta^j_l$, so κ carries the basis $(\varphi^i \otimes \psi^j)$ of $V^* \otimes W^*$ (Theorem 14.2.5)

to the dual basis of $\mathcal{B} \otimes \mathcal{C}$ (Theorem 4.1.3 (a), which characterizes it by these values). A linear map carrying a basis to a basis is an isomorphism, by Theorem 3.2.4 and Theorem 3.3.1.

■

Corollary 14.4.4 — Why the Trace Multiplies

Let V, W be finite-dimensional over F, $S \in \mathcal{L}(V)$ and $T \in \mathcal{L}(W)$. Then $\operatorname{tr}(S \otimes T) = \operatorname{tr} S \cdot \operatorname{tr} T$.

Proof. Both $(S,T) \mapsto \operatorname{tr}(S \otimes T)$ and $(S,T) \mapsto \operatorname{tr} S \cdot \operatorname{tr} T$ are bilinear on $\mathcal{L}(V) \times \mathcal{L}(W)$, by Proposition 14.3.3 (a), (b) and Theorem 3.10.3. The maps of rank at most one span $\mathcal{L}(V)$, since Θ is onto and simple tensors span $V^* \otimes V$ (Proposition 14.2.4); likewise for $\mathcal{L}(W)$. So it suffices to check the identity when $S = \Theta(\varphi \otimes \mathbf{v})$ and $T = \Theta(\psi \otimes \mathbf{w})$.

For such S and T and any $\mathbf{a} \otimes \mathbf{b} \in V \otimes W$,

$$(S \otimes T)(\mathbf{a} \otimes \mathbf{b}) = \varphi(\mathbf{a})\mathbf{v} \otimes \psi(\mathbf{b})\mathbf{w} = \kappa(\varphi \otimes \psi)(\mathbf{a} \otimes \mathbf{b})\,(\mathbf{v} \otimes \mathbf{w}),$$

so $S \otimes T = \Theta\big(\kappa(\varphi \otimes \psi) \otimes (\mathbf{v} \otimes \mathbf{w})\big)$ by Lemma 14.3.2. By Theorem 14.4.1 and Proposition 14.4.3,

$$\operatorname{tr}(S \otimes T) = \kappa(\varphi \otimes \psi)(\mathbf{v} \otimes \mathbf{w}) = \varphi(\mathbf{v})\psi(\mathbf{w}),$$

which is $\operatorname{tr} S \cdot \operatorname{tr} T$ by Corollary 14.4.2.

■

So the trace multiplies because *evaluation* multiplies: a functional on a tensor product is a product of functionals, and contraction is evaluation. Chapter 7 proved this by summing $a_{ii}b_{kk}$ over all pairs (Theorem 7.4.3 (b)), which is the same fact with the sum written out.

14.4.3 Tensors with many slots

Contraction is not confined to one upper and one lower slot; it can be applied to a chosen pair inside a tensor with any number of them. First we name those tensors. Write

$$V^{\otimes p} := \underbrace{V \otimes \cdots \otimes V}_{p}, \qquad V^{\otimes 0} := F,$$

which is unambiguous by Proposition 14.3.5.

Definition 14.4.2 — Tensor of type (p, q)

Let V be a vector space over F and $p, q \geq 0$. A **tensor of type** (p, q) on V is an element of

$$T^p_q(V) := V^{\otimes p} \otimes (V^*)^{\otimes q}.$$

The p copies of V are the **contravariant** slots and the q copies of V^* the **covariant**

slots. The number $p+q$ is the **rank** or **order** of the tensor.

If $\dim V = n$, then $\dim T^p_q(V) = n^{p+q}$ by Theorem 14.2.5 and Corollary 4.1.4. The small cases are all things we have met:

- $T^0_0(V) = F$: scalars.
- $T^1_0(V) = V$ and $T^0_1(V) = V^*$: vectors and functionals.
- $T^1_1(V) = V \otimes V^* \cong \mathcal{L}(V)$: operators, by Theorem 14.3.9 together with the swap of Exercise (C3: Reproving the swap), which sends $\mathbf{v} \otimes \varphi$ to $\varphi \otimes \mathbf{v}$.
- $T^0_2(V) \cong (V \otimes V)^*$ by Proposition 14.4.3, and a functional on $V \otimes V$ is a bilinear form on V by Definition 14.2.1. So a type $(0,2)$ tensor is exactly a bilinear form — the whole subject matter of Chapter 13.

Warning. **The word "rank" is overloaded here.** The rank of a tensor in the sense of Definition 14.4.2 is the number of slots, $p+q$; it has nothing to do with $\operatorname{rank} T$ for a linear map, nor with the smallest number of simple tensors needed to write an element. A type $(1,1)$ tensor always has rank 2 in this sense, whatever the rank of the corresponding operator. Where confusion is possible we say **order**.

Now the general contraction. Contracting slot a against slot b means feeding the b-th functional the a-th vector and keeping everything else.

Definition 14.4.3 — Contraction on a pair of slots

Let V be a vector space over F, let $p, q \geq 1$, and fix $1 \leq a \leq p$ and $1 \leq b \leq q$. The **contraction on slots a and b** is the unique linear map

$$C^a_b \colon T^p_q(V) \to T^{p-1}_{q-1}(V)$$

with, for all $\mathbf{v}_1, \dots, \mathbf{v}_p \in V$ and $\varphi^1, \dots, \varphi^q \in V^*$,

$$\begin{aligned} &C^a_b\big(\mathbf{v}_1 \otimes \cdots \otimes \mathbf{v}_p \otimes \varphi^1 \otimes \cdots \otimes \varphi^q\big) \\ &\qquad = \varphi^b(\mathbf{v}_a)\; \mathbf{v}_1 \otimes \dots \widehat{\mathbf{v}_a} \cdots \otimes \mathbf{v}_p \otimes \varphi^1 \otimes \dots \widehat{\varphi^b} \cdots \otimes \varphi^q, \end{aligned}$$

where a hat means that the factor is omitted.

Well-definedness. The right-hand side is multilinear in the $p+q$ arguments: each argument appears exactly once, either inside the scalar $\varphi^b(\mathbf{v}_a)$ or as one factor of a tensor product, and both are linear in it. By Lemma 14.3.4 there is exactly one linear map on $T^p_q(V)$ with these values. For $p = q = 1$ it lands in $T^0_0(V) = F$ and sends $\mathbf{v} \otimes \varphi$ to $\varphi(\mathbf{v})$: it is Definition 14.4.1 read on $V \otimes V^*$ instead of $V^* \otimes V$, that is, C composed with the swap of Exercise (C3: Reproving the swap). We use that identification silently from here on, and Theorem 14.4.1 applies to either reading.

Warning. **Which slots you contract matters.** Let $\dim V = 2$ with basis $(\mathbf{v}_1, \mathbf{v}_2)$ and dual basis (φ^1, φ^2), and take the type $(2,2)$ tensor

$$t = \mathbf{v}_1 \otimes \mathbf{v}_2 \otimes \varphi^1 \otimes \varphi^2.$$

Then $C^1_1(t) = \varphi^1(\mathbf{v}_1)\, \mathbf{v}_2 \otimes \varphi^2 = \mathbf{v}_2 \otimes \varphi^2$, while $C^1_2(t) = \varphi^2(\mathbf{v}_1)\, \mathbf{v}_2 \otimes \varphi^1 = 0$. The two contractions of the same tensor differ, one of them being zero. There is no "the"

contraction of a tensor of order ≥ 3: the slots must be named.

Quick check. Let $\dim V = 3$ with basis $(\mathbf{v}_1, \mathbf{v}_2, \mathbf{v}_3)$ and dual basis $(\varphi^1, \varphi^2, \varphi^3)$, and let

$$t = \mathbf{v}_1 \otimes \varphi^1 + 2\,\mathbf{v}_2 \otimes \varphi^2 - \mathbf{v}_1 \otimes \varphi^3 \in T^1_1(V).$$

Compute $C^1_1(t)$, and say which operator t corresponds to.

Solution. $C^1_1(t) = \varphi^1(\mathbf{v}_1) + 2\varphi^2(\mathbf{v}_2) - \varphi^3(\mathbf{v}_1) = 1 + 2 - 0 = 3$. The corresponding operator sends $\mathbf{v}_1 \mapsto \mathbf{v}_1$, $\mathbf{v}_2 \mapsto 2\mathbf{v}_2$, $\mathbf{v}_3 \mapsto -\mathbf{v}_1$, so its matrix in $(\mathbf{v}_1, \mathbf{v}_2, \mathbf{v}_3)$ is $\begin{pmatrix} 1 & 0 & -1 \\ 0 & 2 & 0 \\ 0 & 0 & 0 \end{pmatrix}$, of trace 3, in agreement with Theorem 14.4.1.

Index notation, in the next section, makes contraction visibly what it looks like in physics: set an upper index equal to a lower one and sum.

14.4.4 Exercises

14.4.4.1 A. Check your understanding

Exercise A1.

(a) Define the contraction $C\colon V^* \otimes V \to F$, and say what makes it well defined.

(b) State the relation between the trace and the contraction, with its hypothesis.

(c) Explain why there is no canonical linear map $V \otimes V \to F$.

(d) For $\dim V = 4$, what is $\dim T^2_3(V)$?

(e) True or false: for $t \in T^2_2(V)$, the four contractions $C^a_b(t)$ all agree. Justify your answer.

Solution.

(a) C is the unique linear map with $C(\varphi \otimes \mathbf{v}) = \varphi(\mathbf{v})$ (Definition 14.4.1). It is well defined because $(\varphi, \mathbf{v}) \mapsto \varphi(\mathbf{v})$ is bilinear, so Definition 14.2.1 produces exactly one such linear map.

(b) If V is **finite-dimensional**, then $\operatorname{tr}(\Theta(\xi)) = C(\xi)$ for all $\xi \in V^* \otimes V$, where Θ is the isomorphism of Theorem 14.3.9 (Theorem 14.4.1).

(c) Such a map is the same thing as a bilinear form on V, and a vector space has many bilinear forms with none distinguished; each basis produces a different one. Contraction works only because V^* comes with the evaluation pairing built in.

(d) $4^{2+3} = 4^5 = 1024$.

(e) False. Definition 14.4.3's warning gives $t = \mathbf{v}_1 \otimes \mathbf{v}_2 \otimes \varphi^1 \otimes \varphi^2$ with $C^1_1(t) = \mathbf{v}_2 \otimes \varphi^2 \neq 0$ and $C^1_2(t) = 0$.

14.4.4.2 B. Practice

Exercise B1: Contracting a mixed tensor.

Let $\dim V = 3$ with basis $\mathcal{B} = (\mathbf{v}_1, \mathbf{v}_2, \mathbf{v}_3)$ and dual basis $(\varphi^1, \varphi^2, \varphi^3)$. Let

$$t = 2\,\mathbf{v}_1 \otimes \varphi^1 - \mathbf{v}_1 \otimes \varphi^2 + 3\,\mathbf{v}_2 \otimes \varphi^2 + \mathbf{v}_3 \otimes \varphi^1 - 4\,\mathbf{v}_3 \otimes \varphi^3.$$

(a) Write the matrix of the operator S corresponding to t, in the basis $\mathcal{B}$.

(b) Compute $C^1_1(t)$ from Definition 14.4.3, and check it against $\operatorname{tr} S$.

(c) Compute $\operatorname{tr}(S \otimes S)$ without writing down a 9×9 matrix.

Solution.

(a) The tensor $\mathbf{v}_i \otimes \varphi^j$ corresponds to the operator $\mathbf{u} \mapsto \varphi^j(\mathbf{u})\mathbf{v}_i$, whose matrix is the matrix unit $\mathbf{E}_{ij}$ (Theorem 14.3.9). Adding up,

$$[S]^{\mathcal{B}}_{\mathcal{B}} = \begin{pmatrix} 2 & -1 & 0 \\ 0 & 3 & 0 \\ 1 & 0 & -4 \end{pmatrix}.$$

(b) $C^1_1(t) = 2\varphi^1(\mathbf{v}_1) - \varphi^2(\mathbf{v}_1) + 3\varphi^2(\mathbf{v}_2) + \varphi^1(\mathbf{v}_3) - 4\varphi^3(\mathbf{v}_3) = 2 - 0 + 3 + 0 - 4 = 1$, and the diagonal of the matrix in (a) sums to $2 + 3 - 4 = 1$.

(c) By Corollary 14.4.4, $\operatorname{tr}(S \otimes S) = (\operatorname{tr} S)^2 = 1$.

Exercise B2: Two contractions of one tensor.

Let $\dim V = 2$ with basis $(\mathbf{v}_1, \mathbf{v}_2)$ and dual basis (φ^1, φ^2), and let

$$t = \mathbf{v}_1 \otimes \varphi^1 \otimes \varphi^2 + \mathbf{v}_2 \otimes \varphi^2 \otimes \varphi^2 \in T^1_2(V).$$

Compute $C^1_1(t)$ and $C^1_2(t)$, and state which space each lies in.

Solution. Both lie in $T^0_1(V) = V^*$. Contracting the single upper slot against the **first** lower slot,

$$C^1_1(t) = \varphi^1(\mathbf{v}_1)\,\varphi^2 + \varphi^2(\mathbf{v}_2)\,\varphi^2 = \varphi^2 + \varphi^2 = 2\varphi^2.$$

Against the **second** lower slot, the remaining factor is the first functional:

$$C^1_2(t) = \varphi^2(\mathbf{v}_1)\,\varphi^1 + \varphi^2(\mathbf{v}_2)\,\varphi^2 = 0 + \varphi^2 = \varphi^2.$$

So $C^1_1(t) = 2\varphi^2 \neq \varphi^2 = C^1_2(t)$.

Exercise B3: Which statements hold?.

Let V, W be finite-dimensional over F. Determine which of the following hold. Justify your answer.

(a) $C(\xi) = 0$ implies $\xi = 0$.

(b) $\operatorname{tr}(\Theta(\varphi \otimes \mathbf{v})) = \varphi(\mathbf{v})$ for all $\varphi \in V^*$, $\mathbf{v} \in V$.

(c) Every element of $T^0_2(V)$ is a bilinear form on V, and conversely.

(d) $\operatorname{tr}(S \otimes T) = \operatorname{tr}(T \otimes S)$ for $S \in \mathcal{L}(V)$, $T \in \mathcal{L}(W)$.

(e) $C\colon V^* \otimes V \to F$ is surjective whenever $V \neq \{\mathbf{0}\}$.

Solution.

(a) Fails for $\dim V \geq 2$. With a basis and its dual, $\xi = \varphi^1 \otimes \mathbf{v}_2 \neq 0$ (Proposition 14.2.8) but $C(\xi) = \varphi^1(\mathbf{v}_2) = 0$. Contraction is a functional, not an injection; its kernel has dimension $n^2 - 1$.

(b) Holds: Corollary 14.4.2.

(c) Holds. By Proposition 14.4.3, $T_2^0(V) = V^* \otimes V^* \cong (V \otimes V)^*$, and by Definition 14.2.1 the linear maps $V \otimes V \to F$ correspond exactly to the bilinear maps $V \times V \to F$, which are the bilinear forms of Definition 13.1.1.

(d) Holds: both equal $\operatorname{tr} S \cdot \operatorname{tr} T$ by Corollary 14.4.4, the two products of scalars being equal.

(e) Holds. Take $\mathbf{v} \neq \mathbf{0}$; by Theorem 4.1.5 there is φ with $\varphi(\mathbf{v}) = 1$, so $C(c\,\varphi \otimes \mathbf{v}) = c$ for every $c \in F$.

14.4.4.3 C. Going deeper

Exercise C1: Composition, in tensor language.

Let V be finite-dimensional over F and $\Theta\colon V^* \otimes V \to \mathcal{L}(V)$ the isomorphism of Theorem 14.3.9.

(a) Prove that $\Theta(\varphi \otimes \mathbf{v})\,\Theta(\psi \otimes \mathbf{w}) = \varphi(\mathbf{w})\,\Theta(\psi \otimes \mathbf{v})$ for all $\varphi, \psi \in V^*$ and $\mathbf{v}, \mathbf{w} \in V$. Recall that ST means first T, then S.

(b) Hence compute $\operatorname{tr}\big(\Theta(\varphi \otimes \mathbf{v})\,\Theta(\psi \otimes \mathbf{w})\big)$, and observe that the answer is unchanged when $(\varphi, \mathbf{v})$ and $(\psi, \mathbf{w})$ are exchanged.

(c) Deduce that $\operatorname{tr}(ST) = \operatorname{tr}(TS)$ for all $S, T \in \mathcal{L}(V)$.

Solution.

(a) Both sides are operators on V, so evaluate at an arbitrary $\mathbf{u} \in V$. Applying $\Theta(\psi \otimes \mathbf{w})$ first gives $\psi(\mathbf{u})\mathbf{w}$, and then

$$\Theta(\varphi \otimes \mathbf{v})\big(\psi(\mathbf{u})\mathbf{w}\big) = \psi(\mathbf{u})\,\varphi(\mathbf{w})\,\mathbf{v},$$

using linearity of $\Theta(\varphi \otimes \mathbf{v})$. The right side gives $\varphi(\mathbf{w})\,\psi(\mathbf{u})\,\mathbf{v}$, the same scalar times the same vector. Hence the two operators agree at every $\mathbf{u}$.

(b) By (a) and Corollary 14.4.2,

$$\operatorname{tr}\big(\Theta(\varphi \otimes \mathbf{v})\,\Theta(\psi \otimes \mathbf{w})\big) = \varphi(\mathbf{w})\,\psi(\mathbf{v}).$$

Exchanging $(\varphi, \mathbf{v})$ with $(\psi, \mathbf{w})$ turns this into $\psi(\mathbf{v})\,\varphi(\mathbf{w})$, which is the same product of scalars.

(c) The maps $(S, T) \mapsto \operatorname{tr}(ST)$ and $(S, T) \mapsto \operatorname{tr}(TS)$ are bilinear on $\mathcal{L}(V) \times \mathcal{L}(V)$, and the rank-one maps $\Theta(\varphi \otimes \mathbf{v})$ span $\mathcal{L}(V)$ (as Θ is onto and simple tensors span, by Proposition 14.2.4). By (b) the two maps agree on such pairs, hence everywhere.

Exercise C2: The contraction of the identity, over any field.

Let V be finite-dimensional over F, $n = \dim V \geq 1$, and let $\iota \in V^* \otimes V$ be the tensor with $\Theta(\iota) = \mathrm{id}_V$.

(a) Prove that $\iota = \sum_{i=1}^{n} \varphi^i \otimes \mathbf{v}_i$ for **every** basis $\mathcal{B}$ of V with dual basis $\mathcal{B}^*$. (This tensor is basis-free, though each expression for it is not.)

(b) Prove that $C(\iota) = n \cdot 1$ in F.

(c) Over $\mathbb{F}_2$ with $n = 2$, find a tensor $\xi \neq \iota$ in $V^* \otimes V$ with $C(\xi) = C(\iota)$, and relate this to Chapter 3's observation that the trace does not determine the rank of a projection over $\mathbb{F}_2$.

Solution.

(a) By Corollary 14.4.2, $\Theta(\sum_i \varphi^i \otimes \mathbf{v}_i) = \mathrm{id}_V$ for any basis and its dual basis. Since Θ is injective (Theorem 14.3.9), all these tensors are equal, and each equals ι.

(b) $C(\iota) = \sum_i \varphi^i(\mathbf{v}_i) = \sum_i 1 = n \cdot 1$ by Definition 4.1.3.

(c) Take $\xi = 0$. Then $C(\xi) = 0 = 2 \cdot 1 = C(\iota)$ in $\mathbb{F}_2$, while $\xi \neq \iota$ because $\Theta(\iota) = \mathrm{id} \neq 0$. Under Θ these are the identity and the zero operator, both projections, of ranks 2 and 0; this is exactly Theorem 3.10.4's warning that over a field of characteristic 2 the integer $\operatorname{rank} P$ cannot be recovered from $\operatorname{tr} P$. The contraction is faithful to the tensor, but the field can be too small for the resulting scalar to distinguish them.

14.5 Index Notation and the Transformation Law

Outside mathematics, a tensor is usually not a vector in $T^p_q(V)$ at all: it is an array of numbers with some indices written upstairs and some downstairs, together with a rule saying how the array changes when the coordinates change. That older definition is still the working one in physics and in differential geometry, and a reader who meets it after this chapter deserves a dictionary. This section supplies one. We write the components of a tensor, derive — not assert — how they transform under a change of basis, and then prove that the classical definition and ours describe the same objects in finite dimensions. The section ends with the warning the classical definition exists to make: an array of numbers is not automatically a tensor.

14.5.1 Components, upstairs and downstairs

Fix a finite-dimensional V over F with $n = \dim V \geq 1$, an ordered basis $\mathcal{B} = (\mathbf{v}_1, \dots, \mathbf{v}_n)$, and its dual basis $\mathcal{B}^* = (\varphi^1, \dots, \varphi^n)$, characterized by $\varphi^i(\mathbf{v}_j) = \delta^i_j$ (Definition 4.1.3). By Theorem 14.2.5, the n^{p+q} tensors

$$\mathbf{v}_{i_1} \otimes \cdots \otimes \mathbf{v}_{i_p} \otimes \varphi^{j_1} \otimes \cdots \otimes \varphi^{j_q}$$

form a basis of $T^p_q(V)$, so every tensor has unique coordinates in it.

Definition 14.5.1 — Components of a tensor

Let $t \in T^p_q(V)$. The **components of t in the basis $\mathcal{B}$** are the unique scalars $T^{i_1\dots i_p}_{j_1\dots j_q} \in F$, for $1 \le i_1, \dots, i_p, j_1, \dots, j_q \le n$, with

$$t = \sum T^{i_1\dots i_p}_{j_1\dots j_q}\, \mathbf{v}_{i_1} \otimes \cdots \otimes \mathbf{v}_{i_p} \otimes \varphi^{j_1} \otimes \cdots \otimes \varphi^{j_q},$$

the sum running over all $p+q$ indices from 1 to n. An index written **upstairs** belongs to a V-slot and is called **contravariant**; an index written **downstairs** belongs to a V^*-slot and is called **covariant**.

In words: the position of an index records which kind of slot it labels, so that the shape of a symbol already tells you the type of the tensor. Nothing here is new mathematics; it is the coordinate vector of Theorem 14.2.5, with the indices arranged to be readable.

Two pieces of shorthand come with it. The first is the placement rule: a vector has its coordinates upstairs, $\mathbf{v} = \sum_i v^i \mathbf{v}_i$, while a functional has them downstairs, $\xi = \sum_j \xi_j \varphi^j$ — which is Theorem 4.1.3 (c) written in the new notation. The second is the **summation convention**: an index appearing once upstairs and once downstairs in a product is summed over, and the $\sum$ is not written. With it, the displayed formula above reads

$$t = T^{i_1\dots i_p}_{j_1\dots j_q}\, \mathbf{v}_{i_1} \otimes \cdots \otimes \varphi^{j_q},$$

and the evaluation of a functional on a vector is $\xi(\mathbf{v}) = \xi_i v^i$. The rest of this book writes its sums out; this section is the one place where the convention is used, and it is used because the transformation law is unreadable without it.

Examples.

1. **Type $(1,1)$: an operator.** If $t \in T^1_1(V)$ corresponds to $S \in \mathcal{L}(V)$ under Theorem 14.3.9, then T^i_j is the (i,j) entry of $[S]^{\mathcal{B}}_{\mathcal{B}}$: the tensor $\mathbf{v}_i \otimes \varphi^j$ is the operator $\mathbf{u} \mapsto \varphi^j(\mathbf{u})\mathbf{v}_i$, whose matrix is $\mathbf{E}_{ij}$. Upper index = row, lower index = column.
2. **Type $(0,2)$: a bilinear form.** If $t \in T^0_2(V)$ corresponds to the bilinear form β (Proposition 14.4.3 and Exercise (B3: Which statements hold?)), then $T_{ij} = \beta(\mathbf{v}_i, \mathbf{v}_j)$, which is the Gram matrix $[\beta]_{\mathcal{B}}$ of Definition 13.1.2. Both indices downstairs.
3. **Contraction.** In components, Definition 14.4.3 is "set an upper index equal to a lower one and sum". For $t \in T^1_1(V)$,

$$C^1_1(t) = T^i_i \quad \Big(= \sum_{i=1}^{n} T^i_i \Big),$$

which is the trace, by Theorem 14.4.1. This is the whole reason the convention pairs an upper with a lower index: a repeated index is a contraction, and contraction is the only basis-free way to remove slots.

> *Remark.* The names are historically backwards, and it is worth saying so once. A *contravariant* index sits upstairs, on a V-slot, and its components transform by the **inverse** of the matrix that transforms the basis vectors; a *covariant* index sits downstairs and transforms by the same matrix as the basis vectors. The names describe the components, not the slots. Theorem 14.5.2 below is what they refer to.

14.5.2 How the components change

Let $\mathcal{B} = (\mathbf{v}_1, \dots, \mathbf{v}_n)$ and $\mathcal{B}' = (\mathbf{v}'_1, \dots, \mathbf{v}'_n)$ be two ordered bases, and let

$$\mathbf{P} = [\mathrm{id}]^{\mathcal{B}}_{\mathcal{B}'} = (p^i_j)$$

be the change-of-coordinates matrix from $\mathcal{B}'$ to $\mathcal{B}$ (Definition 3.7.1), whose j-th column is $[\mathbf{v}'_j]_{\mathcal{B}}$. That is,

$$\mathbf{v}'_j = \sum_{i=1}^{n} p^i_j \, \mathbf{v}_i,$$

with the row index upstairs and the column index downstairs. Write $\mathbf{Q} = \mathbf{P}^{-1} = (q^i_j)$, which exists because a change-of-coordinates matrix is invertible (Proposition 3.7.2).

The dual bases move by the inverse matrix. This is the one computation the whole section rests on, so we do it first.

Lemma 14.5.1 — Dual Bases Move by the Inverse Matrix

With the notation above, $(\varphi')^k = \sum_{l=1}^{n} q^k_l \, \varphi^l$ for each k, where $(\varphi')^1, \dots, (\varphi')^n$ is the dual basis of $\mathcal{B}'$ supplied by Theorem 4.1.3.

Proof. Both sides are linear maps on V, so by the uniqueness clause of Theorem 3.1.5 it is enough to check that they agree at each vector of the basis $\mathcal{B}'$. By Definition 4.1.3 the left side gives $(\varphi')^k(\mathbf{v}'_j) = \delta^k_j$. The right side gives

$$\sum_{l} q^k_l \, \varphi^l\Big(\sum_{i} p^i_j \mathbf{v}_i\Big) = \sum_{l}\sum_{i} q^k_l \, p^i_j \, \delta^l_i = \sum_{i} q^k_i p^i_j,$$

which is the (k, j) entry of $\mathbf{QP} = \mathbf{I}_n$, that is δ^k_j. The two agree. ∎

So the dual basis vectors carry the entries of $\mathbf{P}^{-1}$, while the basis vectors carry the entries of $\mathbf{P}$. Substituting both into the expansion of a tensor gives the transformation law.

Theorem 14.5.2 — Transformation Law for Components

Let $t \in T^p_q(V)$ have components $T^{i_1 \dots i_p}_{j_1 \dots j_q}$ in $\mathcal{B}$ and $(T')^{k_1 \dots k_p}_{l_1 \dots l_q}$ in $\mathcal{B}'$, and let $\mathbf{P} = (p^i_j)$ and $\mathbf{Q} = \mathbf{P}^{-1} = (q^i_j)$ be as above. Then, with the summation convention,

$$(T')^{k_1 \dots k_p}_{l_1 \dots l_q} = q^{k_1}_{i_1} \cdots q^{k_p}_{i_p} \times p^{j_1}_{l_1} \cdots p^{j_q}_{l_q} \, T^{i_1 \dots i_p}_{j_1 \dots j_q}.$$

Each **upper** index is contracted with a factor of $\mathbf{P}^{-1}$, each **lower** index with a factor of $\mathbf{P}$.

Idea. There is only one move: write t in the new basis, replace every new basis vector and every new dual basis vector by its expression in the old ones, multiply out using multilinearity of $\otimes$, and compare with the expansion of t in the old basis. Coordinates in a basis are unique, so the comparison is an equality of coefficients. Doing it once for type $(1,0)$ shows the whole pattern; the general case is the same computation with more indices.

Proof. Start with the expansion of t in the new basis:

$$t = (T')^{k_1\dots k_p}_{l_1\dots l_q}\, \mathbf{v}'_{k_1} \otimes \cdots \otimes \mathbf{v}'_{k_p} \otimes (\varphi')^{l_1} \otimes \cdots \otimes (\varphi')^{l_q}.$$

Substitute $\mathbf{v}'_k = p^i_k \mathbf{v}_i$ and, by Lemma 14.5.1, $(\varphi')^l = q^l_j \varphi^j$. Since $\otimes$ is linear in each of its slots, the scalars may be pulled out of all $p+q$ factors at once, giving

$$t = (T')^{k_1\dots k_p}_{l_1\dots l_q}\, p^{i_1}_{k_1} \cdots p^{i_p}_{k_p}\, q^{l_1}_{j_1} \cdots q^{l_q}_{j_q} \times\ \mathbf{v}_{i_1} \otimes \cdots \otimes \mathbf{v}_{i_p} \otimes \varphi^{j_1} \otimes \cdots \otimes \varphi^{j_q}.$$

The tensors on the right form a basis of $T^p_q(V)$ (Theorem 14.2.5), so coordinates in them are unique (Theorem 1.5.1). Comparing with Definition 14.5.1,

$$T^{i_1\dots i_p}_{j_1\dots j_q} = p^{i_1}_{k_1} \cdots p^{i_p}_{k_p}\, q^{l_1}_{j_1} \cdots q^{l_q}_{j_q}\, (T')^{k_1\dots k_p}_{l_1\dots l_q}. \tag{$*$}$$

It remains to invert $(*)$. Contract both sides of $(*)$ with $q^{m_1}_{i_1} \cdots q^{m_p}_{i_p}\, p^{j_1}_{r_1} \cdots p^{j_q}_{r_q}$ and sum over $i_1, \dots, i_p, j_1, \dots, j_q$. On the right, each pair $q^m_i p^i_k$ sums to $(\mathbf{QP})^m_k = \delta^m_k$, and each pair $q^l_j p^j_r$ sums to δ^l_r; every delta then collapses one summation. What survives on the right is $(T')^{m_1\dots m_p}_{r_1\dots r_q}$, and what stands on the left is the asserted expression. Renaming m to k and r to l gives the theorem.

■

The two smallest cases are results the book already has, and they are worth reading off as a check.

- **Type $(1,1)$.** The law reads $(T')^k_l = q^k_i\, p^j_l\, T^i_j$, that is $\mathbf{T}' = \mathbf{P}^{-1}\mathbf{T}\mathbf{P}$. This is Theorem 3.7.3: matrices of an operator in two bases are **similar**.
- **Type $(0,2)$.** The law reads $(T')_{kl} = p^i_k\, p^j_l\, T_{ij}$, that is $\mathbf{T}' = \mathbf{P}^{\top}\mathbf{T}\mathbf{P}$. This is Theorem 13.2.1: Gram matrices of a bilinear form in two bases are **congruent**.

So similarity and congruence are not two unrelated relations that happen to look alike. They are the transformation laws of type $(1,1)$ and type $(0,2)$, and the difference between $\mathbf{P}^{-1}$ and $\mathbf{P}^{\top}$ is exactly the difference between an upper and a lower index.

14.5.3 The classical definition

The classical definition turns the theorem into a definition: a tensor *is* a rule producing arrays that obey the law.

Definition 14.5.2 — Classical tensor

Let V be a vector space over F with $\dim V = n \geq 1$, and let $p, q \geq 0$. A **classical tensor of type** (p, q) on V is a rule $\mathcal{B} \mapsto A_{\mathcal{B}}$ assigning to **every** ordered basis $\mathcal{B}$ of V an array

$$A_{\mathcal{B}} = \left(A^{i_1 \dots i_p}_{j_1 \dots j_q}\right)$$

of n^{p+q} scalars, such that for **any two** ordered bases $\mathcal{B}, \mathcal{B}'$, with $\mathbf{P} = [\mathrm{id}]^{\mathcal{B}}_{\mathcal{B}'}$ and $\mathbf{Q} = \mathbf{P}^{-1}$,

$$(A_{\mathcal{B}'})^{k_1 \dots k_p}_{l_1 \dots l_q} = q^{k_1}_{i_1} \cdots q^{k_p}_{i_p} \times p^{j_1}_{l_1} \cdots p^{j_q}_{l_q} \, (A_{\mathcal{B}})^{i_1 \dots i_p}_{j_1 \dots j_q}.$$

Theorem 14.5.3 — The Two Definitions Agree

Let V be finite-dimensional over F with $\dim V = n \geq 1$, and let $p, q \geq 0$. The map sending $t \in T^p_q(V)$ to the rule

$$\mathcal{B} \longmapsto \big(\text{components of } t \text{ in } \mathcal{B}\big)$$

is a bijection from $T^p_q(V)$ onto the set of classical tensors of type (p, q) on V. It is linear for the entrywise operations on arrays.

Idea. Well defined is Theorem 14.5.2. Injective because a tensor is determined by its coordinates in one basis. Surjective is the only step with content, and it is short: fix one basis $\mathcal{B}_0$, build the tensor whose components there are the given array, and then observe that its components in any other basis obey the same law as the rule's array does, starting from the same array — so the two agree.

Proof. **Well defined.** If $t \in T^p_q(V)$, its components in the various bases satisfy the required identity, by Theorem 14.5.2. So the rule attached to t is a classical tensor.

Injective. Fix a basis $\mathcal{B}_0$. If two tensors give the same rule, they have the same components in $\mathcal{B}_0$, hence are equal, since coordinates in the basis of Theorem 14.2.5 are unique (Theorem 1.5.1).

Surjective. Let $\mathcal{B} \mapsto A_{\mathcal{B}}$ be a classical tensor. Fix an ordered basis $\mathcal{B}_0 = (\mathbf{v}_1, \dots, \mathbf{v}_n)$ with dual basis $(\varphi^1, \dots, \varphi^n)$, and define

$$t := (A_{\mathcal{B}_0})^{i_1 \dots i_p}_{j_1 \dots j_q} \, \mathbf{v}_{i_1} \otimes \cdots \otimes \varphi^{j_q} \;\in\; T^p_q(V),$$

so that the components of t in $\mathcal{B}_0$ are exactly $A_{\mathcal{B}_0}$. Let $\mathcal{B}'$ be any other ordered basis and put $\mathbf{P} = [\mathrm{id}]^{\mathcal{B}_0}_{\mathcal{B}'}$. By Theorem 14.5.2 the components of t in $\mathcal{B}'$ are obtained from $A_{\mathcal{B}_0}$ by the law with this $\mathbf{P}$; by Definition 14.5.2, $A_{\mathcal{B}'}$ is obtained from $A_{\mathcal{B}_0}$ by the law with the same $\mathbf{P}$. Both are the value of the same expression, so they are equal. Hence the rule attached to t is the given one.

Linearity. The components of $t + ct'$ in each basis are $A + cA'$, because coordinate maps are linear (Corollary 3.5.5).

■

Why the older definition survives. It is tempting to file Definition 14.5.2 as a historical curiosity, and that would be a mistake. Three honest reasons keep it in use.

- **Components are what gets measured and computed.** A stress tensor, a metric, an inertia tensor: the physicist has numbers in a chosen frame, and the question that matters is what those numbers become in another frame. The transformation law is not a consequence to be derived afterwards; it is the datum.
- **There is often no global basis to be abstract about.** On a curved space, the objects of interest are tensor *fields*, and a manifold generally admits no single coordinate system covering it. What it does admit is many local coordinate patches with prescribed rules for passing between them. In that setting "an array in each chart, transforming correctly on overlaps" is a definition that works, while "an element of $T^p_q(V)$" needs a V that varies from point to point, which is a later and heavier construction.
- **It is a usable test.** Given a recipe that produces an array from a basis, checking the transformation law is a finite computation, and it is the standard way to certify that a quantity is geometric rather than an artifact of the coordinates. The next warning is exactly such a test, failed.

14.5.4 An array is not a tensor

Warning. **A matrix is not automatically a tensor.** Consider the rule that assigns to **every** ordered basis of V the same array, written as a matrix,

$$\mathbf{A}_{\mathcal{B}} = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}, \qquad \dim V = 2,$$

read as a type $(1,1)$ array. Take $\mathcal{B} = (\mathbf{v}_1, \mathbf{v}_2)$ and $\mathcal{B}' = (\mathbf{v}_1, \mathbf{v}_1 + \mathbf{v}_2)$, so that

$$\mathbf{P} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}, \qquad \mathbf{P}^{-1} = \begin{pmatrix} 1 & -1 \\ 0 & 1 \end{pmatrix}.$$

The law demands $\mathbf{A}_{\mathcal{B}'} = \mathbf{P}^{-1}\mathbf{A}_{\mathcal{B}}\mathbf{P}$, which is $\begin{pmatrix} 1 & 1 \\ 0 & 0 \end{pmatrix}$, not $\mathbf{A}_{\mathcal{B}}$. So this rule is **not** a classical tensor of type $(1,1)$: it is a matrix, and nothing more. The operator it describes in $\mathcal{B}$ — projection onto $\operatorname{span}(\mathbf{v}_1)$ along $\operatorname{span}(\mathbf{v}_2)$ — is a perfectly good tensor, but then its array in $\mathcal{B}'$ is the second matrix, not the first. "Write down the same numbers in every basis" is a rule, and almost never a tensor.

Two refinements of the same point are worth having.

The same array can be two different tensors. Take the array $\mathbf{I}_2$. As a type $(1,1)$ rule it *is* a tensor: $\mathbf{P}^{-1}\mathbf{I}_2\mathbf{P} = \mathbf{I}_2$ for every $\mathbf{P}$, and the tensor is the identity operator, which is the ι of Exercise (C2: The contraction of the identity, over any field). As a type $(0,2)$ rule, the same constant array is **not** a tensor: the law demands $\mathbf{P}^{\top}\mathbf{I}_2\mathbf{P}$, and for the $\mathbf{P}$ above that is $\begin{pmatrix} 1 & 1 \\ 1 & 2 \end{pmatrix} \neq \mathbf{I}_2$. Geometrically: "the identity operator" is basis-free, while "the bilinear form whose Gram matrix is the identity", that is, the choice of an inner product declaring the basis orthonormal, is not — it depends on the basis, and orthonormality, as Chapter 10 defines it, is relative to a chosen inner product.

Warning. **Which type an array has is not visible in the array.** The array $\begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}$ transforms as $\mathbf{P}^{-1}\mathbf{A}\mathbf{P}$ if it is the matrix of an operator and as $\mathbf{P}^{\top}\mathbf{A}\mathbf{P}$ if it is the Gram

matrix of a form, and for the $\mathbf{P}$ above those give $\begin{pmatrix} 1 & 1 \\ 0 & 0 \end{pmatrix}$ and $\begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix}$. Same numbers, same basis change, different answers. This is why index position is not decoration: writing A^i_j rather than A_{ij} is a statement about what the object is.

Quick check. Let $\dim V = 2$. Is the rule assigning to every ordered basis the array $A_{ij} = \delta_{ij}$ of type $(0,2)$ ever a classical tensor — say, over $\mathbb{F}_2$, or if we only allow bases obtained from one another by permutation? Decide, with a reason.

Solution. Over $\mathbb{F}_2$ it still fails: with $\mathbf{P} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$, the law demands $\mathbf{P}^\top \mathbf{I}_2 \mathbf{P} = \begin{pmatrix} 1 & 1 \\ 1 & 0 \end{pmatrix}$ (since $2 = 0$ in $\mathbb{F}_2$), which is not $\mathbf{I}_2$. If the bases are restricted to permutations of one fixed basis, then $\mathbf{P}$ is a permutation matrix, so $\mathbf{P}^\top = \mathbf{P}^{-1}$ and $\mathbf{P}^\top \mathbf{I}_2 \mathbf{P} = \mathbf{I}_2$: the rule survives. But Definition 14.5.2 quantifies over **every** ordered basis, and a rule that works only for a restricted family is exactly the kind of coordinate-dependent object the definition is designed to exclude. The lesson is that the law is a demand about all changes of basis, not about some.

14.5.5 Exercises

14.5.5.1 A. Check your understanding

Exercise A1.

(a) Define the components of a tensor of type (p, q) in an ordered basis, and say which indices go upstairs.

(b) State the summation convention, and write $\xi(\mathbf{v})$ with it.

(c) For a type $(1,1)$ tensor, write out the transformation law and name the relation it expresses between the two matrices.

(d) Give the transformation law for type $(0,2)$ and name the relation.

(e) True or false: any $n \times n$ array of scalars, attached to every basis, is a tensor of type $(1,1)$. Justify your answer.

Solution.

(a) They are the unique coordinates of t in the basis of Theorem 14.2.5 built from $\mathcal{B}$ and $\mathcal{B}^*$ (Definition 14.5.1). An index belonging to a V-slot goes upstairs; one belonging to a V^*-slot goes downstairs.

(b) An index occurring once upstairs and once downstairs in a product is summed from 1 to n, with the summation sign suppressed. So $\xi(\mathbf{v}) = \xi_i v^i$.

(c) $(T')^k_l = q^k_i p^j_l T^i_j$, that is $\mathbf{T}' = \mathbf{P}^{-1}\mathbf{T}\mathbf{P}$: the two matrices are **similar** (Theorem 3.7.3).

(d) $(T')_{kl} = p^i_k p^j_l T_{ij}$, that is $\mathbf{T}' = \mathbf{P}^\top \mathbf{T} \mathbf{P}$: the two matrices are **congruent** (Theorem 13.2.1, Definition 13.2.1).

(e) False. The rule must satisfy the transformation law; the constant rule $\begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}$ does not, as the warning above shows.

14.5.5.2 B. Practice

Exercise B1: Transforming components.

Let V be a 2-dimensional space over $\mathbb{Q}$ with basis $\mathcal{B} = (\mathbf{v}_1, \mathbf{v}_2)$, and let $\mathcal{B}' = (\mathbf{v}_1 + \mathbf{v}_2,\ \mathbf{v}_1 + 2\mathbf{v}_2)$.

(a) Write down $\mathbf{P} = [\mathrm{id}]^{\mathcal{B}}_{\mathcal{B}'}$ and $\mathbf{Q} = \mathbf{P}^{-1}$.

(b) Let $t \in T^1_1(V)$ have components $T^1_1 = 1$, $T^1_2 = 2$, $T^2_1 = 3$, $T^2_2 = 4$ in $\mathcal{B}$. Find its components in $\mathcal{B}'$.

(c) Let $s \in T^0_2(V)$ have the same array S_{ij} of components in $\mathcal{B}$. Find its components in $\mathcal{B}'$, and compare with (b).

(d) Compute $C^1_1(t)$ in both bases and check that the two answers agree.

Solution.

(a) The columns of $\mathbf{P}$ are the $\mathcal{B}$-coordinates of the vectors of $\mathcal{B}'$, so

$$\mathbf{P} = \begin{pmatrix} 1 & 1 \\ 1 & 2 \end{pmatrix}, \qquad \mathbf{Q} = \mathbf{P}^{-1} = \begin{pmatrix} 2 & -1 \\ -1 & 1 \end{pmatrix},$$

using Theorem 0.9.8 with $\det \mathbf{P} = 1$.

(b) By Theorem 14.5.2, $\mathbf{T}' = \mathbf{P}^{-1}\mathbf{T}\mathbf{P}$. With $\mathbf{T} = \begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix}$,

$$\mathbf{P}^{-1}\mathbf{T} = \begin{pmatrix} -1 & 0 \\ 2 & 2 \end{pmatrix}, \qquad \mathbf{T}' = \begin{pmatrix} -1 & -1 \\ 4 & 6 \end{pmatrix}.$$

(c) Now the law gives $\mathbf{S}' = \mathbf{P}^{\top}\mathbf{S}\mathbf{P}$. With $\mathbf{P}^{\top} = \begin{pmatrix} 1 & 1 \\ 1 & 2 \end{pmatrix}$ (this $\mathbf{P}$ is symmetric),

$$\mathbf{P}^{\top}\mathbf{S} = \begin{pmatrix} 4 & 6 \\ 7 & 10 \end{pmatrix}, \qquad \mathbf{S}' = \begin{pmatrix} 10 & 16 \\ 17 & 27 \end{pmatrix}.$$

The same array in the same two bases produces completely different answers, because the two objects are of different types.

(d) In $\mathcal{B}$: $T^1_1 + T^2_2 = 1 + 4 = 5$. In $\mathcal{B}'$: $-1 + 6 = 5$. They agree, as they must, since Definition 14.4.3 is defined without reference to a basis. (By contrast, the "trace" of the type $(0, 2)$ arrays is $1 + 4 = 5$ against $10 + 27 = 37$: there is no contraction of two lower indices, and summing S_{ii} is not a basis-free operation.)

Exercise B2: Tensor or not?.

Let $\dim V = 2$. For each rule below, determine whether it is a classical tensor of the stated type. Justify your answer, using $\mathcal{B} = (\mathbf{v}_1, \mathbf{v}_2)$ and $\mathcal{B}' = (\mathbf{v}_2, \mathbf{v}_1)$ or $\mathcal{B}' = (\mathbf{v}_1, \mathbf{v}_1 + \mathbf{v}_2)$ where a counterexample is needed.

(a) Type $(1,1)$: $A_{\mathcal{B}} = \mathbf{I}_2$ for every $\mathcal{B}$.

(b) Type $(1,1)$: $A_{\mathcal{B}} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$ for every $\mathcal{B}$.

(c) Type $(0,2)$: $A_{\mathcal{B}} = \mathbf{0}$ for every $\mathcal{B}$.

(d) Type $(1,1)$: $A_{\mathcal{B}} = (\operatorname{tr} \mathbf{M}_{\mathcal{B}})\mathbf{I}_2$, where $\mathbf{M}_{\mathcal{B}}$ is the matrix in $\mathcal{B}$ of one fixed operator $M \in \mathcal{L}(V)$.

Solution.

(a) Yes. The law demands $\mathbf{P}^{-1}\mathbf{I}_2\mathbf{P} = \mathbf{I}_2$, which holds for every invertible $\mathbf{P}$. The tensor is id_V.

(b) No. With $\mathcal{B}' = (\mathbf{v}_2, \mathbf{v}_1)$ we get $\mathbf{P} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} = \mathbf{P}^{-1}$, and $\mathbf{P}^{-1}A\mathbf{P} = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix} \neq A$. (This is the standard non-diagonalizable matrix of Chapter 8; here it is failing a different test.)

(c) Yes. The law reads $\mathbf{0} = \mathbf{P}^{\top}\mathbf{0}\mathbf{P}$, which holds. The tensor is the zero tensor, and the zero array is the one array that is a tensor of every type.

(d) Yes. By Theorem 3.7.5 the scalar $c = \operatorname{tr} \mathbf{M}_{\mathcal{B}}$ is the same for every $\mathcal{B}$, so the rule is the constant rule $c\,\mathbf{I}_2$, and $\mathbf{P}^{-1}(c\mathbf{I}_2)\mathbf{P} = c\mathbf{I}_2$. The tensor is $c\,\mathrm{id}_V$. The point of contrast with (b) is that c was itself built basis-freely.

14.5.5.3 C. Going deeper

Exercise C1: Contraction in indices.

Let $\dim V = n$ and let $t \in T^1_1(V)$ have components T^i_j in $\mathcal{B}$ and $(T')^k_l$ in $\mathcal{B}'$.

(a) Prove directly from Theorem 14.5.2 that $(T')^k_k = T^i_i$, without using Theorem 14.4.1.

(b) Let $t \in T^2_1(V)$ with components T^{ij}_k. Show that $U^j := T^{ij}_i$ are the components of a type $(1,0)$ tensor, and identify it in terms of Definition 14.4.3.

(c) Let $s \in T^2_0(V)$ have components S^{ij}. Show that the scalar $\sum_i S^{ii}$ is **not** basis-independent, and say which step of (b) fails for it.

Solution.

(a) By the law, $(T')^k_l = q^k_i p^j_l T^i_j$. Setting $l = k$ and summing,

$$(T')^k_k = \sum_k \sum_{i,j} q^k_i p^j_k T^i_j = \sum_{i,j} \Big(\sum_k p^j_k q^k_i \Big) T^i_j = \sum_{i,j} \delta^j_i T^i_j = \sum_i T^i_i,$$

where the inner sum is the (j,i) entry of $\mathbf{P}\mathbf{Q} = \mathbf{I}_n$.

(b) By Theorem 14.5.2 for type $(2,1)$, $(T')^{km}_l = q^k_i q^m_j p^r_l T^{ij}_r$. Setting $l = k$ and summing over k,

$$(U')^m = \sum_k (T')^{km}_k = q^m_j \Big(\sum_{k,i,r} q^k_i p^r_k T^{ij}_r \Big) = q^m_j \, \delta^r_i T^{ij}_r = q^m_j U^j,$$

which is the transformation law for a single upper index. So (U^j) is a classical tensor of type $(1,0)$, and by Theorem 14.5.3 it is a vector; it is $C^1_1(t)$, the contraction

of the first upper slot against the lower one (Definition 14.4.3).

(c) Take $n = 2$ and $s = \mathbf{v}_1 \otimes \mathbf{v}_1$, so $S^{11} = 1$ and the other components vanish; then $\sum_i S^{ii} = 1$. Let $\mathcal{B}' = (\mathbf{v}_1 + \mathbf{v}_2,\ \mathbf{v}_2)$, so that $\mathbf{P} = \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix}$ and $\mathbf{v}_1 = \mathbf{v}'_1 - \mathbf{v}'_2$. Expanding,

$$s = (\mathbf{v}'_1 - \mathbf{v}'_2) \otimes (\mathbf{v}'_1 - \mathbf{v}'_2),$$

so $(S')^{11} = (S')^{22} = 1$ and $(S')^{12} = (S')^{21} = -1$. Hence $\sum_k (S')^{kk} = 2 \neq 1$. The step that fails is the collapse in (b): setting the two indices equal pairs a factor q_i^k with another factor q_j^k, and $\sum_k q_i^k q_j^k$ is an entry of $\mathbf{Q}^\top \mathbf{Q}$, not of $\mathbf{PQ} = \mathbf{I}_n$, so nothing cancels. Only an upper index repeated against a **lower** one is a contraction.

Exercise C2: Raising an index needs a form.

Let V be finite-dimensional over F and let β be a non-degenerate bilinear form on V, with components $g_{ij} = \beta(\mathbf{v}_i, \mathbf{v}_j)$ in $\mathcal{B}$.

(a) Prove that the matrix $\mathbf{G} = (g_{ij})$ is invertible, and let (g^{ij}) denote the entries of $\mathbf{G}^{-1}$.

(b) Let $t \in T_1^0(V)$ have components T_j. Show that $U^i := g^{ij} T_j$ satisfies the type $(1,0)$ transformation law, so that "raising the index with β" produces a genuine tensor.

(c) Explain in one or two sentences why this does **not** contradict the warning that there is no canonical map $V^* \to V$.

Solution.

(a) By Proposition 13.1.2, β is non-degenerate exactly when $\mathbf{G} = [\beta]_{\mathcal{B}}$ is invertible.

(b) By Theorem 13.2.1, $\mathbf{G}' = \mathbf{P}^\top \mathbf{G} \mathbf{P}$, so $(\mathbf{G}')^{-1} = \mathbf{P}^{-1} \mathbf{G}^{-1} (\mathbf{P}^\top)^{-1} = \mathbf{Q} \mathbf{G}^{-1} \mathbf{Q}^\top$, that is $(g')^{kl} = q_i^k q_j^l g^{ij}$: the inverse array carries two upper indices. Also $(T')_l = p_l^r T_r$ by Theorem 14.5.2. Hence

$$\begin{aligned} (U')^k = (g')^{kl} (T')_l &= q_i^k \, g^{ij} \Big(\sum_l q_j^l p_l^r \Big) T_r \\ &= q_i^k \, g^{ij} \, \delta_j^r \, T_r = q_i^k \, g^{ij} T_j = q_i^k U^i, \end{aligned}$$

using $\sum_l p_l^r q_j^l = (\mathbf{PQ})_j^r = \delta_j^r$. That is the type $(1,0)$ law.

(c) The map is canonical *given* β, not given V alone: a different non-degenerate form raises indices differently, and there is no distinguished choice. This is the same point as the warning after Definition 14.4.1: the isomorphism $V \cong V^*$ is extra structure, which Chapter 10 supplies with an inner product and Chapter 13 with a form.

14.6 The Tensor Algebra

Sections 03 and 04 already iterated the tensor product: $V^{\otimes k}$ is $V \otimes \cdots \otimes V$ with k factors, its brackets do not matter (Proposition 14.3.5), and k-linear maps out of V^k become linear maps

on it (Lemma 14.3.4). Two things are still missing, and Chapter 13 needs both. The first is a **basis** of $V^{\otimes k}$, which the next three sections will cut down in two different ways. The second is a single algebra holding all the powers at once: Chapter 13 §12 described it as the algebra of "formal sums of strings of vectors, multiplied by concatenation", said no such algebra had been built, and deferred the Clifford algebra until it was. This section builds it, calls it $\mathrm{T}(V)$, and proves the universal property that Sections 07, 08 and 10 will each quotient.

Throughout, F is a field and V is a finite-dimensional vector space over F, with $n = \dim V$. The letter k always denotes a non-negative integer.

14.6.1 The k-th tensor power

Section 04 wrote $V^{\otimes k}$ for the k-fold tensor product and $V^{\otimes 0} = F$, and Section 03 proved what maps out of it look like. Before using that space three more times it is worth restating the property as a **characterization**, in the form the rest of the chapter will copy: *say what maps out of the object look like, and demand that the object be the most economical one with that property.* The definition below is Definition 14.2.1 with k slots in place of two, and nothing else changes.

The k-th tensor power is the space in which k-linear maps become linear.

Definition 14.6.1 — k-th Tensor Power

Let V be a vector space over F and let $k \geq 1$. A **k-th tensor power of V** is a pair (P, μ), where P is a vector space over F and $\mu\colon V^k \to P$ is a k-linear map, such that

(T1) (**universal property**) for **every** vector space W over F and **every** k-linear map $f\colon V^k \to W$, there is a **unique** linear map $\bar{f}\colon P \to W$ with $\bar{f} \circ \mu = f$.

We write $V^{\otimes k}$ for P and

$$\mathbf{v}_1 \otimes \mathbf{v}_2 \otimes \cdots \otimes \mathbf{v}_k \coloneqq \mu(\mathbf{v}_1, \ldots, \mathbf{v}_k)$$

for the value of μ, and we call such an element a **simple tensor**. By convention $V^{\otimes 0} = F$, with μ the empty product $1 \in F$.

Clause by clause. The pair is what is defined, not the space alone: without μ there is nothing for f to factor through, and a bare vector space of the right dimension satisfies nothing. **Every** vector space W is allowed as a target, including $W = F$ and including P itself; the property is a demand about all of them simultaneously. **Unique** is the clause that does the work later: existence of $\bar{f}$ says P is big enough to record f, and uniqueness says P is not bigger than that.

At $k = 1$ a 1-linear map is a linear map, and the pair (V, id_V) satisfies (T1) with $\bar{f} = f$. So $V^{\otimes 1} = V$, and the notation agrees with itself. At $k = 2$ the definition is Definition 14.2.1 with W replaced by V, so $V^{\otimes 2} = V \otimes V$. The convention $V^{\otimes 0} = F$ is a convention in the same sense as $\mathrm{span}(\emptyset) = \{\mathbf{0}\}$ and $0! = 1$: it is the choice that keeps the formulas below true at the boundary, as the dimension count $\dim V^{\otimes k} = n^k$ and the multiplication rule will both confirm.

Uniqueness first, exactly as in Section 02.

Theorem 14.6.1 — Uniqueness of the Tensor Power

Let (P, μ) and (P', μ') both be k-th tensor powers of V. Then there is a **unique** linear isomorphism $\varphi\colon P \to P'$ with $\varphi \circ \mu = \mu'$.

Proof. This is the proof of Theorem 14.2.1 with k slots in place of two, and we run it once more so that the pattern is visible. Since μ' is k-linear, (T1) for P gives a linear $\varphi\colon P \to P'$ with $\varphi\mu = \mu'$. Since μ is k-linear, (T1) for P' gives a linear $\psi\colon P' \to P$ with $\psi\mu' = \mu$. Then $\psi\varphi\colon P \to P$ is linear with $\psi\varphi\mu = \psi\mu' = \mu$, and id_P is another such map. By the uniqueness clause of (T1) for P, applied to the k-linear map μ itself, the two coincide: $\psi\varphi = \mathrm{id}_P$. Swapping the roles of P and P' gives $\varphi\psi = \mathrm{id}_{P'}$. Hence φ is an isomorphism, and (T1) delivered it uniquely. This proves the theorem. ∎

Four lines, and they used nothing but the property itself. That is the point of defining objects this way, and it is why the remaining uniqueness proofs in this chapter will be compressed to a citation of this one.

Now existence. Here the chapter can be lazy: a k-th tensor power does not need a new construction, because iterating the binary one already produces it.

Theorem 14.6.2 — Existence of the Tensor Power

Let $k \geq 1$ and let $V^{\otimes k} = V \otimes \cdots \otimes V$ be the iterated tensor product of Section 03, with

$$\mu_k(\mathbf{v}_1, \ldots, \mathbf{v}_k) = \mathbf{v}_1 \otimes \cdots \otimes \mathbf{v}_k.$$

Then $(V^{\otimes k}, \mu_k)$ is a k-th tensor power of V, and it is spanned by its simple tensors.

Proof. The map μ_k is k-linear, being $\otimes$ applied $k-1$ times and $\otimes$ bilinear in each use. Property (T1) and the spanning claim are exactly Lemma 14.3.4, read with $V_1 = \cdots = V_k = V$. This proves the theorem. ∎

The proof is one sentence because Section 03 did the induction: freeze the last argument, apply the $(k-1)$-factor statement, let the last argument move again, and finish with the two-factor property. Two consequences are used in every argument below, so they are worth saying in words. **$V^{\otimes k}$ is spanned by its simple tensors**, so two linear maps out of $V^{\otimes k}$ are equal as soon as they agree on simple tensors; and **a k-linear recipe on V^k defines a linear map on $V^{\otimes k}$**, which is how every map out of a tensor power gets built, here and in Sections 07 and 08.

From now on $V^{\otimes k}$ denotes this space, and by Theorem 14.6.1 any other k-th tensor power is identified with it by a unique isomorphism respecting the simple tensors. So it is legitimate to speak of *the* k-th tensor power, and the model may be forgotten: every proof below argues from (T1).

14.6.2 A basis, and the dimension

The count is the one Section 01 predicted. A k-linear map on an n-dimensional space may be prescribed freely on the n^k tuples of basis vectors and is determined by those values (Theorem 14.1.1); so $V^{\otimes k}$ had better have dimension n^k, and it does.

Theorem 14.6.3 — Basis of a Tensor Power

Let $\mathcal{B} = (\mathbf{v}_1, \dots, \mathbf{v}_n)$ be a basis of V and let $k \geq 1$. Then the list of simple tensors

$$\mathbf{v}_{i_1} \otimes \mathbf{v}_{i_2} \otimes \cdots \otimes \mathbf{v}_{i_k}, \qquad (i_1, \dots, i_k) \in \{1, \dots, n\}^k,$$

is a basis of $V^{\otimes k}$. In particular $\dim V^{\otimes k} = n^k$.

Idea. Spanning is multilinear expansion: write each argument in the basis and expand one slot at a time. Independence needs, for each tuple J, a linear functional on $V^{\otimes k}$ that is 1 on the tensor indexed by J and 0 on the others. Build it upstairs, as a product of dual basis functionals, and let the universal property carry it down.

Proof. Spanning. By Theorem 14.6.2, $V^{\otimes k}$ is spanned by its simple tensors, so it suffices to expand one of them in the basis $\mathcal{B}$. Write $\mathbf{u}_t = \sum_{i=1}^{n} c_{ti}\mathbf{v}_i$ for $t = 1, \dots, k$. Expanding $\mathbf{u}_1 \otimes \cdots \otimes \mathbf{u}_k$ in slot 1, then in slot 2, and so on, using k-linearity of μ_k once per slot, gives

$$\mathbf{u}_1 \otimes \cdots \otimes \mathbf{u}_k = \sum_{i_1, \dots, i_k} c_{1i_1} \cdots c_{ki_k}\, \mathbf{v}_{i_1} \otimes \cdots \otimes \mathbf{v}_{i_k},$$

a linear combination of the listed tensors.

Independence. Let $(\varphi_1, \dots, \varphi_n)$ be the dual basis of $\mathcal{B}$ (Theorem 4.1.3), so $\varphi_i(\mathbf{v}_j) = \delta_{ij}$. Fix a tuple $J = (j_1, \dots, j_k)$ and define

$$f_J(\mathbf{u}_1, \dots, \mathbf{u}_k) = \varphi_{j_1}(\mathbf{u}_1)\, \varphi_{j_2}(\mathbf{u}_2) \cdots \varphi_{j_k}(\mathbf{u}_k).$$

This is k-linear: in position t it is the functional φ_{j_t} times a fixed scalar. By (T1) it induces a linear $\bar{f}_J \colon V^{\otimes k} \to F$ with

$$\bar{f}_J(\mathbf{v}_{i_1} \otimes \cdots \otimes \mathbf{v}_{i_k}) = \delta_{j_1 i_1} \cdots \delta_{j_k i_k},$$

which is 1 if $I = J$ and 0 otherwise. Now suppose $\sum_I a_I\, \mathbf{v}_{i_1} \otimes \cdots \otimes \mathbf{v}_{i_k} = \mathbf{0}$, the sum over all n^k tuples I. Applying $\bar{f}_J$ to both sides leaves $a_J = 0$. Since J was arbitrary, every coefficient vanishes.

Hence the list is a basis. It has one member per tuple in $\{1, \dots, n\}^k$, and there are n^k of those, so $\dim V^{\otimes k} = n^k$. This proves the theorem.

■

The count also confirms the convention $V^{\otimes 0} = F$: the formula n^k at $k = 0$ reads $n^0 = 1 = \dim F$, and the only 0-tuple is the empty one.

Quick check. Let $\dim V = 3$. What is $\dim V^{\otimes 4}$, and how many of its basis tensors have all four indices distinct?

Solution. $\dim V^{\otimes 4} = 3^4 = 81$. None: an index tuple of length 4 drawn from $\{1,2,3\}$ must repeat a value, by the pigeonhole principle. This is the first sign that the tensors with a repeated index are not a negligible part of $V^{\otimes k}$ — Section 08 will divide by the span of the simple tensors $\mathbf{u}_1 \otimes \cdots \otimes \mathbf{u}_k$ that repeat a **vector**, a subspace containing every one of these.

Example. (A tensor cube, in coordinates)

Let $V = F^2$ with standard basis $(\mathbf{e}_1, \mathbf{e}_2)$. Write out a basis of $V^{\otimes 3}$, and expand $(\mathbf{e}_1 + \mathbf{e}_2) \otimes (\mathbf{e}_1 - \mathbf{e}_2) \otimes \mathbf{e}_1$ in it.

Solution. By Theorem 14.6.3 a basis is indexed by the $2^3 = 8$ triples of indices from $\{1,2\}$:

$$\mathbf{e}_1 \otimes \mathbf{e}_1 \otimes \mathbf{e}_1, \quad \mathbf{e}_1 \otimes \mathbf{e}_1 \otimes \mathbf{e}_2, \quad \mathbf{e}_1 \otimes \mathbf{e}_2 \otimes \mathbf{e}_1, \quad \mathbf{e}_1 \otimes \mathbf{e}_2 \otimes \mathbf{e}_2,$$
$$\mathbf{e}_2 \otimes \mathbf{e}_1 \otimes \mathbf{e}_1, \quad \mathbf{e}_2 \otimes \mathbf{e}_1 \otimes \mathbf{e}_2, \quad \mathbf{e}_2 \otimes \mathbf{e}_2 \otimes \mathbf{e}_1, \quad \mathbf{e}_2 \otimes \mathbf{e}_2 \otimes \mathbf{e}_2.$$

Expanding slot by slot, first in slot 1 and then in slot 2, and noting that slot 3 is already a basis vector,

$$\begin{aligned}(\mathbf{e}_1 + \mathbf{e}_2) \otimes (\mathbf{e}_1 - \mathbf{e}_2) \otimes \mathbf{e}_1 = {} & \mathbf{e}_1 \otimes \mathbf{e}_1 \otimes \mathbf{e}_1 - \mathbf{e}_1 \otimes \mathbf{e}_2 \otimes \mathbf{e}_1 \\ & + \mathbf{e}_2 \otimes \mathbf{e}_1 \otimes \mathbf{e}_1 - \mathbf{e}_2 \otimes \mathbf{e}_2 \otimes \mathbf{e}_1.\end{aligned}$$

Four of the eight coordinates are non-zero and the other four are 0. Note also that $\mathbf{e}_1 \otimes \mathbf{e}_2 \otimes \mathbf{e}_1$ and $\mathbf{e}_2 \otimes \mathbf{e}_1 \otimes \mathbf{e}_1$ are **different** basis vectors: the order of the slots is part of the data.

14.6.3 Stacking the powers: the tensor algebra

We now have one space for each k. Chapter 13 wanted a single algebra containing all of them, in which $\mathbf{v}_1 \otimes \mathbf{v}_2$ and $\mathbf{v}_3 \otimes \mathbf{v}_4 \otimes \mathbf{v}_5$ could be multiplied to give $\mathbf{v}_1 \otimes \mathbf{v}_2 \otimes \mathbf{v}_3 \otimes \mathbf{v}_4 \otimes \mathbf{v}_5$. The multiplication is concatenation of strings; the only work is to define it without choosing a basis.

First the multiplication on a single pair of powers.

Proposition 14.6.4 — Concatenation of Tensors

Let $k, l \geq 1$. There is a unique bilinear map

$$V^{\otimes k} \times V^{\otimes l} \to V^{\otimes (k+l)}, \qquad (x, y) \mapsto x \cdot y,$$

such that for all $\mathbf{u}_1, \ldots, \mathbf{u}_k, \mathbf{w}_1, \ldots, \mathbf{w}_l \in V$,

$$(\mathbf{u}_1 \otimes \cdots \otimes \mathbf{u}_k) \cdot (\mathbf{w}_1 \otimes \cdots \otimes \mathbf{w}_l) = \mathbf{u}_1 \otimes \cdots \otimes \mathbf{u}_k \otimes \mathbf{w}_1 \otimes \cdots \otimes \mathbf{w}_l.$$

Idea. The same peeling move as in Theorem 14.6.2, applied to the two blocks of slots in turn: first make the last l slots into a linear map, then make the first k slots into a linear map whose values are those linear maps.

Proof. Fix $\mathbf{u}_1, \dots, \mathbf{u}_k \in V$. The map $V^l \to V^{\otimes(k+l)}$ sending $(\mathbf{w}_1, \dots, \mathbf{w}_l)$ to $\mathbf{u}_1 \otimes \cdots \otimes \mathbf{u}_k \otimes \mathbf{w}_1 \otimes \cdots \otimes \mathbf{w}_l$ is l-linear, since μ_{k+l} is $(k+l)$-linear and the first k arguments are fixed. By (T1) for $V^{\otimes l}$ it induces a unique linear map $R(\mathbf{u}_1, \dots, \mathbf{u}_k)\colon V^{\otimes l} \to V^{\otimes(k+l)}$.

Next, $(\mathbf{u}_1, \dots, \mathbf{u}_k) \mapsto R(\mathbf{u}_1, \dots, \mathbf{u}_k)$ is k-linear as a map into $\mathcal{L}(V^{\otimes l}, V^{\otimes(k+l)})$. Indeed, two linear maps $V^{\otimes l} \to V^{\otimes(k+l)}$ are equal as soon as they agree on simple tensors, and on a simple tensor both sides of each linearity identity reduce to linearity of μ_{k+l} in one of its first k slots. By (T1) for $V^{\otimes k}$ we get a linear map

$$M\colon V^{\otimes k} \to \mathcal{L}\big(V^{\otimes l},\, V^{\otimes(k+l)}\big),$$

and we set $x \cdot y = M(x)(y)$. This is linear in x because M is linear, and linear in y because each $M(x)$ is linear, so it is bilinear, and on simple tensors it is the displayed concatenation.

Uniqueness: a bilinear map is determined by its values on pairs of spanning sets, and each factor is spanned by its simple tensors. This proves the proposition.

∎

With $k = 0$ or $l = 0$ we let $\cdot$ be scalar multiplication, which is the only bilinear option on $F \times V^{\otimes l}$ agreeing with "prepend nothing". Now stack.

Definition 14.6.2 — Tensor Algebra

Let V be a vector space over F. The **tensor algebra** of V is the vector space

$$\mathrm{T}(V) = \bigoplus_{k \geq 0} V^{\otimes k},$$

whose elements are the sequences $x = (x_0, x_1, x_2, \dots)$ with $x_k \in V^{\otimes k}$ and $x_k = \mathbf{0}$ for **all but finitely many** k, with componentwise addition and scalar multiplication, and whose multiplication is

$$(xy)_m = \sum_{k+l=m} x_k \cdot y_l,$$

with $\cdot$ as in Proposition 14.6.4. We identify $V^{\otimes k}$ with the set of sequences supported in position k, so that $F = V^{\otimes 0}$ and $V = V^{\otimes 1}$ are subspaces of $\mathrm{T}(V)$. An element of $V^{\otimes k} \subseteq \mathrm{T}(V)$ is called **homogeneous of degree** k.

The "all but finitely many" clause is the same one that makes $F[x]$ a space of polynomials rather than power series (Definition 0.8.1): an element of $\mathrm{T}(V)$ is a **finite** sum $x_0 + x_1 + \cdots + x_N$, not a series. The formula for $(xy)_m$ is then a finite sum, so the product is defined.

Theorem 14.6.5 — The Tensor Algebra Is an Algebra

$\mathrm{T}(V)$ with the above operations is an associative unital F-algebra (Definition 13.12.1), with identity $1 \in F = V^{\otimes 0}$. Moreover $V^{\otimes k} \cdot V^{\otimes l} \subseteq V^{\otimes(k+l)}$ for all k, l.

Proof. Bilinearity of the multiplication is immediate from bilinearity of each $\cdot$ in Proposition 14.6.4, since the components of xy are finite sums of bilinear expressions in the

components of x and y.

For associativity it suffices, by bilinearity in each of the three arguments and because the homogeneous components span, to check $(xy)z = x(yz)$ for homogeneous x, y, z, and then, because each power is spanned by its simple tensors, for simple tensors. Both sides are then the single simple tensor obtained by writing the three strings of vectors one after another, so they agree.

For the identity, $1 \in F = V^{\otimes 0}$ acts on each $V^{\otimes k}$ as scalar multiplication by 1, hence as the identity. The grading statement is the target of Proposition 14.6.4. This proves the theorem.

■

From here on we drop the dot and write xy, and for simple tensors we write $\mathbf{u}_1 \otimes \cdots \otimes \mathbf{u}_k$ for both the element and the product $\mathbf{u}_1\mathbf{u}_2\cdots\mathbf{u}_k$ of k elements of V — they are the same thing, since concatenating k strings of length 1 gives the string of length k.

Warning. $\mathrm{T}(V)$ **is not commutative, and not finite-dimensional.** If $\dim V \geq 2$, pick basis vectors $\mathbf{v}_1 \neq \mathbf{v}_2$; then $\mathbf{v}_1 \otimes \mathbf{v}_2$ and $\mathbf{v}_2 \otimes \mathbf{v}_1$ are **distinct basis vectors** of $V^{\otimes 2}$ by Theorem 14.6.3, so $\mathbf{v}_1\mathbf{v}_2 \neq \mathbf{v}_2\mathbf{v}_1$. And $\dim \mathrm{T}(V) = \sum_k n^k$ is infinite as soon as $n \geq 1$, even though V is finite-dimensional. Every individual element still has only finitely many non-zero components.

Example. (The tensor algebra of a line)

Let $\dim V = 1$, say $V = F\mathbf{v}$. Identify $\mathrm{T}(V)$ with a familiar algebra.

Solution. By Theorem 14.6.3, $V^{\otimes k}$ has the single basis vector $\mathbf{v}^{\otimes k} = \mathbf{v} \otimes \cdots \otimes \mathbf{v}$, so $\dim V^{\otimes k} = 1^k = 1$. An element of $\mathrm{T}(V)$ is therefore a finite sum $a_0 + a_1\mathbf{v} + a_2\mathbf{v}^{\otimes 2} + \ldots$ with $a_k \in F$, and concatenation gives $\mathbf{v}^{\otimes k}\mathbf{v}^{\otimes l} = \mathbf{v}^{\otimes (k+l)}$. Matching $\mathbf{v}^{\otimes k}$ with x^k turns these into exactly the addition and multiplication rules of Definition 0.8.2, so $\mathrm{T}(V) \cong F[x]$ as F-algebras.

In particular $\mathrm{T}(V)$ *is* commutative when $\dim V = 1$: there is only one letter, so no two letters can fail to commute. The warning above needed $\dim V \geq 2$, and it needed it for a reason.

14.6.4 The universal property of the tensor algebra

The tensor powers were characterized by what k-linear maps do. The algebra assembled from them has its own characterization, and it is the one Sections 07, 08 and 10 will use: **to define an algebra homomorphism out of $\mathrm{T}(V)$, you only have to say what it does to the vectors.**

Theorem 14.6.6 — Universal Property of the Tensor Algebra

Let V be a vector space over F, let A be an associative unital F-algebra, and let

$f\colon V \to A$ be a **linear** map. Then there is a **unique** algebra homomorphism

$$\bar{f}\colon \mathrm{T}(V) \to A \qquad \text{with} \qquad \bar{f}\big|_V = f.$$

Explicitly, $\bar{f}(\mathbf{u}_1 \otimes \cdots \otimes \mathbf{u}_k) = f(\mathbf{u}_1)\cdots f(\mathbf{u}_k)$ and $\bar{f}(a) = a1_A$ for $a \in F$.

Idea. Degree by degree. In degree k, the recipe $(\mathbf{u}_1, \dots, \mathbf{u}_k) \mapsto f(\mathbf{u}_1)\cdots f(\mathbf{u}_k)$ is k-linear because the product of A is bilinear and f is linear, so (T1) converts it into a linear map on $V^{\otimes k}$. Assemble the pieces and check multiplicativity on simple tensors, which span.

Proof. Existence. For $k \geq 1$ the map $V^k \to A$ given by $(\mathbf{u}_1, \dots, \mathbf{u}_k) \mapsto f(\mathbf{u}_1)f(\mathbf{u}_2)\cdots f(\mathbf{u}_k)$ is k-linear: with all arguments but the t-th fixed, it is f followed by multiplication on the left and on the right by fixed elements of A, and all three of those maps are linear, the last two by bilinearity of the product (A1). By (T1) there is a unique linear $\bar{f}_k\colon V^{\otimes k} \to A$ with $\bar{f}_k(\mathbf{u}_1 \otimes \cdots \otimes \mathbf{u}_k) = f(\mathbf{u}_1)\cdots f(\mathbf{u}_k)$. Put $\bar{f}_0\colon F \to A$, $a \mapsto a1_A$, and define $\bar{f}(x) = \sum_k \bar{f}_k(x_k)$, a finite sum. This is linear, and $\bar{f}(1) = 1_A$.

Multiplicativity: the maps $(x, y) \mapsto \bar{f}(xy)$ and $(x, y) \mapsto \bar{f}(x)\bar{f}(y)$ are both bilinear, so it suffices to compare them on a spanning set of each argument, and the simple tensors of all degrees span $\mathrm{T}(V)$. For two simple tensors,

$$\begin{aligned}\bar{f}\big((\mathbf{u}_1 \otimes \cdots \otimes \mathbf{u}_k)(\mathbf{w}_1 \otimes \cdots \otimes \mathbf{w}_l)\big) &= f(\mathbf{u}_1)\cdots f(\mathbf{u}_k)f(\mathbf{w}_1)\cdots f(\mathbf{w}_l)\\ &= \bar{f}(\mathbf{u}_1 \otimes \cdots \otimes \mathbf{u}_k)\,\bar{f}(\mathbf{w}_1 \otimes \cdots \otimes \mathbf{w}_l),\end{aligned}$$

the first equality by Proposition 14.6.4 and the definition of $\bar{f}_{k+l}$, the second by the definition of $\bar{f}_k$ and $\bar{f}_l$ together with associativity in A. The degree-0 cases are the identity $\bar{f}(ax) = a\bar{f}(x)$, which holds by linearity. Finally $\bar{f}|_V = \bar{f}_1 = f$.

Uniqueness. Let φ be an algebra homomorphism with $\varphi|_V = f$. Then $\varphi(1) = 1_A$, so $\varphi(a) = a1_A$ on $V^{\otimes 0}$, and for a simple tensor, multiplicativity gives

$$\varphi(\mathbf{u}_1 \otimes \cdots \otimes \mathbf{u}_k) = \varphi(\mathbf{u}_1)\cdots\varphi(\mathbf{u}_k) = f(\mathbf{u}_1)\cdots f(\mathbf{u}_k).$$

So φ agrees with $\bar{f}$ on the simple tensors, which span $\mathrm{T}(V)$, and both are linear. Hence $\varphi = \bar{f}$. This proves the theorem. ∎

In words: $\mathrm{T}(V)$ **is the free associative unital algebra on** V**.** "Free" means that a linear map out of V extends to an algebra map in exactly one way, with no condition on f whatsoever — no multiplicativity is asked of f, because V carries no multiplication to preserve. Compare the corresponding statement one level down, Theorem 3.1.6: a *function* on a basis extends to a linear map in exactly one way. The tensor algebra plays the same role one level up.

Remark. The hypothesis on f is empty, and that is precisely what makes $\mathrm{T}(V)$ too big to be useful on its own. Every interesting algebra built from V is a quotient of $\mathrm{T}(V)$ by the relations one wants to impose, and Theorem 14.6.6 is what shows that the quotient has the expected universal property. Section 07 imposes $\mathbf{uw} = \mathbf{wu}$, Section 08 imposes $\mathbf{vv} = 0$, and Section 10 imposes $\mathbf{vv} = q(\mathbf{v})1$, which is the construction Chapter 13 §12 said was unavailable.

Warning. **Do not confuse the degree with the dimension.** $V^{\otimes k}$ is the space of tensors of degree k; its dimension is n^k, not k. A general element of $V^{\otimes k}$ is a sum of simple tensors, and — exactly as in Section 02 — usually not a single one. A general element of $\mathrm{T}(V)$ is not even homogeneous: $1 + \mathbf{v}_1 + \mathbf{v}_1 \otimes \mathbf{v}_2$ is a perfectly good element of degrees $0, 1, 2$ at once.

14.6.5 Exercises

14.6.5.1 A. Check your understanding

Exercise A1.

(a) State the universal property (T1) of the k-th tensor power, with every quantifier.

(b) Let $\dim V = 4$. Compute $\dim V^{\otimes 0}$, $\dim V^{\otimes 1}$ and $\dim V^{\otimes 3}$.

(c) Give a spanning set of $V^{\otimes k}$, and explain why it lets you check an identity between linear maps out of $V^{\otimes k}$ on simple tensors only.

(d) Determine whether $\mathrm{T}(V)$ is commutative. Justify your answer, distinguishing the possible values of $\dim V$.

(e) State what data is needed to define an algebra homomorphism out of $\mathrm{T}(V)$, and what must be checked about it.

Solution.

(a) For every vector space W over F and every k-linear map $f\colon V^k \to W$, there exists exactly one linear map $\bar{f}\colon V^{\otimes k} \to W$ such that $\bar{f} \circ \mu = f$, where $\mu(\mathbf{v}_1, \dots, \mathbf{v}_k) = \mathbf{v}_1 \otimes \cdots \otimes \mathbf{v}_k$.

(b) $\dim V^{\otimes 0} = \dim F = 1$; $\dim V^{\otimes 1} = 4$; $\dim V^{\otimes 3} = 4^3 = 64$, by Theorem 14.6.3.

(c) The simple tensors $\mathbf{u}_1 \otimes \cdots \otimes \mathbf{u}_k$ span $V^{\otimes k}$ (Theorem 14.6.2); so does the smaller list of Theorem 14.6.3. Two linear maps that agree on a spanning set agree on every linear combination of it, hence everywhere.

(d) It is commutative if $\dim V \leq 1$ and non-commutative if $\dim V \geq 2$. For $\dim V = 0$, $\mathrm{T}(V) = F$; for $\dim V = 1$, $\mathrm{T}(V) \cong F[x]$ by Example (The tensor algebra of a line). For $\dim V \geq 2$, $\mathbf{v}_1 \otimes \mathbf{v}_2$ and $\mathbf{v}_2 \otimes \mathbf{v}_1$ are distinct members of a basis by Theorem 14.6.3, so they are unequal.

(e) A **linear** map $f\colon V \to A$ into an associative unital algebra A, and nothing else: no condition on f needs checking, by Theorem 14.6.6. What must be checked is that A really is an associative unital algebra and that f really is linear.

14.6.5.2 B. Practice

Exercise B1: Expanding a simple tensor.

Let $V = F^2$. Expand each of the following in the basis of Theorem 14.6.3.

(a) $(2\mathbf{e}_1 - \mathbf{e}_2) \otimes (\mathbf{e}_1 + 3\mathbf{e}_2)$ in $V^{\otimes 2}$.

(b) $\mathbf{e}_1 \otimes (\mathbf{e}_1 - \mathbf{e}_2) \otimes (\mathbf{e}_1 + \mathbf{e}_2)$ in $V^{\otimes 3}$.

Solution.

(a) Expanding in slot 1, then slot 2,

$$(2\mathbf{e}_1 - \mathbf{e}_2) \otimes (\mathbf{e}_1 + 3\mathbf{e}_2) = 2\,\mathbf{e}_1 \otimes \mathbf{e}_1 + 6\,\mathbf{e}_1 \otimes \mathbf{e}_2 - \mathbf{e}_2 \otimes \mathbf{e}_1 - 3\,\mathbf{e}_2 \otimes \mathbf{e}_2.$$

(b) Slot 1 is already a basis vector, so expand slots 2 and 3:

$$\mathbf{e}_1 \otimes (\mathbf{e}_1 - \mathbf{e}_2) \otimes (\mathbf{e}_1 + \mathbf{e}_2) = \mathbf{e}_1 \otimes \mathbf{e}_1 \otimes \mathbf{e}_1 + \mathbf{e}_1 \otimes \mathbf{e}_1 \otimes \mathbf{e}_2 - \mathbf{e}_1 \otimes \mathbf{e}_2 \otimes \mathbf{e}_1 - \mathbf{e}_1 \otimes \mathbf{e}_2 \otimes \mathbf{e}_2.$$

The four basis tensors beginning with $\mathbf{e}_2$ have coefficient 0, as they must: every term of the expansion carries $\mathbf{e}_1$ in slot 1.

Exercise B2: A product in the tensor algebra.

Let $V = F^2$ and let $x = 1 + \mathbf{e}_1$ and $y = \mathbf{e}_2 - \mathbf{e}_1 \otimes \mathbf{e}_1$ in $\mathrm{T}(V)$. Compute xy and yx, sort the answers by degree, and say whether x and y commute.

Solution. Multiply out, using that 1 is the identity and that concatenation is Proposition 14.6.4:

$$xy = \mathbf{e}_2 - \mathbf{e}_1 \otimes \mathbf{e}_1 + \mathbf{e}_1 \otimes \mathbf{e}_2 - \mathbf{e}_1 \otimes \mathbf{e}_1 \otimes \mathbf{e}_1,$$
$$yx = \mathbf{e}_2 - \mathbf{e}_1 \otimes \mathbf{e}_1 + \mathbf{e}_2 \otimes \mathbf{e}_1 - \mathbf{e}_1 \otimes \mathbf{e}_1 \otimes \mathbf{e}_1.$$

Both have degree-1 part $\mathbf{e}_2$ and degree-3 part $-\mathbf{e}_1 \otimes \mathbf{e}_1 \otimes \mathbf{e}_1$. Their degree-2 parts differ: $-\mathbf{e}_1 \otimes \mathbf{e}_1 + \mathbf{e}_1 \otimes \mathbf{e}_2$ against $-\mathbf{e}_1 \otimes \mathbf{e}_1 + \mathbf{e}_2 \otimes \mathbf{e}_1$. Since $\mathbf{e}_1 \otimes \mathbf{e}_2 \neq \mathbf{e}_2 \otimes \mathbf{e}_1$ by Theorem 14.6.3, $xy \neq yx$: they do not commute.

Exercise B3: A homomorphism built from the universal property.

Let $V = F^2$ and let $A = M_2(F)$. Define $f\colon V \to A$ by

$$f(x_1\mathbf{e}_1 + x_2\mathbf{e}_2) = \begin{pmatrix} 0 & x_1 \\ x_2 & 0 \end{pmatrix}.$$

Prove that there is a unique algebra homomorphism $\bar{f}\colon \mathrm{T}(V) \to M_2(F)$ with $\bar{f}|_V = f$, and compute $\bar{f}(\mathbf{e}_1 \otimes \mathbf{e}_2)$, $\bar{f}(\mathbf{e}_2 \otimes \mathbf{e}_1)$ and $\bar{f}(\mathbf{e}_1 \otimes \mathbf{e}_1)$.

Solution. $M_2(F)$ is an associative unital F-algebra (Definition 13.12.1) and f is linear, since each entry of $f(\mathbf{x})$ is a linear function of $\mathbf{x}$. By Theorem 14.6.6 there is exactly one algebra homomorphism $\bar{f}$ with $\bar{f}|_V = f$.

On simple tensors $\bar{f}$ is the product of the images, so with $\mathbf{A} = f(\mathbf{e}_1)$ and $\mathbf{B} = f(\mathbf{e}_2)$,

$$\mathbf{A} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}, \quad \mathbf{B} = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix},$$

$$\bar{f}(\mathbf{e}_1 \otimes \mathbf{e}_2) = \mathbf{AB} = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}, \quad \bar{f}(\mathbf{e}_2 \otimes \mathbf{e}_1) = \mathbf{BA} = \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix},$$

and $\bar{f}(\mathbf{e}_1 \otimes \mathbf{e}_1) = \mathbf{A}^2 = \mathbf{0}$. The first two differ, which is another way to see that

$\mathbf{e}_1 \otimes \mathbf{e}_2 \neq \mathbf{e}_2 \otimes \mathbf{e}_1$: a homomorphism cannot separate equal elements. The third shows $\bar{f}$ is far from injective — as it must be, since $\mathrm{T}(V)$ is infinite-dimensional and $M_2(F)$ is not.

14.6.5.3 C. Going deeper

Exercise C1: The grading is a direct sum of subspaces.

(a) Prove that if $x \in V^{\otimes k}$ and $y \in V^{\otimes l}$ with $k \neq l$ are both non-zero, then $x + y$ lies in no single $V^{\otimes m}$.

(b) Deduce that an algebra homomorphism $\varphi\colon \mathrm{T}(V) \to A$ is determined by its restrictions $\varphi|_{V^{\otimes k}}$, and that these are in turn determined by $\varphi|_V$.

Solution.

(a) Under the identification of Definition 14.6.2, x is the sequence with x in position k and $\mathbf{0}$ elsewhere, and similarly for y. Their sum has non-zero entries in both positions k and l. An element of $V^{\otimes m}$ has at most one non-zero entry, in position m. Since $k \neq l$, the sum has two, so it is in no $V^{\otimes m}$.

(b) Every element of $\mathrm{T}(V)$ is the finite sum of its homogeneous components, so a linear map is determined by its restrictions to the $V^{\otimes k}$. By multiplicativity, $\varphi(\mathbf{u}_1 \otimes \cdots \otimes \mathbf{u}_k) = \varphi(\mathbf{u}_1) \cdots \varphi(\mathbf{u}_k)$, which depends only on $\varphi|_V$; and $V^{\otimes k}$ is spanned by its simple tensors, so $\varphi|_{V^{\otimes k}}$ is determined by $\varphi|_V$. (This is the uniqueness half of Theorem 14.6.6, isolated.)

Exercise C2: Extending an operator to the algebra.

Let $T\colon V \to V$ be linear.

(a) Prove that there is a unique algebra homomorphism $\mathrm{T}(T)\colon \mathrm{T}(V) \to \mathrm{T}(V)$ with $\mathrm{T}(T)|_V = T$, and that it maps $V^{\otimes k}$ into $V^{\otimes k}$.

(b) Prove that $\mathrm{T}(ST) = \mathrm{T}(S)\,\mathrm{T}(T)$ for linear $S, T\colon V \to V$, and that $\mathrm{T}(\mathrm{id}_V) = \mathrm{id}$.

(c) Deduce that if T is invertible then so is $\mathrm{T}(T)$.

Solution.

(a) $\mathrm{T}(V)$ is an associative unital algebra and the composite $V \xrightarrow{T} V \hookrightarrow \mathrm{T}(V)$ is linear, so Theorem 14.6.6 gives a unique algebra homomorphism $\mathrm{T}(T)$ restricting to T on V. On a simple tensor it is $\mathbf{u}_1 \otimes \cdots \otimes \mathbf{u}_k \mapsto T\mathbf{u}_1 \otimes \cdots \otimes T\mathbf{u}_k$, which lies in $V^{\otimes k}$; those tensors span $V^{\otimes k}$, so $\mathrm{T}(T)(V^{\otimes k}) \subseteq V^{\otimes k}$.

(b) $\mathrm{T}(S)\,\mathrm{T}(T)$ is a composite of algebra homomorphisms, hence an algebra homomorphism, and on V it is ST. By the uniqueness clause of Theorem 14.6.6 applied to the linear map $ST\colon V \to \mathrm{T}(V)$, it equals $\mathrm{T}(ST)$. Likewise $\mathrm{id}_{\mathrm{T}(V)}$ is an algebra homomorphism restricting to id_V, so it equals $\mathrm{T}(\mathrm{id}_V)$.

(c) By (b), $\mathrm{T}(T)\,\mathrm{T}(T^{-1}) = \mathrm{T}(TT^{-1}) = \mathrm{T}(\mathrm{id}_V) = \mathrm{id}$, and the same with the factors swapped. Hence $\mathrm{T}(T)$ is invertible with inverse $\mathrm{T}(T^{-1})$.

Exercise C3: Why the empty degree is F.

Suppose we had instead set $V^{\otimes 0} = \{\mathbf{0}\}$ and kept every other definition.

(a) Explain why Theorem 14.6.3 would then fail at $k = 0$.

(b) Explain why $\mathrm{T}(V)$ would have no identity element, and hence would not be an algebra in the sense of Definition 13.12.1.

(c) Give one further formula in this section that the convention $V^{\otimes 0} = F$ keeps true at $k = 0$.

Solution.

(a) The theorem counts one basis vector per k-tuple of indices. There is exactly one 0-tuple, the empty one, so the count gives $n^0 = 1$, the dimension of F, not of $\{\mathbf{0}\}$.

(b) The identity of $\mathrm{T}(V)$ is $1 \in V^{\otimes 0}$. With $V^{\otimes 0} = \{\mathbf{0}\}$ there is no candidate: a homogeneous element of degree $m \geq 1$ multiplies $V^{\otimes k}$ into $V^{\otimes (k+m)}$, so it cannot fix a non-zero element of $V^{\otimes k}$, and neither can a sum of such elements, by Exercise (C1: The grading is a direct sum of subspaces) (a). Hypothesis (A3) of Definition 13.12.1 would fail.

(c) The universal property Theorem 14.6.6: its formula $\bar{f}(a) = a1_A$ for $a \in F$ is the degree-0 case, and it is what makes $\bar{f}$ unital. Equally acceptable: $\dim \mathrm{T}(V) = \sum_{k \geq 0} n^k$, or the multiplication rule $V^{\otimes 0} \cdot V^{\otimes l} \subseteq V^{\otimes l}$, which reads "multiplying by a scalar does not change the degree".

14.7 Symmetric Powers

The tensor algebra is free, and being free it is useless on its own: it records the order of the slots even when nothing in the problem cares about the order. A symmetric bilinear form does not care (Definition 13.3.1); nor does a quadratic form; nor does the monomial x_1x_2, which is the same polynomial as x_2x_1. This section forces $\mathrm{T}(V)$ to forget the order, by dividing the tensor power $V^{\otimes k}$ by the span of the differences $\mathbf{u} \otimes \mathbf{w} - \mathbf{w} \otimes \mathbf{u}$. The result, the symmetric power $\mathrm{Sym}^k V$, turns out to have a basis indexed by non-decreasing index tuples, and the algebra assembled from all the $\mathrm{Sym}^k V$ turns out to be the polynomial algebra of Chapter 0, one variable per basis vector.

The construction repeats Section 02's three moves for the second time: universal property, uniqueness, then a model built as a quotient. If the shape of the argument below feels familiar, that is the intention.

Throughout, F is a field, V is a finite-dimensional vector space over F with $n = \dim V \geq 1$, and $k \geq 1$ unless stated otherwise. **The field is arbitrary**, and the single place where the characteristic matters is isolated in the last part of the section.

14.7.1 Symmetric multilinear maps

Before asking for a space, we name the maps it is supposed to linearize. Chapter 13 called a *bilinear form* symmetric when swapping its two arguments changed nothing (Definition 13.3.1).

With k arguments there are more ways to rearrange them, and we demand invariance under all of them.

A symmetric map cannot tell in which order its arguments were handed to it.

Definition 14.7.1 — Symmetric Multilinear Map

Let W be a vector space over F. A k-linear map $f\colon V^k \to W$ (Definition 14.1.1) is **symmetric** if

$$f(\mathbf{u}_{\sigma(1)}, \mathbf{u}_{\sigma(2)}, \dots, \mathbf{u}_{\sigma(k)}) = f(\mathbf{u}_1, \mathbf{u}_2, \dots, \mathbf{u}_k)$$

for every permutation $\sigma \in S_k$ and **for all** $\mathbf{u}_1, \dots, \mathbf{u}_k \in V$.

At $k = 2$ the only non-identity permutation is the swap, so this is exactly Definition 13.3.1 with a general target W in place of F. At $k = 1$ the condition is empty and every linear map is symmetric.

Three examples and one non-example.

- **A symmetric bilinear form**, $\beta\colon V \times V \to F$ with $\beta(\mathbf{u}, \mathbf{w}) = \beta(\mathbf{w}, \mathbf{u})$. This is the case $k = 2$, $W = F$.
- **Products of one fixed functional.** For $\varphi \in V^*$, the map $(\mathbf{u}_1, \dots, \mathbf{u}_k) \mapsto \varphi(\mathbf{u}_1)\varphi(\mathbf{u}_2)\cdots\varphi(\mathbf{u}_k)$ is k-linear, by the third example after Definition 6.2.1, and symmetric because multiplication in F is commutative: rearranging the factors does not change the product.
- **Multiplication in a commutative algebra.** If A is a commutative F-algebra and $f\colon V \to A$ is linear, then $(\mathbf{u}_1, \dots, \mathbf{u}_k) \mapsto f(\mathbf{u}_1)\cdots f(\mathbf{u}_k)$ is symmetric, by commutativity of A.
- **A non-example by minimal change.** On $V = F^2$, the map $(\mathbf{u}, \mathbf{w}) \mapsto u_1 w_2$ is bilinear but not symmetric: it sends $(\mathbf{e}_1, \mathbf{e}_2)$ to 1 and $(\mathbf{e}_2, \mathbf{e}_1)$ to 0. Only the symmetry clause fails; bilinearity survives untouched.

Note which permutations are allowed: **all** of S_k, not only the swaps of adjacent slots. Nothing is lost by asking for all of them, and asking for all of them spares us a lemma about generating S_k.

14.7.2 The symmetric power

Now the object. The demand is Definition 14.6.1's, restricted to the symmetric maps.

The k-th symmetric power is the space in which symmetric k-linear maps become linear.

Definition 14.7.2 — k-th Symmetric Power

A **k-th symmetric power of** V is a pair (P, π), where P is a vector space over F and $\pi\colon V^k \to P$ is a **symmetric** k-linear map, such that

(S1) (**universal property**) for **every** vector space W over F and **every symmetric** k-linear map $f\colon V^k \to W$, there is a **unique** linear map $\bar{f}\colon P \to W$ with $\bar{f} \circ \pi = f$.

We write $\operatorname{Sym}^k V$ for P and denote the value $\pi(\mathbf{u}_1, \dots, \mathbf{u}_k)$ by juxtaposition,

$$\mathbf{u}_1\mathbf{u}_2\cdots\mathbf{u}_k \coloneqq \pi(\mathbf{u}_1, \dots, \mathbf{u}_k),$$

calling it a **symmetric product**. By convention $\operatorname{Sym}^0 V = F$.

The one difference from (T1) is the word **symmetric**, in two places: the structure map π is required to be symmetric, and only symmetric maps f are required to factor. Both changes are needed. If π were not symmetric, the notation $\mathbf{uw} = \mathbf{wu}$ would be false; if non-symmetric maps had to factor, no space could do the job, since $\bar{f} \circ \pi$ is symmetric whenever π is.

Uniqueness is the template of Theorem 14.2.1 for the third time, and we no longer write it out.

Theorem 14.7.1 — Uniqueness of the Symmetric Power

Let (P, π) and (P', π') both be k-th symmetric powers of V. Then there is a unique linear isomorphism $\varphi\colon P \to P'$ with $\varphi \circ \pi = \pi'$.

Proof. Word for word the proof of Theorem 14.6.1, with "symmetric k-linear" in place of "k-linear" throughout: (S1) for P applied to the symmetric map π' gives φ, (S1) for P' applied to π gives ψ, the composite $\psi\varphi$ is a linear self-map of P with $\psi\varphi\pi = \pi$, and the uniqueness clause of (S1) applied to π forces $\psi\varphi = \mathrm{id}_P$. Symmetrically $\varphi\psi = \mathrm{id}_{P'}$. This proves the theorem. ∎

And now the model: the tensor power, divided by the relations we want to impose.

Theorem 14.7.2 — Existence of the Symmetric Power

Let $C_k \subseteq V^{\otimes k}$ be the span of all the elements

$$\mathbf{u}_1 \otimes \cdots \otimes \mathbf{u}_k - \mathbf{u}_{\sigma(1)} \otimes \cdots \otimes \mathbf{u}_{\sigma(k)}, \qquad \mathbf{u}_i \in V,\ \sigma \in S_k,$$

and let $q\colon V^{\otimes k} \to V^{\otimes k}/C_k$ be the quotient map (Definition 3.9.3). Then $V^{\otimes k}/C_k$, together with

$$\pi(\mathbf{u}_1, \dots, \mathbf{u}_k) = q(\mathbf{u}_1 \otimes \cdots \otimes \mathbf{u}_k),$$

is a k-th symmetric power of V. At $k = 2$ the subspace C_2 is the span of the elements $\mathbf{u} \otimes \mathbf{w} - \mathbf{w} \otimes \mathbf{u}$.

Idea. Two things to check, and both are one line each once the right tool is named. That π is symmetric is the definition of C_k: permuting the arguments changes the tensor by an element of C_k, which q kills. That symmetric maps factor is Theorem 3.9.10: turn f into a linear map on $V^{\otimes k}$ by (T1), observe that symmetry of f makes it vanish on the generators of C_k, and let the quotient's universal property do the rest. This is the move the chapter uses three times: **a quotient kills exactly the relations you want.**

Proof. C_k is a subspace, being a span. The map π is k-linear, being the k-linear μ_k of

Theorem 14.6.2 followed by the linear map q. It is symmetric: for $\sigma \in S_k$, the difference

$$\mathbf{u}_1 \otimes \cdots \otimes \mathbf{u}_k - \mathbf{u}_{\sigma(1)} \otimes \cdots \otimes \mathbf{u}_{\sigma(k)}$$

lies in C_k by definition, so the two tensors have the same image under q, that is, $\pi(\mathbf{u}_{\sigma(1)}, \dots, \mathbf{u}_{\sigma(k)}) = \pi(\mathbf{u}_1, \dots, \mathbf{u}_k)$.

Now let $f\colon V^k \to W$ be symmetric k-linear. By (T1) there is a unique linear $\tilde{f}\colon V^{\otimes k} \to W$ with $\tilde{f}(\mathbf{u}_1 \otimes \cdots \otimes \mathbf{u}_k) = f(\mathbf{u}_1, \dots, \mathbf{u}_k)$. On a generator of C_k,

$$\tilde{f}\big(\mathbf{u}_1 \otimes \cdots \otimes \mathbf{u}_k - \mathbf{u}_{\sigma(1)} \otimes \cdots \otimes \mathbf{u}_{\sigma(k)}\big) = f(\mathbf{u}_1, \dots, \mathbf{u}_k) - f(\mathbf{u}_{\sigma(1)}, \dots, \mathbf{u}_{\sigma(k)}),$$

which is 0 because f is symmetric. A linear map vanishing on a spanning set of C_k vanishes on C_k, so $C_k \subseteq \ker \tilde{f}$. By Theorem 3.9.10 (a) there is exactly one linear $\bar{f}\colon V^{\otimes k}/C_k \to W$ with $\bar{f} \circ q = \tilde{f}$, and then

$$\bar{f} \circ \pi = \bar{f} \circ q \circ \mu_k = \tilde{f} \circ \mu_k = f.$$

For uniqueness, suppose h is linear with $h \circ \pi = f$. Since q is surjective and $V^{\otimes k}$ is spanned by its simple tensors (Theorem 14.6.2), the elements $\pi(\mathbf{u}_1, \dots, \mathbf{u}_k)$ span $V^{\otimes k}/C_k$. So h and $\bar{f}$ agree on a spanning set, hence everywhere. This proves the theorem.

■

Warning. $\operatorname{Sym}^k V$ **is a quotient of $V^{\otimes k}$, not a subspace of it.** Its elements are cosets, and the identity $\mathbf{uw} = \mathbf{wu}$ in $\operatorname{Sym}^2 V$ says that $\mathbf{u} \otimes \mathbf{w}$ and $\mathbf{w} \otimes \mathbf{u}$ lie in the **same** coset. It does **not** say $\mathbf{u} \otimes \mathbf{w} = \mathbf{w} \otimes \mathbf{u}$ in $V^{\otimes 2}$, which is false for independent $\mathbf{u}, \mathbf{w}$ by Theorem 14.6.3. Confusing the two is the commonest error here; the safe habit is never to write an element of $\operatorname{Sym}^k V$ as a tensor.

14.7.3 A basis, and the dimension

Sorting an index tuple is now legal, so the basis of Theorem 14.6.3 collapses: only the sorted tuples survive. Counting them is the substance of the section.

Theorem 14.7.3 — Basis of a Symmetric Power

Let $\mathcal{B} = (\mathbf{v}_1, \dots, \mathbf{v}_n)$ be a basis of V and $k \geq 1$. Then the symmetric products

$$\mathbf{v}_{i_1}\mathbf{v}_{i_2}\cdots\mathbf{v}_{i_k}, \qquad 1 \leq i_1 \leq i_2 \leq \cdots \leq i_k \leq n,$$

one for each **non-decreasing** tuple, form a basis of $\operatorname{Sym}^k V$. Consequently

$$\dim \operatorname{Sym}^k V = \binom{n+k-1}{k},$$

over **every** field F.

Idea. Spanning is sorting: the image of any index tuple equals the image of its sorted version, so the sorted ones already span. Independence needs one linear functional per non-decreasing tuple, and it must be built **without dividing by anything**, since we want the theorem over every field. The functional that works is a sum over all ways of dealing out the n dual basis functionals to the k slots with prescribed multiplicities: every coefficient in it is 1. Counting the tuples is then the stars-and-bars bijection, which turns a non-decreasing tuple into a strictly increasing one by adding $0, 1, 2, \dots$ to its entries.

Proof. Spanning. By Theorem 14.6.3 the tensors $\mathbf{v}_{j_1} \otimes \cdots \otimes \mathbf{v}_{j_k}$, over all tuples J, form a basis of $V^{\otimes k}$, and q is surjective, so their images $\mathbf{v}_{j_1} \cdots \mathbf{v}_{j_k}$ span $\operatorname{Sym}^k V$. Given any J, let $\sigma \in S_k$ sort it, so that $(j_{\sigma(1)}, \dots, j_{\sigma(k)})$ is non-decreasing. Since π is symmetric, $\mathbf{v}_{j_1} \cdots \mathbf{v}_{j_k} = \mathbf{v}_{j_{\sigma(1)}} \cdots \mathbf{v}_{j_{\sigma(k)}}$. So the non-decreasing tuples already give a spanning set.

Independence. Let $(\varphi_1, \dots, \varphi_n)$ be the dual basis of $\mathcal{B}$ (Theorem 4.1.3). For a non-decreasing tuple $I = (i_1, \dots, i_k)$, let

$$m_j = |\{\, t : i_t = j \,\}|, \qquad j = 1, \dots, n,$$

be its **multiplicity vector**, so $m_1 + \cdots + m_n = k$, and let $\Phi(I)$ be the set of functions $\tau \colon \{1, \dots, k\} \to \{1, \dots, n\}$ taking the value j exactly m_j times, for each j. Define

$$g_I(\mathbf{u}_1, \dots, \mathbf{u}_k) = \sum_{\tau \in \Phi(I)} \varphi_{\tau(1)}(\mathbf{u}_1)\, \varphi_{\tau(2)}(\mathbf{u}_2) \cdots \varphi_{\tau(k)}(\mathbf{u}_k).$$

Each summand is k-linear, being a product of one functional per slot, so g_I is k-linear.

It is symmetric. Let $\rho \in S_k$. Substituting and then reindexing the product by $s = \rho(t)$,

$$g_I(\mathbf{u}_{\rho(1)}, \dots, \mathbf{u}_{\rho(k)}) = \sum_{\tau \in \Phi(I)} \prod_{s=1}^{k} \varphi_{(\tau\rho^{-1})(s)}(\mathbf{u}_s).$$

The map $\tau \mapsto \tau\rho^{-1}$ is a bijection of $\Phi(I)$ onto itself, since composing with a permutation of the domain does not change how often a value is taken. So the sum is unchanged, and g_I is symmetric.

By (S1), g_I induces a linear $\bar{g}_I \colon \operatorname{Sym}^k V \to F$. Evaluate it on a basis candidate: for any tuple J,

$$\bar{g}_I(\mathbf{v}_{j_1} \cdots \mathbf{v}_{j_k}) = \sum_{\tau \in \Phi(I)} \prod_{t=1}^{k} \delta_{\tau(t)\, j_t}.$$

A summand is 1 exactly when $\tau(t) = j_t$ for every t, and 0 otherwise; so the whole sum is 1 if the function $t \mapsto j_t$ belongs to $\Phi(I)$, and 0 if it does not. For non-decreasing I and J, that function lies in $\Phi(I)$ exactly when J has the same multiplicity vector as I, which for non-decreasing tuples means $J = I$. Hence $\bar{g}_I(\mathbf{v}_{j_1} \cdots \mathbf{v}_{j_k}) = \delta_{IJ}$.

Now suppose $\sum_I a_I\, \mathbf{v}_{i_1} \cdots \mathbf{v}_{i_k} = \mathbf{0}$, the sum over non-decreasing tuples. Applying $\bar{g}_J$ leaves $a_J = 0$. Since J was arbitrary, every coefficient is 0, and the list is independent. So it is a basis.

The count. Send a non-decreasing tuple $(i_1, \dots, i_k)$ to

$$(i_1,\ i_2 + 1,\ i_3 + 2,\ \dots,\ i_k + k - 1).$$

Consecutive entries satisfy $i_t + t - 1 < i_{t+1} + t$ because $i_t \le i_{t+1}$, so the image is **strictly** increasing, and its entries lie between 1 and $n+k-1$. Conversely, subtracting $0, 1, \dots, k-1$ from a strictly increasing tuple in $\{1, \dots, n+k-1\}$ returns a non-decreasing tuple in $\{1, \dots, n\}$: the differences $j_{t+1} - j_t \ge 1$ become $i_{t+1} - i_t \ge 0$, and $1 \le j_1$, $j_k \le n + k - 1$ give $1 \le i_1$ and $i_k \le n$. The two assignments are mutually inverse, so the non-decreasing k-tuples from $\{1, \dots, n\}$ are in bijection with the k-element subsets of $\{1, \dots, n + k - 1\}$, and there are $\binom{n+k-1}{k}$ of those. This proves the theorem.

■

Nothing in the proof divided by an integer, which is why the conclusion holds over $\mathbb{F}_2$ as it does over $\mathbb{C}$. Keep that in view: the last part of this section shows that a *different* and very common description of $\operatorname{Sym}^k V$ does not survive over $\mathbb{F}_2$, and the difference between the two is exactly one division.

Quick check. Let $\dim V = 3$. Compute $\dim \operatorname{Sym}^2 V$ and $\dim V^{\otimes 2}$, and say which basis tensors of $V^{\otimes 2}$ become equal in $\operatorname{Sym}^2 V$.

Solution. $\dim \operatorname{Sym}^2 V = \binom{4}{2} = 6$ and $\dim V^{\otimes 2} = 3^2 = 9$. The six surviving basis elements are $\mathbf{v}_1^2, \mathbf{v}_1\mathbf{v}_2, \mathbf{v}_1\mathbf{v}_3, \mathbf{v}_2^2, \mathbf{v}_2\mathbf{v}_3, \mathbf{v}_3^2$. The three pairs $\mathbf{v}_i \otimes \mathbf{v}_j$ and $\mathbf{v}_j \otimes \mathbf{v}_i$ with $i < j$ become equal, which removes 3 from the count: $9 - 3 = 6$.

Example. (A symmetric square, in coordinates)

Let $V = F^2$. Write down a basis of $\operatorname{Sym}^2 V$ and expand $(\mathbf{e}_1 + 2\mathbf{e}_2)(3\mathbf{e}_1 - \mathbf{e}_2)$ in it.

Solution. By Theorem 14.7.3 a basis is $(\mathbf{e}_1^2,\ \mathbf{e}_1\mathbf{e}_2,\ \mathbf{e}_2^2)$, of size $\binom{3}{2} = 3$. Expanding one slot at a time and then using $\mathbf{e}_2\mathbf{e}_1 = \mathbf{e}_1\mathbf{e}_2$,

$$\begin{aligned}(\mathbf{e}_1 + 2\mathbf{e}_2)(3\mathbf{e}_1 - \mathbf{e}_2) &= 3\mathbf{e}_1\mathbf{e}_1 - \mathbf{e}_1\mathbf{e}_2 + 6\mathbf{e}_2\mathbf{e}_1 - 2\mathbf{e}_2\mathbf{e}_2 \\ &= 3\mathbf{e}_1^2 + 5\mathbf{e}_1\mathbf{e}_2 - 2\mathbf{e}_2^2.\end{aligned}$$

Compare with expanding $(x + 2y)(3x - y) = 3x^2 + 5xy - 2y^2$ in ordinary algebra. That is not a coincidence, and the next part of this section says exactly what it is.

Warning. **Not every element of $\operatorname{Sym}^k V$ is a product of k vectors.** Take $F = \mathbb{R}$, $V = \mathbb{R}^2$ and $\omega = \mathbf{e}_1^2 + \mathbf{e}_2^2 \in \operatorname{Sym}^2 V$. If $\omega = \mathbf{u}\mathbf{w}$ with $\mathbf{u} = a\mathbf{e}_1 + b\mathbf{e}_2$ and $\mathbf{w} = c\mathbf{e}_1 + d\mathbf{e}_2$, then comparing coordinates in the basis $(\mathbf{e}_1^2, \mathbf{e}_1\mathbf{e}_2, \mathbf{e}_2^2)$ gives $ac = 1$, $ad + bc = 0$ and $bd = 1$. The first and last force $a, b, c, d \neq 0$, and multiplying $ad = -bc$ by bc gives $-(bc)^2 = (ac)(bd) = 1$, impossible in $\mathbb{R}$. This is the same phenomenon as the non-simple tensors of Section 02, and it is why $\operatorname{Sym}^k V$ is much larger than the set of products.

14.7.4 The symmetric algebra is a polynomial algebra

Stacking the symmetric powers gives an algebra, exactly as stacking the tensor powers did, and the multiplication descends from concatenation.

Proposition 14.7.4 — The Symmetric Product of Two Symmetric Tensors

Let $k, l \geq 1$. There is a unique bilinear map $\operatorname{Sym}^k V \times \operatorname{Sym}^l V \to \operatorname{Sym}^{k+l} V$ with

$$(\mathbf{u}_1 \cdots \mathbf{u}_k)\,(\mathbf{w}_1 \cdots \mathbf{w}_l) = \mathbf{u}_1 \cdots \mathbf{u}_k \mathbf{w}_1 \cdots \mathbf{w}_l.$$

Proof. Concatenation carries the relations into the relations. Let $x \in C_k$ and $y \in V^{\otimes l}$. For a generator $x = \mathbf{u}_1 \otimes \cdots \otimes \mathbf{u}_k - \mathbf{u}_{\sigma(1)} \otimes \cdots \otimes \mathbf{u}_{\sigma(k)}$ and a simple $y = \mathbf{w}_1 \otimes \cdots \otimes \mathbf{w}_l$, the product $x \cdot y$ of Proposition 14.6.4 is again a generator of C_{k+l}, for the permutation acting as σ on the first k slots and fixing the last l. Since generators span C_k, since $V^{\otimes l}$ is spanned by its simple tensors, and since $\cdot$ is bilinear, $C_k \cdot V^{\otimes l} \subseteq C_{k+l}$. Swapping the roles of the two blocks gives $V^{\otimes k} \cdot C_l \subseteq C_{k+l}$.

Descending, one argument at a time. Let $q_m \colon V^{\otimes m} \to \operatorname{Sym}^m V$ denote the quotient maps. Fix $y \in V^{\otimes l}$. The linear map $x \mapsto q_{k+l}(x \cdot y)$ kills C_k by the first inclusion, so Theorem 3.9.10 gives a unique linear $\beta_y \colon \operatorname{Sym}^k V \to \operatorname{Sym}^{k+l} V$ with $\beta_y(q_k x) = q_{k+l}(x \cdot y)$. The assignment $y \mapsto \beta_y$ is linear, since $\beta_{ay+y'}$ and $a\beta_y + \beta_{y'}$ agree on the spanning set $q_k(V^{\otimes k}) = \operatorname{Sym}^k V$; and it kills C_l, since $y \in C_l$ gives $x \cdot y \in C_{k+l}$ and hence $\beta_y = 0$. By Theorem 3.9.10 again it descends to a linear map $\operatorname{Sym}^l V \to \mathcal{L}(\operatorname{Sym}^k V, \operatorname{Sym}^{k+l} V)$, and evaluating gives the required bilinear map. It is unique because the products of vectors span each factor. When $k = 0$ or $l = 0$ the product is scalar multiplication, as in Section 06. This proves the proposition.

■

Definition 14.7.3 — Symmetric Algebra

The **symmetric algebra** of V is the vector space

$$\operatorname{Sym}(V) = \bigoplus_{k \geq 0} \operatorname{Sym}^k V,$$

of sequences with finitely many non-zero components, with the multiplication assembled from Proposition 14.7.4 by $(xy)_m = \sum_{k+l=m} x_k y_l$.

Proposition 14.7.5 — $\operatorname{Sym}(V)$ Is a Commutative Algebra

$\operatorname{Sym}(V)$ is an associative, **commutative**, unital F-algebra with identity $1 \in \operatorname{Sym}^0 V = F$, and $\operatorname{Sym}^k V \cdot \operatorname{Sym}^l V \subseteq \operatorname{Sym}^{k+l} V$.

Proof. Bilinearity, associativity and the identity are proved exactly as in Theorem 14.6.5: all three are identities between multilinear expressions, so it suffices to check them on products of vectors, which span each $\operatorname{Sym}^k V$, and there all three read "concatenate the strings".

Commutativity is the new point. Both $(\mathbf{u}_1 \cdots \mathbf{u}_k)(\mathbf{w}_1 \cdots \mathbf{w}_l)$ and $(\mathbf{w}_1 \cdots \mathbf{w}_l)(\mathbf{u}_1 \cdots \mathbf{u}_k)$ equal the symmetric product of the same $k + l$ vectors in two different orders, and π is symmetric, so they are equal. Two bilinear maps agreeing on spanning sets of both

arguments agree everywhere, so $xy = yx$ for all x, y. This proves the proposition.

■

To name what $\mathrm{Sym}(V)$ is, we need polynomials in more than one variable. Chapter 0 built $F[x]$; the several-variable version is the same construction with monomials indexed by exponent vectors.

Definition 14.7.4 — The Polynomial Algebra $F[x_1, \dots, x_n]$

Let $n \geq 1$. The **polynomial algebra in n variables** over F is the vector space $F[x_1, \dots, x_n]$ with basis the **monomials**

$$x^{\mathbf{a}} = x_1^{a_1} x_2^{a_2} \cdots x_n^{a_n}, \qquad \mathbf{a} = (a_1, \dots, a_n) \in \mathbb{N}^n,$$

with the unique bilinear multiplication satisfying $x^{\mathbf{a}} x^{\mathbf{b}} = x^{\mathbf{a}+\mathbf{b}}$. The **degree** of $x^{\mathbf{a}}$ is $|\mathbf{a}| = a_1 + \cdots + a_n$, and $F[x_1, \dots, x_n]_k$ denotes the span of the monomials of degree k.

The bilinear extension exists and is unique because a bilinear map may be prescribed freely on a pair of bases, by the argument used twice in the proof of Proposition 14.6.4. The multiplication is associative, commutative and unital, with identity the monomial all of whose exponents are 0, because exponent addition in $\mathbb{N}^n$ is associative, commutative and has an identity. For $n = 1$ the monomials are $1, x, x^2, \dots$ and the rule is $x^a x^b = x^{a+b}$, so $F[x_1]$ is the ring $F[x]$ of Definition 0.8.2, whose basis of monomials is Example (A Basis of $F[x]$). Everything Chapter 5 proved — division, greatest common divisors, unique factorization — lives in that one-variable case.

Theorem 14.7.6 — The Symmetric Algebra Is a Polynomial Algebra

Let $\mathcal{B} = (\mathbf{v}_1, \dots, \mathbf{v}_n)$ be a basis of V. Then there is an isomorphism of F-algebras

$$\Psi \colon \mathrm{Sym}(V) \xrightarrow{\sim} F[x_1, \dots, x_n], \qquad \Psi(\mathbf{v}_i) = x_i,$$

and it carries $\mathrm{Sym}^k V$ onto $F[x_1, \dots, x_n]_k$. In particular

$$\dim F[x_1, \dots, x_n]_k = \binom{n+k-1}{k}.$$

Idea. Both sides have a basis indexed by the same combinatorial object: a non-decreasing k-tuple on the left, a degree-k monomial on the right, and each is determined by its multiplicity vector $\mathbf{m} \in \mathbb{N}^n$ with $|\mathbf{m}| = k$. So match the bases, which gives a linear isomorphism for free, and then check multiplicativity on basis elements, where both products are "add the exponent vectors".

Proof. Write $|\mathbf{m}| = m_1 + \cdots + m_n$ for $\mathbf{m} \in \mathbb{N}^n$. Given $\mathbf{m}$ with $|\mathbf{m}| = k$, let $I(\mathbf{m})$ be the non-decreasing tuple taking the value j exactly m_j times, and write $\mathbf{v}^{\mathbf{m}}$ for the corresponding symmetric product $\mathbf{v}_{i_1} \cdots \mathbf{v}_{i_k}$. The assignment $\mathbf{m} \mapsto I(\mathbf{m})$ is a bijection onto the non-decreasing k-tuples, since a non-decreasing tuple is recovered from its multiplicity vector and conversely. So by Theorem 14.7.3 the family $(\mathbf{v}^{\mathbf{m}})_{|\mathbf{m}|=k}$ is a basis

of $\mathrm{Sym}^k V$, and hence $(\mathbf{v}^{\mathbf{m}})_{\mathbf{m}\in\mathbb{N}^n}$ is a basis of $\mathrm{Sym}(V)$.

Define Ψ to be the unique linear map with $\Psi(\mathbf{v}^{\mathbf{m}}) = x^{\mathbf{m}}$, which exists by Theorem 3.1.6. It sends a basis of $\mathrm{Sym}(V)$ bijectively onto the basis of monomials, so it is a linear isomorphism, and it sends the degree-k basis onto the degree-k monomials, so $\Psi(\mathrm{Sym}^k V) = F[x_1, \dots, x_n]_k$.

Multiplicativity: the maps $(y, z) \mapsto \Psi(yz)$ and $(y, z) \mapsto \Psi(y)\Psi(z)$ are bilinear, so it is enough to compare them on the basis. By Proposition 14.7.4, $\mathbf{v}^{\mathbf{m}}\mathbf{v}^{\mathbf{m}'}$ is the symmetric product of the $|\mathbf{m}| + |\mathbf{m}'|$ vectors of the two strings, which after sorting is $\mathbf{v}^{\mathbf{m}+\mathbf{m}'}$; and $x^{\mathbf{m}}x^{\mathbf{m}'} = x^{\mathbf{m}+\mathbf{m}'}$ by Definition 14.7.4. Also Ψ sends the empty product 1 to the monomial with all exponents 0, which is 1. Hence Ψ is an algebra isomorphism. Finally $\mathbf{v}_i$ is the basis element $\mathbf{v}^{\mathbf{m}}$ whose $\mathbf{m}$ has a single 1 in position i, so $\Psi(\mathbf{v}_i) = x_i$.

The dimension formula follows from Theorem 14.7.3, since Ψ restricts to an isomorphism in each degree. This proves the theorem.

■

So the symmetric algebra is nothing exotic: *it is the polynomial algebra, with one variable per basis vector of V.* The isomorphism depends on the basis, exactly as the coordinate isomorphism $V \cong F^n$ does; $\mathrm{Sym}(V)$ is the basis-free version of "polynomials in n variables", and $\mathrm{Sym}^k V$ is the basis-free version of "homogeneous polynomials of degree k". Read backwards, the theorem also computes something Chapter 5 never did: the number of monomials of degree k in n variables is $\binom{n+k-1}{k}$.

Remark. The case $k = 2$ recovers a count from Chapter 13. A symmetric bilinear form on V is a symmetric 2-linear map into F, so by (S1) the symmetric forms on V are in bijection with the linear functionals on $\mathrm{Sym}^2 V$, and there are $\binom{n+1}{2} = n(n+1)/2$ dimensions of them — the number of entries on and above the diagonal of a symmetric matrix, which is what Proposition 13.3.1 would give by counting.

14.7.5 Symmetric powers versus symmetric tensors

Here is the trap, and it is worth the space. Many treatments define the k-th symmetric power as a **subspace** of $V^{\otimes k}$: the tensors left fixed by every permutation of the slots. That is a different construction from the quotient above, and over a field of characteristic 0 the two agree. Over $\mathbb{F}_2$ they do not, and the reason is a single division by $k!$.

We first need the permutation operators.

Lemma 14.7.7 — Permuting the Slots of a Tensor

For each $\sigma \in S_k$ there is a unique linear operator P_σ on $V^{\otimes k}$ with

$$P_\sigma(\mathbf{u}_1 \otimes \cdots \otimes \mathbf{u}_k) = \mathbf{u}_{\sigma(1)} \otimes \cdots \otimes \mathbf{u}_{\sigma(k)},$$

and $P_\sigma P_\tau = P_{\tau\sigma}$ for all $\sigma, \tau \in S_k$, with $P_{\mathrm{id}} = \mathrm{id}$.

Proof. The map $(\mathbf{u}_1, \dots, \mathbf{u}_k) \mapsto \mathbf{u}_{\sigma(1)} \otimes \cdots \otimes \mathbf{u}_{\sigma(k)}$ is k-linear, since in slot t it is μ_k in slot $\sigma^{-1}(t)$. So (T1) gives a unique linear P_σ with the stated values, and uniqueness

holds because those tensors span $V^{\otimes k}$. For the composition rule, put $\mathbf{w}_t = \mathbf{u}_{\tau(t)}$; then

$$P_\sigma P_\tau(\mathbf{u}_1 \otimes \cdots \otimes \mathbf{u}_k) = P_\sigma(\mathbf{w}_1 \otimes \cdots \otimes \mathbf{w}_k) = \mathbf{w}_{\sigma(1)} \otimes \cdots \otimes \mathbf{w}_{\sigma(k)},$$

and $\mathbf{w}_{\sigma(t)} = \mathbf{u}_{\tau(\sigma(t))}$, which is the t-th argument of $P_{\tau\sigma}$. Both sides are linear and agree on simple tensors, hence are equal. This proves the lemma.

■

Definition 14.7.5 — Symmetric Tensor

A tensor $x \in V^{\otimes k}$ is **symmetric** if $P_\sigma x = x$ for **every** $\sigma \in S_k$. The symmetric tensors form a subspace of $V^{\otimes k}$, which we write $(V^{\otimes k})^{S_k}$; it is the intersection of the kernels of the linear maps $P_\sigma - \mathrm{id}$.

Theorem 14.7.8 — Symmetric Tensors and the Symmetric Power

Let $n = \dim V \geq 1$ and $k \geq 1$, and let $\iota\colon (V^{\otimes k})^{S_k} \to \operatorname{Sym}^k V$ be the restriction of the quotient map q.

(a) Over **every** field, $\dim(V^{\otimes k})^{S_k} = \binom{n+k-1}{k} = \dim \operatorname{Sym}^k V$.

(b) If $\operatorname{char} F = 0$ or $\operatorname{char} F > k$, then ι is an isomorphism.

(c) If $\operatorname{char} F = 2$, $k = 2$ and $n \geq 2$, then ι is **neither** injective nor surjective.

Idea. For (a), a symmetric tensor must have equal coordinates along each orbit of basis tensors, so the **orbit sums** are a basis; orbits correspond to multisets, which Theorem 14.7.3 already counted. For (b), average: $s = \sum_\sigma P_\sigma$ maps everything into the symmetric tensors and kills C_k, so $\frac{1}{k!}s$ is an inverse for ι — provided $k!$ is invertible, which is exactly the hypothesis. For (c), the tensor $\mathbf{v}_1 \otimes \mathbf{v}_2 + \mathbf{v}_2 \otimes \mathbf{v}_1$ is symmetric and non-zero, but its image is $2\mathbf{v}_1\mathbf{v}_2 = 0$.

Proof.

(a) Let $\mathcal{B} = (\mathbf{v}_1, \ldots, \mathbf{v}_n)$ be a basis of V. For a tuple J write $\mathbf{v}_J = \mathbf{v}_{j_1} \otimes \cdots \otimes \mathbf{v}_{j_k}$, so that $(\mathbf{v}_J)_J$ is a basis of $V^{\otimes k}$ (Theorem 14.6.3), and note $P_\sigma \mathbf{v}_J = \mathbf{v}_{J\sigma}$, where $J\sigma$ is the tuple $t \mapsto j_{\sigma(t)}$. Two tuples lie in the same **orbit** when one is a rearrangement of the other, that is, when they have the same multiplicity vector. For each non-decreasing I let $s_I = \sum_{J \in O_I} \mathbf{v}_J$, the sum over the orbit of I.
Each s_I is symmetric, because $J \mapsto J\sigma$ permutes O_I. The s_I are independent, because distinct orbits involve disjoint sets of basis vectors. They span: if $x = \sum_J a_J \mathbf{v}_J$ satisfies $P_\sigma x = x$ for every σ, then comparing coordinates in $\sum_J a_J \mathbf{v}_{J\sigma} = \sum_J a_J \mathbf{v}_J$ gives $a_J = a_{J\sigma}$ for all J and σ, so $J \mapsto a_J$ is constant on orbits and $x = \sum_I a_I s_I$. Hence (s_I) is a basis, with one member per orbit, that is, per multiplicity vector of total k. By the bijection in the proof of Theorem 14.7.3 there are $\binom{n+k-1}{k}$ of those. No division occurred, so this holds over every field.

(b) Let $s = \sum_{\sigma \in S_k} P_\sigma$, a linear operator on $V^{\otimes k}$. By Lemma 14.7.7, for any τ,

$$P_\tau s = \sum_\sigma P_\tau P_\sigma = \sum_\sigma P_{\sigma\tau} = s, \qquad s P_\tau = \sum_\sigma P_\sigma P_\tau = \sum_\sigma P_{\tau\sigma} = s,$$

since $\sigma \mapsto \sigma\tau$ and $\sigma \mapsto \tau\sigma$ are bijections of S_k. The first identity says $\operatorname{im} s \subseteq (V^{\otimes k})^{S_k}$. The second gives $s(\mathrm{id} - P_\tau) = 0$, and the generators of C_k are exactly the elements $(\mathrm{id} - P_\sigma)(\mathbf{u}_1 \otimes \cdots \otimes \mathbf{u}_k)$, so $C_k \subseteq \ker s$.
By hypothesis $k! \cdot 1 \neq 0$ in F. Indeed $k! \cdot 1 = (1 \cdot 1)(2 \cdot 1) \cdots (k \cdot 1)$ in F, a product of k factors; if $\operatorname{char} F = 0$ none of them is 0, and if $\operatorname{char} F = p > k$ then $i \cdot 1 \neq 0$ for $1 \leq i \leq k < p$ by Definition 0.7.2. A field has no zero divisors, so the product is non-zero, hence invertible. Since $C_k \subseteq \ker s$, Theorem 3.9.10 gives a linear map $\theta \colon \operatorname{Sym}^k V \to (V^{\otimes k})^{S_k}$ with $\theta(q(x)) = \frac{1}{k!} s(x)$.
Now compute both composites. For $x \in V^{\otimes k}$, each $P_\sigma x$ differs from x by an element of C_k, so $q(s(x)) = \sum_\sigma q(P_\sigma x) = k!\, q(x)$, whence

$$\iota\theta(q(x)) = \tfrac{1}{k!} q(s(x)) = q(x),$$

and q is surjective, so $\iota\theta = \mathrm{id}$. Conversely, if x is symmetric then $s(x) = \sum_\sigma P_\sigma x = k!\, x$, so $\theta\iota(x) = \theta(q(x)) = \frac{1}{k!} k!\, x = x$. Hence ι is an isomorphism with inverse θ.

(c) Let $\operatorname{char} F = 2$, $k = 2$, $n \geq 2$, and put $t = \mathbf{v}_1 \otimes \mathbf{v}_2 + \mathbf{v}_2 \otimes \mathbf{v}_1$. It is symmetric, since the only non-identity element of S_2 swaps the two summands, and it is non-zero, being a sum of two distinct basis vectors of $V^{\otimes 2}$ (Theorem 14.6.3). But

$$\iota(t) = \mathbf{v}_1\mathbf{v}_2 + \mathbf{v}_2\mathbf{v}_1 = 2\,\mathbf{v}_1\mathbf{v}_2 = 0$$

because $1 + 1 = 0$ in F. So $\ker \iota \neq \{\mathbf{0}\}$ and ι is not injective. By (a) the two spaces have the same finite dimension, so a surjective ι would be injective by Theorem 3.3.1; hence ι is not surjective either. This proves the theorem.

■

Part (b) is where the division lives, and part (c) is what it costs. The operator s still exists over $\mathbb{F}_2$; what fails is the *rescaling* $\frac{1}{k!} s$, and with it the splitting of the quotient.

Warning. **In characteristic $p \leq k$, "symmetric power" and "symmetric tensors" are different objects.** They have the same dimension by Theorem 14.7.8 (a), so they are abstractly isomorphic, but the *natural* map between them is not an isomorphism, and no natural one is available. So: do not define $\operatorname{Sym}^k V$ as $(V^{\otimes k})^{S_k}$, do not write $\frac{1}{k!} \sum_\sigma P_\sigma$ without saying that $k!$ is invertible, and do not transport a statement proved for one to the other. This is Chapter 13's discipline again, where alternating and skew-symmetric forms coincided only away from characteristic 2 (Theorem 13.3.3): the same clause, the same division, and the same smallest witness, $\mathbb{F}_2^2$.

Everything else in this section is characteristic-free. In particular Theorem 14.7.3, Theorem 14.7.6 and the dimension $\binom{n+k-1}{k}$ hold over every field, because the quotient construction never divides. The next section takes the same care with the same reward: the exterior power is built from a relation chosen so that no division is ever needed.

14.7.6 Exercises

14.7.6.1 A. Check your understanding

Exercise A1.

(a) State the universal property (S1), with every quantifier, and say which maps are required to factor.

(b) Which subspace of $V^{\otimes k}$ is divided out to build $\operatorname{Sym}^k V$? Write down its generators for $k = 3$.

(c) Let $\dim V = 4$. Compute $\dim \operatorname{Sym}^3 V$ and $\dim V^{\otimes 3}$.

(d) Determine whether $\operatorname{Sym}^2 V$ is a subspace of $V^{\otimes 2}$. Justify your answer.

(e) What hypothesis on F makes the symmetric tensors of degree k naturally isomorphic to $\operatorname{Sym}^k V$, and which step of the proof needs it?

Solution.

(a) For every vector space W over F and every **symmetric** k-linear map $f\colon V^k \to W$, there exists exactly one linear $\bar{f}\colon \operatorname{Sym}^k V \to W$ with $\bar{f}\circ\pi = f$. Only the symmetric maps factor; a non-symmetric one cannot, since $\bar{f}\circ\pi$ is symmetric for every linear $\bar{f}$.

(b) The subspace C_k of Theorem 14.7.2, spanned by the differences $\mathbf{u}_1 \otimes \cdots \otimes \mathbf{u}_k - \mathbf{u}_{\sigma(1)} \otimes \cdots \otimes \mathbf{u}_{\sigma(k)}$. For $k = 3$ the generators are the six differences obtained from the six $\sigma \in S_3$, for all $\mathbf{u}_1, \mathbf{u}_2, \mathbf{u}_3 \in V$.

(c) $\dim \operatorname{Sym}^3 V = \binom{4+3-1}{3} = \binom{6}{3} = 20$ and $\dim V^{\otimes 3} = 4^3 = 64$.

(d) No. It is a quotient of $V^{\otimes 2}$, and its elements are cosets of C_2, not tensors. (Over a field of characteristic 0 there is a subspace of $V^{\otimes 2}$ naturally isomorphic to it, namely the symmetric tensors, but the isomorphism is not an equality, and it does not exist in characteristic 2.)

(e) $\operatorname{char} F = 0$ or $\operatorname{char} F > k$, so that $k!$ is invertible in F (Theorem 14.7.8 (b)). The step that needs it is the construction of the inverse map θ, which divides the symmetrization $s = \sum_\sigma P_\sigma$ by $k!$.

14.7.6.2 B. Practice

Exercise B1: Expanding symmetric products.

Let $V = F^2$.

(a) Expand $(2\mathbf{e}_1 - \mathbf{e}_2)(\mathbf{e}_1 + 3\mathbf{e}_2)$ in the basis $(\mathbf{e}_1^2, \mathbf{e}_1\mathbf{e}_2, \mathbf{e}_2^2)$ of $\operatorname{Sym}^2 V$.

(b) Expand $(\mathbf{e}_1 + \mathbf{e}_2)(\mathbf{e}_1 - \mathbf{e}_2)\mathbf{e}_1$ in the basis of $\operatorname{Sym}^3 V$ given by Theorem 14.7.3.

Solution.

(a) Expanding one slot at a time and then using $\mathbf{e}_2\mathbf{e}_1 = \mathbf{e}_1\mathbf{e}_2$,

$$(2\mathbf{e}_1 - \mathbf{e}_2)(\mathbf{e}_1 + 3\mathbf{e}_2) = 2\mathbf{e}_1^2 + 6\mathbf{e}_1\mathbf{e}_2 - \mathbf{e}_1\mathbf{e}_2 - 3\mathbf{e}_2^2 = 2\mathbf{e}_1^2 + 5\mathbf{e}_1\mathbf{e}_2 - 3\mathbf{e}_2^2.$$

(b) The basis is $(\mathbf{e}_1^3,\ \mathbf{e}_1^2\mathbf{e}_2,\ \mathbf{e}_1\mathbf{e}_2^2,\ \mathbf{e}_2^3)$, of size $\binom{4}{3} = 4$. Expanding the first two slots,

$$(\mathbf{e}_1 + \mathbf{e}_2)(\mathbf{e}_1 - \mathbf{e}_2)\mathbf{e}_1 = \mathbf{e}_1^2\mathbf{e}_1 - \mathbf{e}_1\mathbf{e}_2\mathbf{e}_1 + \mathbf{e}_2\mathbf{e}_1\mathbf{e}_1 - \mathbf{e}_2^2\mathbf{e}_1,$$

and the two middle terms are equal after sorting, so they cancel:

$$(\mathbf{e}_1 + \mathbf{e}_2)(\mathbf{e}_1 - \mathbf{e}_2)\mathbf{e}_1 = \mathbf{e}_1^3 - \mathbf{e}_1\mathbf{e}_2^2.$$

In the polynomial language of Theorem 14.7.6 this is $(x+y)(x-y)x = x^3 - xy^2$.

Exercise B2: Counting.

(a) Compute $\dim \operatorname{Sym}^k V$ for $\dim V = 3$ and $k = 0, 1, 2, 3, 4$.

(b) For $\dim V = n$, compute $\dim \operatorname{Sym}^2 V$ in closed form and check it against the number of entries on or above the diagonal of an $n \times n$ matrix.

(c) Determine all pairs (n, k) with $k \geq 1$ for which $\dim \operatorname{Sym}^k V = \dim V^{\otimes k}$. Justify your answer.

Solution.

(a) $\binom{k+2}{k}$ for $n = 3$, giving $1, 3, 6, 10, 15$ for $k = 0, 1, 2, 3, 4$.

(b) $\binom{n+1}{2} = n(n+1)/2$. An $n \times n$ matrix has n diagonal entries and $(n^2 - n)/2$ entries strictly above the diagonal, and $n + (n^2 - n)/2 = n(n+1)/2$. The agreement is the remark after Theorem 14.7.6: a symmetric bilinear form is the same data as a functional on $\operatorname{Sym}^2 V$, and also the same data as a symmetric matrix.

(c) Exactly those with $n = 1$, or with $k = 1$. If $k = 1$ both sides are n. If $n = 1$ both sides are 1. Otherwise $n \geq 2$ and $k \geq 2$, and then $\mathbf{v}_1 \otimes \mathbf{v}_2 \neq \mathbf{v}_2 \otimes \mathbf{v}_1$ are two basis tensors with the same image, so $C_k \neq \{\mathbf{0}\}$ and $\dim \operatorname{Sym}^k V = n^k - \dim C_k < n^k$ by Theorem 3.9.5.

Exercise B3: A form factored through the symmetric square.

Let β be a symmetric bilinear form on V. Prove that there is a unique linear functional $\bar{\beta} \in (\operatorname{Sym}^2 V)^*$ with $\bar{\beta}(\mathbf{uw}) = \beta(\mathbf{u}, \mathbf{w})$ for all $\mathbf{u}, \mathbf{w} \in V$, and compute $\bar{\beta}$ on the basis of Theorem 14.7.3 when $V = F^2$ and $\beta(\mathbf{x}, \mathbf{y}) = x_1y_1 - x_2y_2$.

Solution. β is a symmetric 2-linear map $V^2 \to F$ (Definition 14.7.1 with $k = 2$, $W = F$), so (S1) gives exactly one linear $\bar{\beta}\colon \operatorname{Sym}^2 V \to F$ with $\bar{\beta} \circ \pi = \beta$, which is the displayed identity.

For the given β: $\bar{\beta}(\mathbf{e}_1^2) = \beta(\mathbf{e}_1, \mathbf{e}_1) = 1$, $\bar{\beta}(\mathbf{e}_1\mathbf{e}_2) = \beta(\mathbf{e}_1, \mathbf{e}_2) = 0$ and $\bar{\beta}(\mathbf{e}_2^2) = \beta(\mathbf{e}_2, \mathbf{e}_2) = -1$. So in the coordinates given by the basis $(\mathbf{e}_1^2, \mathbf{e}_1\mathbf{e}_2, \mathbf{e}_2^2)$ the functional reads $(1, 0, -1)$, and under Theorem 14.7.6 it is the rule "read off the coefficients of x^2 and y^2 and subtract".

14.7.6.3 C. Going deeper

Exercise C1: The characteristic-two witness in full.

Let $F = \mathbb{F}_2$ and $V = \mathbb{F}_2^2$, and take $k = 2$.

(a) Write down a basis of $(V^{\otimes 2})^{S_2}$ and verify that its dimension is 3.

(b) Compute $\dim C_2$ and $\dim \operatorname{Sym}^2 V$, and identify $\ker \iota$ and $\operatorname{im} \iota$ for the map ι of Theorem 14.7.8.

(c) Are $(V^{\otimes 2})^{S_2}$ and $\operatorname{Sym}^2 V$ isomorphic as vector spaces? Explain why this does not repair the situation.

Solution.

(a) Here $S_2 = \{\mathrm{id}, \sigma\}$ with σ the swap, and P_σ exchanges $\mathbf{e}_1 \otimes \mathbf{e}_2$ with $\mathbf{e}_2 \otimes \mathbf{e}_1$ and fixes $\mathbf{e}_1 \otimes \mathbf{e}_1$ and $\mathbf{e}_2 \otimes \mathbf{e}_2$. So $x = a\,\mathbf{e}_1 \otimes \mathbf{e}_1 + b\,\mathbf{e}_1 \otimes \mathbf{e}_2 + c\,\mathbf{e}_2 \otimes \mathbf{e}_1 + d\,\mathbf{e}_2 \otimes \mathbf{e}_2$ is symmetric if and only if $b = c$. A basis is

$$\mathbf{e}_1 \otimes \mathbf{e}_1, \qquad \mathbf{e}_2 \otimes \mathbf{e}_2, \qquad \mathbf{e}_1 \otimes \mathbf{e}_2 + \mathbf{e}_2 \otimes \mathbf{e}_1,$$

the orbit sums of Theorem 14.7.8 (a), so the dimension is $3 = \binom{3}{2}$.

(b) C_2 is spanned by the elements $\mathbf{u} \otimes \mathbf{w} - \mathbf{w} \otimes \mathbf{u}$. Writing $\mathbf{u} = a\mathbf{e}_1 + b\mathbf{e}_2$ and $\mathbf{w} = c\mathbf{e}_1 + d\mathbf{e}_2$ and expanding both slots, the $\mathbf{e}_1 \otimes \mathbf{e}_1$ and $\mathbf{e}_2 \otimes \mathbf{e}_2$ terms cancel and

$$\mathbf{u} \otimes \mathbf{w} - \mathbf{w} \otimes \mathbf{u} = (ad - bc)\big(\mathbf{e}_1 \otimes \mathbf{e}_2 - \mathbf{e}_2 \otimes \mathbf{e}_1\big).$$

So C_2 is the line spanned by $\mathbf{e}_1 \otimes \mathbf{e}_2 + \mathbf{e}_2 \otimes \mathbf{e}_1$, the sign being irrelevant over $\mathbb{F}_2$, and $\dim C_2 = 1$ and $\dim \operatorname{Sym}^2 V = 4 - 1 = 3$ by Theorem 3.9.5. Now $\ker \iota = (V^{\otimes 2})^{S_2} \cap C_2 = C_2$, of dimension 1, and $\operatorname{im} \iota$ is therefore 2-dimensional, spanned by $\mathbf{e}_1^2$ and $\mathbf{e}_2^2$; it misses $\mathbf{e}_1\mathbf{e}_2$.

(c) Yes, they are isomorphic: both have dimension 3 over $\mathbb{F}_2$, and Theorem 3.5.4 applies. It does not repair anything, because the isomorphism is not ι and does not respect the structure maps: an isomorphism chosen by hand would not satisfy $\varphi(\mathbf{u} \otimes \mathbf{w}) = \mathbf{u}\mathbf{w}$, so it could not be used to transport statements about products of vectors. A construction is only as good as its universal property, and $(V^{\otimes 2})^{S_2}$ has none here.

Exercise C2: $\operatorname{Sym}(V)$ is the free commutative algebra.

(a) Prove that the products $\mathbf{u}_1 \cdots \mathbf{u}_k$ with $\mathbf{u}_i \in V$ span $\operatorname{Sym}^k V$, and deduce that an algebra homomorphism out of $\operatorname{Sym}(V)$ is determined by its restriction to V.

(b) Prove that for every **commutative** associative unital F-algebra A and every linear map $f\colon V \to A$ there is a unique algebra homomorphism $\bar{f}\colon \operatorname{Sym}(V) \to A$ with $\bar{f}|_V = f$.

(c) Explain in one sentence why (b) fails if the word "commutative" is deleted, and name the algebra that has the corresponding property for all A.

Solution.

(a) $V^{\otimes k}$ is spanned by its simple tensors (Theorem 14.6.2) and q is surjective and linear, so their images, the products $\mathbf{u}_1 \cdots \mathbf{u}_k$, span $\operatorname{Sym}^k V$. If φ, ψ are algebra homomorphisms agreeing on V, then $\varphi(\mathbf{u}_1 \cdots \mathbf{u}_k) = \varphi(\mathbf{u}_1) \cdots \varphi(\mathbf{u}_k) = \psi(\mathbf{u}_1 \cdots \mathbf{u}_k)$, and

both send 1 to 1_A; since these elements span $\mathrm{Sym}(V)$ and both maps are linear, $\varphi = \psi$.

(b) For $k \geq 1$ the map $(\mathbf{u}_1, \ldots, \mathbf{u}_k) \mapsto f(\mathbf{u}_1) \cdots f(\mathbf{u}_k)$ is k-linear, as in the proof of Theorem 14.6.6, and it is **symmetric** because A is commutative (the third example after Definition 14.7.1). By (S1) it induces a linear $\bar{f}_k \colon \mathrm{Sym}^k V \to A$; set $\bar{f}_0(a) = a1_A$ and $\bar{f} = \sum_k \bar{f}_k$ on the direct sum. Multiplicativity is checked on products of vectors, which span, exactly as in Theorem 14.6.6, and $\bar{f}|_V = f$. Uniqueness is (a).

(c) It fails because $\bar{f}$ would have to satisfy $f(\mathbf{u})f(\mathbf{w}) = \bar{f}(\mathbf{uw}) = \bar{f}(\mathbf{wu}) = f(\mathbf{w})f(\mathbf{u})$, so the images of V would be forced to commute, which need not happen in a non-commutative A. The algebra with the property for **all** A is the tensor algebra $\mathrm{T}(V)$, by Theorem 14.6.6.

Exercise C3: One variable.

Let $\dim V = 1$.

(a) Prove that $C_k = \{\mathbf{0}\}$ for every k, and deduce that the quotient map $\mathrm{T}(V) \to \mathrm{Sym}(V)$ assembled from the q's is an isomorphism of algebras.

(b) Hence deduce that $\mathrm{T}(V) \cong \mathrm{Sym}(V) \cong F[x]$, and reconcile this with the fact that $\mathrm{T}(V)$ is non-commutative for $\dim V \geq 2$.

Solution.

(a) Write $V = F\mathbf{v}$. By Theorem 14.6.3, $V^{\otimes k}$ is spanned by $\mathbf{v}^{\otimes k}$. A generator of C_k is $\mathbf{u}_1 \otimes \cdots \otimes \mathbf{u}_k - \mathbf{u}_{\sigma(1)} \otimes \cdots \otimes \mathbf{u}_{\sigma(k)}$; writing $\mathbf{u}_t = c_t\mathbf{v}$ and expanding, both terms equal $c_1c_2 \cdots c_k\, \mathbf{v}^{\otimes k}$, since the scalars multiply in the same way whatever the order. So every generator is $\mathbf{0}$ and $C_k = \{\mathbf{0}\}$. Hence each $q \colon V^{\otimes k} \to \mathrm{Sym}^k V$ is an isomorphism (Theorem 3.9.5, or directly: its kernel is C_k), and the assembled map is a bijective algebra homomorphism, so an isomorphism.

(b) By Example (The tensor algebra of a line), $\mathrm{T}(V) \cong F[x]$, so (a) gives $\mathrm{Sym}(V) \cong F[x]$ as well; the same conclusion comes from Theorem 14.7.6 with $n = 1$. There is no tension with non-commutativity: $\mathrm{T}(V)$ is commutative precisely when $\dim V \leq 1$, because non-commutativity needs two independent vectors to put in the two slots (the warning after Theorem 14.6.5). With one variable there is nothing to reorder, so imposing the symmetry relations imposes nothing.

14.8 Exterior Powers

The symmetric power made the slots of a tensor interchangeable. This section makes them *hostile*: we divide $V^{\otimes k}$ by a subspace chosen so that a tensor dies as soon as two of its slots hold the same vector. The result, the exterior power $\Lambda^k V$, has a basis indexed by **strictly increasing** index tuples, so $\dim \Lambda^k V = \binom{n}{k}$ and $\Lambda^k V = \{\mathbf{0}\}$ once k exceeds n. That collapse is the whole reason the determinant exists, and Section 09 will read the determinant off the top exterior power.

One choice in the construction is delicate, and it is the choice Chapter 13 prepared us for. There

are two natural ways to say "the value flips when two slots are exchanged", and they are not the same condition: Theorem 13.3.3 showed that *alternating* implies *skew-symmetric* over every field, while the converse needs $\operatorname{char} F \neq 2$. We must therefore decide which relation to divide by, and the answer is the one that works over every field.

This is Section 02's method for the third time: universal property, uniqueness, then a model built as a quotient of the tensor power. Throughout, F is a field, V is a finite-dimensional vector space over F with $n = \dim V$, and $k \geq 1$ unless stated otherwise. **No hypothesis on the characteristic is made anywhere in this section**, and the construction is arranged so that none is needed.

14.8.1 Alternating multilinear maps

Chapter 6 defined alternating k-linear **forms**, valued in F (Definition 6.2.2), because that is all the determinant needed. The target plays no role in the definition, so we extend it, as Section 01 extended multilinearity.

An alternating map dies the moment two of its arguments coincide.

Definition 14.8.1 — Alternating Multilinear Map

Let W be a vector space over F. A k-linear map $f\colon V^k \to W$ (Definition 14.1.1) is **alternating** if

$$f(\mathbf{u}_1, \dots, \mathbf{u}_k) = \mathbf{0} \qquad \text{whenever } \mathbf{u}_i = \mathbf{u}_j \text{ for some pair of positions } i \neq j.$$

The condition is on **some** pair of positions, adjacent or not, and it says nothing about inputs whose entries are all distinct. For $W = F$ this is Definition 6.2.2 verbatim. The examples of Chapter 6 are all available: the determinant $\det(\mathbf{a}_1, \dots, \mathbf{a}_n)$ as a function of the columns; the signed area $(\mathbf{u}, \mathbf{w}) \mapsto u_1 w_2 - u_2 w_1$ on F^2; any linear functional, vacuously, at $k = 1$. A non-example by minimal change: the dot product on F^2 is bilinear but $\mathbf{e}_1 \cdot \mathbf{e}_1 = 1 \neq 0$, so the alternating clause fails at that one input while bilinearity survives.

Everything Chapter 6 deduced from the definition used only the vector-space structure of the target, so it carries over.

Lemma 14.8.1 — Properties of Alternating Maps

Let $f\colon V^k \to W$ be alternating k-linear, let $\mathbf{u}_1, \dots, \mathbf{u}_k \in V$, and let $\sigma \in S_k$.

(a) Exchanging two arguments multiplies the value by -1; in particular f is skew-symmetric.

(b) $f(\mathbf{u}_{\sigma(1)}, \dots, \mathbf{u}_{\sigma(k)}) = \operatorname{sgn}(\sigma)\, f(\mathbf{u}_1, \dots, \mathbf{u}_k)$.

(c) If $(\mathbf{u}_1, \dots, \mathbf{u}_k)$ is linearly dependent, then $f(\mathbf{u}_1, \dots, \mathbf{u}_k) = \mathbf{0}$.

Proof.

(a) Fix positions $i < j$, freeze the other arguments, and let $g(\mathbf{x}, \mathbf{y}) \in W$ be the value of f with $\mathbf{x}$ in position i and $\mathbf{y}$ in position j. Then g is bilinear and $g(\mathbf{x}, \mathbf{x}) = \mathbf{0}$,

so expanding

$$\mathbf{0} = g(\mathbf{u}_i + \mathbf{u}_j, \mathbf{u}_i + \mathbf{u}_j) = g(\mathbf{u}_i, \mathbf{u}_j) + g(\mathbf{u}_j, \mathbf{u}_i)$$

gives the swap rule. This is the computation of Theorem 6.2.1 (a), which used nothing about F as a target beyond its being a vector space.

(b) For $k = 1$ the only permutation is the identity and there is nothing to prove. For $k \geq 2$, use Theorem 0.10.4 to write $\sigma = \tau_1 \cdots \tau_r$ as a product of transpositions. Applying (a) once per transposition multiplies the value by $(-1)^r$, and $(-1)^r = \operatorname{sgn}(\sigma)$ by Theorem 6.3.1 and Corollary 6.3.2. This is Lemma 6.4.1, with the same proof.

(c) By the Linear Dependence Lemma (Theorem 1.4.1) some $\mathbf{u}_j$ lies in $\operatorname{span}(\mathbf{u}_1, \ldots, \mathbf{u}_{j-1})$. Expanding f in slot j writes the value as a combination of values in which some $\mathbf{u}_m$ with $m < j$ sits both in slot m and in slot j, and each such value is $\mathbf{0}$. This is Theorem 6.2.1 (d). If $j = 1$ then $\mathbf{u}_1 = \mathbf{0}$ and linearity in slot 1 gives $\mathbf{0}$ at once.

■

14.8.2 Which relation to divide by

Now the delicate point, stated before the definition so that the definition looks inevitable. We want a quotient of $V^{\otimes k}$ in which the image of $\mathbf{u}_1 \otimes \cdots \otimes \mathbf{u}_k$ vanishes exactly when it should. There are two candidate subspaces to divide by:

$$A_k = \operatorname{span}\{\, \mathbf{u}_1 \otimes \cdots \otimes \mathbf{u}_k \;:\; \mathbf{u}_i = \mathbf{u}_j \text{ for some } i \neq j \,\},$$
$$N_k = \operatorname{span}\{\, x + P_\tau x \;:\; x \text{ a simple tensor, } \tau \text{ a transposition} \,\},$$

where P_τ permutes the slots as in Lemma 14.7.7. Dividing by A_k imposes "repeat a vector and you get zero"; dividing by N_k imposes "swap two slots and the sign flips". The two are not the same subspace.

Proposition 14.8.2 — The Repetition Relations Are the Stronger Ones

For every field F and every $k \geq 2$ we have $N_k \subseteq A_k$. If $\operatorname{char} F \neq 2$, then $N_k = A_k$. If $\operatorname{char} F = 2$, $k = 2$ and $n \geq 1$, the inclusion is **strict**.

Idea. For the inclusion, feed the sum $\mathbf{u}_i + \mathbf{u}_j$ into **both** slots i and j: the resulting tensor is in A_k, and expanding it produces the two "square" terms, also in A_k, plus the two cross terms, whose sum is therefore in A_k too. That is Theorem 13.3.3 (a) transcribed into tensors. For the reverse, a tensor with a repeat is its own swap, so $x + P_\tau x = 2x$, and recovering x is a division by 2 — the same division, in the same place, as in Theorem 13.3.3 (b).

Proof. ($\subseteq$) Let $x = \mathbf{u}_1 \otimes \cdots \otimes \mathbf{u}_k$ be simple and τ the transposition of positions $i < j$. Let y be the tensor obtained from x by putting $\mathbf{u}_i + \mathbf{u}_j$ in **both** positions i and j, which lies in A_k because those two slots now agree. Expanding y by multilinearity in those two slots gives four terms:

$$y = [\mathbf{u}_i, \mathbf{u}_i] + [\mathbf{u}_i, \mathbf{u}_j] + [\mathbf{u}_j, \mathbf{u}_i] + [\mathbf{u}_j, \mathbf{u}_j],$$

where $[\mathbf{p}, \mathbf{q}]$ denotes x with $\mathbf{p}$ in position i and $\mathbf{q}$ in position j. The first and last terms lie in A_k, again by a repeat, and $[\mathbf{u}_i, \mathbf{u}_j] = x$ while $[\mathbf{u}_j, \mathbf{u}_i] = P_\tau x$. Hence $x + P_\tau x = y - [\mathbf{u}_i, \mathbf{u}_i] - [\mathbf{u}_j, \mathbf{u}_j] \in A_k$. Generators of N_k lie in A_k, so $N_k \subseteq A_k$.

($\supseteq$), assuming $\operatorname{char} F \neq 2$. Let $x = \mathbf{u}_1 \otimes \cdots \otimes \mathbf{u}_k$ with $\mathbf{u}_i = \mathbf{u}_j$, $i \neq j$, and let τ swap i and j. Then $P_\tau x = x$, so $x + P_\tau x = (1+1)x$ lies in N_k. Since $\operatorname{char} F \neq 2$, the scalar $1+1$ is invertible (Definition 0.7.2), so $x \in N_k$. Generators of A_k lie in N_k, so $A_k \subseteq N_k$.

Strictness in characteristic 2, $k = 2$. Suppose $\operatorname{char} F = 2$ and $n \geq 1$, and fix a basis $(\mathbf{v}_1, \ldots, \mathbf{v}_n)$. Expand a generator of N_2 in the basis of Theorem 14.6.3: writing $\mathbf{u} = \sum_i a_i \mathbf{v}_i$ and $\mathbf{w} = \sum_j b_j \mathbf{v}_j$,

$$\mathbf{u} \otimes \mathbf{w} + \mathbf{w} \otimes \mathbf{u} = \sum_{i,j} (a_i b_j + a_j b_i)\, \mathbf{v}_i \otimes \mathbf{v}_j,$$

and the coefficient of a **diagonal** basis tensor $\mathbf{v}_i \otimes \mathbf{v}_i$ is $2a_i b_i = 0$. Every element of N_2 therefore has coefficient 0 on $\mathbf{v}_1 \otimes \mathbf{v}_1$. But $\mathbf{v}_1 \otimes \mathbf{v}_1$ is itself a generator of A_2, and it is a basis vector of $V^{\otimes 2}$, hence non-zero. So $\mathbf{v}_1 \otimes \mathbf{v}_1 \in A_2 \setminus N_2$ and the inclusion is strict. This proves the proposition.

■

So the two relations differ, and we must choose. **We divide by A_k.** Three reasons, and they are the same three that made Chapter 6 build the determinant on alternation rather than skewness:

- The quotient by A_k is the object whose maps are the **alternating** ones, and alternating is the condition the determinant satisfies over every field.
- A_k is the larger subspace, so the quotient by it is the smaller space; and by Proposition 14.8.2 the two quotients agree whenever $\operatorname{char} F \neq 2$. So nothing is lost outside characteristic 2, and something is gained inside it.
- The dimension $\binom{n}{k}$ comes out right over every field. Dividing by N_2 instead would give, for $V = \mathbb{F}_2^2$, a space of dimension 3 where $\binom{2}{2} = 1$ is wanted; Exercise C1 carries out that count.

14.8.3 The exterior power

The k-th exterior power is the space in which alternating k-linear maps become linear.

Definition 14.8.2 — k-th Exterior Power

A **k-th exterior power of** V is a pair $(P, \wedge)$, where P is a vector space over F and $\wedge\colon V^k \to P$ is an **alternating** k-linear map, such that

(E1) (**universal property**) for **every** vector space W over F and **every alternating** k-linear map $f\colon V^k \to W$, there is a **unique** linear map $\bar{f}\colon P \to W$ with $\bar{f} \circ \wedge = f$.

We write $\Lambda^k V$ for P and

$$\mathbf{v}_1 \wedge \mathbf{v}_2 \wedge \cdots \wedge \mathbf{v}_k \coloneqq \wedge(\mathbf{v}_1, \ldots, \mathbf{v}_k),$$

calling it a **wedge** of the list. By convention $\Lambda^0 V = F$.

Clause by clause, and the small words matter. The structure map $\wedge$ must itself be **alternating**, which is what makes $\mathbf{v} \wedge \mathbf{v} = \mathbf{0}$ a fact rather than a wish. Only **alternating** maps are required to factor, and that is forced: $\bar{f} \circ \wedge$ is alternating for every linear $\bar{f}$, so no space could linearize a non-alternating map. **Unique** does the usual two jobs: existence of $\bar{f}$ says $\Lambda^k V$ is large enough, uniqueness says it is no larger.

At $k = 1$ the condition is vacuous and (V, id_V) works, so $\Lambda^1 V = V$. At $k = 0$ the convention $\Lambda^0 V = F$ is the one that makes $\binom{n}{k}$ correct at $k = 0$, where it reads $\binom{n}{0} = 1$.

Theorem 14.8.3 — Uniqueness of the Exterior Power

Let $(P, \wedge)$ and $(P', \wedge')$ both be k-th exterior powers of V. Then there is a unique linear isomorphism $\varphi\colon P \to P'$ with $\varphi \circ \wedge = \wedge'$.

Proof. The proof of Theorem 14.6.1, with "alternating k-linear" in place of "k-linear": (E1) for P applied to $\wedge'$ gives φ, (E1) for P' applied to $\wedge$ gives ψ, and $\psi\varphi$ is a linear self-map of P with $\psi\varphi\wedge = \wedge$, so the uniqueness clause of (E1) applied to $\wedge$ forces $\psi\varphi = \mathrm{id}_P$; symmetrically $\varphi\psi = \mathrm{id}_{P'}$. This proves the theorem. ∎

Theorem 14.8.4 — Existence of the Exterior Power

Let $A_k \subseteq V^{\otimes k}$ be as above and let $q\colon V^{\otimes k} \to V^{\otimes k}/A_k$ be the quotient map (Definition 3.9.3). Then $V^{\otimes k}/A_k$, together with

$$\mathbf{v}_1 \wedge \cdots \wedge \mathbf{v}_k = q(\mathbf{v}_1 \otimes \cdots \otimes \mathbf{v}_k),$$

is a k-th exterior power of V.

Proof. A_k is a subspace, being a span, and $\wedge$ is k-linear, being μ_k followed by the linear map q. It is alternating: if $\mathbf{u}_i = \mathbf{u}_j$ with $i \neq j$, then $\mathbf{u}_1 \otimes \cdots \otimes \mathbf{u}_k$ is by definition a generator of A_k, so its image under q is $\mathbf{0}$.

Let $f\colon V^k \to W$ be alternating k-linear. By (T1) there is a unique linear $\tilde{f}\colon V^{\otimes k} \to W$ with $\tilde{f}(\mathbf{u}_1 \otimes \cdots \otimes \mathbf{u}_k) = f(\mathbf{u}_1, \ldots, \mathbf{u}_k)$. On a generator of A_k, that is, on a simple tensor with $\mathbf{u}_i = \mathbf{u}_j$ for some $i \neq j$, the value is $f(\mathbf{u}_1, \ldots, \mathbf{u}_k) = \mathbf{0}$ because f is alternating. A linear map vanishing on a spanning set of A_k vanishes on A_k, so $A_k \subseteq \ker \tilde{f}$, and Theorem 3.9.10 (a) gives exactly one linear $\bar{f}$ on the quotient with $\bar{f} \circ q = \tilde{f}$, whence $\bar{f} \circ \wedge = f$.

Uniqueness: q is surjective and $V^{\otimes k}$ is spanned by its simple tensors (Theorem 14.6.2), so the wedges $\mathbf{u}_1 \wedge \cdots \wedge \mathbf{u}_k$ span $V^{\otimes k}/A_k$, and two linear maps agreeing on them agree everywhere. This proves the theorem. ∎

From Lemma 14.8.1 applied to the alternating map $\wedge$ itself we get the rules used in every

computation below, for all $\mathbf{u}_i \in V$ and $\sigma \in S_k$:

$$\mathbf{u}_{\sigma(1)} \wedge \cdots \wedge \mathbf{u}_{\sigma(k)} = \operatorname{sgn}(\sigma)\ \mathbf{u}_1 \wedge \cdots \wedge \mathbf{u}_k,$$
$$\mathbf{u}_1 \wedge \cdots \wedge \mathbf{u}_k = \mathbf{0} \quad \text{if the list is dependent.}$$

Four instances, smallest first, and one look-alike that is not one.

- **One slot.** $\Lambda^1 V = V$, and the wedge of a single vector is the vector itself. The alternating condition asks about pairs of positions, and with one position there are none.
- **The plane.** For $V = F^2$, expanding both slots and canceling the two repeats gives $\mathbf{u} \wedge \mathbf{w} = (u_1 w_2 - u_2 w_1)\, \mathbf{e}_1 \wedge \mathbf{e}_2$. The coefficient is the signed area of Chapter 6 §01; the wedge is that number, moved out of F and into a line inside $\Lambda^2 V$.
- **Polynomials.** On $V = F[x]_{\le 2}$ with basis $(1, x, x^2)$, the same expansion gives $(1 + x) \wedge (x + x^2) = 1 \wedge x + 1 \wedge x^2 + x \wedge x^2$, the term $x \wedge x$ having died.
- **A degenerate case.** If $V = \{\mathbf{0}\}$ then every wedge of $k \ge 1$ vectors is $\mathbf{0}$, so $\Lambda^k V = \{\mathbf{0}\}$. It matters because it is the base of the count below: $\binom{0}{k} = 0$ for $k \ge 1$.
- **Not an example: the symmetric product.** In $\operatorname{Sym}^2 V$ the product $\mathbf{uw}$ is bilinear and satisfies $\mathbf{uw} = \mathbf{wu}$, but $\mathbf{e}_1\mathbf{e}_1 \neq 0$ by Theorem 14.7.3, so the symmetric product map is **not** alternating. Exactly one clause differs between the two constructions, and it is this one.

> *Warning.* **The relation is $\mathbf{v} \wedge \mathbf{v} = \mathbf{0}$, not $\mathbf{u} \wedge \mathbf{w} = -\mathbf{w} \wedge \mathbf{u}$.** The second follows from the first (Lemma 14.8.1 (a)), but not conversely: over $\mathbb{F}_2$ the two say different things, since $-1 = 1$ there makes "$\mathbf{u} \wedge \mathbf{w} = -\mathbf{w} \wedge \mathbf{u}$" mean "$\mathbf{u} \wedge \mathbf{w} = \mathbf{w} \wedge \mathbf{u}$", which is no condition at all on a repeated slot. This is exactly Theorem 13.3.3, transcribed from forms to tensors by Proposition 14.8.2, and it is why the construction above divides by A_k. A reader who remembers that theorem should recognize the choice as the only characteristic-free one.

> *Quick check.* In $\Lambda^2 V$, simplify $(\mathbf{u} + \mathbf{w}) \wedge (\mathbf{u} - \mathbf{w})$.

> *Solution.* Expand both slots: $\mathbf{u} \wedge \mathbf{u} - \mathbf{u} \wedge \mathbf{w} + \mathbf{w} \wedge \mathbf{u} - \mathbf{w} \wedge \mathbf{w}$. The first and last terms are $\mathbf{0}$ because $\wedge$ is alternating, and $\mathbf{w} \wedge \mathbf{u} = -\mathbf{u} \wedge \mathbf{w}$ by Lemma 14.8.1 (a). So the value is $-2\,\mathbf{u} \wedge \mathbf{w}$. Over $\mathbb{F}_2$ that is $\mathbf{0}$, which is correct there and not a sign of anything going wrong: over $\mathbb{F}_2$, $\mathbf{u} + \mathbf{w}$ and $\mathbf{u} - \mathbf{w}$ are the same vector, so the wedge of the pair must vanish.

14.8.4 A basis, and the dimension

Sorting is again the move, but now it costs a sign, and tuples with a repeat are simply gone. What survives is the strictly increasing tuples.

Theorem 14.8.5 — Basis of an Exterior Power

Let $\mathcal{B} = (\mathbf{v}_1, \ldots, \mathbf{v}_n)$ be a basis of V and $k \ge 1$. Then the wedges

$$\mathbf{v}_{i_1} \wedge \mathbf{v}_{i_2} \wedge \cdots \wedge \mathbf{v}_{i_k}, \qquad 1 \le i_1 < i_2 < \cdots < i_k \le n,$$

one for each **strictly increasing** tuple, form a basis of $\Lambda^k V$. Consequently

$$\dim \Lambda^k V = \binom{n}{k}, \qquad \text{and} \qquad \Lambda^k V = \{\mathbf{0}\} \ \text{ for } k > n,$$

over **every** field F.

Idea. Spanning: start from the basis of Theorem 14.6.3, throw away every tuple with a repeated index — those wedges are $\mathbf{0}$ — and sort the rest, paying a sign. Independence: one linear functional per increasing tuple I, and the functional must be **alternating**, so the natural candidate is a determinant: read the k arguments through the k dual functionals $\varphi_{i_1}, \dots, \varphi_{i_k}$, assemble the $k \times k$ matrix of values, and take its determinant. Determinants are alternating in their columns by construction, which is exactly what is needed, and the value at the basis wedge indexed by J is $\det \mathbf{I}_k = 1$ if $I = J$ and 0 otherwise, because some row is then zero.

Proof. Spanning. By Theorem 14.6.3 the tensors $\mathbf{v}_{j_1} \otimes \cdots \otimes \mathbf{v}_{j_k}$, over all tuples J, form a basis of $V^{\otimes k}$, and q is surjective, so the wedges $\mathbf{v}_{j_1} \wedge \cdots \wedge \mathbf{v}_{j_k}$ span $\Lambda^k V$. If J has two equal entries, the corresponding wedge is $\mathbf{0}$ because $\wedge$ is alternating. If the entries of J are distinct, let $\sigma \in S_k$ sort them into increasing order; then by Lemma 14.8.1 (b) the wedge equals $\pm$ the wedge of the sorted tuple. So the increasing tuples already span, and if $k > n$ there are no such tuples at all, whence $\Lambda^k V = \{\mathbf{0}\}$.

Independence. Let $(\varphi_1, \dots, \varphi_n)$ be the dual basis of $\mathcal{B}$ (Theorem 4.1.3). For an increasing tuple $I = (i_1 < \cdots < i_k)$ define

$$g_I(\mathbf{u}_1, \dots, \mathbf{u}_k) = \det\Big(\varphi_{i_a}(\mathbf{u}_b)\Big)_{a,b=1}^{k} \in F,$$

the determinant of the $k \times k$ matrix whose (a, b) entry is $\varphi_{i_a}(\mathbf{u}_b)$. Column b of that matrix depends linearly on $\mathbf{u}_b$, because each φ_{i_a} is linear, and det is linear in each column and vanishes when two columns coincide (Theorem 6.4.3). Hence g_I is k-linear, and alternating: if $\mathbf{u}_a = \mathbf{u}_b$ with $a \neq b$, two columns of the matrix are equal and the determinant is 0.

By (E1), g_I induces a linear $\bar{g}_I \colon \Lambda^k V \to F$. Evaluate it at the wedge of an increasing tuple J: the matrix has (a, b) entry $\varphi_{i_a}(\mathbf{v}_{j_b}) = \delta_{i_a j_b}$. If $I = J$ this matrix is $\mathbf{I}_k$ and the determinant is 1. If $I \neq J$, then since I and J each list k distinct indices and are not the same increasing tuple, some i_a is not among $j_1, \dots, j_k$; row a is then zero, so the rows are dependent, and by Theorem 6.4.5 together with Theorem 6.2.1 (d) the determinant is 0. Hence $\bar{g}_I(\mathbf{v}_{j_1} \wedge \cdots \wedge \mathbf{v}_{j_k}) = \delta_{IJ}$.

Now let $\sum_I a_I \, \mathbf{v}_{i_1} \wedge \cdots \wedge \mathbf{v}_{i_k} = \mathbf{0}$, the sum over increasing tuples. Applying $\bar{g}_J$ leaves $a_J = 0$, and J was arbitrary. So the list is independent, hence a basis.

The count. An increasing k-tuple in $\{1, \dots, n\}$ is the same thing as a k-element subset of $\{1, \dots, n\}$, listed in its only increasing order. There are $\binom{n}{k}$ such subsets, and none at all when $k > n$. No step divided by an integer, so the conclusion holds over every field. This proves the theorem.

■

Corollary 14.8.6 — The Top Exterior Power Is a Line

If $\dim V = n \geq 1$, then $\dim \Lambda^n V = 1$, with basis the single wedge $\mathbf{v}_1 \wedge \cdots \wedge \mathbf{v}_n$ of any basis of V. For $k > n$, $\Lambda^k V = \{\mathbf{0}\}$.

Proof. There is exactly one increasing n-tuple in $\{1,\dots,n\}$, namely $(1,2,\dots,n)$, so Theorem 14.8.5 gives a basis with one member, and $\binom{n}{n}=1$. The second statement is the last clause of that theorem. ∎

That one-dimensionality is the source of the determinant, and Section 09 is about it. For now, notice the shape of the numbers: $\dim \Lambda^k V$ rises from 1 at $k=0$ to a maximum in the middle and back to 1 at $k=n$, and then stops. Compare $\dim \operatorname{Sym}^k V = \binom{n+k-1}{k}$, which grows forever. The symmetric power forgets the order; the exterior power forgets the order **and** forbids repetition, and forbidding repetition is what makes the tower finite.

Remark. The two counts fit together at $k=2$: $\binom{n+1}{2}+\binom{n}{2}=n^2=\dim V^{\otimes 2}$ over every field. In characteristic $\neq 2$ this reflects an actual decomposition of $V^{\otimes 2}$ into symmetric and alternating tensors, in the manner of Theorem 13.3.4. Over $\mathbb{F}_2$ the identity between the numbers survives while the decomposition does not, exactly as in Theorem 14.7.8.

Warning. **$\Lambda^k V$ is a quotient of $V^{\otimes k}$, not a subspace.** Its elements are cosets of A_k, and $\mathbf{u}\wedge\mathbf{w}=-\mathbf{w}\wedge\mathbf{u}$ is an identity between cosets, not between tensors. It is also a mistake to replace it by a subspace of $V^{\otimes k}$ — say "the tensors that change sign under every swap of two slots". Over $\mathbb{F}_2$ that subspace is the space of symmetric tensors of Definition 14.7.5, because $-1=1$ there; for $V=\mathbb{F}_2^2$ and $k=2$ it has dimension $\binom{3}{2}=3$ by Theorem 14.7.8 (a), while $\Lambda^2 V$ has dimension $\binom{2}{2}=1$.

Example. (A wedge in $\Lambda^2(F^3)$)

Let $V=F^3$, $\mathbf{u}=\mathbf{e}_1+2\mathbf{e}_2+3\mathbf{e}_3$ and $\mathbf{w}=4\mathbf{e}_1+5\mathbf{e}_2+6\mathbf{e}_3$. Write out a basis of $\Lambda^2 V$ and expand $\mathbf{u}\wedge\mathbf{w}$ in it.

Solution. By Theorem 14.8.5 a basis is $(\mathbf{e}_1\wedge\mathbf{e}_2,\ \mathbf{e}_1\wedge\mathbf{e}_3,\ \mathbf{e}_2\wedge\mathbf{e}_3)$, of size $\binom{3}{2}=3$. Expanding both slots gives nine terms; the three with a repeated index vanish, and each remaining pair combines by $\mathbf{e}_j\wedge\mathbf{e}_i=-\mathbf{e}_i\wedge\mathbf{e}_j$. The coefficient of $\mathbf{e}_i\wedge\mathbf{e}_j$ is therefore $u_iw_j-u_jw_i$:

$$\begin{aligned}\mathbf{u}\wedge\mathbf{w} &= (1\cdot 5-2\cdot 4)\,\mathbf{e}_1\wedge\mathbf{e}_2+(1\cdot 6-3\cdot 4)\,\mathbf{e}_1\wedge\mathbf{e}_3\\ &\quad+(2\cdot 6-3\cdot 5)\,\mathbf{e}_2\wedge\mathbf{e}_3\\ &= -3\,\mathbf{e}_1\wedge\mathbf{e}_2-6\,\mathbf{e}_1\wedge\mathbf{e}_3-3\,\mathbf{e}_2\wedge\mathbf{e}_3.\end{aligned}$$

The three coefficients are the 2×2 minors of the 3×2 matrix with columns $\mathbf{u}$ and $\mathbf{w}$. That is not an accident, and Section 09 proves it in general.

14.8.5 Independence detects wedges

The last result of the section is small to state and is the tool everything after it uses: **a wedge is non-zero exactly when its factors are independent.** One direction is Lemma 14.8.1 (c); the other needs Theorem 14.8.5, which is why it comes last.

Theorem 14.8.7 — Wedges Detect Independence

Let $\mathbf{u}_1, \dots, \mathbf{u}_k \in V$ with $1 \le k \le n$. Then

$$\mathbf{u}_1 \wedge \mathbf{u}_2 \wedge \cdots \wedge \mathbf{u}_k \neq \mathbf{0}$$
$$\text{if and only if } (\mathbf{u}_1, \dots, \mathbf{u}_k) \text{ is independent.}$$

For $k > n$ the wedge is always $\mathbf{0}$.

Idea. ($\Rightarrow$) is the contrapositive of "alternating maps kill dependent lists". ($\Leftarrow$) is the reason Theorem 14.8.5 was worth proving: an independent list extends to a basis of V, and that theorem then says its wedge **is** one of the basis vectors of $\Lambda^k V$, hence non-zero.

Proof. ($\Rightarrow$) We prove the contrapositive. If $(\mathbf{u}_1, \dots, \mathbf{u}_k)$ is dependent, then $\mathbf{u}_1 \wedge \cdots \wedge \mathbf{u}_k = \mathbf{0}$ by Lemma 14.8.1 (c), applied to the alternating map $\wedge$.

($\Leftarrow$) Suppose the list is independent. By the Basis Extension Theorem (Theorem 1.6.5) it extends to a basis $\mathcal{B} = (\mathbf{u}_1, \dots, \mathbf{u}_k, \mathbf{u}_{k+1}, \dots, \mathbf{u}_n)$ of V, which is possible because $k \le n$. Apply Theorem 14.8.5 to $\mathcal{B}$: the wedges indexed by increasing k-tuples form a basis of $\Lambda^k V$, and $\mathbf{u}_1 \wedge \cdots \wedge \mathbf{u}_k$ is the one indexed by $(1, 2, \dots, k)$. A member of a basis is non-zero, so $\mathbf{u}_1 \wedge \cdots \wedge \mathbf{u}_k \neq \mathbf{0}$.

For $k > n$, $\Lambda^k V = \{\mathbf{0}\}$ by Theorem 14.8.5, so every wedge vanishes; consistently, any $k > n$ vectors in V are dependent. This proves the theorem.

■

Remark. The theorem turns a question about a list into a question about a single vector, and that is its value. Section 09 uses it to prove that $\Lambda^n T$ is multiplication by $\det T$ and that T is invertible exactly when that scalar is non-zero; Section 10 uses it to decide which elements of $\Lambda^2 V$ are wedges at all. Note the hypothesis it does **not** need: no assumption on F, because neither half divided by anything.

14.8.6 Exercises

14.8.6.1 A. Check your understanding

Exercise A1.

(a) State the universal property (E1), with every quantifier, and say which maps are required to factor.

(b) Which subspace of $V^{\otimes k}$ is divided out, and why is the other candidate N_k rejected?

(c) Let $\dim V = 5$. Compute $\dim \Lambda^k V$ for $k = 0, 1, 2, 3, 4, 5, 6$.

(d) Determine whether $\mathbf{u} \wedge \mathbf{w} \wedge \mathbf{u}$ can be non-zero. Justify your answer.

(e) State the test for $\mathbf{u}_1 \wedge \cdots \wedge \mathbf{u}_k \neq \mathbf{0}$, and say which hypothesis on the field it needs.

Solution.

(a) For every vector space W over F and every **alternating** k-linear map $f\colon V^k \to W$, there exists exactly one linear $\bar{f}\colon \Lambda^k V \to W$ with $\bar{f}\circ\wedge = f$. Only alternating maps factor; a non-alternating one cannot, since $\bar{f}\circ\wedge$ is alternating for every linear $\bar{f}$.

(b) The subspace A_k spanned by the simple tensors with a repeated entry (Theorem 14.8.4). The candidate N_k, spanned by the elements $x + P_\tau x$, is rejected because $N_k \subsetneq A_k$ in characteristic 2 (Proposition 14.8.2), so the quotient by N_k would have the wrong dimension there and its maps would be the skew-symmetric ones rather than the alternating ones.

(c) $\binom{5}{k}$, giving $1, 5, 10, 10, 5, 1, 0$ for $k = 0, \dots, 6$.

(d) No: the list $(\mathbf{u}, \mathbf{w}, \mathbf{u})$ repeats $\mathbf{u}$ in positions 1 and 3, so the wedge is $\mathbf{0}$ because $\wedge$ is alternating. (Equivalently, the list is dependent, so Theorem 14.8.7 applies.)

(e) $\mathbf{u}_1 \wedge \cdots \wedge \mathbf{u}_k \neq \mathbf{0}$ if and only if the list is linearly independent (Theorem 14.8.7). It needs no hypothesis on F.

14.8.6.2 B. Practice

Exercise B1: Computing wedges.

Let $V = F^3$ with $F = \mathbb{Q}$.

(a) Expand $(2\mathbf{e}_1 - \mathbf{e}_2 + \mathbf{e}_3) \wedge (\mathbf{e}_1 + \mathbf{e}_2 - \mathbf{e}_3)$ in the basis $(\mathbf{e}_1 \wedge \mathbf{e}_2, \mathbf{e}_1 \wedge \mathbf{e}_3, \mathbf{e}_2 \wedge \mathbf{e}_3)$.

(b) Expand $\mathbf{e}_1 \wedge (\mathbf{e}_1 + \mathbf{e}_2) \wedge (\mathbf{e}_1 + \mathbf{e}_2 + \mathbf{e}_3)$ in the basis of $\Lambda^3 V$.

Solution.

(a) With $\mathbf{u} = (2, -1, 1)$ and $\mathbf{w} = (1, 1, -1)$, the coefficient of $\mathbf{e}_i \wedge \mathbf{e}_j$ is $u_i w_j - u_j w_i$, as in Example (A wedge in $\Lambda^2(F^3)$):

$$2 \cdot 1 - (-1) \cdot 1 = 3, \qquad 2 \cdot (-1) - 1 \cdot 1 = -3,$$
$$(-1) \cdot (-1) - 1 \cdot 1 = 0,$$

so the wedge is $3\,\mathbf{e}_1 \wedge \mathbf{e}_2 - 3\,\mathbf{e}_1 \wedge \mathbf{e}_3$.

(b) By Corollary 14.8.6 the basis is the single wedge $\mathbf{e}_1 \wedge \mathbf{e}_2 \wedge \mathbf{e}_3$. Expand from the left: in the second slot, $\mathbf{e}_1 \wedge \mathbf{e}_1 \wedge \cdots = \mathbf{0}$, so only $\mathbf{e}_2$ survives; then in the third slot, both $\mathbf{e}_1$ and $\mathbf{e}_2$ already occur, so only $\mathbf{e}_3$ survives. Hence the wedge is $\mathbf{e}_1 \wedge \mathbf{e}_2 \wedge \mathbf{e}_3$. (Equivalently, the three vectors are the columns of a unit upper triangular matrix, of determinant 1; Exercise C3 explains why the answer had to be that determinant.)

Exercise B2: Independence by wedging.

Determine whether each list is linearly independent, by computing a wedge. Justify your answer.

(a) $\big((1, 2), (3, 6)\big)$ in $\mathbb{Q}^2$.

(b) $\big((1, 0, 1), (0, 1, 1), (1, 1, 2)\big)$ in $\mathbb{Q}^3$.

(c) $\big((1, 0, 0), (0, 1, 0), (0, 0, 1), (1, 1, 1)\big)$ in $\mathbb{Q}^3$.

Solution.

(a) $(1,2)\wedge(3,6) = (1\cdot 6 - 2\cdot 3)\,\mathbf{e}_1\wedge\mathbf{e}_2 = \mathbf{0}$. By Theorem 14.8.7 the list is dependent, as it visibly is: the second vector is three times the first.

(b) The minor computation $(1\cdot 1 - 0\cdot 0,\ 1\cdot 1 - 1\cdot 0,\ 0\cdot 1 - 1\cdot 1) = (1,1,-1)$ gives, for the first two vectors, $\mathbf{e}_1\wedge\mathbf{e}_2 + \mathbf{e}_1\wedge\mathbf{e}_3 - \mathbf{e}_2\wedge\mathbf{e}_3$. Wedging with the third vector $(1,1,2)$ and keeping only the terms with all three indices distinct,

$$\begin{aligned}&(\mathbf{e}_1\wedge\mathbf{e}_2)\wedge 2\mathbf{e}_3 + (\mathbf{e}_1\wedge\mathbf{e}_3)\wedge\mathbf{e}_2 - (\mathbf{e}_2\wedge\mathbf{e}_3)\wedge\mathbf{e}_1\\ &\quad = (2-1-1)\,\mathbf{e}_1\wedge\mathbf{e}_2\wedge\mathbf{e}_3 = \mathbf{0},\end{aligned}$$

using $\mathbf{e}_1\wedge\mathbf{e}_3\wedge\mathbf{e}_2 = -\mathbf{e}_1\wedge\mathbf{e}_2\wedge\mathbf{e}_3$ and $\mathbf{e}_2\wedge\mathbf{e}_3\wedge\mathbf{e}_1 = \mathbf{e}_1\wedge\mathbf{e}_2\wedge\mathbf{e}_3$ from Lemma 14.8.1 (b). So the list is dependent; indeed the third vector is the sum of the first two.

(c) Here $k = 4 > 3 = n$, so $\Lambda^4(\mathbb{Q}^3) = \{\mathbf{0}\}$ by Theorem 14.8.5 and the wedge is $\mathbf{0}$ without any computation. The list is dependent, as any 4 vectors in a 3-dimensional space must be.

Exercise B3: A functional built from the universal property.

Let $V = F^3$ and let $f\colon V^2 \to F$ be $f(\mathbf{u},\mathbf{w}) = u_1w_3 - u_3w_1$.

(a) Prove that f is alternating and bilinear, and deduce that there is a unique linear $\bar{f}\colon \Lambda^2 V \to F$ with $\bar{f}(\mathbf{u}\wedge\mathbf{w}) = f(\mathbf{u},\mathbf{w})$.

(b) Compute $\bar{f}$ on the basis $(\mathbf{e}_1\wedge\mathbf{e}_2, \mathbf{e}_1\wedge\mathbf{e}_3, \mathbf{e}_2\wedge\mathbf{e}_3)$, and evaluate $\bar{f}$ on the answer to Example (A wedge in $\Lambda^2(F^3)$).

Solution.

(a) Each slot is a linear functional with the other fixed, so f is bilinear, and $f(\mathbf{u},\mathbf{u}) = u_1u_3 - u_3u_1 = 0$, so f is alternating (Definition 14.8.1 with $k=2$). By (E1) there is exactly one linear $\bar{f}\colon \Lambda^2 V \to F$ with $\bar{f}\circ\wedge = f$.

(b) $\bar{f}(\mathbf{e}_1\wedge\mathbf{e}_2) = f(\mathbf{e}_1,\mathbf{e}_2) = 0$; $\bar{f}(\mathbf{e}_1\wedge\mathbf{e}_3) = 1$; $\bar{f}(\mathbf{e}_2\wedge\mathbf{e}_3) = 0$. So $\bar{f}$ reads off the $\mathbf{e}_1\wedge\mathbf{e}_3$ coordinate. On $\mathbf{u}\wedge\mathbf{w} = -3\mathbf{e}_1\wedge\mathbf{e}_2 - 6\mathbf{e}_1\wedge\mathbf{e}_3 - 3\mathbf{e}_2\wedge\mathbf{e}_3$ it gives -6, which agrees with $f(\mathbf{u},\mathbf{w}) = 1\cdot 6 - 3\cdot 4 = -6$.

14.8.6.3 C. Going deeper

Exercise C1: The characteristic-two witness.

Let $F = \mathbb{F}_2$, $V = \mathbb{F}_2^2$ and $k = 2$.

(a) List the elements of A_2 and of N_2, and compute both dimensions.

(b) Compute $\dim \Lambda^2 V$ from (a) and check it against Theorem 14.8.5.

(c) Compute $\dim(V^{\otimes 2}/N_2)$ and explain, in one sentence, what would go wrong if the exterior power had been defined as that quotient.

Solution.

(a) By Theorem 14.6.3, $V^{\otimes 2}$ has basis $\mathbf{e}_1\otimes\mathbf{e}_1, \mathbf{e}_1\otimes\mathbf{e}_2, \mathbf{e}_2\otimes\mathbf{e}_1, \mathbf{e}_2\otimes\mathbf{e}_2$. Now A_2 is

spanned by the tensors $\mathbf{u}\otimes\mathbf{u}$, and the three choices $\mathbf{u}=\mathbf{e}_1,\mathbf{e}_2,\mathbf{e}_1+\mathbf{e}_2$ give

$$\mathbf{e}_1\otimes\mathbf{e}_1,\quad \mathbf{e}_2\otimes\mathbf{e}_2,\quad \mathbf{e}_1\otimes\mathbf{e}_1+\mathbf{e}_1\otimes\mathbf{e}_2+\mathbf{e}_2\otimes\mathbf{e}_1+\mathbf{e}_2\otimes\mathbf{e}_2,$$

whose span also contains $t=\mathbf{e}_1\otimes\mathbf{e}_2+\mathbf{e}_2\otimes\mathbf{e}_1$. Those three vectors $\mathbf{e}_1\otimes\mathbf{e}_1,\mathbf{e}_2\otimes\mathbf{e}_2,t$ are independent, being distinct disjoint sums of basis vectors, and they span all three listed generators, so $\dim A_2=3$; there are no further generators, since $\mathbf{0}$ is the only remaining vector of $\mathbb{F}_2^2$. For N_2, the coefficient formula in the proof of Proposition 14.8.2 gives

$$\mathbf{u}\otimes\mathbf{w}+\mathbf{w}\otimes\mathbf{u}=(a_1b_2+a_2b_1)\,t,$$

since the diagonal coefficients vanish and the two off-diagonal ones are equal. Hence $N_2=\operatorname{span}(t)$ and $\dim N_2=1$.

(b) $\dim\Lambda^2V=4-3=1$ by Theorem 3.9.5, matching $\binom{2}{2}=1$.

(c) $\dim(V^{\otimes2}/N_2)=4-1=3$. Defining Λ^2V as that quotient would make the image of $\mathbf{e}_1\otimes\mathbf{e}_1$ non-zero, so $\mathbf{v}\wedge\mathbf{v}\neq\mathbf{0}$ for some $\mathbf{v}$, the structure map would be skew-symmetric but not alternating, and the dimension would be 3 instead of $\binom{2}{2}=1$.

Exercise C2: Alternating forms, recounted.

(a) Prove that the alternating k-linear forms on V are in bijection with the linear functionals on Λ^kV, and that the bijection is an isomorphism of vector spaces.

(b) Deduce that the space of alternating k-linear forms on V has dimension $\binom{n}{k}$.

(c) Hence recover Corollary 6.4.4: the alternating n-linear forms on F^n form a line.

Solution.

(a) Write $\mathcal{A}$ for the space of alternating k-linear forms on V, a vector space by Theorem 6.2.3. The map $\Theta\colon(\Lambda^kV)^*\to\mathcal{A}$, $\Theta(\lambda)=\lambda\circ\wedge$, is well defined, since a composite of the alternating $\wedge$ with a linear map is alternating and k-linear, and it is linear in λ because composition with a fixed map is. It is injective: if $\lambda\circ\wedge=0$ then λ vanishes on the wedges, which span Λ^kV (Theorem 14.8.4), so $\lambda=0$. It is surjective: given $f\in\mathcal{A}$, (E1) supplies $\bar f$ with $\bar f\circ\wedge=f$. So Θ is an isomorphism.

(b) By (a) and Corollary 4.1.4, $\dim\mathcal{A}=\dim(\Lambda^kV)^*=\dim\Lambda^kV=\binom{n}{k}$, using Theorem 14.8.5.

(c) Take $V=F^n$ and $k=n$: the dimension is $\binom{n}{n}=1$. Since det is a non-zero alternating n-linear form (Theorem 6.4.3, with $\det\mathbf{I}_n=1$), it spans that line, which is Corollary 6.4.4.

Exercise C3: A wedge sees only the subspace.

Let $(\mathbf{u}_1,\dots,\mathbf{u}_k)$ and $(\mathbf{w}_1,\dots,\mathbf{w}_k)$ be two lists in V with $\mathbf{w}_b=\sum_{a=1}^k p_{ab}\,\mathbf{u}_a$ for a matrix $\mathbf{P}=(p_{ab})\in M_k(F)$.

(a) Prove that $\mathbf{w}_1\wedge\cdots\wedge\mathbf{w}_k=(\det\mathbf{P})\;\mathbf{u}_1\wedge\cdots\wedge\mathbf{u}_k$.

(b) Deduce that if $(\mathbf{u}_1,\dots,\mathbf{u}_k)$ and $(\mathbf{w}_1,\dots,\mathbf{w}_k)$ are two bases of the **same** k-dimensional subspace $U\subseteq V$, then their wedges differ by a non-zero scalar factor.

(c) Deduce that the line $\operatorname{span}(\mathbf{u}_1 \wedge \cdots \wedge \mathbf{u}_k) \subseteq \Lambda^k V$ depends only on U, not on the basis chosen for it.

Hint: for (a), expand every slot and use Lemma 14.8.1 (b) together with Definition 6.4.1.

Solution.

(a) Expanding slot by slot,

$$\mathbf{w}_1 \wedge \cdots \wedge \mathbf{w}_k = \sum_{a_1,\ldots,a_k} p_{a_1 1} \cdots p_{a_k k}\, \mathbf{u}_{a_1} \wedge \cdots \wedge \mathbf{u}_{a_k},$$

the sum over all k-tuples $(a_1, \ldots, a_k)$ from $\{1, \ldots, k\}$. A term with two equal indices has a repeated argument, so its wedge is $\mathbf{0}$. A term with all indices distinct has $(a_1, \ldots, a_k) = (\sigma(1), \ldots, \sigma(k))$ for a unique $\sigma \in S_k$, and then $\mathbf{u}_{\sigma(1)} \wedge \cdots \wedge \mathbf{u}_{\sigma(k)} = \operatorname{sgn}(\sigma)\, \mathbf{u}_1 \wedge \cdots \wedge \mathbf{u}_k$ by Lemma 14.8.1 (b). Hence

$$\mathbf{w}_1 \wedge \cdots \wedge \mathbf{w}_k = \Big(\sum_{\sigma \in S_k} \operatorname{sgn}(\sigma)\, p_{\sigma(1)1} \cdots p_{\sigma(k)k} \Big) \mathbf{u}_1 \wedge \cdots \wedge \mathbf{u}_k,$$

and the bracket is $\det \mathbf{P}$ by Definition 6.4.1.

(b) Both lists are bases of U, so each $\mathbf{w}_b$ is a combination of the $\mathbf{u}_a$, giving $\mathbf{P}$ as above, and $\mathbf{P}$ is the change-of-coordinates matrix between two bases of U, hence invertible (Proposition 3.7.2). By Theorem 6.5.2, $\det \mathbf{P} \neq 0$, and (a) gives the claim. Both wedges are non-zero, by Theorem 14.8.7.

(c) By (b) the two wedges are non-zero scalar multiples of each other, so they span the same one-dimensional subspace of $\Lambda^k V$. Any basis of U therefore determines the same line, which consequently depends on U alone. (This line is the object that Section 09's coordinates — the $k \times k$ minors — describe, and it is how a k-dimensional subspace is turned into a single point.)

14.9 The Determinant as a Top Exterior Power

Chapter 6 built the determinant twice. First it proved that an alternating n-linear form on F^n is determined by its value at the standard basis (Theorem 6.4.2), which says *at most one* normalized such form exists; then it wrote the Leibniz sum down and checked the three rules (Theorem 6.4.3), which says *at least one* does. The number $\det \mathbf{A}$ of Definition 6.4.1 is that form's value. This section builds the determinant a third time, and the honest way to describe what it adds is to say up front what it does not: no new value, no faster computation, and no theorem Chapter 6 was missing. What it adds is an **object**. The exterior powers of the previous section turn $\det T$ from a number attached to a matrix into the operator that T induces on a one-dimensional space, and from that description multiplicativity stops being a computation and becomes the statement that composing two induced maps induces the composite.

Throughout, F is a field, V and W are finite-dimensional vector spaces over F, and $\Lambda^k V$, the wedge $\mathbf{v}_1 \wedge \cdots \wedge \mathbf{v}_k$, and the universal property for alternating maps are as in Definition 14.8.2. We use freely that the wedges $\mathbf{v}_{i_1} \wedge \cdots \wedge \mathbf{v}_{i_k}$ over strictly increasing index tuples form a basis of $\Lambda^k V$, so that $\dim \Lambda^k V = \binom{n}{k}$ when $\dim V = n$ (Theorem 14.8.5), and that a wedge of vectors is non-zero exactly when the list is linearly independent (Theorem 14.8.7).

14.9.1 Wedging with a fixed vector

Two facts from the previous section will be used on every page, and one small tool is still missing.

The first fact is the **reordering rule**: the wedge map $(\mathbf{v}_1, \dots, \mathbf{v}_k) \mapsto \mathbf{v}_1 \wedge \cdots \wedge \mathbf{v}_k$ is alternating (Definition 14.8.2), and an alternating multilinear map satisfies

$$f(\mathbf{v}_{\sigma(1)}, \dots, \mathbf{v}_{\sigma(k)}) = \operatorname{sgn}(\sigma)\, f(\mathbf{v}_1, \dots, \mathbf{v}_k)$$

for every $\sigma \in S_k$, by Lemma 14.8.1 (b). Reordering a wedge costs the sign of the permutation, and nothing else. The second is that $\Lambda^n V$ is one-dimensional when $\dim V = n \geq 1$ (Corollary 14.8.6); that is the whole engine of this section.

The missing tool is the ability to wedge a fixed vector onto a whole exterior power, not just onto a list of vectors. Section 10 builds the product on all of ΛV; here one vector at a time is enough.

Lemma 14.9.1 — Wedging with a Fixed Vector

Let $\mathbf{v} \in V$ and $k \geq 1$. There is a **unique** linear map

$$\varepsilon_{\mathbf{v}} \colon \Lambda^k V \to \Lambda^{k+1} V, \qquad \varepsilon_{\mathbf{v}}(\mathbf{w}_1 \wedge \cdots \wedge \mathbf{w}_k) = \mathbf{v} \wedge \mathbf{w}_1 \wedge \cdots \wedge \mathbf{w}_k.$$

Proof. The map $V^k \to \Lambda^{k+1} V$ sending $(\mathbf{w}_1, \dots, \mathbf{w}_k)$ to $\mathbf{v} \wedge \mathbf{w}_1 \wedge \cdots \wedge \mathbf{w}_k$ is k-linear, because the wedge of $k+1$ vectors is linear in each slot and the first slot is frozen at $\mathbf{v}$; and it is alternating, because if $\mathbf{w}_p = \mathbf{w}_r$ with $p \neq r$ then the wedge of $k+1$ vectors has two equal arguments and is $\mathbf{0}$. By the universal property in Definition 14.8.2 it factors through $\Lambda^k V$, giving a linear $\varepsilon_{\mathbf{v}}$ with the stated values. Uniqueness holds because the wedges $\mathbf{w}_1 \wedge \cdots \wedge \mathbf{w}_k$ span $\Lambda^k V$ (Theorem 14.8.5), and a linear map is determined on a spanning set.

■

14.9.2 Induced maps on exterior powers

A linear map should act on everything built from its domain. A map $T \colon V \to W$ sends a list $(\mathbf{v}_1, \dots, \mathbf{v}_k)$ to the list $(T\mathbf{v}_1, \dots, T\mathbf{v}_k)$, so it ought to send the wedge $\mathbf{v}_1 \wedge \cdots \wedge \mathbf{v}_k$ to $T\mathbf{v}_1 \wedge \cdots \wedge T\mathbf{v}_k$. The only question is whether that rule defines a map at all: an element of $\Lambda^k V$ can be written as a wedge in many ways, and an assignment made on wedges must be checked. The universal property answers it in two lines, and that is the point of having a universal property.

The k-th exterior power of a map wedges its values together.

Definition 14.9.1 — Exterior Power of a Linear Map

Let $T \colon V \to W$ be linear and let $k \geq 1$. The **k-th exterior power** of T is the unique linear map

$$\Lambda^k T \colon \Lambda^k V \to \Lambda^k W$$

satisfying $\Lambda^k T(\mathbf{v}_1 \wedge \cdots \wedge \mathbf{v}_k) = T\mathbf{v}_1 \wedge \cdots \wedge T\mathbf{v}_k$ for all $\mathbf{v}_1, \dots, \mathbf{v}_k \in V$.

Well-definedness. The map $V^k \to \Lambda^k W$ sending $(\mathbf{v}_1, \dots, \mathbf{v}_k)$ to $T\mathbf{v}_1 \wedge \cdots \wedge T\mathbf{v}_k$ is k-linear, since T is linear and the wedge in W is linear in each slot; and it is alternating, since $\mathbf{v}_p = \mathbf{v}_r$ forces $T\mathbf{v}_p = T\mathbf{v}_r$ and a wedge with two equal arguments is $\mathbf{0}$. So Definition 14.8.2 produces exactly one linear map on $\Lambda^k V$ with the stated values, and the wedges span $\Lambda^k V$ (Theorem 14.8.5), so no other linear map has them.

Examples.

- $k = 1$. $\Lambda^1 V = V$ and $\Lambda^1 T = T$: the definition says nothing new in degree one.
- **The identity.** $\Lambda^k(\mathrm{id}_V) = \mathrm{id}$, since both sides send $\mathbf{v}_1 \wedge \cdots \wedge \mathbf{v}_k$ to itself.
- **A scalar.** For $T = c\,\mathrm{id}_V$, $\Lambda^k T(\mathbf{v}_1 \wedge \cdots \wedge \mathbf{v}_k) = c^k\,\mathbf{v}_1 \wedge \cdots \wedge \mathbf{v}_k$, so $\Lambda^k T = c^k\,\mathrm{id}$. One factor of c comes out of each of the k slots.
- **A degenerate case.** If $k > \dim V$ then $\Lambda^k V = \{\mathbf{0}\}$ (Theorem 14.8.5) and $\Lambda^k T$ is the zero map between zero spaces. Worth recording so that statements below need no size caveat.

Non-example by minimal change. Replace "alternating" by nothing: the rule $\mathbf{v}_1 \otimes \cdots \otimes \mathbf{v}_k \mapsto T\mathbf{v}_1 \wedge \cdots \wedge T\mathbf{v}_k$ on $V^{\otimes k}$ is perfectly well defined, but it is **not** the map above, because $\Lambda^k V$ is a quotient of $V^{\otimes k}$ and not a subspace of it. What makes Definition 14.9.1 legal is precisely that the rule kills the relations that were divided out.

The reason for having the notation is the next sentence.

Theorem 14.9.2 — Exterior Powers Respect Composition

Let $T\colon U \to V$ and $S\colon V \to W$ be linear, and let $k \geq 1$. Then

$$\Lambda^k(ST) = (\Lambda^k S)(\Lambda^k T), \qquad \Lambda^k(\mathrm{id}_V) = \mathrm{id}_{\Lambda^k V}.$$

Proof. Both $\Lambda^k(ST)$ and $(\Lambda^k S)(\Lambda^k T)$ are linear maps $\Lambda^k U \to \Lambda^k W$, so it suffices to compare them on the wedges, which span $\Lambda^k U$ (Theorem 14.8.5). By Definition 14.9.1 applied three times,

$$(\Lambda^k S)(\Lambda^k T)(\mathbf{u}_1 \wedge \cdots \wedge \mathbf{u}_k) = ST\mathbf{u}_1 \wedge \cdots \wedge ST\mathbf{u}_k = \Lambda^k(ST)(\mathbf{u}_1 \wedge \cdots \wedge \mathbf{u}_k).$$

The second identity was checked above. This proves the theorem. ∎

Example. (The second exterior power of a 3×3 matrix)

Let $T\colon \mathbb{Q}^3 \to \mathbb{Q}^3$ have matrix

$$\mathbf{A} = \begin{pmatrix} 2 & 1 & 3 \\ 0 & 4 & 1 \\ 5 & 2 & 1 \end{pmatrix}$$

in the standard basis. Find the matrix of $\Lambda^2 T$ in the basis $(\mathbf{e}_1 \wedge \mathbf{e}_2,\ \mathbf{e}_1 \wedge \mathbf{e}_3,\ \mathbf{e}_2 \wedge \mathbf{e}_3)$ of $\Lambda^2 \mathbb{Q}^3$, and compute its determinant.

Solution. By Definition 14.9.1, $\Lambda^2 T(\mathbf{e}_i \wedge \mathbf{e}_j) = \mathbf{a}_i \wedge \mathbf{a}_j$, where $\mathbf{a}_1, \mathbf{a}_2, \mathbf{a}_3$ are the columns

of $\mathbf{A}$. Expand one column:

$$\begin{aligned}\mathbf{a}_1 \wedge \mathbf{a}_2 &= (2\mathbf{e}_1 + 5\mathbf{e}_3) \wedge (\mathbf{e}_1 + 4\mathbf{e}_2 + 2\mathbf{e}_3) \\ &= 8\,\mathbf{e}_1 \wedge \mathbf{e}_2 + 4\,\mathbf{e}_1 \wedge \mathbf{e}_3 + 5\,\mathbf{e}_3 \wedge \mathbf{e}_1 + 20\,\mathbf{e}_3 \wedge \mathbf{e}_2 \\ &= 8\,\mathbf{e}_1 \wedge \mathbf{e}_2 - \mathbf{e}_1 \wedge \mathbf{e}_3 - 20\,\mathbf{e}_2 \wedge \mathbf{e}_3,\end{aligned}$$

where the terms $2\,\mathbf{e}_1 \wedge \mathbf{e}_1$ and $10\,\mathbf{e}_3 \wedge \mathbf{e}_3$ were dropped in the second line because a wedge with a repeated vector is $\mathbf{0}$, and the third line used $\mathbf{e}_3 \wedge \mathbf{e}_1 = -\mathbf{e}_1 \wedge \mathbf{e}_3$ and $\mathbf{e}_3 \wedge \mathbf{e}_2 = -\mathbf{e}_2 \wedge \mathbf{e}_3$ (Lemma 14.8.1 (b)). The coefficients $8, -1, -20$ are the three 2×2 minors of the first two columns of $\mathbf{A}$, on rows $\{1,2\}, \{1,3\}, \{2,3\}$ — a pattern the last part of this section explains. Doing the same for the other two column pairs gives

$$[\Lambda^2 T] = \begin{pmatrix} 8 & 2 & -11 \\ -1 & -13 & -5 \\ -20 & -5 & 2 \end{pmatrix},$$

whose determinant is 2601. Since $\det \mathbf{A} = -51$, this is $(\det \mathbf{A})^2$.

Quick check. In the example, why is $\Lambda^2 T$ **not** multiplication by a scalar, while $\Lambda^3 T$ is?

Solution. $\dim \Lambda^2 \mathbb{Q}^3 = \binom{3}{2} = 3$ by Theorem 14.8.5, and the displayed matrix is not a scalar multiple of $\mathbf{I}_3$, so $\Lambda^2 T$ is an operator on a three-dimensional space with no reason to be scalar. But $\dim \Lambda^3 \mathbb{Q}^3 = \binom{3}{3} = 1$, and every linear operator on a one-dimensional space is multiplication by a scalar. Being a line is what makes the top power special.

14.9.3 The top exterior power

That last observation is the whole theorem. When k equals $\dim V$, the space $\Lambda^k V$ is a line, an operator on a line is a scalar, and the scalar can be read off by feeding in a basis.

Theorem 14.9.3 — The Determinant Is the Top Exterior Power

Let V be a vector space over F with $\dim V = n \geq 1$, and let $T \in \mathcal{L}(V)$. Then $\dim \Lambda^n V = 1$, and $\Lambda^n T$ is multiplication by $\det T$:

$$\Lambda^n T(\omega) = (\det T)\,\omega \qquad \text{for every } \omega \in \Lambda^n V.$$

Equivalently, for all $\mathbf{v}_1, \ldots, \mathbf{v}_n \in V$,

$$T\mathbf{v}_1 \wedge \cdots \wedge T\mathbf{v}_n = (\det T)\,\mathbf{v}_1 \wedge \cdots \wedge \mathbf{v}_n. \tag{14.9.1}$$

Idea. Three moves. ① $\Lambda^n V$ is one-dimensional, so $\Lambda^n T$ is multiplication by one unknown scalar c. ② To find c, evaluate on a basis wedge $\mathbf{v}_1 \wedge \cdots \wedge \mathbf{v}_n$ and expand each $T\mathbf{v}_j$ in the basis. ③ The expansion produces one term for every function from slots to basis indices; the non-injective ones die because a wedge with a repeat is zero, and what survives is a sum over permutations with signs — the Leibniz formula, arriving on its own.

Proof. Fix a basis $\mathcal{B} = (\mathbf{v}_1, \dots, \mathbf{v}_n)$ of V. By Corollary 14.8.6, $\dim \Lambda^n V = 1$ with basis the single wedge $\omega_0 = \mathbf{v}_1 \wedge \cdots \wedge \mathbf{v}_n$. Since $\Lambda^n T$ is a linear operator on a one-dimensional space, there is a unique $c \in F$ with $\Lambda^n T(\omega_0) = c\,\omega_0$, and then $\Lambda^n T(a\omega_0) = ac\,\omega_0$ for every $a \in F$, so $\Lambda^n T = c$ id on all of $\Lambda^n V$.

It remains to show $c = \det T$. Let $\mathbf{A} = [T]_{\mathcal{B}}^{\mathcal{B}}$ have entries a_{ij}, so that $T\mathbf{v}_j = \sum_{i=1}^{n} a_{ij}\mathbf{v}_i$ (Definition 3.6.1). The wedge of n vectors is linear in each slot, so expanding slot by slot gives one term for each function $\varphi\colon \{1, \dots, n\} \to \{1, \dots, n\}$:

$$T\mathbf{v}_1 \wedge \cdots \wedge T\mathbf{v}_n = \sum_{\varphi} a_{\varphi(1)1} \cdots a_{\varphi(n)n}\, \mathbf{v}_{\varphi(1)} \wedge \cdots \wedge \mathbf{v}_{\varphi(n)}.$$

If φ is not injective, two slots hold the same vector and the wedge is $\mathbf{0}$. A non-injective φ is possible only because the domain and codomain are finite of the same size, so the surviving φ are exactly the bijections, that is, the permutations $\sigma \in S_n$. For those, Lemma 14.8.1 (b) gives $\mathbf{v}_{\sigma(1)} \wedge \cdots \wedge \mathbf{v}_{\sigma(n)} = \operatorname{sgn}(\sigma)\,\omega_0$. Therefore

$$\Lambda^n T(\omega_0) = \Big(\sum_{\sigma \in S_n} \operatorname{sgn}(\sigma)\, a_{\sigma(1)1} \cdots a_{\sigma(n)n} \Big) \omega_0,$$

and the bracket is $\det \mathbf{A}$ by Definition 6.4.1, which is $\det T$ by Definition 6.5.1. So $c = \det T$.

For the last display, note that both sides of Eq. 14.9.1 are n-linear in $(\mathbf{v}_1, \dots, \mathbf{v}_n)$ and agree when the list is the basis $\mathcal{B}$; but in fact no extra argument is needed, since $\mathbf{v}_1 \wedge \cdots \wedge \mathbf{v}_n \in \Lambda^n V$ for **any** list, and the first display applies to it. This proves the theorem. ∎

Warning. **Only the top power is a line.** For $1 \le k < n$ the operator $\Lambda^k T$ is not multiplication by a scalar in general: Example (The second exterior power of a 3×3 matrix) exhibits a $\Lambda^2 T$ with three different diagonal entries. The determinant appears because $\binom{n}{n} = 1$, not because exterior powers are scalars.

Warning. **A map between different spaces still has no determinant.** If $T\colon V \to W$ is linear with $\dim V = \dim W = n$, then $\Lambda^n T$ is a linear map between two **different** one-dimensional spaces, and there is no scalar attached to it until bases of $\Lambda^n V$ and $\Lambda^n W$ are chosen. Changing the basis of $\Lambda^n W$ alone rescales the number arbitrarily. This is the same obstruction Chapter 6 recorded after Definition 6.5.1, now visible as the failure of a line to have a canonical generator.

Quick check. Let T be the operator on F^3 with $T\mathbf{e}_1 = \mathbf{e}_2$, $T\mathbf{e}_2 = \mathbf{e}_3$ and $T\mathbf{e}_3 = \mathbf{e}_1$. Read $\det T$ off Eq. 14.9.1, without writing down a matrix.

Solution. $T\mathbf{e}_1 \wedge T\mathbf{e}_2 \wedge T\mathbf{e}_3 = \mathbf{e}_2 \wedge \mathbf{e}_3 \wedge \mathbf{e}_1$. The permutation carrying $(1, 2, 3)$ to $(2, 3, 1)$ is a 3-cycle, of sign $+1$ (Proposition 6.3.4), so by Lemma 14.8.1 (b) this equals $\mathbf{e}_1 \wedge \mathbf{e}_2 \wedge \mathbf{e}_3$. Comparing with Eq. 14.9.1 on the non-zero element $\mathbf{e}_1 \wedge \mathbf{e}_2 \wedge \mathbf{e}_3$ gives $\det T = 1$.

14.9.4 What the third construction adds

It is worth saying plainly, because the temptation to oversell a slick construction is real.

It adds no new value. The scalar produced in the proof is the Leibniz sum, arrived at by the same expansion that proved Theorem 6.4.2 in Chapter 6: expand multilinearly, discard the terms with a repeated basis vector, sort the survivors and collect signs. Anyone who has read Chapter 6 §04 has read that computation. The exterior power did not compute the determinant; it stored the same computation in a different place.

It adds no faster method. Nothing here helps evaluate a determinant. Elimination remains the way to do that (Example (A 4×4 Determinant by Elimination)).

What it does add is that det **is a map, not just a number.** Chapter 6 defined $\det \mathbf{A}$ by a formula in the entries and then had to *prove* that operators inherit it: the formula depends on a basis, so Corollary 6.5.7 was needed before Definition 6.5.1 could be written down. Here $\Lambda^n T$ is defined with no basis in sight, and the scalar exists because $\Lambda^n V$ is a line. Basis-independence is not a theorem about the determinant; it is the absence of any choice to be independent of. One honest qualification: the route is not self-contained. Theorem 14.8.5, which is what makes $\Lambda^n V$ a line in the first place, proves independence with a $k \times k$ determinant, and the identification of the scalar with $\det T$ goes through Definition 6.5.1. Chapter 6 is not being replaced here; it is being re-read.

And from that, multiplicativity is free.

Corollary 14.9.4 — Multiplicativity and Invertibility, from Functoriality

Let $\dim V = n \geq 1$ and $S, T \in \mathcal{L}(V)$.

(a) $\det(ST) = \det S \det T$, and $\det \mathrm{id}_V = 1$.

(b) T is invertible if and only if $\det T \neq 0$.

Proof.

(a) By Theorem 14.9.2, $\Lambda^n(ST) = (\Lambda^n S)(\Lambda^n T)$. By Theorem 14.9.3 all three maps are multiplications by scalars on the line $\Lambda^n V$, namely by $\det(ST)$, $\det S$ and $\det T$; and multiplication by $\det T$ followed by multiplication by $\det S$ is multiplication by $\det S \det T$. Two scalar multiplications on a non-zero space are equal only if the scalars are, so $\det(ST) = \det S \det T$. Likewise $\Lambda^n(\mathrm{id}_V) = \mathrm{id}$, so $\det \mathrm{id}_V = 1$.

(b) ($\Rightarrow$) If T is invertible, apply (a) to $TT^{-1} = \mathrm{id}_V$: then $\det T \cdot \det(T^{-1}) = 1$, so $\det T \neq 0$. ($\Leftarrow$) Suppose T is not invertible. Then T is not injective, so $\ker T \neq \{\mathbf{0}\}$; choose $\mathbf{v}_1 \in \ker T$ with $\mathbf{v}_1 \neq \mathbf{0}$ and extend to a basis $(\mathbf{v}_1, \ldots, \mathbf{v}_n)$ of V (Theorem 1.6.5). Since $T\mathbf{v}_1 = \mathbf{0}$ and the wedge is linear in its first slot, $T\mathbf{v}_1 \wedge \cdots \wedge T\mathbf{v}_n = \mathbf{0}$. By Eq. 14.9.1 this is $(\det T)\, \mathbf{v}_1 \wedge \cdots \wedge \mathbf{v}_n$, and the wedge of a basis is non-zero (Theorem 14.8.7), so $\det T = 0$.

■

Part (b) is the promise Theorem 14.8.7 made: the test "is this list independent?" and the test "is this determinant non-zero?" are the same test, once the determinant is read as an induced

map.

Compare the work this replaces. Chapter 6 proved Theorem 6.5.4 by fixing $\mathbf{A}$, checking that $\mathbf{B} \mapsto \det(\mathbf{AB})$ is alternating and n-linear in the columns of $\mathbf{B}$, and applying uniqueness. That proof is short and correct; what the present one shows is that the content is not really about determinants at all. Multiplicativity is the statement that Λ^n turns composition into composition — and Λ^n does that for the same reason that Λ^k does it for every k, where no scalar is available and no multiplicativity statement can even be phrased.

> *Remark.* What is **not** improved: Theorem 6.4.5. The identity $\det \mathbf{A}^\top = \det \mathbf{A}$ is a statement about rows versus columns, and Λ^n sees only the map T, which has no rows. Chapter 6's proof, reindexing the Leibniz sum by σ^{-1}, remains the natural one.

14.9.5 The coordinates of a wedge

The example above produced the minors of a matrix as the coefficients of a wedge, apparently by accident. It was not an accident, and the general statement is the bridge between this chapter and Chapter 6 §07.

Fix $n \geq 1$, write $[n] = \{1, \dots, n\}$ as Chapter 6 §07 does, and recall the notation of Definition 6.7.1: for $\mathbf{A} \in M_{n\times k}(F)$ and a set $I = \{i_1 < \cdots < i_k\} \subseteq [n]$ of size k, the submatrix $\mathbf{A}_{I,[k]} \in M_k(F)$ keeps the rows in I and all k columns, and its determinant is a $k \times k$ minor of $\mathbf{A}$. Write

$$\mathbf{e}_I := \mathbf{e}_{i_1} \wedge \mathbf{e}_{i_2} \wedge \cdots \wedge \mathbf{e}_{i_k} \in \Lambda^k F^n,$$

so that the $\mathbf{e}_I$, over all k-element $I \subseteq [n]$, form the basis of Theorem 14.8.5.

Theorem 14.9.5 — The Coordinates of a Wedge Are the Minors

Let $1 \leq k \leq n$, let $\mathbf{v}_1, \dots, \mathbf{v}_k \in F^n$, and let $\mathbf{A} \in M_{n\times k}(F)$ be the matrix with these vectors as its columns. Then

$$\mathbf{v}_1 \wedge \mathbf{v}_2 \wedge \cdots \wedge \mathbf{v}_k = \sum_I \left(\det \mathbf{A}_{I,[k]}\right) \mathbf{e}_I,$$

the sum running over all subsets $I \subseteq [n]$ with $|I| = k$. That is, the coordinate of $\mathbf{v}_1 \wedge \cdots \wedge \mathbf{v}_k$ at $\mathbf{e}_I$ is the $k \times k$ minor of $\mathbf{A}$ on the rows I.

> *Idea.* The same expansion as in Theorem 14.9.3, but now the index functions run into a bigger set. An injective $\varphi\colon [k] \to [n]$ is a choice of image set I followed by an ordering of it, so the terms group into one bunch per I, and each bunch is a signed sum over S_k: a determinant of size k.

> *Proof.* Write $\mathbf{A} = (a_{ij})$, so $\mathbf{v}_j = \sum_{i=1}^n a_{ij}\mathbf{e}_i$. Expanding the wedge in each of its k slots gives one term per function $\varphi\colon [k] \to [n]$:
>
> $$\mathbf{v}_1 \wedge \cdots \wedge \mathbf{v}_k = \sum_{\varphi} a_{\varphi(1)1} \cdots a_{\varphi(k)k}\, \mathbf{e}_{\varphi(1)} \wedge \cdots \wedge \mathbf{e}_{\varphi(k)}.$$
>
> A non-injective φ repeats a basis vector, so its wedge is $\mathbf{0}$ and its term drops out. An injective φ is determined by its image $I = \{i_1 < \cdots < i_k\}$ together with the permutation $\sigma \in S_k$ defined by $\varphi(j) = i_{\sigma(j)}$; conversely every pair (I, σ) arises from exactly one

injective φ. For such a φ, Lemma 14.8.1 (b) gives

$$\mathbf{e}_{\varphi(1)} \wedge \cdots \wedge \mathbf{e}_{\varphi(k)} = \mathbf{e}_{i_{\sigma(1)}} \wedge \cdots \wedge \mathbf{e}_{i_{\sigma(k)}} = \operatorname{sgn}(\sigma)\, \mathbf{e}_I.$$

Grouping the terms by I therefore gives

$$\mathbf{v}_1 \wedge \cdots \wedge \mathbf{v}_k = \sum_I \Big(\sum_{\sigma \in S_k} \operatorname{sgn}(\sigma)\, a_{i_{\sigma(1)}1} \cdots a_{i_{\sigma(k)}k} \Big) \mathbf{e}_I.$$

By Definition 6.7.1 the (p,q)-entry of $\mathbf{A}_{I,[k]}$ is $a_{i_p q}$, so the inner sum is exactly the Leibniz sum of Definition 6.4.1 for the $k \times k$ matrix $\mathbf{A}_{I,[k]}$, that is, $\det \mathbf{A}_{I,[k]}$. This proves the theorem.

■

Example. (A wedge of two vectors in four-dimensional space)

In $\mathbb{Q}^4$, let $\mathbf{v}_1 = (1,0,2,1)$ and $\mathbf{v}_2 = (0,1,1,3)$. Write $\mathbf{v}_1 \wedge \mathbf{v}_2$ in the basis of $\Lambda^2 \mathbb{Q}^4$.

Solution. Let $\mathbf{A} \in M_{4\times 2}(\mathbb{Q})$ have these two vectors as its columns, so that $\mathbf{A}_{\{1,2\},[2]} = \left(\begin{smallmatrix} 1 & 0 \\ 0 & 1 \end{smallmatrix}\right)$ and the other five 2×2 submatrices read off the same way. Their determinants are

$$\det \mathbf{A}_{\{1,2\}} = 1, \quad \det \mathbf{A}_{\{1,3\}} = 1, \quad \det \mathbf{A}_{\{1,4\}} = 3,$$
$$\det \mathbf{A}_{\{2,3\}} = -2, \quad \det \mathbf{A}_{\{2,4\}} = -1, \quad \det \mathbf{A}_{\{3,4\}} = 5,$$

abbreviating $\mathbf{A}_{I,[2]}$ to $\mathbf{A}_I$. By Theorem 14.9.5,

$$\mathbf{v}_1 \wedge \mathbf{v}_2 = \mathbf{e}_{12} + \mathbf{e}_{13} + 3\,\mathbf{e}_{14} - 2\,\mathbf{e}_{23} - \mathbf{e}_{24} + 5\,\mathbf{e}_{34}.$$

As a check, some coordinate is non-zero, so $\mathbf{v}_1 \wedge \mathbf{v}_2 \neq \mathbf{0}$, so $(\mathbf{v}_1, \mathbf{v}_2)$ is linearly independent by Theorem 14.8.7 — which is visible directly, since neither vector is a multiple of the other.

That check generalizes at once, and what comes out is a theorem of Chapter 6.

Corollary 14.9.6 — Independence via Minors

Let $\mathbf{v}_1, \ldots, \mathbf{v}_k \in F^n$ and let $\mathbf{A} \in M_{n\times k}(F)$ have these vectors as its columns. Then $(\mathbf{v}_1, \ldots, \mathbf{v}_k)$ is linearly independent if and only if some $k \times k$ minor of $\mathbf{A}$ is non-zero.

Proof. By Theorem 14.8.7 the list is independent exactly when $\mathbf{v}_1 \wedge \cdots \wedge \mathbf{v}_k \neq \mathbf{0}$. By Theorem 14.9.5 the coordinates of that wedge in the basis $(\mathbf{e}_I)$ of Theorem 14.8.5 are the $k \times k$ minors of $\mathbf{A}$, and a vector is $\mathbf{0}$ exactly when all of its coordinates in a basis vanish. (For $k > n$ both sides fail: $\Lambda^k F^n = \{\mathbf{0}\}$ and $\mathbf{A}$ has no $k \times k$ submatrix.)

■

This is Theorem 6.7.1 in the case of full column rank, and the general case follows from it: $\operatorname{rank} \mathbf{A}$ is the largest number of independent columns, hence the largest k for which some k

columns carry a non-zero $k \times k$ minor. Chapter 6 proved it with two careful steps involving pivot columns and row rank. The wedge proves it by naming the coordinates.

14.9.6 Laplace expansion

Cofactor expansion also comes out of the coordinate theorem, once the wedge of $n-1$ vectors is available. The route is: pull the chosen column out of the wedge, recognize what is left as an element of $\Lambda^{n-1}F^n$ whose coordinates are the $(n-1)\times(n-1)$ minors, and wedge $\mathbf{e}_i$ back on.

Corollary 14.9.7 — Cofactor Expansion, from a Wedge

Let $n \geq 2$, let $\mathbf{A} \in M_n(F)$ with minors M_{ij} as in Definition 6.6.1, and fix $j \in [n]$. Then

$$\det \mathbf{A} = \sum_{i=1}^{n} (-1)^{i+j} a_{ij} M_{ij}.$$

Idea. Write $\det \mathbf{A}$ as the wedge of the columns. Linearity in the j-th slot splits it into n pieces, one per i, with $\mathbf{e}_i$ sitting in that slot. Move $\mathbf{e}_i$ to the front at a cost of $(-1)^{j-1}$; the remaining $n-1$ columns form a wedge whose coordinates are the minors of the matrix with column j deleted, and wedging $\mathbf{e}_i$ on kills every coordinate except the one whose index set misses i.

Proof. Let $\mathbf{a}_1, \dots, \mathbf{a}_n$ be the columns of $\mathbf{A}$ and $\omega_0 = \mathbf{e}_1 \wedge \cdots \wedge \mathbf{e}_n$. By Theorem 14.9.3 applied to the operator $\mathbf{x} \mapsto \mathbf{A}\mathbf{x}$, whose matrix in the standard basis is $\mathbf{A}$,

$$\mathbf{a}_1 \wedge \cdots \wedge \mathbf{a}_n = (\det \mathbf{A})\, \omega_0.$$

Substituting $\mathbf{a}_j = \sum_{i=1}^{n} a_{ij}\mathbf{e}_i$ and using linearity in slot j,

$$(\det \mathbf{A})\, \omega_0 = \sum_{i=1}^{n} a_{ij}\, \mathbf{a}_1 \wedge \cdots \wedge \underset{\text{slot } j}{\mathbf{e}_i} \wedge \cdots \wedge \mathbf{a}_n.$$

Fix i. Moving $\mathbf{e}_i$ from slot j to the front means $j-1$ exchanges of neighbors, so by Lemma 14.8.1 (b) the i-th wedge above equals $(-1)^{j-1}\, \varepsilon_{\mathbf{e}_i}(\eta)$, where $\eta = \mathbf{a}_1 \wedge \cdots \wedge \widehat{\mathbf{a}_j} \wedge \cdots \wedge \mathbf{a}_n \in \Lambda^{n-1}F^n$ omits the j-th column, and $\varepsilon_{\mathbf{e}_i}$ is the map of Lemma 14.9.1.

Let $\mathbf{B} \in M_{n\times(n-1)}(F)$ be $\mathbf{A}$ with column j deleted. By Theorem 14.9.5,

$$\eta = \sum_{l=1}^{n} \big(\det \mathbf{B}_{[n]\setminus\{l\},\,[n-1]}\big)\, \mathbf{e}_{[n]\setminus\{l\}},$$

since the $(n-1)$-element subsets of $[n]$ are exactly the complements of single elements. Deleting row l from $\mathbf{B}$ deletes row l and column j from $\mathbf{A}$, so $\det \mathbf{B}_{[n]\setminus\{l\},[n-1]} = M_{lj}$ by Definition 6.6.1. Now apply $\varepsilon_{\mathbf{e}_i}$. For $l \neq i$ the index set $[n]\setminus\{l\}$ contains i, so $\mathbf{e}_i \wedge \mathbf{e}_{[n]\setminus\{l\}}$ repeats $\mathbf{e}_i$ and vanishes; for $l = i$, moving $\mathbf{e}_i$ into its place costs $i-1$ exchanges, so $\mathbf{e}_i \wedge \mathbf{e}_{[n]\setminus\{i\}} = (-1)^{i-1}\omega_0$ by Lemma 14.8.1 (b). Hence $\varepsilon_{\mathbf{e}_i}(\eta) = (-1)^{i-1} M_{ij}\, \omega_0$, and

$$(\det \mathbf{A})\, \omega_0 = \sum_{i=1}^{n} a_{ij} (-1)^{j-1} (-1)^{i-1} M_{ij}\, \omega_0.$$

Since $(-1)^{i+j-2} = (-1)^{i+j}$ and $\omega_0 \neq \mathbf{0}$ (Theorem 14.8.7), comparing coefficients gives the stated formula.

■

This is Theorem 6.6.1 (a). The row version follows from it by Theorem 6.4.5, exactly as in Chapter 6. The gain is again structural rather than practical: the sign $(-1)^{i+j}$, which in Chapter 6 arrived from a careful count of row and column moves, is here the price of two reversals, $j-1$ in one direction and $i-1$ in the other.

14.9.7 Exercises

14.9.7.1 A. Check your understanding

Exercise A1.

(a) State the defining property of $\Lambda^k T$, and say why a rule given on wedges needs an argument before it defines a map.

(b) State Theorem 14.9.3.

(c) Name one thing this section's construction of the determinant adds to Chapter 6's, and one thing it does not.

(d) True or false: for every $T \in \mathcal{L}(V)$ and every k, the map $\Lambda^k T$ is multiplication by a scalar. Justify your answer.

(e) What are the coordinates of $\mathbf{v}_1 \wedge \cdots \wedge \mathbf{v}_k$ in $\Lambda^k F^n$, in the basis $(\mathbf{e}_I)$?

Solution.

(a) $\Lambda^k T$ is the unique linear map $\Lambda^k V \to \Lambda^k W$ with $\Lambda^k T(\mathbf{v}_1 \wedge \cdots \wedge \mathbf{v}_k) = T\mathbf{v}_1 \wedge \cdots \wedge T\mathbf{v}_k$ (Definition 14.9.1). An element of $\Lambda^k V$ has many expressions as a sum of wedges, so a rule stated on wedges might assign two different values to one element; the universal property of Definition 14.8.2 removes the danger by producing the map from an alternating multilinear map upstairs.

(b) If $\dim V = n \geq 1$ and $T \in \mathcal{L}(V)$, then $\dim \Lambda^n V = 1$ and $\Lambda^n T(\omega) = (\det T)\omega$ for every $\omega \in \Lambda^n V$.

(c) It adds that the determinant is the induced map on a line, so that no basis and no similarity-invariance argument is needed to define $\det T$, and multiplicativity becomes Theorem 14.9.2. It does not add a new value, a new method of computation, or any improvement to $\det \mathbf{A}^\top = \det \mathbf{A}$.

(d) False. It is true when $k = n = \dim V$, and when $k > n$ for the trivial reason that $\Lambda^k V = \{\mathbf{0}\}$. For $1 \leq k < n$ it usually fails: see Example (The second exterior power of a 3×3 matrix), where $\Lambda^2 T$ has matrix with rows $(8, 2, -11)$, $(-1, -13, -5)$, $(-20, -5, 2)$, not a scalar matrix.

(e) The $k \times k$ minors of the matrix whose columns are $\mathbf{v}_1, \ldots, \mathbf{v}_k$: the coordinate at $\mathbf{e}_I$ is $\det \mathbf{A}_{I,[k]}$ (Theorem 14.9.5).

14.9.7.2 B. Practice

Exercise B1: A second exterior power.

Let $T\colon \mathbb{Q}^3 \to \mathbb{Q}^3$ have standard matrix

$$\mathbf{A} = \begin{pmatrix} 1 & 2 & 0 \\ 0 & 1 & 3 \\ 2 & 0 & 1 \end{pmatrix}.$$

Find the matrix of $\Lambda^2 T$ in the basis $(\mathbf{e}_1\wedge\mathbf{e}_2, \mathbf{e}_1\wedge\mathbf{e}_3, \mathbf{e}_2\wedge\mathbf{e}_3)$. Hence verify that $\det(\Lambda^2 T) = (\det T)^2$.

Solution. By Definition 14.9.1 and Theorem 14.9.5, the entry of $[\Lambda^2 T]$ in row I and column J is $\det \mathbf{A}_{I,J}$, with rows and columns indexed by $\{1,2\},\{1,3\},\{2,3\}$ in that order. Computing the nine 2×2 minors,

$$[\Lambda^2 T] = \begin{pmatrix} 1 & 3 & 6 \\ -4 & 1 & 2 \\ -2 & -6 & 1 \end{pmatrix}.$$

Its determinant is 169. Expanding $\det \mathbf{A}$ along the first column (Theorem 6.6.1) gives $1\cdot(1-0) + 2\cdot(6-0) = 13$, and $13^2 = 169$.

Exercise B2: Independence by minors.

In $\mathbb{Q}^4$, let $\mathbf{v}_1 = (1,2,0,1)$, $\mathbf{v}_2 = (0,1,1,1)$ and $\mathbf{v}_3 = (1,0,-2,-1)$. Compute the coordinates of $\mathbf{v}_1\wedge\mathbf{v}_2\wedge\mathbf{v}_3$ in $\Lambda^3\mathbb{Q}^4$, and hence determine whether the list is linearly independent. Justify your answer.

Solution. Let $\mathbf{A}\in M_{4\times 3}(\mathbb{Q})$ have these columns. By Theorem 14.9.5 the four coordinates are the 3×3 minors on the row sets $\{1,2,3\},\{1,2,4\},\{1,3,4\},\{2,3,4\}$. Computing them,

$$\det \mathbf{A}_{\{1,2,3\}} = \det \begin{pmatrix} 1 & 0 & 1 \\ 2 & 1 & 0 \\ 0 & 1 & -2 \end{pmatrix} = 0,$$

and the same for the other three: $\det \mathbf{A}_{\{1,2,4\}} = \det \mathbf{A}_{\{1,3,4\}} = \det \mathbf{A}_{\{2,3,4\}} = 0$. So $\mathbf{v}_1\wedge\mathbf{v}_2\wedge\mathbf{v}_3 = \mathbf{0}$, and by Theorem 14.8.7 the list is **dependent**. Indeed $\mathbf{v}_3 = \mathbf{v}_1 - 2\mathbf{v}_2$.

Exercise B3: Determinant of an inverse.

Let $\dim V = n \geq 1$ and let $T\in\mathcal{L}(V)$ be invertible. Using Theorem 14.9.2 and Theorem 14.9.3, and no formula for the determinant, prove that $\Lambda^n T$ is invertible and that $\det(T^{-1}) = (\det T)^{-1}$.

Solution. By Theorem 14.9.2, $(\Lambda^n T)(\Lambda^n T^{-1}) = \Lambda^n(TT^{-1}) = \Lambda^n(\mathrm{id}_V) = \mathrm{id}$, and symmetrically in the other order. So $\Lambda^n T$ is invertible with inverse $\Lambda^n T^{-1}$. By Theorem 14.9.3 these two maps are multiplication by $\det T$ and by $\det(T^{-1})$ on the line $\Lambda^n V$, and their composite is multiplication by $\det T\cdot\det(T^{-1})$, which equals id. Since $\Lambda^n V \neq \{\mathbf{0}\}$, this forces $\det T\cdot\det(T^{-1}) = 1$. In particular $\det T \neq 0$, and $\det(T^{-1}) = (\det T)^{-1}$.

14.9.7.3 C. Going deeper

Exercise C1: The trace of an exterior power.

Let $\mathbf{A} \in M_n(F)$ and $1 \le k \le n$, and let $T\colon F^n \to F^n$ be $\mathbf{x} \mapsto \mathbf{A}\mathbf{x}$.

(a) Prove that the matrix of $\Lambda^k T$ in the basis $(\mathbf{e}_I)$ has (I,J)-entry $\det \mathbf{A}_{I,J}$.

(b) Deduce that $\operatorname{tr}(\Lambda^k T)$ is the sum of the $\binom{n}{k}$ **principal** $k \times k$ minors of $\mathbf{A}$, those with $I = J$.

(c) Compute $\operatorname{tr}(\Lambda^2 T)$ for the matrix $\mathbf{A}$ of Example (The second exterior power of a 3 × 3 matrix), and check it against the matrix found there.

Solution.

(a) Column $J = \{j_1 < \cdots < j_k\}$ of the matrix is the coordinate vector of $\Lambda^k T(\mathbf{e}_J) = \mathbf{a}_{j_1} \wedge \cdots \wedge \mathbf{a}_{j_k}$, where $\mathbf{a}_j = T\mathbf{e}_j$ is the j-th column of $\mathbf{A}$ (Definition 14.9.1). By Theorem 14.9.5 applied to the $n \times k$ matrix with columns $\mathbf{a}_{j_1}, \dots, \mathbf{a}_{j_k}$, the coordinate at $\mathbf{e}_I$ is the determinant of its submatrix on rows I, which is $\det \mathbf{A}_{I,J}$ (Definition 6.7.1).

(b) The trace is the sum of the diagonal entries, that is, of the entries with $I = J$, and by (a) those are the principal minors $\det \mathbf{A}_{I,I}$.

(c) The three principal 2×2 minors of $\mathbf{A}$ are $\det\left(\begin{smallmatrix} 2 & 1 \\ 0 & 4 \end{smallmatrix}\right) = 8$, $\det\left(\begin{smallmatrix} 2 & 3 \\ 5 & 1 \end{smallmatrix}\right) = -13$ and $\det\left(\begin{smallmatrix} 4 & 1 \\ 2 & 1 \end{smallmatrix}\right) = 2$. Their sum is -3, which is the sum of the diagonal entries $8, -13, 2$ of the matrix computed in Example (The second exterior power of a 3 × 3 matrix).

Exercise C2: Cauchy–Binet from a wedge.

Let $m \le n$, let $\mathbf{A} \in M_{m\times n}(F)$ and $\mathbf{B} \in M_{n\times m}(F)$, and let $T_{\mathbf{A}}\colon F^n \to F^m$ and $T_{\mathbf{B}}\colon F^m \to F^n$ be the associated maps.

(a) Show that $\Lambda^m T_{\mathbf{B}}(\mathbf{e}_1 \wedge \cdots \wedge \mathbf{e}_m) = \sum_J (\det \mathbf{B}_{J,[m]})\, \mathbf{e}_J$, the sum over m-element subsets $J \subseteq [n]$.

(b) Show that $\Lambda^m T_{\mathbf{A}}(\mathbf{e}_J) = (\det \mathbf{A}_{[m],J})\, \mathbf{e}_1 \wedge \cdots \wedge \mathbf{e}_m$ for each such J.

(c) Hence deduce the Cauchy–Binet formula $\det(\mathbf{A}\mathbf{B}) = \sum_J \det \mathbf{A}_{[m],J} \det \mathbf{B}_{J,[m]}$ (Theorem 6.7.2).

Solution.

(a) $\Lambda^m T_{\mathbf{B}}(\mathbf{e}_1 \wedge \cdots \wedge \mathbf{e}_m) = \mathbf{B}\mathbf{e}_1 \wedge \cdots \wedge \mathbf{B}\mathbf{e}_m$ by Definition 14.9.1, and the columns of $\mathbf{B}$ are $\mathbf{B}\mathbf{e}_1, \dots, \mathbf{B}\mathbf{e}_m$. Apply Theorem 14.9.5 in F^n with $k = m$.

(b) Writing $J = \{j_1 < \cdots < j_m\}$, we get $\Lambda^m T_{\mathbf{A}}(\mathbf{e}_J) = \mathbf{A}\mathbf{e}_{j_1} \wedge \cdots \wedge \mathbf{A}\mathbf{e}_{j_m}$, a wedge of m vectors of F^m. By Theorem 14.9.5 with $k = m = n$ there is only one index set, $[m]$ itself, and the coefficient is the determinant of the matrix with those columns, which is $\mathbf{A}_{[m],J}$.

(c) By Theorem 14.9.2, $\Lambda^m(T_{\mathbf{A}} T_{\mathbf{B}}) = (\Lambda^m T_{\mathbf{A}})(\Lambda^m T_{\mathbf{B}})$. The map $T_{\mathbf{A}} T_{\mathbf{B}}$ is the operator on F^m with matrix $\mathbf{A}\mathbf{B}$, so by Theorem 14.9.3 the left side sends $\mathbf{e}_1 \wedge \cdots \wedge \mathbf{e}_m$ to $\det(\mathbf{A}\mathbf{B})\, \mathbf{e}_1 \wedge \cdots \wedge \mathbf{e}_m$. By (a) and then (b), the right side sends it to $\sum_J \det \mathbf{B}_{J,[m]} \det \mathbf{A}_{[m],J}\, \mathbf{e}_1 \wedge \cdots \wedge \mathbf{e}_m$. Comparing coefficients on the basis vector $\mathbf{e}_1 \wedge \cdots \wedge \mathbf{e}_m \neq \mathbf{0}$ gives the formula.

Exercise C3: Exterior powers of an injection.

Let $T\colon V \to W$ be an **injective** linear map between finite-dimensional spaces and let $1 \le k \le \dim V$. Prove that $\Lambda^k T$ is injective. Is the analogous statement true with "injective" replaced by "surjective"?

Hint: choose a basis of V and use Theorem 14.8.5 in both spaces.

Solution. Let $(\mathbf{v}_1, \dots, \mathbf{v}_m)$ be a basis of V. Since T is injective, $(T\mathbf{v}_1, \dots, T\mathbf{v}_m)$ is linearly independent in W, so it extends to a basis $(T\mathbf{v}_1, \dots, T\mathbf{v}_m, \mathbf{w}_{m+1}, \dots)$ of W (Theorem 1.6.5). By Theorem 14.8.5, the wedges $\mathbf{v}_{i_1} \wedge \cdots \wedge \mathbf{v}_{i_k}$ over increasing tuples form a basis of $\Lambda^k V$, and $\Lambda^k T$ sends each of them to $T\mathbf{v}_{i_1} \wedge \cdots \wedge T\mathbf{v}_{i_k}$, which is one of the basis vectors of $\Lambda^k W$ provided by the extended basis. So $\Lambda^k T$ carries a basis to a linearly independent list, hence is injective.

Yes for surjective as well, and more cheaply: if T is surjective then every $\mathbf{w}_1 \wedge \cdots \wedge \mathbf{w}_k$ equals $T\mathbf{v}_1 \wedge \cdots \wedge T\mathbf{v}_k$ for preimages $\mathbf{v}_i$, so the image of $\Lambda^k T$ contains a spanning set of $\Lambda^k W$ (Theorem 14.8.5) and is therefore all of it.

14.10 The Exterior Algebra, and Clifford at Last

The exterior powers have so far been used one degree at a time, and the wedge of two of them has had nowhere to live: $\Lambda^2 V$ and $\Lambda^3 V$ are different spaces, and until now nothing said what $(\mathbf{u}\wedge\mathbf{w})\wedge\mathbf{x}$ means as an operation. Stacking them fixes that, exactly as stacking the tensor powers produced the tensor algebra (Definition 14.6.2) and stacking the symmetric powers produced the symmetric algebra (Definition 14.7.3). The result is a 2^n-dimensional algebra, and it is the last object this chapter needs. With it we can finally pay the debt Chapter 13 recorded in writing: a Clifford algebra of (V, q) exists, and its dimension is 2^n.

Throughout, F is a field and V is a vector space over F with $\dim V = n$. From the subsection on decomposability on, $\operatorname{char} F \neq 2$, because Definition 13.12.2 assumes it. We use the exterior powers of Definition 14.8.2 with their universal property for alternating maps, their bases of increasing wedges (Theorem 14.8.5), the test Theorem 14.8.7, and the reordering rule Lemma 14.8.1 (b) of the previous section.

14.10.1 Stacking the exterior powers

The pieces are already in place; only the multiplication is missing. The pattern is the one Proposition 14.7.4 used for symmetric powers: a product of a k-fold wedge and an l-fold wedge ought to be the $(k + l)$-fold wedge of all the vectors, and the only thing to check is that this depends on the two factors and not on the way each was written.

Proposition 14.10.1 — The Wedge of Two Exterior Powers

Let $k, l \geq 1$. There is a **unique** bilinear map

$$\Lambda^k V \times \Lambda^l V \to \Lambda^{k+l} V, \qquad (\omega, \eta) \mapsto \omega \wedge \eta,$$

such that for all $\mathbf{u}_1, \ldots, \mathbf{u}_k, \mathbf{w}_1, \ldots, \mathbf{w}_l \in V$,

$$(\mathbf{u}_1 \wedge \cdots \wedge \mathbf{u}_k) \wedge (\mathbf{w}_1 \wedge \cdots \wedge \mathbf{w}_l) = \mathbf{u}_1 \wedge \cdots \wedge \mathbf{u}_k \wedge \mathbf{w}_1 \wedge \cdots \wedge \mathbf{w}_l.$$

Idea. Freeze the second factor's vectors and use the universal property once, in the first k slots; that turns the left-hand factor into an element of $\Lambda^k V$. Then let the second factor's vectors vary: what we have built depends on them l-linearly, and vanishes as soon as two of them coincide, with values in a space of linear maps, so the universal property applies a second time.

Proof. Fix $\mathbf{w}_1, \ldots, \mathbf{w}_l \in V$. The map $V^k \to \Lambda^{k+l} V$ given by

$$(\mathbf{u}_1, \ldots, \mathbf{u}_k) \mapsto \mathbf{u}_1 \wedge \cdots \wedge \mathbf{u}_k \wedge \mathbf{w}_1 \wedge \cdots \wedge \mathbf{w}_l$$

is k-linear, since the wedge of $k+l$ vectors is linear in each slot and the last l are frozen, and alternating, since a repeat among the first k arguments is a repeat among all $k+l$. By Definition 14.8.2 it induces a unique linear map

$$R(\mathbf{w}_1, \ldots, \mathbf{w}_l) \colon \Lambda^k V \to \Lambda^{k+l} V$$

with $R(\mathbf{w}_1, \ldots, \mathbf{w}_l)(\mathbf{u}_1 \wedge \cdots \wedge \mathbf{u}_k)$ equal to the displayed wedge.

Now let the $\mathbf{w}$'s vary. The assignment $(\mathbf{w}_1, \ldots, \mathbf{w}_l) \mapsto R(\mathbf{w}_1, \ldots, \mathbf{w}_l)$, with values in the vector space $\mathcal{L}(\Lambda^k V, \Lambda^{k+l} V)$, is l-linear and alternating: two linear maps on $\Lambda^k V$ are equal as soon as they agree on the wedges $\mathbf{u}_1 \wedge \cdots \wedge \mathbf{u}_k$, which span $\Lambda^k V$ (Theorem 14.8.5), and on those the required identities are the linearity and the alternation of the wedge of $k+l$ vectors in its last l slots. So Definition 14.8.2 applies again and gives a unique linear map

$$\Lambda^l V \to \mathcal{L}(\Lambda^k V, \Lambda^{k+l} V), \qquad \mathbf{w}_1 \wedge \cdots \wedge \mathbf{w}_l \mapsto R(\mathbf{w}_1, \ldots, \mathbf{w}_l).$$

Reading a linear map into a space of linear maps as a bilinear map gives the required product, with the stated values. It is unique because the wedges span both factors and a bilinear map is determined on a pair of spanning sets. This proves the proposition.

■

With the product in hand, the algebra assembles itself.

The exterior algebra is all the exterior powers at once, multiplied by wedging.

Definition 14.10.1 — Exterior Algebra

Let V be a vector space over F, with $\Lambda^0 V = F$ and $\Lambda^1 V = V$ as in Definition 14.8.2. The **exterior algebra**, or **Grassmann algebra**, of V is the vector space

$$\Lambda V := \bigoplus_{k \geq 0} \Lambda^k V,$$

whose elements are the sequences $x = (x_0, x_1, \dots)$ with $x_k \in \Lambda^k V$ and only finitely many x_k non-zero, with componentwise operations, and whose multiplication is

$$(x \wedge y)_m = \sum_{k+l=m} x_k \wedge y_l,$$

where $\wedge$ on the right is Proposition 14.10.1 for $k, l \geq 1$, and is scalar multiplication when $k = 0$ or $l = 0$. We identify each $\Lambda^k V$ with the sequences supported in position k, so that F and V are subspaces of ΛV, and call an element of $\Lambda^k V \subseteq \Lambda V$ **homogeneous of degree** k.

In words: an element of ΛV is a finite sum $x_0 + x_1 + \cdots + x_N$ of pieces of different degrees, the scalars sit inside as the degree-0 piece, and **the product adds degrees**. The finiteness clause is automatic here, since $\Lambda^k V = \{\mathbf{0}\}$ once $k > n$ (Theorem 14.8.5).

Theorem 14.10.2 — Structure of the Exterior Algebra

Let $\dim V = n$ with basis $(\mathbf{e}_1, \dots, \mathbf{e}_n)$. For a subset $S = \{i_1 < \cdots < i_k\} \subseteq [n]$ write $\mathbf{e}_S = \mathbf{e}_{i_1} \wedge \cdots \wedge \mathbf{e}_{i_k}$, with $\mathbf{e}_\emptyset = 1$. Then

(a) ΛV is an associative unital F-algebra with identity $1 \in \Lambda^0 V = F$, and $\Lambda^k V \wedge \Lambda^l V \subseteq \Lambda^{k+l} V$.

(b) The 2^n elements $\mathbf{e}_S$, one for each subset $S \subseteq [n]$, form a basis of ΛV. In particular $\dim_F \Lambda V = 2^n$.

(c) ΛV is generated as an algebra by 1 and V.

Proof.

(a) Bilinearity of the product holds componentwise, by Proposition 14.10.1. For associativity, both $(x \wedge y) \wedge z$ and $x \wedge (y \wedge z)$ are trilinear in (x, y, z), so it is enough to compare them on homogeneous elements, and then on the wedges of vectors, which span each $\Lambda^k V$ for $k \geq 1$ (Theorem 14.8.5) while $\Lambda^0 V$ is spanned by 1. On those both sides are the single wedge of all the listed vectors in order, by the defining identity of Proposition 14.10.1 applied twice. The scalar 1 acts on each $\Lambda^k V$ as multiplication by 1, hence as the identity. The grading statement is built into the definition of the product.

(b) By Theorem 14.8.5 the $\mathbf{e}_S$ with $|S| = k$ form a basis of $\Lambda^k V$, and $\Lambda^k V = \{\mathbf{0}\}$ for $k > n$. A basis of a direct sum is the union of bases of the summands, so the $\mathbf{e}_S$ over all $S \subseteq [n]$ form a basis of ΛV. Their number is $\sum_{k=0}^{n} \binom{n}{k} = 2^n$, by the binomial theorem applied to $(1 + 1)^n$.

(c) Each $\mathbf{e}_S$ is a product of elements of V by the defining identity of the product, and the $\mathbf{e}_S$ span by (b).

■

The one structural fact that is not inherited from the tensor algebra is how the order of a product matters.

Theorem 14.10.3 — Graded Commutativity

Let $\omega \in \Lambda^k V$ and $\eta \in \Lambda^l V$. Then

$$\omega \wedge \eta = (-1)^{kl}\, \eta \wedge \omega.$$

In particular $\omega \wedge \omega = \mathbf{0}$ whenever k is **odd**, over every field.

Idea. Count the swaps. To turn $\mathbf{w}_1 \wedge \cdots \wedge \mathbf{w}_l \wedge \mathbf{u}_1 \wedge \cdots \wedge \mathbf{u}_k$ into $\mathbf{u}_1 \wedge \cdots \wedge \mathbf{u}_k \wedge \mathbf{w}_1 \wedge \cdots \wedge \mathbf{w}_l$, each of the k vectors $\mathbf{u}_i$ must cross each of the l vectors $\mathbf{w}_j$, and every crossing costs a sign.

Proof. Both sides are bilinear in (ω, η), so by Theorem 14.8.5 it suffices to take $\omega = \mathbf{u}_1 \wedge \cdots \wedge \mathbf{u}_k$ and $\eta = \mathbf{w}_1 \wedge \cdots \wedge \mathbf{w}_l$, and the cases $k = 0$ or $l = 0$ are scalar multiplication and are clear. The permutation of $\{1, \dots, k+l\}$ carrying the list $(\mathbf{w}_1, \dots, \mathbf{w}_l, \mathbf{u}_1, \dots, \mathbf{u}_k)$ to $(\mathbf{u}_1, \dots, \mathbf{u}_k, \mathbf{w}_1, \dots, \mathbf{w}_l)$ has exactly kl inversions, one for each pair consisting of a $\mathbf{u}$ and a $\mathbf{w}$, so its sign is $(-1)^{kl}$ (Definition 6.3.2). By Lemma 14.8.1 (b) the two wedges differ by that factor, which is the claim.

For the last sentence let k be odd and $\omega \in \Lambda^k V$. Write $\omega = \sum_S c_S\, \mathbf{e}_S$ in the basis of Theorem 14.10.2, the sum over the S with $|S| = k$. Then

$$\omega \wedge \omega = \sum_S \sum_T c_S c_T\, \mathbf{e}_S \wedge \mathbf{e}_T.$$

A term with $S = T$ has a repeated vector, so $\mathbf{e}_S \wedge \mathbf{e}_S = \mathbf{0}$. A pair $S \neq T$ occurs twice, and the two occurrences are $c_S c_T\, \mathbf{e}_S \wedge \mathbf{e}_T$ and $c_T c_S\, \mathbf{e}_T \wedge \mathbf{e}_S = -c_S c_T\, \mathbf{e}_S \wedge \mathbf{e}_T$, since $(-1)^{kl} = (-1)^{k^2} = -1$ for odd k. So the two cancel, and nothing divides by 2 anywhere.

■

Warning. **Graded commutative is not commutative.** In ΛF^2 we have $\mathbf{e}_1 \wedge \mathbf{e}_2 = -\mathbf{e}_2 \wedge \mathbf{e}_1$, and these are different elements unless $\operatorname{char} F = 2$. What is true in all degrees is only the signed rule. And the sign is $+1$ as soon as one of the degrees is even, so an element of $\Lambda^2 V$ commutes with everything, while two elements of $\Lambda^1 V = V$ anticommute.

Warning. $\omega \wedge \omega$ **need not be zero.** The identity $\mathbf{v} \wedge \mathbf{v} = \mathbf{0}$ is a statement about degree 1. For $\omega = \mathbf{e}_1 \wedge \mathbf{e}_2 + \mathbf{e}_3 \wedge \mathbf{e}_4$ in ΛF^4, a direct expansion gives $\omega \wedge \omega = 2\, \mathbf{e}_1 \wedge \mathbf{e}_2 \wedge \mathbf{e}_3 \wedge \mathbf{e}_4$, which is non-zero whenever $\operatorname{char} F \neq 2$. Squaring to zero is the privilege of odd degree.

Example. (The exterior algebra of a three-dimensional space)

Describe ΛF^3 completely, and compute $(\mathbf{e}_1 + \mathbf{e}_2 \wedge \mathbf{e}_3) \wedge (\mathbf{e}_2 + \mathbf{e}_1 \wedge \mathbf{e}_3)$.

Solution. By Theorem 14.10.2 it has dimension $2^3 = 8$, with basis

$$1; \quad \mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3; \quad \mathbf{e}_{12}, \mathbf{e}_{13}, \mathbf{e}_{23}; \quad \mathbf{e}_{123},$$

writing $\mathbf{e}_{ij}$ for $\mathbf{e}_i \wedge \mathbf{e}_j$ and $\mathbf{e}_{123}$ for $\mathbf{e}_1 \wedge \mathbf{e}_2 \wedge \mathbf{e}_3$. The degrees have dimensions $1, 3, 3, 1$. Every product of two elements of degree ≥ 2 lands in degree ≥ 4, hence is $\mathbf{0}$.

For the computation, expand by bilinearity into four products:

$$\begin{aligned} \mathbf{e}_1 \wedge \mathbf{e}_2 &= \mathbf{e}_{12}, \\ \mathbf{e}_1 \wedge (\mathbf{e}_1 \wedge \mathbf{e}_3) &= \mathbf{0} \quad \text{(repeated } \mathbf{e}_1\text{)}, \\ (\mathbf{e}_2 \wedge \mathbf{e}_3) \wedge \mathbf{e}_2 &= \mathbf{0} \quad \text{(repeated } \mathbf{e}_2\text{)}, \\ (\mathbf{e}_2 \wedge \mathbf{e}_3) \wedge (\mathbf{e}_1 \wedge \mathbf{e}_3) &= \mathbf{0} \quad \text{(degree 4)}. \end{aligned}$$

So the product is $\mathbf{e}_{12}$, while the reversed product is $-\mathbf{e}_{12}$ plus the same three zeros.

Quick check. In ΛF^4, what is $(\mathbf{e}_1 \wedge \mathbf{e}_2) \wedge (\mathbf{e}_2 \wedge \mathbf{e}_3)$, and what is $(\mathbf{e}_1 \wedge \mathbf{e}_2) \wedge (\mathbf{e}_3 \wedge \mathbf{e}_4)$?

Solution. The first is $\mathbf{e}_1 \wedge \mathbf{e}_2 \wedge \mathbf{e}_2 \wedge \mathbf{e}_3 = \mathbf{0}$, since $\mathbf{e}_2$ is repeated. The second is $\mathbf{e}_1 \wedge \mathbf{e}_2 \wedge \mathbf{e}_3 \wedge \mathbf{e}_4$, a basis vector of $\Lambda^4 F^4$, so it is non-zero. Wedging two 2-vectors gives zero exactly when the four vectors involved are dependent.

14.10.2 Decomposable elements

Section 2 warned that not every element of $V \otimes W$ is a simple tensor $\mathbf{v} \otimes \mathbf{w}$, and proved it with $\mathbf{e}_1 \otimes \mathbf{e}_1 + \mathbf{e}_2 \otimes \mathbf{e}_2$ (Example (A tensor that is not simple)). The same thing happens one floor up, and for the same reason: the simple objects form a low-dimensional cone inside a large space, and a sum of two of them usually escapes it.

Definition 14.10.2 — Decomposable Element

Let $k \geq 1$. An element $\omega \in \Lambda^k V$ is **decomposable**, or a **k-blade**, if there exist $\mathbf{v}_1, \ldots, \mathbf{v}_k \in V$ with

$$\omega = \mathbf{v}_1 \wedge \mathbf{v}_2 \wedge \cdots \wedge \mathbf{v}_k.$$

Examples. Every element of $\Lambda^1 V = V$ is decomposable, with $k = 1$; so is $\mathbf{0}$, being $\mathbf{v} \wedge \mathbf{v} \wedge \mathbf{v}_3 \wedge \cdots \wedge \mathbf{v}_k$; and so is every element of the line $\Lambda^n V$, since $c\,\mathbf{e}_1 \wedge \cdots \wedge \mathbf{e}_n = (c\mathbf{e}_1) \wedge \mathbf{e}_2 \wedge \cdots \wedge \mathbf{e}_n$.

Why the word. A decomposable $\omega \neq \mathbf{0}$ carries a k-dimensional subspace: its factors are independent by Theorem 14.8.7, and they span one. Non-decomposable elements are exactly those that come from no single subspace, which is why the failure below is a phenomenon and not a notational accident.

Theorem 14.10.4 — Not Every 2-Vector Is Decomposable

Let $\dim V = n \geq 4$, let $(\mathbf{e}_1, \ldots, \mathbf{e}_n)$ be a basis of V, and set

$$\omega = \mathbf{e}_1 \wedge \mathbf{e}_2 + \mathbf{e}_3 \wedge \mathbf{e}_4 \in \Lambda^2 V.$$

Then ω is **not** decomposable.

Idea. A decomposable 2-vector $\mathbf{u} \wedge \mathbf{w}$ squares to zero, because the four-fold wedge $\mathbf{u} \wedge \mathbf{w} \wedge \mathbf{u} \wedge \mathbf{w}$ repeats a vector. So compute $\omega \wedge \omega$ and find it non-zero. That test needs

char $F \neq 2$; the proof below takes a second route that does not, by asking which vectors annihilate ω.

Proof. Suppose $\omega = \mathbf{u} \wedge \mathbf{w}$ for some $\mathbf{u}, \mathbf{w} \in V$. Since $\mathbf{e}_1 \wedge \mathbf{e}_2$ and $\mathbf{e}_3 \wedge \mathbf{e}_4$ are distinct basis vectors of $\Lambda^2 V$ (Theorem 14.8.5), $\omega \neq \mathbf{0}$, so $(\mathbf{u}, \mathbf{w})$ is linearly independent by Theorem 14.8.7; in particular $\mathbf{u} \neq \mathbf{0}$.

Consider $\mathbf{u} \wedge \omega = \mathbf{u} \wedge \mathbf{u} \wedge \mathbf{w} = \mathbf{0}$, the wedge having a repeated argument. We show this is impossible. Let $\mathbf{v} = \sum_{i=1}^{n} x_i \mathbf{e}_i$ be any vector and compute $\mathbf{v} \wedge \omega$, using bilinearity and dropping every term with a repeated basis vector:

$$\begin{aligned} \mathbf{v} \wedge \omega = {} & x_3\, \mathbf{e}_3 \wedge \mathbf{e}_1 \wedge \mathbf{e}_2 + x_4\, \mathbf{e}_4 \wedge \mathbf{e}_1 \wedge \mathbf{e}_2 \\ & + x_1\, \mathbf{e}_1 \wedge \mathbf{e}_3 \wedge \mathbf{e}_4 + x_2\, \mathbf{e}_2 \wedge \mathbf{e}_3 \wedge \mathbf{e}_4 \\ & + \sum_{i \geq 5} x_i\, (\mathbf{e}_i \wedge \mathbf{e}_1 \wedge \mathbf{e}_2 + \mathbf{e}_i \wedge \mathbf{e}_3 \wedge \mathbf{e}_4). \end{aligned}$$

Sorting each wedge by Lemma 14.8.1 (b) turns this into a combination of the distinct basis vectors

$$\mathbf{e}_{123},\ \mathbf{e}_{124},\ \mathbf{e}_{134},\ \mathbf{e}_{234},\ \mathbf{e}_{12i},\ \mathbf{e}_{34i}\ (i \geq 5)$$

of $\Lambda^3 V$, with coefficients x_3, x_4, x_1, x_2 and x_i, x_i respectively, up to signs. Since these basis vectors are distinct and the $\mathbf{e}_S$ are independent (Theorem 14.8.5), $\mathbf{v} \wedge \omega = \mathbf{0}$ forces $x_1 = x_2 = \cdots = x_n = 0$, that is, $\mathbf{v} = \mathbf{0}$. This contradicts $\mathbf{u} \neq \mathbf{0}$ with $\mathbf{u} \wedge \omega = \mathbf{0}$. Hence ω is not decomposable.

■

Remark. When char $F \neq 2$ there is a one-line version: $\omega \wedge \omega = 2\, \mathbf{e}_1 \wedge \mathbf{e}_2 \wedge \mathbf{e}_3 \wedge \mathbf{e}_4 \neq \mathbf{0}$, whereas $(\mathbf{u} \wedge \mathbf{w}) \wedge (\mathbf{u} \wedge \mathbf{w}) = \mathbf{0}$ always. The proof above was written to avoid that division, because the test fails over $\mathbb{F}_2$ — see the warning next.

Warning. **The square test is blind in characteristic 2.** Over $\mathbb{F}_2$ every $\omega \in \Lambda^2 V$ satisfies $\omega \wedge \omega = \mathbf{0}$: in the expansion $\sum_{S,T} c_S c_T\, \mathbf{e}_S \wedge \mathbf{e}_T$ the diagonal terms vanish and each off-diagonal pair contributes $2 c_S c_T\, \mathbf{e}_S \wedge \mathbf{e}_T = \mathbf{0}$. So over $\mathbb{F}_2$ the vanishing of $\omega \wedge \omega$ says nothing at all, while $\mathbf{e}_1 \wedge \mathbf{e}_2 + \mathbf{e}_3 \wedge \mathbf{e}_4$ is still not decomposable, by the proof above. A criterion and a phenomenon are different things.

Quick check. Why does Theorem 14.10.4 need $n \geq 4$? Show that every element of $\Lambda^2 V$ is decomposable when $\dim V = 3$.

Solution. With $n \leq 3$ there is no room to write $\mathbf{e}_1 \wedge \mathbf{e}_2 + \mathbf{e}_3 \wedge \mathbf{e}_4$ at all. For $n = 3$, take $\omega = a\, \mathbf{e}_{12} + b\, \mathbf{e}_{13} + c\, \mathbf{e}_{23}$. If $a = b = c = 0$ then $\omega = \mathbf{0}$, which is decomposable. If $a \neq 0$, then

$$\left(\mathbf{e}_1 - \tfrac{c}{a}\mathbf{e}_3\right) \wedge (a\mathbf{e}_2 + b\mathbf{e}_3) = a\, \mathbf{e}_{12} + b\, \mathbf{e}_{13} + c\, \mathbf{e}_{23} = \omega,$$

using $\mathbf{e}_3 \wedge \mathbf{e}_2 = -\mathbf{e}_{23}$. If $a = 0$, relabel the basis so that the surviving non-zero coefficient sits in the first slot and repeat. So the phenomenon starts exactly at $n = 4$.

Together with Example (A tensor that is not simple) this is the chapter's negative result, stated in its two forms: a general tensor is not a simple tensor, and a general k-vector is not a blade. The optimistic reading — that every element of a space built from V is built from finitely many vectors of V in the obvious way — is false in both places, and Section 11 will find the first form

of it wearing a physical name.

14.10.3 Algebras modulo relations

One tool is still missing. The Clifford algebra is to be built by imposing relations on $\mathrm{T}(V)$, and imposing relations on an **algebra** means dividing by more than a subspace: the relations must stay relations after multiplication on either side. Chapter 5 met the commutative version of the idea for $F[x]$ (Definition 5.2.1).

Definition 14.10.3 — Two-Sided Ideal, and the Ideal Generated by a Set

Let A be an F-algebra (Definition 13.12.1). A **two-sided ideal** of A is a subspace $\mathcal{I} \subseteq A$ such that $yx \in \mathcal{I}$ and $xy \in \mathcal{I}$ for **every** $x \in \mathcal{I}$ and **every** $y \in A$. For a subset $S \subseteq A$, the **ideal generated by** S is

$$\langle S \rangle \coloneqq \operatorname{span}\{\, ysz \;:\; y, z \in A,\ s \in S \,\}.$$

Examples. In $F[x]$ the ideals are the sets $\langle p \rangle$ of Definition 5.2.1; in any A, both $\{0\}$ and A are ideals. **Non-example by minimal change.** The diagonal matrices in $M_2(F)$ form a subspace closed under multiplication, but not an ideal: it contains $\mathbf{E}_{11}$, while $\mathbf{E}_{21}\mathbf{E}_{11} = \mathbf{E}_{21}$ is not diagonal. Being closed among one's own elements is not the condition; absorbing products with the **whole** algebra is.

The span above is a subspace by construction, and it is a two-sided ideal because $a(ysz) = (ay)sz$ and $(ysz)a = ys(za)$ are again of the listed form. It contains S, taking $y = z = 1_A$, and every two-sided ideal containing S contains each ysz; so $\langle S \rangle$ is the smallest two-sided ideal containing S, which is what "generated" means.

Lemma 14.10.5 — Quotient of an Algebra by an Ideal

Let A be an F-algebra and $\mathcal{I}$ a two-sided ideal of A.

(a) The quotient space $A/\mathcal{I}$ carries exactly one multiplication making the quotient map $\pi\colon A \to A/\mathcal{I}$ an algebra homomorphism, namely $(x + \mathcal{I})(y + \mathcal{I}) = xy + \mathcal{I}$; with it $A/\mathcal{I}$ is an F-algebra with identity $1_A + \mathcal{I}$, and $\ker \pi = \mathcal{I}$.

(b) If $\varphi\colon A \to B$ is an algebra homomorphism with $\mathcal{I} \subseteq \ker \varphi$, then there is exactly one algebra homomorphism $\bar{\varphi}\colon A/\mathcal{I} \to B$ with $\bar{\varphi} \circ \pi = \varphi$.

(c) The kernel of any algebra homomorphism is a two-sided ideal.

Proof.

(a) The rule is well defined: if $x' = x + u$ and $y' = y + w$ with $u, w \in \mathcal{I}$, then

$$x'y' = xy + uy + xw + uw \in xy + \mathcal{I},$$

since $\mathcal{I}$ absorbs multiplication on both sides and is closed under addition. Bilinearity, associativity and the identity are then inherited from A, because each is an identity among cosets that follows by applying π to the corresponding identity in

A. Any multiplication making π multiplicative must satisfy the displayed rule, and π is surjective, so the multiplication is unique. Finally $\ker\pi = \mathcal{I}$ by Lemma 3.9.3.

(b) Since φ is linear with $\mathcal{I} \subseteq \ker\varphi$, Theorem 3.9.10 (a) gives exactly one **linear** $\bar{\varphi}$ with $\bar{\varphi}\pi = \varphi$. It is multiplicative: every element of $A/\mathcal{I}$ is $\pi(x)$ for some x, and

$$\bar{\varphi}(\pi(x)\pi(y)) = \bar{\varphi}(\pi(xy)) = \varphi(xy) = \varphi(x)\varphi(y),$$

which is $\bar{\varphi}(\pi(x))\,\bar{\varphi}(\pi(y))$. Also $\bar{\varphi}(\pi(1_A)) = \varphi(1_A) = 1_B$. Uniqueness is already contained in the uniqueness of the linear map.

(c) If $\varphi(x) = 0$ and $y \in A$, then $\varphi(xy) = \varphi(x)\varphi(y) = 0$ and $\varphi(yx) = 0$; and $\ker\varphi$ is a subspace because φ is linear.

■

14.10.4 The Clifford algebra, constructed

Chapter 13 §12 defined a Clifford algebra of (V, q) as a pair (C, ι) with $\iota\colon V \to C$ linear satisfying

- (C1) $\iota(\mathbf{v})^2 = q(\mathbf{v})1_C$ for every $\mathbf{v} \in V$, and
- (C2) the universal property: every linear $f\colon V \to A$ into an F-algebra with $f(\mathbf{v})^2 = q(\mathbf{v})1_A$ factors as $f = \bar{f} \circ \iota$ for a unique algebra homomorphism $\bar{f}$,

and then said in as many words that it could not produce one: "The definition says what a Clifford algebra would be; it does not produce one." What it needed was an algebra of formal strings of vectors, which is now Definition 14.6.2, and a way to impose the relation $\mathbf{v}\otimes\mathbf{v} = q(\mathbf{v})1$, which is now Lemma 14.10.5.

Theorem 14.10.6 — Existence of the Clifford Algebra

Let F be a field with $\operatorname{char} F \neq 2$, let V be a finite-dimensional F-vector space, let β be a symmetric bilinear form on V and $q(\mathbf{v}) = \beta(\mathbf{v}, \mathbf{v})$. Let

$$\mathcal{I}_q := \left\langle\, \mathbf{v}\otimes\mathbf{v} - q(\mathbf{v})1 \;:\; \mathbf{v} \in V \,\right\rangle \subseteq \mathrm{T}(V)$$

be the two-sided ideal generated by these elements, put $\mathrm{Cl}(q) := \mathrm{T}(V)/\mathcal{I}_q$, and let $\iota\colon V \to \mathrm{Cl}(q)$ be the restriction to $V \subseteq \mathrm{T}(V)$ of the quotient map π. Then $(\mathrm{Cl}(q), \iota)$ is a Clifford algebra of (V, q) in the sense of Definition 13.12.2.

In particular a Clifford algebra exists for every (V, q), and by Proposition 13.12.1 any two are isomorphic by a unique isomorphism compatible with the structure maps.

Idea. The tensor algebra is the free associative algebra on V: a linear map out of V extends uniquely to it (Theorem 14.6.6), with no relations in the way. Dividing by the smallest ideal containing $\mathbf{v}\otimes\mathbf{v} - q(\mathbf{v})1$ imposes exactly the relation (C1) and nothing else, and "nothing else" is precisely what the universal property (C2) asserts.

Proof. By Lemma 14.10.5 (a), $\mathrm{Cl}(q)$ is an F-algebra and π is a surjective algebra homomorphism with $\ker\pi = \mathcal{I}_q$. The map $\iota = \pi|_V$ is linear, being a restriction of a linear map.

(C1). Let $\mathbf{v} \in V$. In $\mathrm{T}(V)$ the product of $\mathbf{v}$ with itself is $\mathbf{v} \otimes \mathbf{v}$ (Definition 14.6.2), and $\mathbf{v} \otimes \mathbf{v} - q(\mathbf{v})1$ is a generator of $\mathcal{I}_q = \ker \pi$. Since π is multiplicative and linear,

$$\iota(\mathbf{v})^2 = \pi(\mathbf{v})\pi(\mathbf{v}) = \pi(\mathbf{v} \otimes \mathbf{v}) = \pi\big(q(\mathbf{v})1\big) = q(\mathbf{v})1_{\mathrm{Cl}(q)}.$$

(C2). Let A be an F-algebra and let $f\colon V \to A$ be linear with $f(\mathbf{v})^2 = q(\mathbf{v})1_A$ for every $\mathbf{v} \in V$. By Theorem 14.6.6 there is a unique algebra homomorphism $\tilde{f}\colon \mathrm{T}(V) \to A$ with $\tilde{f}|_V = f$. For every $\mathbf{v} \in V$,

$$\tilde{f}\big(\mathbf{v} \otimes \mathbf{v} - q(\mathbf{v})1\big) = f(\mathbf{v})f(\mathbf{v}) - q(\mathbf{v})1_A = 0,$$

so $\ker \tilde{f}$ contains every generator of $\mathcal{I}_q$. By Lemma 14.10.5 (c), $\ker \tilde{f}$ is a two-sided ideal, and $\mathcal{I}_q$ is the **smallest** one containing those generators (Definition 14.10.3), so $\mathcal{I}_q \subseteq \ker \tilde{f}$. By Lemma 14.10.5 (b) there is exactly one algebra homomorphism $\bar{f}\colon \mathrm{Cl}(q) \to A$ with $\bar{f} \circ \pi = \tilde{f}$, and restricting to V gives $\bar{f} \circ \iota = \tilde{f}|_V = f$.

For the uniqueness clause of (C2), let $g\colon \mathrm{Cl}(q) \to A$ be any algebra homomorphism with $g \circ \iota = f$. Then $g \circ \pi$ is an algebra homomorphism $\mathrm{T}(V) \to A$ whose restriction to V is $g\iota = f$, so $g\pi = \tilde{f}$ by the uniqueness clause of Theorem 14.6.6. Hence $g\pi = \bar{f}\pi$, and π is surjective, so $g = \bar{f}$. This proves the theorem.

■

Remark. Neither $\mathrm{char}\, F \neq 2$ nor finite dimension was used in this proof; the construction and both checks work for any V and any quadratic form. The hypotheses are carried because Definition 13.12.2 states them, and because the dimension count below needs an orthogonal basis.

14.10.5 The dimension, at last

Chapter 13 proved half of the count. Its Proposition 13.12.3 showed that for an orthogonal basis $(\mathbf{e}_1, \dots, \mathbf{e}_n)$ of β the 2^n **sorted products**

$$\iota(\mathbf{e}_{i_1})\iota(\mathbf{e}_{i_2}) \cdots \iota(\mathbf{e}_{i_k}), \qquad i_1 < i_2 < \cdots < i_k,$$

span C, so that $\dim_F C \leq 2^n$. The other half — their independence — is what this section owes. The idea is to make ΛV, which has exactly the right dimension, into a place where the vectors of V act with square $q(\mathbf{v})$; the universal property then sends C into the operators on ΛV, and evaluating at 1 turns the sorted products into distinct basis vectors.

Two families of operators on ΛV do the work: wedging a basis vector on, and deleting it again.

Lemma 14.10.7 — Creation and Deletion Operators

Let $(\mathbf{e}_1, \dots, \mathbf{e}_n)$ be a basis of V, and for $S \subseteq [n]$ let $\mathbf{e}_S$ be as in Theorem 14.10.2. For $i \in [n]$ write $\sigma(i, S) = |\{j \in S : j < i\}|$. Let $E_i \in \mathcal{L}(\Lambda V)$ be left multiplication by $\mathbf{e}_i$, that is, $E_i(\omega) = \mathbf{e}_i \wedge \omega$, and let $D_i \in \mathcal{L}(\Lambda V)$ be the unique linear map with

$$D_i(\mathbf{e}_S) = \begin{cases} (-1)^{\sigma(i,S)}\, \mathbf{e}_{S \setminus \{i\}}, & i \in S, \\ \mathbf{0}, & i \notin S, \end{cases}$$

which exists and is unique because the $\mathbf{e}_S$ form a basis (Theorem 14.10.2). Then for all $i, j \in [n]$,

$$E_i E_j + E_j E_i = 0,$$
$$D_i D_j + D_j D_i = 0,$$
$$D_i E_j + E_j D_i = \delta_{ij}\ \mathrm{id}_{\Lambda V}\,.$$

Idea. E_i inserts the index i into the set S and D_i removes it, each at the cost of the sign needed to move $\mathbf{e}_i$ past the smaller members of S. All three identities are then a comparison of two signs, and in the third the two cases "$i \in S$" and "$i \notin S$" are exactly the two ways the identity can be satisfied: one term is zero and the other is $\mathbf{e}_S$.

Proof. First record what E_i does on the basis. If $i \in S$ then $\mathbf{e}_i \wedge \mathbf{e}_S$ repeats $\mathbf{e}_i$ and is $\mathbf{0}$. If $i \notin S$, then sorting $\mathbf{e}_i \wedge \mathbf{e}_S$ moves $\mathbf{e}_i$ past the $\sigma(i, S)$ members of S smaller than i, so by Lemma 14.8.1 (b)

$$E_i(\mathbf{e}_S) = (-1)^{\sigma(i,S)}\,\mathbf{e}_{S\cup\{i\}}.$$

First identity. For every $\omega \in \Lambda V$, $E_i E_j(\omega) = \mathbf{e}_i \wedge \mathbf{e}_j \wedge \omega$ and $E_j E_i(\omega) = \mathbf{e}_j \wedge \mathbf{e}_i \wedge \omega$, and $\mathbf{e}_j \wedge \mathbf{e}_i = -\mathbf{e}_i \wedge \mathbf{e}_j$ by Theorem 14.10.3. Adding gives 0. (For $i = j$ each term is separately 0.)

Third identity, case $i = j$. If $i \notin S$, then $D_i(\mathbf{e}_S) = \mathbf{0}$ and $E_i(\mathbf{e}_S) = (-1)^{\sigma(i,S)}\mathbf{e}_{S\cup\{i\}}$; since $\sigma(i, S \cup \{i\}) = \sigma(i, S)$, applying D_i returns $(-1)^{2\sigma(i,S)}\mathbf{e}_S = \mathbf{e}_S$. If $i \in S$, then $E_i(\mathbf{e}_S) = \mathbf{0}$ and $D_i(\mathbf{e}_S) = (-1)^{\sigma(i,S)}\mathbf{e}_{S\setminus\{i\}}$; since $\sigma(i, S \setminus \{i\}) = \sigma(i, S)$, applying E_i returns $\mathbf{e}_S$. Either way the sum is $\mathbf{e}_S$.

Third identity, case $i \neq j$. If $j \in S$ then $E_j(\mathbf{e}_S) = \mathbf{0}$, and $D_i(\mathbf{e}_S)$ is either $\mathbf{0}$ or a multiple of $\mathbf{e}_{S\setminus\{i\}}$, which still contains j, so E_j kills it; both terms vanish. If $j \notin S$ and $i \notin S$ then $D_i(\mathbf{e}_S) = \mathbf{0}$ and $D_i(\mathbf{e}_{S\cup\{j\}}) = \mathbf{0}$ as well, since $i \neq j$; again both terms vanish. So let $j \notin S$ and $i \in S$. Then

$$D_i E_j(\mathbf{e}_S) = (-1)^{\sigma(j,S)+\sigma(i,S\cup\{j\})}\,\mathbf{e}_{(S\cup\{j\})\setminus\{i\}},$$
$$E_j D_i(\mathbf{e}_S) = (-1)^{\sigma(i,S)+\sigma(j,S\setminus\{i\})}\,\mathbf{e}_{(S\setminus\{i\})\cup\{j\}},$$

and the two index sets agree. Now $\sigma(i, S \cup \{j\}) = \sigma(i, S) + [\,j < i\,]$ and $\sigma(j, S \setminus \{i\}) = \sigma(j, S) - [\,i < j\,]$, writing $[\,P\,]$ for 1 if P holds and 0 otherwise. So the two exponents differ by $[\,j < i\,] + [\,i < j\,] = 1$, which is odd because $i \neq j$. The two terms therefore cancel.

Second identity. Both $D_i D_j(\mathbf{e}_S)$ and $D_j D_i(\mathbf{e}_S)$ vanish unless $i, j \in S$ and $i \neq j$, and in that case they are $(-1)^{\sigma(j,S)+\sigma(i,S\setminus\{j\})}$ and $(-1)^{\sigma(i,S)+\sigma(j,S\setminus\{i\})}$ times the same $\mathbf{e}_{S\setminus\{i,j\}}$. The same two identities for σ show the exponents differ by an odd number, so the terms cancel. For $i = j$, $D_i^2(\mathbf{e}_S) = \mathbf{0}$ because $i \notin S \setminus \{i\}$. This proves the lemma.

■

Theorem 14.10.8 — Dimension of a Clifford Algebra

Let F be a field with $\operatorname{char} F \neq 2$, let $\dim V = n$, let β be a symmetric bilinear form on V with quadratic form q, and let (C, ι) be a Clifford algebra of (V, q). Let $(\mathbf{e}_1, \ldots, \mathbf{e}_n)$ be an orthogonal basis of V for β. Then the 2^n sorted products of Proposition 13.12.3

form a **basis** of C. Consequently

$$\dim_F C = 2^n,$$

the map ι is injective, and C is isomorphic to ΛV **as a vector space**. This is Theorem 13.12.4.

Idea. Build a representation. ① Turn each basis vector $\mathbf{e}_i$ into the operator $c_i = E_i + d_i D_i$ on ΛV, where $d_i = q(\mathbf{e}_i)$; Lemma 14.10.7 makes these anticommute and gives $c_i^2 = d_i\,\mathrm{id}$, which is exactly (C1). ② The universal property then hands us an algebra homomorphism $C \to \mathcal{L}(\Lambda V)$. ③ Evaluate at the element $1 \in \Lambda^0 V$: the sorted product for the index set S is sent to $\mathbf{e}_S$, because at each step the new index is smaller than all the ones already there, so the deletion half contributes nothing. Distinct basis vectors come out, so the sorted products were independent.

Proof. An orthogonal basis exists by Theorem 13.4.2, since $\operatorname{char} F \neq 2$. Write $d_i = q(\mathbf{e}_i)$ and $c_i = E_i + d_i D_i \in \mathcal{L}(\Lambda V)$, with E_i, D_i as in Lemma 14.10.7. By Proposition 13.12.3 the sorted products span C and $\dim_F C \leq 2^n$, so only independence is left.

Step 1: the c_i satisfy the Clifford relations. Expanding the product and collecting the four brackets,

$$\begin{aligned} c_i c_j + c_j c_i = {} & (E_iE_j + E_jE_i) + d_j(E_iD_j + D_jE_i) \\ & + d_i(D_iE_j + E_jD_i) + d_id_j(D_iD_j + D_jD_i). \end{aligned}$$

By Lemma 14.10.7 the first and last brackets are 0 and each middle bracket is $\delta_{ij}\,\mathrm{id}$. So $c_ic_j = -c_jc_i$ for $i \neq j$. Setting $i = j$ in the display would give $2c_i^2$, so expand c_i^2 directly instead; with $E_i^2 = D_i^2 = 0$, which were checked separately in the lemma,

$$c_i^2 = E_i^2 + d_i(E_iD_i + D_iE_i) + d_i^2 D_i^2 = d_i\,\mathrm{id},$$

with no division by 2 anywhere. Now $\mathcal{L}(\Lambda V)$ is an F-algebra under composition (Definition 13.12.1). Let $f\colon V \to \mathcal{L}(\Lambda V)$ be the linear map with $f(\mathbf{e}_i) = c_i$, which exists and is unique by Theorem 3.1.6. For $\mathbf{v} = \sum_i x_i\mathbf{e}_i$,

$$f(\mathbf{v})^2 = \sum_i x_i^2 c_i^2 + \sum_{i<j} x_ix_j(c_ic_j + c_jc_i) = \Big(\sum_i d_i x_i^2\Big)\,\mathrm{id},$$

the cross terms vanishing because $i \neq j$ there. Since the basis is orthogonal, $\beta(\mathbf{e}_i, \mathbf{e}_j) = 0$ for $i \neq j$, so $q(\mathbf{v}) = \beta(\mathbf{v}, \mathbf{v}) = \sum_i d_i x_i^2$. Hence $f(\mathbf{v})^2 = q(\mathbf{v})\,\mathrm{id}$, which is (C1) for f.

Step 2: the induced homomorphism. By the universal property (C2) of Definition 13.12.2 there is an algebra homomorphism $\Psi\colon C \to \mathcal{L}(\Lambda V)$ with $\Psi\iota = f$. Define the linear map

$$\Phi\colon C \to \Lambda V, \qquad \Phi(x) = \Psi(x)(1),$$

where $1 \in \Lambda^0 V = F \subseteq \Lambda V$. It is linear because Ψ is linear and evaluation at a fixed element is linear.

Step 3: Φ sends sorted products to basis vectors. Let $S = \{i_1 < \cdots < i_k\} \subseteq [n]$. Since Ψ is multiplicative and $\Psi\iota = f$,

$$\Psi\big(\iota(\mathbf{e}_{i_1}) \cdots \iota(\mathbf{e}_{i_k})\big) = c_{i_1}c_{i_2}\cdots c_{i_k}.$$

We claim $c_{i_r} c_{i_{r+1}} \cdots c_{i_k}(1) = \mathbf{e}_{T_r}$ with $T_r = \{i_r, \ldots, i_k\}$, by downward induction on r. For $r = k+1$ the product is empty and the value is $1 = \mathbf{e}_\emptyset$. Assume the claim for $r+1$. Because $i_r < i_{r+1}$ and the indices increase, $i_r \notin T_{r+1}$, so $D_{i_r}(\mathbf{e}_{T_{r+1}}) = \mathbf{0}$; and i_r is smaller than every element of T_{r+1}, so $\sigma(i_r, T_{r+1}) = 0$ and $E_{i_r}(\mathbf{e}_{T_{r+1}}) = \mathbf{e}_{T_r}$. Hence $c_{i_r}(\mathbf{e}_{T_{r+1}}) = \mathbf{e}_{T_r}$, completing the induction. Taking $r = 1$,

$$\Phi\big(\iota(\mathbf{e}_{i_1}) \cdots \iota(\mathbf{e}_{i_k})\big) = \mathbf{e}_S,$$

and for $S = \emptyset$, $\Phi(1_C) = \mathrm{id}(1) = 1 = \mathbf{e}_\emptyset$.

Step 4: conclusion. Suppose a linear combination of the sorted products is 0. Applying Φ gives the same combination of the $\mathbf{e}_S$, which are linearly independent by Theorem 14.10.2 (b); so all coefficients vanish. The sorted products are therefore linearly independent, and being also a spanning list they form a basis of C, of size 2^n. Thus $\dim_F C = 2^n$.

Since 1_C and $\iota(\mathbf{e}_1), \ldots, \iota(\mathbf{e}_n)$ are among the basis elements just found, the list $(\iota(\mathbf{e}_1), \ldots, \iota(\mathbf{e}_n))$ is independent, so ι carries a basis of V to an independent list and is injective. Finally Φ carries the basis of C bijectively onto the basis $(\mathbf{e}_S)$ of ΛV, so Φ is a vector space isomorphism. This proves the theorem.

■

The debt, and how it was paid. Chapter 13 §12 stated Theorem 13.12.4 and then wrote, under the heading "What is proved here, and what is not", that the inequality $\dim_F C \le 2^n$ was proved in full, while "the reverse inequality — that the 2^n sorted products are linearly independent — is **not proved in this section**", and that the two halves would have to be established together by exhibiting one algebra of dimension exactly 2^n satisfying (C1) and (C2). Both halves are now supplied. The missing one was independence, and Theorem 14.10.8 supplies it; the prior question, whether any Clifford algebra exists at all, is Theorem 14.10.6. Chapter 13 read the statement for $n \ge 3$ "as quoted from Chapter 14 and not as proved here"; it may now be read as proved.

The prediction was right in substance and slightly off in shape. The algebra of dimension 2^n that settled the matter is the exterior algebra, but it is not the Clifford algebra: it is only a space that $\mathrm{Cl}(q)$ acts on, and independence came from the action rather than from an identification. Chapter 13 also guessed that "$\mathrm{Cl}(q)$ is assembled from the exterior powers $\Lambda^k V$, one for each k", and Φ is that assembly, matching the sorted product on S with the wedge $\mathbf{e}_S$.

Warning. $\mathrm{Cl}(q)$ **and ΛV are the same size, not the same algebra.** The map Φ above is an isomorphism of **vector spaces** only. It is not multiplicative, and no other map is either, unless $q = 0$: in ΛV the square of a vector is $\mathbf{0}$, while in $\mathrm{Cl}(q)$ it is $q(\mathbf{v})1$. Writing an element of $\mathrm{Cl}(q)$ as a sum of wedges is a choice of coordinates, not a description of the multiplication.

That warning deserves a proof rather than a slogan.

Proposition 14.10.9 — Comparing the Two Algebras

Let $\mathrm{char}\, F \neq 2$ and $\dim V = n \ge 1$, and let q be the quadratic form of a symmetric bilinear form on V.

(a) If $q = 0$, then $\mathrm{Cl}(0)$ and ΛV are isomorphic as F-algebras.
(b) If $q \neq 0$, they are **not** isomorphic as F-algebras, although they are isomorphic as vector spaces.

Idea. For (b), find a property of ΛV that $\mathrm{Cl}(q)$ fails. In ΛV everything of positive degree is nilpotent, so an element whose square is a **non-zero scalar** can have no positive-degree part at all; but in $\mathrm{Cl}(q)$ a vector $\mathbf{v}$ with $q(\mathbf{v}) \neq 0$ squares to a non-zero scalar and is not a scalar itself.

Proof.

(a) Let $q = 0$ and let $j\colon V \to \Lambda V$ be the inclusion $V = \Lambda^1 V \subseteq \Lambda V$. Then $j(\mathbf{v})^2 = \mathbf{v} \wedge \mathbf{v} = \mathbf{0} = q(\mathbf{v})1$, so (C1) holds for j. By the universal property (C2) of $\mathrm{Cl}(0)$ there is an algebra homomorphism $\psi\colon \mathrm{Cl}(0) \to \Lambda V$ with $\psi\iota = j$. Its image is a subalgebra containing 1 and V, hence all of ΛV by Theorem 14.10.2 (c); so ψ is surjective. Both spaces have dimension 2^n, by Theorem 14.10.8 and Theorem 14.10.2 (b), so ψ is bijective and is an algebra isomorphism.
(b) *Claim.* If $x \in \Lambda V$ and $x \wedge x = a \cdot 1$ with $a \in F$, $a \neq 0$, then $x \in F \cdot 1$.

Proof of claim. Throughout, y^t means the t-fold wedge product of y with itself. Write $x = x_0 + m$ with $x_0 \in \Lambda^0 V = F$ and m the sum of the components of positive degree. Then

$$x \wedge x = x_0^2 + 2x_0 m + m \wedge m,$$

and the only degree-0 term is x_0^2, so $x_0^2 = a \neq 0$ and hence $x_0 \neq 0$. Canceling that term leaves

$$m \wedge (2x_0 \cdot 1 + m) = \mathbf{0}.$$

Every product of $n+1$ elements of positive degree lies in $\bigoplus_{k>n} \Lambda^k V = \{\mathbf{0}\}$, so $m^{n+1} = \mathbf{0}$. Put $c = 2x_0$, which is non-zero because $\operatorname{char} F \neq 2$ and $x_0 \neq 0$, and $u = -c^{-1}m$, so that $u^{n+1} = \mathbf{0}$ and $c \cdot 1 + m = c(1 - u)$. Then

$$(1 - u) \wedge (1 + u + u^2 + \cdots + u^n) = 1 - u^{n+1} = 1,$$

and likewise in the other order, so $c \cdot 1 + m$ is invertible. Multiplying $m \wedge (c \cdot 1 + m) = \mathbf{0}$ by its inverse gives $m = \mathbf{0}$, so $x = x_0 \in F \cdot 1$, proving the claim.

Now suppose $q \neq 0$ and let $\varphi\colon \mathrm{Cl}(q) \to \Lambda V$ be an algebra isomorphism. Choose $\mathbf{v} \in V$ with $q(\mathbf{v}) \neq 0$ and put $x = \varphi(\iota(\mathbf{v}))$. Then

$$x \wedge x = \varphi\big(\iota(\mathbf{v})^2\big) = \varphi\big(q(\mathbf{v})1\big) = q(\mathbf{v}) \cdot 1,$$

a non-zero scalar, so $x \in F \cdot 1$ by the claim, say $x = c \cdot 1 = \varphi(c\,1_{\mathrm{Cl}(q)})$. Since φ is injective, $\iota(\mathbf{v}) = c\,1_{\mathrm{Cl}(q)}$. But by Theorem 14.10.8 the elements $1_{\mathrm{Cl}(q)}, \iota(\mathbf{e}_1), \ldots, \iota(\mathbf{e}_n)$ are part of a basis of $\mathrm{Cl}(q)$, and $\iota(\mathbf{v})$ is a combination of $\iota(\mathbf{e}_1), \ldots, \iota(\mathbf{e}_n)$ alone; comparing coordinates forces $c = 0$ and $\iota(\mathbf{v}) = 0$, contradicting $\iota(\mathbf{v})^2 = q(\mathbf{v})1 \neq 0$. So no such φ exists. The vector space isomorphism is Theorem 14.10.8.

■

The dimension count also makes Clifford algebras easy to recognize, which is how one identifies them in practice.

Corollary 14.10.10 — Recognizing a Clifford Algebra

Let $\operatorname{char} F \neq 2$, $\dim V = n$, and let q be as above. Let A be an F-algebra with $\dim_F A = 2^n$, and let $\iota_A \colon V \to A$ be linear with $\iota_A(\mathbf{v})^2 = q(\mathbf{v})1_A$ for every $\mathbf{v} \in V$. If A is generated as an algebra by 1_A and $\iota_A(V)$, then (A, ι_A) is a Clifford algebra of (V, q).

Proof. Let (C, ι) be the Clifford algebra of Theorem 14.10.6. By its universal property there is an algebra homomorphism $\psi \colon C \to A$ with $\psi\iota = \iota_A$. Its image is a subalgebra of A containing 1_A and $\iota_A(V)$, hence is all of A by the generation hypothesis. So ψ is surjective, and $\dim_F C = 2^n = \dim_F A$ by Theorem 14.10.8, so ψ is an isomorphism.

It remains to transport (C2). Let $f \colon V \to B$ be linear with $f(\mathbf{v})^2 = q(\mathbf{v})1_B$. Then $\bar{f}\psi^{-1} \colon A \to B$ is an algebra homomorphism with $\bar{f}\psi^{-1}\iota_A = \bar{f}\iota = f$, where $\bar{f} \colon C \to B$ comes from (C2) for C; and if $g \colon A \to B$ is another one, then $g\psi \colon C \to B$ satisfies $g\psi\iota = g\iota_A = f$, so $g\psi = \bar{f}$ by uniqueness for C, whence $g = \bar{f}\psi^{-1}$.

■

Example. (The Clifford algebra of the Euclidean plane)

Let $V = \mathbb{R}^2$ with $q(\mathbf{x}) = x_1^2 + x_2^2$, the form of signature $(2, 0)$. Show that $\mathrm{Cl}_{2,0}(\mathbb{R}) \cong M_2(\mathbb{R})$.

Solution. Put

$$\mathbf{A} = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}, \qquad \mathbf{B} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$$

in $M_2(\mathbb{R})$, and let $\iota(\mathbf{x}) = x_1\mathbf{A} + x_2\mathbf{B}$, a linear map $\mathbb{R}^2 \to M_2(\mathbb{R})$. Multiplying out, $\mathbf{A}^2 = \mathbf{B}^2 = \mathbf{I}_2$ and $\mathbf{AB} = -\mathbf{BA}$, the products being $\left(\begin{smallmatrix} 0 & 1 \\ -1 & 0 \end{smallmatrix}\right)$ and its negative. Hence

$$\iota(\mathbf{x})^2 = x_1^2\mathbf{A}^2 + x_1x_2(\mathbf{AB} + \mathbf{BA}) + x_2^2\mathbf{B}^2 = q(\mathbf{x})\mathbf{I}_2,$$

which is (C1). Next, $\dim_{\mathbb{R}} M_2(\mathbb{R}) = 4 = 2^2$, and the four matrices $\mathbf{I}_2, \mathbf{A}, \mathbf{B}, \mathbf{AB}$ are linearly independent: the first two span the diagonal matrices and the last two span the off-diagonal ones, and the diagonal and off-diagonal matrices meet only in 0. So they are a basis, and $M_2(\mathbb{R})$ is generated by $\mathbf{I}_2$ and $\iota(\mathbb{R}^2)$. By Corollary 14.10.10, $(M_2(\mathbb{R}), \iota)$ is a Clifford algebra of $(\mathbb{R}^2, q)$, so $\mathrm{Cl}_{2,0}(\mathbb{R}) \cong M_2(\mathbb{R})$.

Compare Chapter 13's $\mathrm{Cl}_{0,2}(\mathbb{R}) = \mathbb{H}$ (Example (The quaternions)). All three of $\mathbb{H}$, $M_2(\mathbb{R})$ and $\Lambda\mathbb{R}^2$ have dimension 4, and no two are isomorphic: $\mathbb{H}$ has no zero divisors, $M_2(\mathbb{R})$ has plenty, and $\Lambda\mathbb{R}^2$ differs from both by Proposition 14.10.9 (b). Changing a sign in q changes the algebra completely and never changes its size.

Quick check. Where in the proof of Theorem 14.10.8 is the hypothesis $\operatorname{char} F \neq 2$ used?

Solution. Twice, both times through the orthogonal basis. It is needed to produce one at all: Theorem 13.4.2 assumes $\operatorname{char} F \neq 2$. And it is needed for Chapter 13's Proposition 13.12.3, which supplies the spanning half, since that proof uses Lemma 13.12.2, which comes from polarization. The operator identities of Lemma 14.10.7 and the induction of Step 3 use no such hypothesis.

With that, Chapter 13's last open statement is closed and the construction side of this chapter is complete. The final section spends the machinery on one application, where the failure of decomposability proved above reappears under another name.

14.10.6 Exercises

14.10.6.1 A. Check your understanding

Exercise A1.

(a) Define the exterior algebra ΛV and state its dimension when $\dim V = n$.

(b) State the graded commutativity rule, and say what it gives when both degrees are odd.

(c) Define what it means for $\omega \in \Lambda^k V$ to be decomposable, and give one decomposable and one non-decomposable element of $\Lambda^2 F^4$.

(d) Which half of Theorem 13.12.4 was left unproved in Chapter 13, and which result of this section supplies it?

(e) True or false: $\mathrm{Cl}(q)$ and ΛV are isomorphic algebras. Justify your answer.

Solution.

(a) $\Lambda V = \bigoplus_{k \geq 0} \Lambda^k V$ with the product of Proposition 14.10.1 extended by bilinearity (Definition 14.10.1). Its dimension is $\sum_k \binom{n}{k} = 2^n$ (Theorem 14.10.2).

(b) $\omega \wedge \eta = (-1)^{kl} \eta \wedge \omega$ for $\omega \in \Lambda^k V$, $\eta \in \Lambda^l V$ (Theorem 14.10.3). Both odd gives $\omega \wedge \eta = -\eta \wedge \omega$: odd-degree elements anticommute.

(c) ω is decomposable if $\omega = \mathbf{v}_1 \wedge \cdots \wedge \mathbf{v}_k$ for some $\mathbf{v}_i \in V$ (Definition 14.10.2). Decomposable: $\mathbf{e}_1 \wedge \mathbf{e}_2$. Non-decomposable: $\mathbf{e}_1 \wedge \mathbf{e}_2 + \mathbf{e}_3 \wedge \mathbf{e}_4$ (Theorem 14.10.4).

(d) The independence of the 2^n sorted products, that is, the inequality $\dim_F C \geq 2^n$. It is supplied by Theorem 14.10.8, which needs Theorem 14.10.6 first so that the object exists.

(e) False in general. They are isomorphic as vector spaces, and as algebras exactly when $q = 0$ (Proposition 14.10.9).

14.10.6.2 B. Practice

Exercise B1: Multiplying in the exterior algebra.

In ΛF^4 with $F = \mathbb{Q}$, put $x = \mathbf{e}_1 + \mathbf{e}_2 \wedge \mathbf{e}_3$ and $y = \mathbf{e}_2 + \mathbf{e}_1 \wedge \mathbf{e}_4$. Compute the following, expressed in the basis of Theorem 14.10.2.

(a) $x \wedge y$.

(b) $y \wedge x$.

(c) $x \wedge x$.

Solution. Write $\mathbf{e}_S$ for the sorted wedge on S.

(a) Expanding into four products:

$$\mathbf{e}_1 \wedge \mathbf{e}_2 = \mathbf{e}_{12}, \qquad \mathbf{e}_1 \wedge (\mathbf{e}_1 \wedge \mathbf{e}_4) = \mathbf{0},$$
$$(\mathbf{e}_2 \wedge \mathbf{e}_3) \wedge \mathbf{e}_2 = \mathbf{0}, \qquad (\mathbf{e}_2 \wedge \mathbf{e}_3) \wedge (\mathbf{e}_1 \wedge \mathbf{e}_4) = \mathbf{e}_{1234}.$$

The last one sorts as $\mathbf{e}_2 \wedge \mathbf{e}_3 \wedge \mathbf{e}_1 \wedge \mathbf{e}_4 = \mathbf{e}_{1234}$, since moving $\mathbf{e}_1$ two places to the left costs $(-1)^2$. So $x \wedge y = \mathbf{e}_{12} + \mathbf{e}_{1234}$.

(b) The surviving products are $\mathbf{e}_2 \wedge \mathbf{e}_1 = -\mathbf{e}_{12}$ and $(\mathbf{e}_1 \wedge \mathbf{e}_4) \wedge (\mathbf{e}_2 \wedge \mathbf{e}_3) = \mathbf{e}_{1234}$, the latter because $\mathbf{e}_1 \wedge \mathbf{e}_4 \wedge \mathbf{e}_2 \wedge \mathbf{e}_3$ sorts with two transpositions. So $y \wedge x = -\mathbf{e}_{12} + \mathbf{e}_{1234}$. This agrees with Theorem 14.10.3 applied degree by degree: the $(1,1)$ part changes sign, the $(1,2)$ and $(2,2)$ parts do not.

(c) $x \wedge x = \mathbf{e}_1 \wedge \mathbf{e}_1 + \mathbf{e}_1 \wedge \mathbf{e}_2 \wedge \mathbf{e}_3 + \mathbf{e}_2 \wedge \mathbf{e}_3 \wedge \mathbf{e}_1 + \mathbf{0} = 2\,\mathbf{e}_{123}$, since $\mathbf{e}_2 \wedge \mathbf{e}_3 \wedge \mathbf{e}_1 = \mathbf{e}_{123}$. An inhomogeneous element need not square to zero.

Exercise B2: Decomposable or not.

In $\Lambda^2 \mathbb{Q}^4$, writing $\mathbf{e}_{ij} = \mathbf{e}_i \wedge \mathbf{e}_j$, determine whether each of the following is decomposable. Justify your answer.

$$\omega_1 = \mathbf{e}_{12} + \mathbf{e}_{13} + 3\mathbf{e}_{14} - 2\mathbf{e}_{23} - \mathbf{e}_{24} + 5\mathbf{e}_{34}, \qquad \omega_2 = \mathbf{e}_{12} + \mathbf{e}_{34} + \mathbf{e}_{14}.$$

Solution. For $\omega = \sum_{i<j} c_{ij}\mathbf{e}_{ij}$ in $\Lambda^2 \mathbb{Q}^4$, expanding gives

$$\omega \wedge \omega = 2(c_{12}c_{34} - c_{13}c_{24} + c_{14}c_{23})\,\mathbf{e}_{1234},$$

since the only pairs of index sets with empty intersection are $\{12\},\{34\}$ and $\{13\},\{24\}$ and $\{14\},\{23\}$, each occurring in two orders, and $\mathbf{e}_{13} \wedge \mathbf{e}_{24} = -\mathbf{e}_{1234}$ while the other two products are $+\mathbf{e}_{1234}$.

For ω_1: $1\cdot 5 - 1\cdot(-1) + 3\cdot(-2) = 5 + 1 - 6 = 0$, so $\omega_1 \wedge \omega_1 = \mathbf{0}$ and the test is inconclusive. In fact ω_1 **is** decomposable: it is $\mathbf{v}_1 \wedge \mathbf{v}_2$ for $\mathbf{v}_1 = (1,0,2,1)$ and $\mathbf{v}_2 = (0,1,1,3)$, by Example (A wedge of two vectors in four-dimensional space).

For ω_2: $1 \cdot 1 - 0 \cdot 0 + 1 \cdot 0 = 1$, so $\omega_2 \wedge \omega_2 = 2\,\mathbf{e}_{1234} \neq \mathbf{0}$. A decomposable $\mathbf{u} \wedge \mathbf{w}$ satisfies $(\mathbf{u} \wedge \mathbf{w}) \wedge (\mathbf{u} \wedge \mathbf{w}) = \mathbf{0}$, so ω_2 is **not** decomposable.

Exercise B3: A Clifford algebra of a line.

Let $V = \mathbb{R}$ with $q(x) = x^2$, the form of signature $(1,0)$. Let $A = \mathbb{R} \times \mathbb{R}$ with componentwise operations, and $\iota_A(x) = (x, -x)$. Prove that (A, ι_A) is a Clifford algebra of (V, q), so that $\mathrm{Cl}_{1,0}(\mathbb{R}) \cong \mathbb{R} \times \mathbb{R}$. Contrast this with $\mathrm{Cl}_{0,1}(\mathbb{R})$.

Solution. A is an associative unital $\mathbb{R}$-algebra with identity $(1,1)$ and $\dim_{\mathbb{R}} A = 2 = 2^1$. The map ι_A is linear, and

$$\iota_A(x)^2 = (x,-x)(x,-x) = (x^2, x^2) = q(x)(1,1),$$

which is (C1). The subalgebra generated by $(1,1)$ and $\iota_A(\mathbb{R}) = \mathrm{span}\{(1,-1)\}$ contains the independent pair $(1,1),(1,-1)$, hence is all of A. By Corollary 14.10.10, (A, ι_A) is a Clifford algebra of (V, q).

The contrast: Chapter 13 showed $\mathrm{Cl}_{0,1}(\mathbb{R}) = \mathbb{C}$ (Example (The complex numbers)), where $q(x) = -x^2$. Both algebras have dimension 2, but $\mathbb{C}$ is a field and $\mathbb{R} \times \mathbb{R}$ has zero divisors, $(1,0)(0,1) = (0,0)$. A single sign in q decides which.

14.10.6.3 C. Going deeper

Exercise C1: The Plücker relation.

Let $\dim V = 4$ with basis $(\mathbf{e}_1, \dots, \mathbf{e}_4)$, let $\operatorname{char} F \neq 2$, and let $\omega = \sum_{i<j} c_{ij}\mathbf{e}_{ij} \in \Lambda^2 V$.

(a) Prove that $\omega \wedge \omega = 2(c_{12}c_{34} - c_{13}c_{24} + c_{14}c_{23})\,\mathbf{e}_{1234}$.

(b) Deduce that if $c_{12}c_{34} - c_{13}c_{24} + c_{14}c_{23} \neq 0$ then ω is not decomposable.

(c) Prove the converse: if the expression vanishes, then ω is decomposable. *Hint: if $\omega \neq \mathbf{0}$, some $c_{ij} \neq 0$; after relabeling the basis assume $c_{12} \neq 0$ and look for ω as a wedge of two vectors whose first two coordinates you may normalize.*

Solution.

(a) By bilinearity, $\omega \wedge \omega = \sum_{S,T} c_S c_T\, \mathbf{e}_S \wedge \mathbf{e}_T$ over 2-element sets S, T. A term vanishes unless $S \cap T = \emptyset$, so the surviving pairs are $(\{1,2\},\{3,4\})$, $(\{1,3\},\{2,4\})$, $(\{1,4\},\{2,3\})$ and their reverses. By Theorem 14.10.3 with $k = l = 2$, reversing a pair does not change the product, so each contributes twice. Sorting, $\mathbf{e}_{12} \wedge \mathbf{e}_{34} = \mathbf{e}_{1234}$; $\mathbf{e}_{13} \wedge \mathbf{e}_{24} = \mathbf{e}_1 \wedge \mathbf{e}_3 \wedge \mathbf{e}_2 \wedge \mathbf{e}_4 = -\mathbf{e}_{1234}$, one transposition; and $\mathbf{e}_{14} \wedge \mathbf{e}_{23} = \mathbf{e}_1 \wedge \mathbf{e}_4 \wedge \mathbf{e}_2 \wedge \mathbf{e}_3 = \mathbf{e}_{1234}$, two transpositions. Collecting gives the stated formula.

(b) If $\omega = \mathbf{u} \wedge \mathbf{w}$ then $\omega \wedge \omega = \mathbf{u} \wedge \mathbf{w} \wedge \mathbf{u} \wedge \mathbf{w} = \mathbf{0}$, a wedge with a repeated vector. Since $\operatorname{char} F \neq 2$, (a) then forces the bracket to vanish. Contrapositively, a nonzero bracket rules out decomposability.

(c) If $\omega = \mathbf{0}$ it is decomposable. Otherwise relabel the basis so that $c_{12} \neq 0$; this is legitimate because a permutation of the basis permutes the six coefficients up to sign and changes the bracket by at most a sign, so both the hypothesis and the conclusion are preserved. Put

$$\mathbf{u} = c_{12}\mathbf{e}_1 - c_{23}\mathbf{e}_3 - c_{24}\mathbf{e}_4, \qquad \mathbf{w} = \mathbf{e}_2 + \tfrac{c_{13}}{c_{12}}\mathbf{e}_3 + \tfrac{c_{14}}{c_{12}}\mathbf{e}_4.$$

Expanding and sorting each wedge,

$$\begin{aligned}\mathbf{u} \wedge \mathbf{w} = {} & c_{12}\mathbf{e}_{12} + c_{13}\mathbf{e}_{13} + c_{14}\mathbf{e}_{14} \\ & + c_{23}\mathbf{e}_{23} + c_{24}\mathbf{e}_{24} + \tfrac{1}{c_{12}}(c_{13}c_{24} - c_{14}c_{23})\,\mathbf{e}_{34}.\end{aligned}$$

Each of the first five coefficients is read off a single product: for instance the $\mathbf{e}_{23}$ term comes from $(-c_{23}\mathbf{e}_3) \wedge \mathbf{e}_2 = c_{23}\mathbf{e}_{23}$, and the $\mathbf{e}_{13}$ term from $c_{12}\mathbf{e}_1 \wedge \tfrac{c_{13}}{c_{12}}\mathbf{e}_3$. The last comes from

$$(-c_{23}\mathbf{e}_3 - c_{24}\mathbf{e}_4) \wedge \left(\tfrac{c_{13}}{c_{12}}\mathbf{e}_3 + \tfrac{c_{14}}{c_{12}}\mathbf{e}_4\right) = \tfrac{c_{13}c_{24} - c_{14}c_{23}}{c_{12}}\,\mathbf{e}_{34}.$$

By hypothesis $c_{13}c_{24} - c_{14}c_{23} = c_{12}c_{34}$, so that coefficient is c_{34} and $\mathbf{u} \wedge \mathbf{w} = \omega$. Hence ω is decomposable.

Exercise C2: Characteristic two.

Let $F = \mathbb{F}_2$ and $\dim V = 4$ with basis $(\mathbf{e}_1, \dots, \mathbf{e}_4)$.

(a) Prove that $\omega \wedge \omega = \mathbf{0}$ for **every** $\omega \in \Lambda^2 V$.

(b) Explain why (a) does not make every element of $\Lambda^2 V$ decomposable, and name the element and the argument that settle it.

(c) Is the statement "$\omega \wedge \omega = \mathbf{0}$ for every ω of odd degree" also special to characteristic 2? Justify your answer.

Solution.

(a) By the computation of Exercise (C1: The Plücker relation) (a), $\omega \wedge \omega$ is 2 times an element of $\Lambda^4 V$, and $2 = 0$ in $\mathbb{F}_2$. (Equivalently: in $\sum_{S,T} c_S c_T \, \mathbf{e}_S \wedge \mathbf{e}_T$ the diagonal terms vanish and the off-diagonal ones pair up, each pair summing to $2c_S c_T \, \mathbf{e}_S \wedge \mathbf{e}_T = \mathbf{0}$.)

(b) Because $\omega \wedge \omega = \mathbf{0}$ is only a **necessary** condition for decomposability, and over $\mathbb{F}_2$ everything satisfies it, so it carries no information at all. The element $\omega = \mathbf{e}_1 \wedge \mathbf{e}_2 + \mathbf{e}_3 \wedge \mathbf{e}_4$ is still not decomposable, by Theorem 14.10.4, whose proof computes $\mathbf{v} \wedge \omega$ for a general $\mathbf{v}$ and never divides by 2.

(c) No, that one is characteristic-free: Theorem 14.10.3 proves $\omega \wedge \omega = \mathbf{0}$ for odd degree over every field, by pairing off the terms with $S \neq T$ rather than by dividing. Over $\mathbb{F}_2$ the statement is true but vacuous as a test, for the same reason as in (a).

Exercise C3: The even part of a Clifford algebra.

Let $\operatorname{char} F \neq 2$, $\dim V = n \geq 1$, and let (C, ι) be a Clifford algebra of (V, q), and let $(\mathbf{e}_1, \dots, \mathbf{e}_n)$ be an orthogonal basis of V for β. Let $C^+ \subseteq C$ be the span of the sorted products with k **even**, and C^- the span of those with k odd. Prove that $C = C^+ \oplus C^-$, that C^+ is a subalgebra of C, and that $\dim_F C^+ = \dim_F C^- = 2^{n-1}$. Is C^- a subalgebra?

Hint: what does the sorting procedure of Proposition 13.12.3 do to the parity of the length of a product?

Solution. The sorted products form a basis of C by Theorem 14.10.8, and they are partitioned by the parity of $|S|$, so $C = C^+ \oplus C^-$ and the two dimensions are $\sum_{k \text{ even}} \binom{n}{k}$ and $\sum_{k \text{ odd}} \binom{n}{k}$. These are equal and sum to 2^n, since $\sum_k (-1)^k \binom{n}{k} = (1-1)^n = 0$ for $n \geq 1$; so each is 2^{n-1}.

For the subalgebra claim, note that the two moves in the proof of Proposition 13.12.3 — swapping two neighboring distinct factors, and replacing $\iota(\mathbf{e}_i)^2$ by the scalar d_i — change the length of a product by 0 and by 2 respectively. Both preserve parity. So the product of two sorted products of lengths k and l is a combination of sorted products of length congruent to $k + l$ modulo 2. Hence $C^+ C^+ \subseteq C^+$, and since $1_C \in C^+$ (the empty product, of length 0), C^+ is a subalgebra.

C^- is not: $1_C \notin C^-$, and $C^- C^- \subseteq C^+$ by the same parity count, so C^- fails to be closed as soon as it holds an element with non-zero square, such as $\iota(\mathbf{e}_i)$ with $q(\mathbf{e}_i) \neq 0$.

14.11 Tensors in Quantum Mechanics

The chapter ends outside mathematics, and the arrangement is the one Chapter 13 used for Minkowski space and for the second derivative test: physics supplies a modeling assumption, the book quotes it and proves nothing about it, and everything after it is linear algebra. The assumption is that a composite quantum system is the tensor product of its parts. Two things follow. One is a phenomenon, **entanglement**, which turns out to be nothing but §02's observation that not every element of $V \otimes W$ is a simple tensor. The other is a theorem, the **Schmidt decomposition**, which turns out to be Chapter 12's singular value decomposition wearing different notation. The second is the real payoff, and it is why this section closes Part IV: it joins the two halves of the book's later chapters at a single point.

14.11.1 What is quoted and what is proved

Quantum mechanics, as a physical theory, is not derived here and cannot be. What we take from it is a short list of modeling conventions, stated once so that the reader can see exactly where the mathematics starts.

(Q1) The states of a quantum system are the **unit vectors** of a complex inner product space V, where two unit vectors differing by a scalar of modulus 1 describe the same state.

(Q2) If a system A has state space V and a system B has state space W, then the composite system "A together with B" has state space $V \otimes W$.

(Q3) If A is in the state $\mathbf{v}$ and B is in the state $\mathbf{w}$, then the composite is in the state $\mathbf{v} \otimes \mathbf{w}$.

None of (Q1)–(Q3) is a theorem, and this book does not argue for any of them. They are quoted exactly as Taylor's theorem was quoted in Chapter 13 §06 — as hypotheses that give the mathematics below something to stand on. Everything proved in this section is a statement about finite-dimensional complex inner product spaces, true whether or not (Q1)–(Q3) describe the world.

Two remarks make the list less arbitrary. First, $\otimes$ rather than $\oplus$ is visible in a dimension count: a spin has a two-dimensional state space, a **qubit**, and two spins together have a four-dimensional one, not a three-dimensional one. Of the two standard constructions, only $\otimes$ produces the observed count, since $\dim(V \otimes W) = \dim V \cdot \dim W$ by Theorem 14.2.5. Second, (Q3) very nearly forces (Q2): the assignment $(\mathbf{v}, \mathbf{w}) \mapsto$ (joint state) is required to be bilinear, and by Definition 14.2.1 every bilinear map out of $V \times W$ factors uniquely through $V \otimes W$. The universal property is the precise statement that the joint state depends on the parts bilinearly and in no other way.

Genuine quantum mechanics uses infinite-dimensional spaces with a completeness condition. Everything below is finite-dimensional, which is where this book lives, and where qubits live too.

Before states can be unit vectors, $V \otimes W$ needs an inner product. There is only one reasonable candidate, and it exists.

Proposition 14.11.1 — The Inner Product on a Tensor Product

Let V and W be finite-dimensional inner product spaces over $F = \mathbb{C}$ (or over $\mathbb{R}$). Then

there is **exactly one** inner product on $V \otimes W$ satisfying

$$\langle \mathbf{v} \otimes \mathbf{w}, \mathbf{v}' \otimes \mathbf{w}' \rangle = \langle \mathbf{v}, \mathbf{v}' \rangle \, \langle \mathbf{w}, \mathbf{w}' \rangle$$

for all $\mathbf{v}, \mathbf{v}' \in V$ and $\mathbf{w}, \mathbf{w}' \in W$. Moreover, if $\mathcal{E}$ and $\mathcal{F}$ are orthonormal bases of V and W, then $(\mathbf{e}_i \otimes \mathbf{f}_j)$ is an orthonormal basis of $V \otimes W$.

Proof. Uniqueness. The simple tensors span $V \otimes W$ (Proposition 14.2.4), and an inner product is additive in the first slot and conjugate-additive in the second, so its values on all pairs of vectors are determined by its values on pairs of simple tensors.

Existence. Fix orthonormal bases $\mathcal{E} = (\mathbf{e}_1, \dots, \mathbf{e}_m)$ of V and $\mathcal{F} = (\mathbf{f}_1, \dots, \mathbf{f}_n)$ of W, which exist by Theorem 10.2.2. By Theorem 14.2.5 the mn vectors $\mathbf{e}_i \otimes \mathbf{f}_j$ form a basis of $V \otimes W$, so the rule

$$\Big\langle \sum_{i,j} c_{ij}\, \mathbf{e}_i \otimes \mathbf{f}_j,\ \sum_{i,j} d_{ij}\, \mathbf{e}_i \otimes \mathbf{f}_j \Big\rangle := \sum_{i,j} c_{ij} \overline{d_{ij}}$$

is well defined; it is the standard inner product of coordinate vectors, hence satisfies (IP1)–(IP3) of Definition 10.1.1. To check the product formula, write $\mathbf{v} = \sum_i a_i \mathbf{e}_i$ and $\mathbf{w} = \sum_j b_j \mathbf{f}_j$. Bilinearity of $\otimes$ gives $\mathbf{v} \otimes \mathbf{w} = \sum_{i,j} a_i b_j\, \mathbf{e}_i \otimes \mathbf{f}_j$, and likewise for $\mathbf{v}' \otimes \mathbf{w}'$, so

$$\langle \mathbf{v} \otimes \mathbf{w}, \mathbf{v}' \otimes \mathbf{w}' \rangle = \sum_{i,j} a_i b_j \overline{a'_i b'_j} = \Big(\sum_i a_i \overline{a'_i} \Big) \Big(\sum_j b_j \overline{b'_j} \Big),$$

which is $\langle \mathbf{v}, \mathbf{v}' \rangle \langle \mathbf{w}, \mathbf{w}' \rangle$ by Theorem 10.2.1. Finally, the product formula gives $\langle \mathbf{e}_i \otimes \mathbf{f}_j, \mathbf{e}_k \otimes \mathbf{f}_l \rangle = \delta_{ik}\delta_{jl}$ for **any** orthonormal $\mathcal{E}$ and $\mathcal{F}$, so the displayed construction did not depend on the pair chosen. This proves the proposition.

■

14.11.2 Entanglement is failure of simplicity

The whole phenomenon fits in the language the chapter already has. A state of the composite is a unit vector of $V \otimes W$, and a state of the form $\mathbf{v} \otimes \mathbf{w}$ is one in which each part has a state of its own. Section 02 proved that not every vector of a tensor product has that form; a composite state that does not describes a system whose parts have no separate states at all.

A state is entangled when it is a vector of $V \otimes W$ that is not a simple tensor.

Definition 14.11.1 — Product State, Entangled State

Let V and W be finite-dimensional complex inner product spaces, and let $\mathbf{z} \in V \otimes W$ be a unit vector. Then $\mathbf{z}$ is a **product state**, also called **separable**, if

$$\mathbf{z} = \mathbf{v} \otimes \mathbf{w} \quad \text{for some } \mathbf{v} \in V,\ \mathbf{w} \in W,$$

and $\mathbf{z}$ is **entangled** otherwise. The same words are used for any non-zero $\mathbf{z} \in V \otimes W$, the unit-length condition playing no part in the distinction.

Clause by clause. **Product state** is a synonym for "simple tensor", the term of §02; only the context is new. The definition is relative to the **splitting** $V \otimes W$, not to the vector alone: "entangled" is a statement about a vector *and* a choice of two factors. And $\mathbf{v}$ and $\mathbf{w}$ need not be unit vectors, though they can be taken so: $\|\mathbf{v} \otimes \mathbf{w}\| = \|\mathbf{v}\|\|\mathbf{w}\|$ by Proposition 14.11.1, so rescaling one factor up and the other down costs nothing.

Example. (The Bell state)

In $\mathbb{C}^2 \otimes \mathbb{C}^2$, write $\mathcal{E} = (\mathbf{e}_1, \mathbf{e}_2)$ for the standard orthonormal basis of the first factor and $\mathcal{F} = (\mathbf{f}_1, \mathbf{f}_2)$ for the same basis regarded as sitting in the second factor, the two names being there only to keep the factors apart. Let

$$\mathbf{z}_0 \coloneqq \tfrac{1}{\sqrt{2}}\big(\mathbf{e}_1 \otimes \mathbf{f}_1 + \mathbf{e}_2 \otimes \mathbf{f}_2\big).$$

Show that $\mathbf{z}_0$ is a unit vector, and that it is entangled.

Solution. By Proposition 14.11.1 the four vectors $\mathbf{e}_i \otimes \mathbf{f}_j$ are orthonormal, so $\|\mathbf{z}_0\|^2 = \frac{1}{2}(1+1) = 1$.

For entanglement there is nothing to prove that §02 has not already proved. Once the two bases are recognized as the same one, $\mathbf{e}_1 \otimes \mathbf{f}_1 + \mathbf{e}_2 \otimes \mathbf{f}_2$ is exactly the tensor of Example (A tensor that is not simple), and $\mathbf{z}_0$ is a non-zero multiple of it: if $\mathbf{z}_0 = \mathbf{v} \otimes \mathbf{w}$ then $\mathbf{e}_1 \otimes \mathbf{f}_1 + \mathbf{e}_2 \otimes \mathbf{f}_2 = (\sqrt{2}\,\mathbf{v}) \otimes \mathbf{w}$, which Example (A tensor that is not simple) rules out. So $\mathbf{z}_0$ is entangled.

The physical reading is one paragraph long, and the book stops there. Under (Q1)–(Q3), a composite in the state $\mathbf{z}_0$ is a pair of qubits of which two things are true at once: the pair has a completely specified state, and neither member has a state at all, since $\mathbf{z}_0$ is not of the form $\mathbf{v} \otimes \mathbf{w}$. Nothing about the individual qubits is being suppressed; the postulates simply do not assign them states. That is what is meant by calling the two qubits entangled, and it is why the word attaches to a piece of linear algebra rather than to a measurement. Whether the postulates are true of the world is a question this book does not address.

Warning. **A sum of simple tensors can still be simple.** "Entangled" does not mean "written as a sum of more than one term". In $\mathbb{C}^2 \otimes \mathbb{C}^2$,

$$\tfrac{1}{2}\big(\mathbf{e}_1 \otimes \mathbf{f}_1 + \mathbf{e}_1 \otimes \mathbf{f}_2 + \mathbf{e}_2 \otimes \mathbf{f}_1 + \mathbf{e}_2 \otimes \mathbf{f}_2\big) = \tfrac{\mathbf{e}_1+\mathbf{e}_2}{\sqrt{2}} \otimes \tfrac{\mathbf{f}_1+\mathbf{f}_2}{\sqrt{2}},$$

a four-term expression for a product state. Entanglement is a property of the **vector**, not of an expression for it, and deciding it needs an invariant. Supplying one is the job of the rest of this section.

Quick check. Is $\mathbf{z} = \frac{1}{\sqrt{3}}\big(\mathbf{e}_1 \otimes \mathbf{f}_1 + \mathbf{e}_1 \otimes \mathbf{f}_2 + \mathbf{e}_2 \otimes \mathbf{f}_1\big)$ in $\mathbb{C}^2 \otimes \mathbb{C}^2$ entangled?

Solution. Yes. Suppose $\mathbf{z} = \mathbf{v} \otimes \mathbf{w}$ with $\mathbf{v} = a_1\mathbf{e}_1 + a_2\mathbf{e}_2$ and $\mathbf{w} = b_1\mathbf{f}_1 + b_2\mathbf{f}_2$. Expanding, $\mathbf{v} \otimes \mathbf{w} = \sum_{i,j} a_i b_j\, \mathbf{e}_i \otimes \mathbf{f}_j$, and the $\mathbf{e}_i \otimes \mathbf{f}_j$ are a basis (Theorem 14.2.5), so comparing coefficients gives

$$a_1b_1 = a_1b_2 = a_2b_1 = \tfrac{1}{\sqrt{3}}, \qquad a_2b_2 = 0.$$

Then $(a_1b_1)(a_2b_2) = 0$ while $(a_1b_2)(a_2b_1) = \frac{1}{3}$; but both products equal $a_1a_2b_1b_2$. So no such $\mathbf{v}, \mathbf{w}$ exist.

14.11.3 The Schmidt decomposition

The Quick check used a 2×2 determinant on an array of coefficients, and that is a hint about where to look. Section 03 already said what the array is: by Theorem 14.3.9 a tensor **is** a linear map, and a linear map between finite-dimensional spaces is a matrix. Chapter 12 knows exactly one thing about an arbitrary matrix, and it knows it completely.

Write out the identification for the case at hand. Fix bases $\mathcal{E} = (\mathbf{e}_1, \dots, \mathbf{e}_m)$ of V and $\mathcal{F} = (\mathbf{f}_1, \dots, \mathbf{f}_n)$ of W, and let $(\varphi_1, \dots, \varphi_n)$ be the basis of W^* dual to $\mathcal{F}$ (Theorem 4.1.3). The map

$$V \times W \to \mathcal{L}(W^*, V), \qquad (\mathbf{v}, \mathbf{w}) \mapsto \big(\varphi \mapsto \varphi(\mathbf{w})\,\mathbf{v}\big),$$

is bilinear in $(\mathbf{v}, \mathbf{w})$, so by Definition 14.2.1 it induces a linear $\Theta\colon V \otimes W \to \mathcal{L}(W^*, V)$. It sends $\mathbf{e}_i \otimes \mathbf{f}_j$ to the map $\varphi_k \mapsto \delta_{jk}\mathbf{e}_i$, whose matrix from $(\varphi_1, \dots, \varphi_n)$ to $\mathcal{E}$ is the matrix unit $\mathbf{E}_{ij}$. The matrix units are a basis of $M_{m\times n}(\mathbb{C})$ and taking the matrix of a map in fixed bases is an isomorphism (Theorem 3.6.4), so Θ carries a basis to a basis and is itself an isomorphism. It is Theorem 14.3.9 with the two factors in the other order and W identified with W^{**} (Theorem 4.4.6), and for coordinate spaces it is §02's matrix model Theorem 14.2.7; the letter is shared for that reason. What matters below is the consequence: the matrix of $\Theta(\mathbf{z})$ is the array of coefficients of $\mathbf{z}$ in the basis $(\mathbf{e}_i \otimes \mathbf{f}_j)$.

Theorem 14.11.2 — Schmidt Decomposition

Let V and W be finite-dimensional complex inner product spaces of dimensions m and n, and let $\mathbf{z} \in V \otimes W$ be non-zero. Then there are an integer r with $1 \le r \le \min(m, n)$, real numbers

$$\sigma_1 \ge \sigma_2 \ge \cdots \ge \sigma_r > 0,$$

an orthonormal list $(\mathbf{x}_1, \dots, \mathbf{x}_r)$ in V and an orthonormal list $(\mathbf{y}_1, \dots, \mathbf{y}_r)$ in W such that

$$\mathbf{z} = \sum_{k=1}^{r} \sigma_k\, \mathbf{x}_k \otimes \mathbf{y}_k. \tag{14.11.1}$$

Moreover r and the numbers $\sigma_1, \dots, \sigma_r$ are determined by $\mathbf{z}$: they do not depend on the lists chosen, nor on any basis. Finally $\|\mathbf{z}\|^2 = \sum_k \sigma_k^2$, so $\mathbf{z}$ is a unit vector exactly when $\sum_k \sigma_k^2 = 1$.

Idea. The statement is the singular value decomposition of Theorem 12.8.1 with the words changed, so the plan is to change the words back. ① Fix orthonormal bases on both sides; Theorem 14.2.5 turns $\mathbf{z}$ into a matrix $\mathbf{C}$ of coefficients, which by the paragraph above is the matrix of the linear map $\Theta(\mathbf{z})$. ② Feed $\mathbf{C}$ to the compact singular value decomposition, Theorem 12.8.3, which over $\mathbb{C}$ still returns **real positive** numbers σ_k and two orthonormal lists of complex column vectors. ③ Read the column vectors back as vectors of V and W; orthonormal columns become orthonormal vectors because coordinates in an orthonormal basis compute inner products. For uniqueness, run ③ backwards: any expression of the shape Eq. 14.11.1 turns into a factorization $\mathbf{C} = \mathbf{X}\mathbf{D}\mathbf{Y}^{\top}$ with $\mathbf{X}, \mathbf{Y}$ having orthonormal columns, and then $\mathbf{C}\mathbf{C}^{*} = \mathbf{X}\mathbf{D}^2\mathbf{X}^{*}$ hands over the σ_k^2 as the non-zero eigenvalues of a matrix built from $\mathbf{z}$ alone.

Proof. **Step 1: turn z into a matrix.** Fix orthonormal bases $\mathcal{E} = (\mathbf{e}_1, \dots, \mathbf{e}_m)$ of V and $\mathcal{F} = (\mathbf{f}_1, \dots, \mathbf{f}_n)$ of W (Theorem 10.2.2). By Theorem 14.2.5 there are unique scalars $c_{ij} \in \mathbb{C}$ with $\mathbf{z} = \sum_{i,j} c_{ij}\, \mathbf{e}_i \otimes \mathbf{f}_j$. Let $\mathbf{C} \in M_{m\times n}(\mathbb{C})$ be the matrix with entries c_{ij}; it is the matrix of the linear map $\Theta(\mathbf{z})$ described above, and it is non-zero because $\mathbf{z}$ is.

Step 2: decompose the matrix. Put $r = \operatorname{rank}\mathbf{C} \geq 1$. By Theorem 12.8.3 there are orthonormal lists $(\mathbf{u}_1, \dots, \mathbf{u}_r)$ in $\mathbb{C}^m$ and $(\mathbf{v}_1, \dots, \mathbf{v}_r)$ in $\mathbb{C}^n$, and the non-zero singular values $\sigma_1 \geq \cdots \geq \sigma_r > 0$ of $\mathbf{C}$ (Definition 12.8.1), with

$$\mathbf{C} = \sum_{k=1}^{r} \sigma_k\, \mathbf{u}_k \mathbf{v}_k^{*}, \qquad \text{that is} \qquad c_{ij} = \sum_{k=1}^{r} \sigma_k (\mathbf{u}_k)_i \overline{(\mathbf{v}_k)_j}.$$

The σ_k are real and positive even though $\mathbf{C}$ is complex, since they are square roots of eigenvalues of the positive semidefinite matrix $\mathbf{C}^{*}\mathbf{C}$. Also $r = \operatorname{rank}\mathbf{C} \leq \min(m, n)$.

Step 3: read the columns back. Set

$$\mathbf{x}_k \coloneqq \sum_{i=1}^{m} (\mathbf{u}_k)_i\, \mathbf{e}_i \ \in V,$$
$$\mathbf{y}_k \coloneqq \sum_{j=1}^{n} \overline{(\mathbf{v}_k)_j}\, \mathbf{f}_j \ \in W.$$

Substituting the formula for c_{ij} into $\mathbf{z} = \sum_{i,j} c_{ij}\, \mathbf{e}_i \otimes \mathbf{f}_j$ and interchanging the three finite sums, bilinearity of $\otimes$ gives

$$\mathbf{z} = \sum_{k=1}^{r} \sigma_k \Big(\sum_i (\mathbf{u}_k)_i \mathbf{e}_i \Big) \otimes \Big(\sum_j \overline{(\mathbf{v}_k)_j} \mathbf{f}_j \Big) = \sum_{k=1}^{r} \sigma_k\, \mathbf{x}_k \otimes \mathbf{y}_k.$$

Since $\mathcal{E}$ is orthonormal, Theorem 10.2.1 gives

$$\langle \mathbf{x}_k, \mathbf{x}_l \rangle = \sum_i (\mathbf{u}_k)_i \overline{(\mathbf{u}_l)_i} = \langle \mathbf{u}_k, \mathbf{u}_l \rangle = \delta_{kl},$$

and likewise, since $\mathcal{F}$ is orthonormal,

$$\langle \mathbf{y}_k, \mathbf{y}_l \rangle = \sum_j \overline{(\mathbf{v}_k)_j} (\mathbf{v}_l)_j = \langle \mathbf{v}_l, \mathbf{v}_k \rangle = \delta_{kl}.$$

So both lists are orthonormal, and Eq. 14.11.1 holds.

Step 4: uniqueness. Suppose $\mathbf{z} = \sum_{k=1}^{s} \tau_k\, \mathbf{x}'_k \otimes \mathbf{y}'_k$ is **any** expression of the stated shape, with $\tau_1 \geq \cdots \geq \tau_s > 0$ and both lists orthonormal. Keep the bases $\mathcal{E}, \mathcal{F}$ and write $\mathbf{x}'_k = \sum_i \xi_{ik} \mathbf{e}_i$ and $\mathbf{y}'_k = \sum_j \eta_{jk} \mathbf{f}_j$. Let $\mathbf{X} \in M_{m\times s}(\mathbb{C})$ have entries ξ_{ik} and $\mathbf{Y} \in M_{n\times s}(\mathbb{C})$ have entries η_{jk}. Orthonormality of the two lists says, by Theorem 10.2.1 again, that the columns of $\mathbf{X}$ and of $\mathbf{Y}$ are orthonormal, that is

$$\mathbf{X}^{*}\mathbf{X} = \mathbf{I}_s, \qquad \mathbf{Y}^{*}\mathbf{Y} = \mathbf{I}_s.$$

Expanding the expression for $\mathbf{z}$ in the basis $(\mathbf{e}_i \otimes \mathbf{f}_j)$ and comparing with the unique coefficients c_{ij} of Step 1,

$$c_{ij} = \sum_{k=1}^{s} \tau_k \, \xi_{ik} \eta_{jk}, \qquad \text{i.e.} \qquad \mathbf{C} = \mathbf{X}\mathbf{D}\mathbf{Y}^{\top},$$

where $\mathbf{D} = \operatorname{diag}(\tau_1, \dots, \tau_s)$. Taking conjugate transposes and using $\mathbf{Y}^{\top}\overline{\mathbf{Y}} = \overline{\mathbf{Y}^{*}\mathbf{Y}} = \mathbf{I}_s$,

$$\mathbf{C}\mathbf{C}^{*} = \mathbf{X}\mathbf{D}\big(\mathbf{Y}^{\top}\overline{\mathbf{Y}}\big)\mathbf{D}\mathbf{X}^{*} = \mathbf{X}\mathbf{D}^{2}\mathbf{X}^{*}.$$

Now read off the eigenvalues of $\mathbf{C}\mathbf{C}^{*} \in M_m(\mathbb{C})$. For each k, the k-th column $\mathbf{X}\mathbf{e}_k$ satisfies

$$\mathbf{C}\mathbf{C}^{*}(\mathbf{X}\mathbf{e}_k) = \mathbf{X}\mathbf{D}^{2}\mathbf{X}^{*}\mathbf{X}\mathbf{e}_k = \mathbf{X}\mathbf{D}^{2}\mathbf{e}_k = \tau_k^{2}\,(\mathbf{X}\mathbf{e}_k),$$

and these s columns are orthonormal. If instead $\mathbf{z}' \in \mathbb{C}^m$ is orthogonal to every column of $\mathbf{X}$ then $\mathbf{X}^{*}\mathbf{z}' = \mathbf{0}$, so $\mathbf{C}\mathbf{C}^{*}\mathbf{z}' = \mathbf{0}$. Since $\mathbb{C}^m = \operatorname{col}(\mathbf{X}) \oplus \operatorname{col}(\mathbf{X})^{\perp}$ by Theorem 10.3.2, putting an orthonormal basis of $\operatorname{col}(\mathbf{X})^{\perp}$ beside the columns of $\mathbf{X}$ produces an orthonormal basis of $\mathbb{C}^m$ consisting of eigenvectors of $\mathbf{C}\mathbf{C}^{*}$. Hence the eigenvalue list of $\mathbf{C}\mathbf{C}^{*}$, with multiplicity, is $\tau_1^2, \dots, \tau_s^2$ together with $m - s$ zeros.

Every τ_k^2 is positive, so s is the number of non-zero eigenvalues of $\mathbf{C}\mathbf{C}^{*}$, and $(\tau_1^2, \dots, \tau_s^2)$ is the list of those eigenvalues in decreasing order. Both are determined by $\mathbf{C}$, which is determined by $\mathbf{z}$ once $\mathcal{E}$ and $\mathcal{F}$ are fixed. So any two expressions of the shape Eq. 14.11.1 have the same s and the same τ_k; in particular they agree with the r and σ_k of Steps 2 and 3, and since the statement "$\mathbf{z}$ admits Eq. 14.11.1 with these r, σ_k" mentions no basis, the numbers cannot depend on $\mathcal{E}$ and $\mathcal{F}$ either.

Step 5: the norm. By Proposition 14.11.1, $\langle \mathbf{x}_k \otimes \mathbf{y}_k, \mathbf{x}_l \otimes \mathbf{y}_l \rangle = \langle \mathbf{x}_k, \mathbf{x}_l \rangle \langle \mathbf{y}_k, \mathbf{y}_l \rangle = \delta_{kl}$, so the r vectors $\mathbf{x}_k \otimes \mathbf{y}_k$ are orthonormal in $V \otimes W$. By Theorem 10.1.3, $\|\mathbf{z}\|^2 = \sum_k \sigma_k^2$. This proves the theorem.

■

Definition 14.11.2 — Schmidt Coefficients, Schmidt Rank

Let $\mathbf{z} \in V \otimes W$ be non-zero. The numbers $\sigma_1 \geq \cdots \geq \sigma_r > 0$ of Theorem 14.11.2 are the **Schmidt coefficients** of $\mathbf{z}$, and the integer r is the **Schmidt rank** of $\mathbf{z}$. By convention the Schmidt rank of $\mathbf{0}$ is 0.

Both are well defined precisely because of Step 4, and the proof identifies them: the Schmidt coefficients are the non-zero singular values of the coefficient matrix of $\mathbf{z}$ in any pair of orthonormal bases, and the Schmidt rank is the rank of that matrix. That is the invariant the warning above asked for, and it is also §02's: the smallest number of simple tensors summing to $\mathbf{z}$ is the rank of $\Theta(\mathbf{z})$, and Theorem 14.11.2 now exhibits a shortest such sum, with its terms orthogonal on both sides at once.

Corollary 14.11.3 — Entanglement Is Schmidt Rank at Least Two

A non-zero $\mathbf{z} \in V \otimes W$ is a product state if and only if its Schmidt rank is 1. Hence a state is entangled exactly when its Schmidt rank is at least 2.

Proof. ($\Leftarrow$) If $r = 1$ then $\mathbf{z} = \sigma_1 \mathbf{x}_1 \otimes \mathbf{y}_1 = (\sigma_1 \mathbf{x}_1) \otimes \mathbf{y}_1$, a simple tensor.

($\Rightarrow$) Suppose $\mathbf{z} = \mathbf{v} \otimes \mathbf{w}$. Neither factor is $\mathbf{0}$, since $\mathbf{z} \neq \mathbf{0}$. Put $\mathbf{x}_1 = \mathbf{v}/\|\mathbf{v}\|$ and $\mathbf{y}_1 = \mathbf{w}/\|\mathbf{w}\|$, which is legitimate because $\|\mathbf{v}\|, \|\mathbf{w}\| > 0$. Then $\mathbf{z} = \sigma_1 \mathbf{x}_1 \otimes \mathbf{y}_1$ with $\sigma_1 = \|\mathbf{v}\|\|\mathbf{w}\| > 0$, and the one-term lists $(\mathbf{x}_1)$, $(\mathbf{y}_1)$ are orthonormal. This is an expression of the shape Eq. 14.11.1 with one term, so the uniqueness clause of Theorem 14.11.2 gives $r = 1$.

■

Warning. **The Schmidt coefficients are determined; the vectors are not.** For the Bell state $\mathbf{z}_0$ of Example (The Bell state) the coefficient matrix is $\frac{1}{\sqrt{2}}\mathbf{I}_2$, whose singular values are $\frac{1}{\sqrt{2}}, \frac{1}{\sqrt{2}}$. Repeated coefficients leave the lists free, exactly as a repeated eigenvalue of $\mathbf{A}^*\mathbf{A}$ leaves $\mathbf{V}$ free in Theorem 12.8.2: for **every** orthonormal basis $(\mathbf{x}_1, \mathbf{x}_2)$ of $\mathbb{C}^2$ one has $\mathbf{z}_0 = \frac{1}{\sqrt{2}}(\mathbf{x}_1 \otimes \mathbf{y}_1 + \mathbf{x}_2 \otimes \mathbf{y}_2)$ for a suitable orthonormal $(\mathbf{y}_1, \mathbf{y}_2)$. Never speak of *the* Schmidt vectors; speak of *the* Schmidt coefficients.

Example. (A Schmidt decomposition in two by three)

In $\mathbb{C}^2 \otimes \mathbb{C}^3$, find the Schmidt decomposition, the Schmidt rank and the Schmidt coefficients of

$$\mathbf{z} = \tfrac{1}{2}\big(\mathbf{e}_1 \otimes \mathbf{f}_1 + \mathbf{e}_1 \otimes \mathbf{f}_3 + \mathbf{e}_2 \otimes \mathbf{f}_2 - \mathbf{e}_2 \otimes \mathbf{f}_3\big),$$

where $\mathcal{E}$ and $\mathcal{F}$ are the standard orthonormal bases.

Solution. The coefficient matrix is

$$\mathbf{C} = \tfrac{1}{2}\begin{pmatrix} 1 & 0 & 1 \\ 0 & 1 & -1 \end{pmatrix} \in M_{2\times 3}(\mathbb{R}).$$

This is half the matrix of Example (A singular value decomposition of a 2 by 3 matrix), so by Exercise (B4: Determine whether) (b) its singular values are half of those found there: $\sigma_1 = \frac{\sqrt{3}}{2}$ and $\sigma_2 = \frac{1}{2}$. Both are non-zero, so $\operatorname{rank}\mathbf{C} = 2$ and the Schmidt rank is 2; by Corollary 14.11.3, $\mathbf{z}$ is entangled. As a check, $\sigma_1^2 + \sigma_2^2 = \frac{3}{4} + \frac{1}{4} = 1$, and indeed $\|\mathbf{z}\|^2 = 4 \cdot \frac{1}{4} = 1$.

For the vectors, Theorem 12.8.3 asks for an orthonormal eigenbasis of the 3×3 matrix $\mathbf{C}^*\mathbf{C}$; as in Example (A singular value decomposition of a 2 by 3 matrix) it is cheaper to work with the smaller $\mathbf{C}\mathbf{C}^\top = \frac{1}{4}\left(\begin{smallmatrix} 2 & -1 \\ -1 & 2 \end{smallmatrix}\right)$, whose orthonormal eigenvectors are the left singular vectors $\mathbf{u}_k$. They are $\frac{1}{\sqrt{2}}(1,-1)$ for the eigenvalue $\frac{3}{4}$ and $\frac{1}{\sqrt{2}}(1,1)$ for $\frac{1}{4}$. So $\mathbf{u}_1 = \frac{1}{\sqrt{2}}(1,-1)$ and $\mathbf{u}_2 = \frac{1}{\sqrt{2}}(1,1)$, and the relation $\mathbf{C}^*\mathbf{u}_i = \sigma_i \mathbf{v}_i$ of Eq. 12.8.3 gives

$$\mathbf{v}_1 = \frac{\mathbf{C}^\top \mathbf{u}_1}{\sigma_1} = \tfrac{1}{\sqrt{6}}(1,-1,2), \qquad \mathbf{v}_2 = \frac{\mathbf{C}^\top \mathbf{u}_2}{\sigma_2} = \tfrac{1}{\sqrt{2}}(1,1,0).$$

All entries are real, so the conjugation in Step 3 of Theorem 14.11.2 does nothing here, and reading the columns back gives

$$\mathbf{x}_1 = \tfrac{1}{\sqrt{2}}(\mathbf{e}_1 - \mathbf{e}_2), \quad \mathbf{y}_1 = \tfrac{1}{\sqrt{6}}(\mathbf{f}_1 - \mathbf{f}_2 + 2\mathbf{f}_3),$$
$$\mathbf{x}_2 = \tfrac{1}{\sqrt{2}}(\mathbf{e}_1 + \mathbf{e}_2), \quad \mathbf{y}_2 = \tfrac{1}{\sqrt{2}}(\mathbf{f}_1 + \mathbf{f}_2),$$

so that $\mathbf{z} = \frac{\sqrt{3}}{2}\,\mathbf{x}_1 \otimes \mathbf{y}_1 + \frac{1}{2}\,\mathbf{x}_2 \otimes \mathbf{y}_2$. Multiplying out recovers $\mathbf{z}$: the two terms are

$\frac{1}{4}(\mathbf{e}_1 - \mathbf{e}_2) \otimes (\mathbf{f}_1 - \mathbf{f}_2 + 2\mathbf{f}_3)$ and $\frac{1}{4}(\mathbf{e}_1 + \mathbf{e}_2) \otimes (\mathbf{f}_1 + \mathbf{f}_2)$, whose coefficients at $\mathbf{e}_1 \otimes \mathbf{f}_2$ and at $\mathbf{e}_2 \otimes \mathbf{f}_1$ cancel, leaving $\frac{1}{2}$ at $\mathbf{e}_1 \otimes \mathbf{f}_1$, $\mathbf{e}_1 \otimes \mathbf{f}_3$ and $\mathbf{e}_2 \otimes \mathbf{f}_2$ and $-\frac{1}{2}$ at $\mathbf{e}_2 \otimes \mathbf{f}_3$.

Remark. Truncating Eq. 14.11.1 after k terms is truncating a singular value decomposition, so Theorem 12.10.3 applies verbatim: the closest state of Schmidt rank at most k is the truncated sum, at distance $(\sum_{i>k} \sigma_i^2)^{1/2}$. Exercise (C2: Best approximation by a state of small Schmidt rank) works this out. The remark also marks the limit of the theorem: everything here concerns **two** factors, because a matrix has two indices. For $V \otimes W \otimes U$ a general vector admits no expression as a sum of simple tensors built from three orthonormal families; the book records that without proof.

14.11.4 Looking back at Part IV

Part IV asked one question in two ways. Chapter 13 took a single bilinear form and asked what it is up to a change of basis; Chapter 14 asked what all multilinear maps have in common, and answered by building the space that turns every one of them into a linear map.

The two chapters answer each other. Chapter 13 worked one form at a time and classified: congruence rather than similarity, complete the square, split off a hyperbolic plane, count signs rather than values. Every invariant it produced — the inertia of Theorem 13.5.1, the Witt index of Definition 13.7.4, the discriminant of Definition 13.2.2 — was a number attached to a form that survives a change of basis, and every classification theorem said that a short list of such numbers is all there is. Chapter 14 worked with all forms at once and constructed: define by universal property and then build a model, impose relations by a quotient, define a map out of a quotient upstairs first, and count a basis by counting index tuples. Where Chapter 13 diagonalized a symmetric form by completing the square, Chapter 14 produced the space $\mathrm{Sym}^2 V$ on which that form is a single linear functional; where Chapter 13 proved that alternating is the characteristic-free strengthening of skew, Chapter 14 built $\Lambda^k V$ by killing $\mathbf{v} \otimes \mathbf{v}$ for exactly that reason; and where Chapter 13 could only say that a Clifford algebra is unique if it exists, Chapter 14 built one out of $T(V)$ and settled its dimension.

This last section adds a third connection, backwards rather than sideways. The Schmidt decomposition is not a new theorem; it is Theorem 12.8.3 with $V \otimes W$ written in place of $M_{m\times n}$. Part III spent a chapter on what a matrix does to two orthonormal bases, one in each of two spaces; Part IV spent a chapter on the space in which a pair of vectors, one from each of two spaces, becomes a single object. Those are the same statement read in two directions, and Theorem 14.3.9 is the sentence that says so. Asked years from now what the tensor product is for, a reader may answer that it is where a bilinear map becomes linear; the shortest true answer is that $V \otimes W$ is where the two sides of a matrix live.

14.11.5 Exercises

14.11.5.1 A. Check your understanding

Exercise A1.

(a) State the three modeling assumptions (Q1)–(Q3) of this section, and say which of them this book proves.

(b) Define **product state** and **entangled state**, and say what data the words depend on besides the vector itself.

(c) State the Schmidt decomposition, with every hypothesis, and say what is unique in it and what is not.

(d) Define the Schmidt rank, and give the criterion for entanglement in terms of it.

(e) True or false: a state written as a sum of three simple tensors has Schmidt rank 3. Justify your answer.

(f) Which theorem of Chapter 12 is the Schmidt decomposition, and which theorem of §03 licenses the translation?

Solution.

(a) (Q1) states are unit vectors of a complex inner product space, up to a scalar of modulus 1; (Q2) the state space of a composite system is the tensor product of the state spaces of the parts; (Q3) if the parts are in states $\mathbf{v}$ and $\mathbf{w}$, the composite is in the state $\mathbf{v} \otimes \mathbf{w}$. The book proves none of them: they are quoted from physics.

(b) A unit vector $\mathbf{z} \in V \otimes W$ is a product state if $\mathbf{z} = \mathbf{v} \otimes \mathbf{w}$ for some $\mathbf{v} \in V$ and $\mathbf{w} \in W$, and entangled otherwise (Definition 14.11.1). The words depend on the **splitting**: the pair of factors V and W, not the vector alone.

(c) Theorem 14.11.2: for V, W finite-dimensional complex inner product spaces and $\mathbf{z} \in V \otimes W$ non-zero, there are $r \geq 1$, reals $\sigma_1 \geq \cdots \geq \sigma_r > 0$ and orthonormal lists $(\mathbf{x}_k)$ in V and $(\mathbf{y}_k)$ in W with $\mathbf{z} = \sum_k \sigma_k \mathbf{x}_k \otimes \mathbf{y}_k$. The number r and the σ_k are unique; the lists are not.

(d) The Schmidt rank is that r (Definition 14.11.2). By Corollary 14.11.3, $\mathbf{z}$ is entangled exactly when $r \geq 2$.

(e) False. The Schmidt rank is at most 3, but need not equal 3: the warning after Definition 14.11.1 displays a four-term sum whose Schmidt rank is 1.

(f) It is Theorem 12.8.3, the compact form of the Singular Value Decomposition Theorem 12.8.1. The translation is licensed by Theorem 14.3.9, which identifies a tensor with a linear map and hence, in bases, with a matrix.

14.11.5.2 B. Practice

Exercise B1: Determine which are entangled.

Work in $\mathbb{C}^2 \otimes \mathbb{C}^2$ with the standard orthonormal bases. Determine which of the following unit vectors are entangled. Justify your answer, and for each product state exhibit the two factors.

(a) $\frac{1}{2}(\mathbf{e}_1 \otimes \mathbf{f}_1 + \mathbf{e}_1 \otimes \mathbf{f}_2 + \mathbf{e}_2 \otimes \mathbf{f}_1 + \mathbf{e}_2 \otimes \mathbf{f}_2)$

(b) $\frac{1}{\sqrt{2}}(\mathbf{e}_1 \otimes \mathbf{f}_2 - \mathbf{e}_2 \otimes \mathbf{f}_1)$

(c) $\frac{1}{\sqrt{3}}(\mathbf{e}_1 \otimes \mathbf{f}_1 + \mathbf{e}_1 \otimes \mathbf{f}_2 + \mathbf{e}_2 \otimes \mathbf{f}_2)$

(d) $\frac{1}{\sqrt{10}}(\mathbf{e}_1 \otimes \mathbf{f}_1 + 2\mathbf{e}_1 \otimes \mathbf{f}_2 - \mathbf{e}_2 \otimes \mathbf{f}_1 - 2\mathbf{e}_2 \otimes \mathbf{f}_2)$

Solution. By Corollary 14.11.3 and the identification of the Schmidt rank with the rank of the coefficient matrix, it suffices to compute $\operatorname{rank} \mathbf{C}$ in each case, and for a 2×2 matrix that is decided by the determinant.

(a) $\mathbf{C} = \frac{1}{2}\left(\begin{smallmatrix}1&1\\1&1\end{smallmatrix}\right)$, with $\det \mathbf{C} = 0$ and $\mathbf{C} \neq \mathbf{0}$, so $\operatorname{rank} \mathbf{C} = 1$: a product state. Indeed it equals $\frac{1}{\sqrt{2}}(\mathbf{e}_1 + \mathbf{e}_2) \otimes \frac{1}{\sqrt{2}}(\mathbf{f}_1 + \mathbf{f}_2)$.

(b) $\mathbf{C} = \frac{1}{\sqrt{2}}\left(\begin{smallmatrix}0&1\\-1&0\end{smallmatrix}\right)$, with $\det \mathbf{C} = \frac{1}{2} \neq 0$, so $\operatorname{rank} \mathbf{C} = 2$: entangled.

(c) $\mathbf{C} = \frac{1}{\sqrt{3}}\left(\begin{smallmatrix}1&1\\0&1\end{smallmatrix}\right)$, with $\det \mathbf{C} = \frac{1}{3} \neq 0$, so $\operatorname{rank} \mathbf{C} = 2$: entangled.

(d) $\mathbf{C} = \frac{1}{\sqrt{10}}\left(\begin{smallmatrix}1&2\\-1&-2\end{smallmatrix}\right)$, with $\det \mathbf{C} = 0$ and $\mathbf{C} \neq \mathbf{0}$, so $\operatorname{rank} \mathbf{C} = 1$: a product state, equal to $\frac{1}{\sqrt{2}}(\mathbf{e}_1 - \mathbf{e}_2) \otimes \frac{1}{\sqrt{5}}(\mathbf{f}_1 + 2\mathbf{f}_2)$.

Exercise B2: A Schmidt decomposition.

In $\mathbb{C}^2 \otimes \mathbb{C}^2$, let

$$\mathbf{z} = \frac{1}{\sqrt{10}}\big(\mathbf{e}_1 \otimes \mathbf{f}_1 + 2\mathbf{e}_1 \otimes \mathbf{f}_2 + 2\mathbf{e}_2 \otimes \mathbf{f}_1 + \mathbf{e}_2 \otimes \mathbf{f}_2\big).$$

Find the Schmidt coefficients, the Schmidt rank and a Schmidt decomposition of $\mathbf{z}$, and verify that $\sum_k \sigma_k^2 = 1$.

Solution. The coefficient matrix is $\mathbf{C} = \frac{1}{\sqrt{10}}\left(\begin{smallmatrix}1&2\\2&1\end{smallmatrix}\right)$, which is real symmetric. Then

$$\mathbf{C}\mathbf{C}^{\top} = \frac{1}{10}\begin{pmatrix}5&4\\4&5\end{pmatrix},$$

with characteristic polynomial $x^2 - x + \frac{9}{100}$ and eigenvalues $\frac{9}{10}$ and $\frac{1}{10}$. So the Schmidt coefficients are $\sigma_1 = \frac{3}{\sqrt{10}}$ and $\sigma_2 = \frac{1}{\sqrt{10}}$, the Schmidt rank is 2, and $\sigma_1^2 + \sigma_2^2 = \frac{9}{10} + \frac{1}{10} = 1$.

Eigenvectors of $\mathbf{C}\mathbf{C}^{\top}$ are $\mathbf{u}_1 = \frac{1}{\sqrt{2}}(1,1)$ for $\frac{9}{10}$ and $\mathbf{u}_2 = \frac{1}{\sqrt{2}}(1,-1)$ for $\frac{1}{10}$. Then

$$\mathbf{v}_1 = \frac{\mathbf{C}^{\top}\mathbf{u}_1}{\sigma_1} = \frac{1}{\sqrt{2}}(1,1), \qquad \mathbf{v}_2 = \frac{\mathbf{C}^{\top}\mathbf{u}_2}{\sigma_2} = \frac{1}{\sqrt{2}}(-1,1).$$

All entries are real, so reading the columns back as in Step 3 of Theorem 14.11.2,

$$\mathbf{x}_1 = \frac{\mathbf{e}_1 + \mathbf{e}_2}{\sqrt{2}}, \quad \mathbf{y}_1 = \frac{\mathbf{f}_1 + \mathbf{f}_2}{\sqrt{2}},$$
$$\mathbf{x}_2 = \frac{\mathbf{e}_1 - \mathbf{e}_2}{\sqrt{2}}, \quad \mathbf{y}_2 = \frac{-\mathbf{f}_1 + \mathbf{f}_2}{\sqrt{2}},$$

and $\mathbf{z} = \frac{3}{\sqrt{10}}\,\mathbf{x}_1 \otimes \mathbf{y}_1 + \frac{1}{\sqrt{10}}\,\mathbf{x}_2 \otimes \mathbf{y}_2$. Expanding the two terms gives $\frac{1}{2\sqrt{10}}(3-1)\mathbf{e}_1 \otimes \mathbf{f}_1$ and similarly for the other three coefficients, recovering $\mathbf{z}$.

Exercise B3: How large can the Schmidt rank be?.

Let V and W be complex inner product spaces with $\dim V = m$ and $\dim W = n$.

(a) Prove that every non-zero $\mathbf{z} \in V \otimes W$ has Schmidt rank at most $\min(m, n)$.

(b) Give, for each r with $1 \le r \le \min(m, n)$, a unit vector of Schmidt rank exactly r.

Solution.

(a) Fix orthonormal bases and let $\mathbf{C} \in M_{m\times n}(\mathbb{C})$ be the coefficient matrix of $\mathbf{z}$. By Theorem 14.11.2 the Schmidt rank is $\operatorname{rank} \mathbf{C}$, and the rank of an $m \times n$ matrix is at

most $\min(m,n)$ because $\operatorname{rank}\mathbf{C} = \dim\operatorname{col}(\mathbf{C}) \le m$ and $\operatorname{rank}\mathbf{C} = \dim\operatorname{row}(\mathbf{C}) \le n$.

(b) Take $\mathbf{z}_r = \frac{1}{\sqrt{r}}\sum_{k=1}^{r}\mathbf{e}_k \otimes \mathbf{f}_k$. The lists $(\mathbf{e}_1,\dots,\mathbf{e}_r)$ and $(\mathbf{f}_1,\dots,\mathbf{f}_r)$ are orthonormal and every coefficient $1/\sqrt{r}$ is positive, so this is already an expression of the shape Eq. 14.11.1; by the uniqueness clause the Schmidt rank is r. It is a unit vector since $r\cdot(1/\sqrt{r})^2 = 1$.

14.11.5.3 C. Going deeper

Exercise C1: Acting on one part at a time.

Let $S \in \mathcal{L}(V)$ and $T \in \mathcal{L}(W)$ be unitary, and let $\mathbf{z} \in V \otimes W$ be non-zero.

(a) Prove that $(S\otimes T)(\mathbf{z})$ has the same Schmidt coefficients, and hence the same Schmidt rank, as $\mathbf{z}$.

(b) Hence deduce that no operator of the form $S \otimes T$ with S, T unitary carries the Bell state $\mathbf{z}_0$ of Example (The Bell state) to a product state.

Hint for (a): apply $S\otimes T$ to a Schmidt decomposition.

Solution.

(a) Write $\mathbf{z} = \sum_{k=1}^{r}\sigma_k\,\mathbf{x}_k\otimes\mathbf{y}_k$ as in Theorem 14.11.2. By Definition 14.3.1, $(S\otimes T)(\mathbf{x}_k\otimes\mathbf{y}_k) = S\mathbf{x}_k\otimes T\mathbf{y}_k$, so by linearity

$$(S\otimes T)(\mathbf{z}) = \sum_{k=1}^{r}\sigma_k\,(S\mathbf{x}_k)\otimes(T\mathbf{y}_k).$$

A unitary operator preserves inner products (Theorem 10.7.3), so $\langle S\mathbf{x}_k, S\mathbf{x}_l\rangle = \langle\mathbf{x}_k,\mathbf{x}_l\rangle = \delta_{kl}$ and likewise for T. Both lists are therefore orthonormal, the σ_k are still positive and decreasing, and the display is an expression of the shape Eq. 14.11.1 for $(S\otimes T)(\mathbf{z})$. By the uniqueness clause of Theorem 14.11.2, its Schmidt coefficients are $\sigma_1,\dots,\sigma_r$ and its Schmidt rank is r.

(b) The Schmidt rank of $\mathbf{z}_0$ is 2, as computed in the warning after Corollary 14.11.3. By (a), $(S\otimes T)(\mathbf{z}_0)$ also has Schmidt rank 2, and by Corollary 14.11.3 a product state has Schmidt rank 1. So $(S\otimes T)(\mathbf{z}_0)$ is entangled.

Exercise C2: Best approximation by a state of small Schmidt rank.

Let $\mathbf{z} \in V\otimes W$ be non-zero with Schmidt decomposition $\mathbf{z} = \sum_{k=1}^{r}\sigma_k\,\mathbf{x}_k\otimes\mathbf{y}_k$, and let $0 \le k \le r$. Put $\mathbf{z}_{(k)} = \sum_{i=1}^{k}\sigma_i\,\mathbf{x}_i\otimes\mathbf{y}_i$.

(a) Fix orthonormal bases of V and W and let $\mathbf{C}$ be the coefficient matrix of $\mathbf{z}$. Prove that $\|\mathbf{z}\| = \|\mathbf{C}\|_F$, and that the Schmidt rank of a vector equals the rank of its coefficient matrix.

(b) Hence deduce that for every $\mathbf{z}' \in V\otimes W$ of Schmidt rank at most k,

$$\|\mathbf{z}-\mathbf{z}'\| \;\ge\; \Big(\sum_{i>k}\sigma_i^2\Big)^{1/2},$$

with equality for $\mathbf{z}' = \mathbf{z}_{(k)}$.

Solution.

(a) By Proposition 14.11.1 the basis $(\mathbf{e}_i \otimes \mathbf{f}_j)$ of $V \otimes W$ is orthonormal, so $\|\mathbf{z}\|^2 = \sum_{i,j} |c_{ij}|^2$ by Theorem 10.9.2, and that sum is $\|\mathbf{C}\|_F^2$ by the definition of the Frobenius norm. For the second claim, Step 2 of Theorem 14.11.2 produced the Schmidt coefficients as the non-zero singular values of $\mathbf{C}$, and Theorem 12.8.1 says there are $\operatorname{rank}\mathbf{C}$ of them.

(b) The map $\mathbf{z} \mapsto \mathbf{C}$ is the coordinate isomorphism attached to the basis $(\mathbf{e}_i \otimes \mathbf{f}_j)$ (Corollary 3.5.5), with the mn coordinates arranged in a rectangle, so it is linear and bijective; and by (a) it carries $\|\cdot\|$ to $\|\cdot\|_F$ and Schmidt rank to matrix rank. Let $\mathbf{B}$ be the coefficient matrix of $\mathbf{z}'$, so $\operatorname{rank}\mathbf{B} \le k$. By Theorem 12.10.3,

$$\|\mathbf{z} - \mathbf{z}'\| = \|\mathbf{C} - \mathbf{B}\|_F \;\ge\; \Big(\sum_{i>k} \sigma_i^2\Big)^{1/2},$$

since the non-zero σ_i are the singular values of $\mathbf{C}$. Running Step 3 of Theorem 14.11.2 backwards turns $\mathbf{z}_{(k)}$ into the rank-k truncation $\mathbf{C}_k$ (Definition 12.10.1) of a compact singular value decomposition of $\mathbf{C}$ (Theorem 12.8.3), and Theorem 12.10.3 attains equality there.

Exercise C3: Does the field matter?.

Let V and W be **real** inner product spaces of dimensions m and n, with orthonormal bases $\mathcal{E}$ and $\mathcal{F}$, and let $\mathbf{z} \in V \otimes W$ have coefficient matrix $\mathbf{C} \in M_{m\times n}(\mathbb{R})$. Let $\mathbf{z}_{\mathbb{C}} \in \mathbb{C}^m \otimes \mathbb{C}^n$ be the vector whose coefficient matrix in the standard orthonormal bases is the same $\mathbf{C}$.

(a) Prove that Theorem 14.11.2 holds verbatim over $\mathbb{R}$, with orthonormal lists of real vectors.

(b) Prove that $\mathbf{z}$ and $\mathbf{z}_{\mathbb{C}}$ have the same Schmidt coefficients and the same Schmidt rank.

(c) Is the same true of the Schmidt **vectors**? Justify your answer.

Solution.

(a) Every step of the proof runs over $F = \mathbb{R}$. Theorem 10.2.2, Theorem 14.2.5, Theorem 12.8.3, Theorem 10.2.1 and Theorem 10.3.2 are all stated for $F = \mathbb{R}$ or $\mathbb{C}$, and over $\mathbb{R}$ the conjugations in Step 3 and Step 4 are the identity, so $\mathbf{y}_k = \sum_j (\mathbf{v}_k)_j \mathbf{f}_j$ and $\mathbf{C}\mathbf{C}^{\top} = \mathbf{X}\mathbf{D}^2\mathbf{X}^{\top}$.

(b) By Step 4 of Theorem 14.11.2, read over each field in turn, the Schmidt coefficients of $\mathbf{z}$ and of $\mathbf{z}_{\mathbb{C}}$ are both times the positive square roots of the non-zero eigenvalues of $\mathbf{C}\mathbf{C}^{\top}$, and both Schmidt ranks equal $\operatorname{rank}\mathbf{C}$. This is one and the same real symmetric matrix with one and the same characteristic polynomial, so the eigenvalues agree; and $\operatorname{rank}\mathbf{C}$ is unchanged because row reduction over $\mathbb{R}$ is row reduction over $\mathbb{C}$.

(c) No. The warning after Corollary 14.11.3 says why: a repeated Schmidt coefficient leaves the vectors free, and over $\mathbb{C}$ there is more freedom to use. For $\mathbf{z}_0$ the

orthonormal pair $\mathbf{x}_1 = \frac{1}{\sqrt{2}}(\mathbf{e}_1 + i\mathbf{e}_2)$, $\mathbf{x}_2 = \frac{1}{\sqrt{2}}(\mathbf{e}_1 - i\mathbf{e}_2)$ occurs in a complex Schmidt decomposition — with $\mathbf{y}_1 = \frac{1}{\sqrt{2}}(\mathbf{f}_1 - i\mathbf{f}_2)$ and $\mathbf{y}_2 = \frac{1}{\sqrt{2}}(\mathbf{f}_1 + i\mathbf{f}_2)$ — and has no real counterpart. What is invariant is the coefficient list, not the vectors.

Chapter 15

Norms and Matrix Analysis

Nine chapters have been writing promissory notes. Chapter 8 asked what happens to $\mathbf{A}^m$ and Chapter 9 §10 answered exactly, entry by entry, with no number attached to the answer: Theorem 9.10.2 says *whether* the powers die out, never *how fast*. Chapter 9 §09 built $e^{\mathbf{A}}$ out of a series (Definition 9.9.2) and promised that the estimates would come once there was something to estimate with. Chapter 10 solved the least-squares problem (Theorem 10.4.2) and then, at Theorem 10.8.1, recommended one algorithm over another for a reason it could not yet state. Chapter 11 §01 proved that every matrix has a diagonalizable matrix arbitrarily close to it (Corollary 11.1.6) and left the word "close" doing work no definition supported. Chapter 12 §08 met a number, the largest stretching factor of a matrix, and said that this chapter would give it a name. Every one of those debts is the same debt: the book has had no way to say **how big** a vector or a matrix is, except through one particular inner product.

A **norm** is that way. It keeps exactly what measurement needs — a length is zero only for the zero vector, it scales with the scalar, and a detour is never shorter than the direct route — and it throws away the inner product that Chapter 10 used to produce it. There are many norms, and the first surprise is that in finite dimension it does not matter which one you pick: any two of them are trapped between constant multiples of each other, so they agree about every limit, every bounded set and every continuous function. The second surprise is that the constants cannot be made independent of the dimension, and that the whole theorem collapses in infinite dimension. From there the chapter measures matrices, and then uses the measurements: the spectral radius as the infimum of all the norms, a geometric series that inverts $\mathbf{I}-\mathbf{A}$, quantitative bounds for the exponential, the continuity of eigenvalues, and finally the condition number, which is the exact constant in the sentence "a small change in the data produces a small change in the answer".

The field in this chapter is $\mathbb{R}$ or $\mathbb{C}$. A norm returns a real number and its homogeneity clause uses $|c|$, so the scalars must have an absolute value; no other field in this book has one. This is the same restriction Chapters 10 to 12 worked under, and for the same reason.

15.0.1 The analysis this chapter imports

This chapter leans on analysis harder than any before it, and the book's practice is to name what it borrows rather than let it pass unnoticed — as Chapter 13 §06 did with Taylor's theorem, and Chapter 10 with the theorem of Abel and Ruffini. Here is the complete list. Each item is standard, each is quoted without proof, and **each is named again at the point where it is used**.

(A1) *(Completeness.)* Every non-empty set of real numbers that is bounded above has a least upper bound; equivalently, every Cauchy sequence of real or complex numbers converges. One standard consequence is used as well: every real number is the limit of a sequence of rational numbers.

(A2) *(Monotone convergence.)* An increasing sequence of real numbers that is bounded above converges, and its limit is its least upper bound.

(A3) *(Compactness of the closed unit ball.)* In $\mathbb{R}^n$ and in $\mathbb{C}^n$ with the Euclidean norm, every sequence lying in a closed bounded set has a subsequence converging to a point **of that set**. In particular the closed unit ball and the unit sphere are compact.

(A4) *(Extreme value theorem.)* A continuous real-valued function on a non-empty compact set attains a maximum value and a minimum value; the bounds are not merely approached, they are reached.

(A5) *(Intermediate value theorem.)* A continuous real-valued function on an interval takes every value between any two of its values.

(A6) *(Mean value theorem.)* A real-valued function differentiable on an interval satisfies $f(b) - f(a) = f'(c)(b-a)$ for some c strictly between a and b. Two consequences are used: a function with negative derivative throughout an interval is strictly decreasing there, and a function whose derivative is positive to the left of a point and negative to its right attains its maximum at that point.

Alongside these, the **elementary algebra of limits** is used throughout without further comment: limits respect sums, products and quotients with non-vanishing denominator; sums, products and composites of continuous functions are continuous; and a non-strict inequality survives a limit, so that $a_k \le M$ for every k forces $\lim a_k \le M$. Chapter 9 §09 quoted the same package as its fact (A3). What the list above records is everything beyond that.

Several of these speak of **continuity**, which the book has not needed until now, so fix the meaning here. A function f defined on a subset of a normed space is **continuous at $\mathbf{x}$** when $\|\mathbf{x}_k - \mathbf{x}\| \to 0$ forces $f(\mathbf{x}_k) \to f(\mathbf{x})$ for every sequence $(\mathbf{x}_k)$ in its domain, and **continuous** when it is continuous at every point of its domain. This is the sequential form, matching the way (A3) is stated. Every continuity claim in this chapter is established the same cheap way: by exhibiting a constant M with $|f(\mathbf{x}) - f(\mathbf{y})| \le M\|\mathbf{x} - \mathbf{y}\|$, which gives the implication at once. §02 proves the first such bound.

Nothing else analytic enters silently. Where a section needs a fact outside this list — the differentiability of the entries of a matrix-valued function, or the continuous dependence of the roots of a polynomial on its coefficients — it is recorded as an assumption in the same manner, with a counterexample proved where one is available, and never used as a step in a proof that pretends to be self-contained.

15.0.2 What you need

The chapter is built on results the book already has. Gathered by source, so that a reader can go back to one place at a time:

- **Chapter 1 and Chapter 3** — bases, dimension and coordinates: Definition 1.5.1, Definition 1.6.1, Definition 1.5.2, Theorem 1.5.2, Corollary 3.5.5.
- **Chapter 10 §01** — the inner product and the norm it induces, with their three properties and the two inequalities that follow: Definition 10.1.1, Definition 10.1.3, Theorem 10.1.2, Theorem 10.1.5, Corollary 10.1.6, together with the two exercises that recover an inner

product from its norm, Exercise (C1: The parallelogram law characterizes inner-product norms) and Exercise (C2: Recovering the inner product from the norm).

- **Chapter 10 §04 and §08** — least squares and the **QR** factorization whose stability claim was deferred: Theorem 10.4.2, Corollary 10.4.4, Theorem 10.8.1.
- **Chapter 9 §10** — the whole convergence apparatus that this chapter re-proves with numbers attached: Definition 9.10.1, Lemma 9.10.1, Theorem 9.10.2, Theorem 9.10.3, Theorem 9.10.4, Theorem 9.10.6, Corollary 9.10.5.
- **Chapter 9 §09 and §03** — the matrix exponential and the Jordan form: Definition 9.9.2, Theorem 9.9.3, Theorem 9.9.4, Theorem 9.3.1.
- **Chapter 11** — Schur triangularization with its density corollary, and the Frobenius norm with the defect it measures: Theorem 11.1.2, Corollary 11.1.6, Lemma 11.11.1, Theorem 11.11.2, Definition 11.11.1.
- **Chapter 12** — the singular value decomposition and the two constructions built on it: Theorem 12.8.1, Definition 12.8.1, Definition 12.11.1.

15.0.3 Roadmap

- **Norms.** The three axioms, the 1-, 2- and ∞-norms with their unit balls drawn, and the test that decides which norms come from an inner product: the parallelogram law. This pays off a promise made in Chapter 10 §01.
- **All norms agree.** On a finite-dimensional space any two norms are trapped between constant multiples of each other. Compactness enters the book here, and the payoff is that Chapter 9 §10's entrywise convergence is simply *the* convergence, whatever norm one prefers.
- **Measuring a matrix.** Submultiplicativity, and the operator norm $\|\mathbf{A}\| = \max\{\|\mathbf{Ax}\| : \|\mathbf{x}\| = 1\}$ induced by a vector norm. Its formulas for $p = 1, 2, \infty$, including $\|\mathbf{A}\|_2 = \sigma_1(\mathbf{A})$, which is the name Chapter 12 §08 asked for.
- **The spectral radius.** $\rho(\mathbf{A}) \le \|\mathbf{A}\|$ for every matrix norm, a norm that comes within ε of $\rho(\mathbf{A})$, and Gelfand's formula $\rho(\mathbf{A}) = \lim \|\mathbf{A}^k\|^{1/k}$.
- **Inverting a perturbation of the identity.** The Neumann series, the openness of the invertible matrices, and the first perturbation estimate.
- **The exponential, with bounds; and derivatives.** $\|e^{\mathbf{A}}\| \le e^{\|\mathbf{A}\|}$, decay when the spectrum sits in the left half plane, and the derivatives of the determinant and of the inverse.
- **Eigenvalues move continuously.** Continuously as a multiset, and no better: a Jordan block's eigenvalues move like $\varepsilon^{1/k}$.
- **How wrong can the answer be?** The condition number $\kappa(\mathbf{A}) = \|\mathbf{A}\|\|\mathbf{A}^{-1}\|$, what it predicts about solving $\mathbf{Ax} = \mathbf{b}$, and why the normal equations square it.

15.0.4 Named moves

- **Compactness turns "for all unit vectors" into a maximum.** A supremum over the unit sphere is hard to control; a maximum is attained at a vector you can name and feed back into the argument. Both the equivalence of norms and the very existence of the operator norm are this one move.
- **Ask for submultiplicativity.** A matrix is a vector, so a matrix norm is a vector norm; what makes it useful is the extra clause $\|\mathbf{AB}\| \le \|\mathbf{A}\|\|\mathbf{B}\|$, which is the only reason a bound on $\|\mathbf{A}\|$ says anything about $\mathbf{A}^k$. Test every candidate against it, and expect natural-looking candidates to fail.

- **Bound the tail of a series.** Neumann, the exponential and Gelfand all reduce to estimating $\sum_{k\geq K}\|\mathbf{A}\|^k$ or $\sum_{k\geq K}\|\mathbf{A}\|^k/k!$ by something that visibly tends to zero.
- **Perturb and compare.** Replace $\mathbf{A}$ by $\mathbf{A}+\mathbf{E}$, subtract the two conclusions, and read the result as a bound on the relative change in the answer by a constant times the relative change in the data. The constant is the condition number.
- **Reduce to the 2-norm.** Equivalence of norms means any single norm may be used as the hub: prove the estimate for the Euclidean norm, where the inner product and the singular value decomposition are available, and transfer.

15.1 Norms

Chapter 10 measured vectors, and measured them in exactly one way: $\|\mathbf{v}\| = \sqrt{\langle \mathbf{v}, \mathbf{v}\rangle}$. Every length in Chapters 10 to 12 came out of that formula. This section keeps the measuring and throws the inner product away. The reason is not economy. The quantities this part of the book owes — how fast a sequence of matrices settles down, how far a solution moves when the data moves — are often measured most naturally by a size that no inner product produces, and the arguments that use them turn out to need only three properties of a length.

The field here is $\mathbb{R}$ or $\mathbb{C}$, as it is throughout the chapter. A length is a real number, and the scaling rule below multiplies it by $|c|$; so the scalars must carry an absolute value, and these are the only fields in this book that do.

15.1.1 What measurement actually needs

Look back at how $\|\cdot\|$ was used after Chapter 10 defined it. Cauchy–Schwarz needed the inner product. So did Pythagoras, orthogonality and the adjoint. But a long list of arguments did not: that a convergent sequence is bounded, that $\|\mathbf{Ax}\|$ is small when $\mathbf{x}$ is small, that a limit of unit vectors is a unit vector, that $\|\mathbf{u}-\mathbf{w}\| \leq \|\mathbf{u}-\mathbf{v}\| + \|\mathbf{v}-\mathbf{w}\|$. Every one of those used only that $\|\mathbf{v}\|$ vanishes just for $\mathbf{v}=\mathbf{0}$, that $\|c\mathbf{v}\| = |c|\|\mathbf{v}\|$, and the triangle inequality of Corollary 10.1.6. Three properties, used over and over. Following the book's habit, we give the three of them a name and see what else satisfies them.

A norm is a length: zero only at the zero vector, scaling with the scalar, and never rewarding a detour.

Definition 15.1.1 — Norm

Let F be $\mathbb{R}$ or $\mathbb{C}$ and let V be a vector space **over** F. A **norm** on V is a function

$$\|\cdot\| : V \to \mathbb{R}$$

such that for **all** $\mathbf{u}, \mathbf{v} \in V$ and **all** $c \in F$:

(N1) $\|\mathbf{v}\| \geq 0$, and $\|\mathbf{v}\| = 0$ **only** for $\mathbf{v} = \mathbf{0}$ (**positive definiteness**);
(N2) $\|c\mathbf{v}\| = |c|\,\|\mathbf{v}\|$ (**absolute homogeneity**);
(N3) $\|\mathbf{u}+\mathbf{v}\| \leq \|\mathbf{u}\| + \|\mathbf{v}\|$ (**the triangle inequality**).

A vector space carrying a norm is a **normed space**. A vector with $\|\mathbf{v}\| = 1$ is a **unit**

vector, and replacing a non-zero $\mathbf{v}$ by $\mathbf{v}/\|\mathbf{v}\|$ is **normalizing** it.

In words, clause by clause. (N1) says the output is a genuine non-negative size, and that only the zero vector has size zero; the word **only** is the whole content, since the reverse implication is free (take $c = 0$ in (N2) to get $\|\mathbf{0}\| = 0 \cdot \|\mathbf{0}\| = 0$). (N2) says that stretching a vector by c stretches its length by $|c|$ — the **absolute value** of c, so that $\|-\mathbf{v}\| = \|\mathbf{v}\|$ and, over $\mathbb{C}$, $\|i\mathbf{v}\| = \|\mathbf{v}\|$. (N3) says that going from $\mathbf{0}$ to $\mathbf{u}+\mathbf{v}$ directly is at most as long as going by way of $\mathbf{u}$. Note what the definition does not mention: no second vector is paired with the first, no angle appears, and there is no inner product anywhere.

Two remarks on the shape of the definition. First, the codomain is $\mathbb{R}$ even when $F = \mathbb{C}$: a length is never complex. Second, the three clauses are not independent of the arithmetic of $\mathbb{R}$ — (N3) is an inequality, and inequalities are why the field had to be restricted.

Example. (The 1-, 2- and ∞-norms on F^n)

For $\mathbf{x} = (x_1, \dots, x_n) \in F^n$ put

$$\begin{aligned} \|\mathbf{x}\|_1 &= |x_1| + \cdots + |x_n|, \\ \|\mathbf{x}\|_2 &= \left(|x_1|^2 + \cdots + |x_n|^2\right)^{1/2}, \\ \|\mathbf{x}\|_\infty &= \max\{|x_1|, \dots, |x_n|\}. \end{aligned}$$

Check each of them against Definition 15.1.1.

Solution. (N1) holds for all three: each is a sum, a square root of a sum, or a maximum of the non-negative numbers $|x_i|$, so each is ≥ 0; and each vanishes only when every $|x_i| = 0$, that is, only for $\mathbf{x} = \mathbf{0}$. (N2) holds because $|cx_i| = |c||x_i|$ for every i, and the common factor $|c|$ comes out of a sum, out of a square root of a sum of squares, and out of a maximum of non-negative numbers alike.

For (N3), the 1-norm inherits it one coordinate at a time: $|x_i + y_i| \leq |x_i| + |y_i|$ for each i by the triangle inequality for the modulus (Theorem 0.6.4, which covers $F = \mathbb{R}$ as well), and summing over i gives $\|\mathbf{x}+\mathbf{y}\|_1 \leq \|\mathbf{x}\|_1 + \|\mathbf{y}\|_1$. The ∞-norm inherits it too, but from one coordinate rather than all: for each i,

$$|x_i + y_i| \leq |x_i| + |y_i| \leq \|\mathbf{x}\|_\infty + \|\mathbf{y}\|_\infty,$$

and a bound valid for every i bounds the maximum. The 2-norm is the norm induced by the standard inner product on F^n (Definition 10.1.3), so its triangle inequality is Corollary 10.1.6 and needs no fresh argument.

So one space carries at least three different norms. For $\mathbf{x} = (3, -4, 12) \in \mathbb{R}^3$ they give $\|\mathbf{x}\|_1 = 19$, $\|\mathbf{x}\|_2 = 13$ and $\|\mathbf{x}\|_\infty = 12$ — three honest answers to "how big is $\mathbf{x}$", and no reason yet to prefer one.

Remark. There is a p-norm $\|\mathbf{x}\|_p = \left(\sum_i |x_i|^p\right)^{1/p}$ for every real $p \geq 1$, and $\|\mathbf{x}\|_\infty$ is its limit as $p \to \infty$. Its triangle inequality is Minkowski's inequality, which Chapter 17 proves from Hölder's inequality (and which is the first place real powers t^p and the logarithm are set up properly). This chapter uses only $p = 1, 2, \infty$, and each of those was verified above from scratch.

Example. (Inner products, weights, and a function space)

Three further families.

(a) **Every inner product gives a norm.** If V is an inner product space, then $\|\mathbf{v}\| = \sqrt{\langle \mathbf{v}, \mathbf{v}\rangle}$ satisfies (N1) and (N2) by Theorem 10.1.2 (a), (b) and (N3) by Corollary 10.1.6. In particular the Frobenius norm $\|\mathbf{A}\|_F$ on $M_{m\times n}(F)$ and the norm $\left(\int_0^1 |f|^2\right)^{1/2}$ on $C[0,1]$ are norms.

(b) **Weighted norms.** Fix real weights $w_1, \dots, w_n > 0$ and put $\|\mathbf{x}\|_w = \max_i w_i|x_i|$. All three clauses go through exactly as for $\|\cdot\|_\infty$, the weights riding along untouched; positivity of every w_i is what (N1) needs.

(c) **The sup norm.** On $C[0,1]$, the real continuous functions on $[0,1]$, put $\|f\|_\infty = \max_{t\in[0,1]}|f(t)|$.

For (c) the maximum has to exist before the formula defines anything, and that is the first place this chapter borrows: $[0,1]$ is compact and $|f|$ is continuous, so by **the extreme value theorem, fact (A4) of the chapter introduction**, the maximum is attained. Granting that, (N1) says a continuous function with $\max|f| = 0$ is the zero function, which is true pointwise; (N2) and (N3) follow from the corresponding facts about $|\cdot|$ at each point, exactly as for $\|\cdot\|_\infty$ on F^n. Note that $C[0,1]$ is infinite-dimensional — it contains all the polynomials — and it is kept in view deliberately, because §02's main theorem will fail on it.

A degenerate case is worth one line. On $V = F$ itself, $\|c\| = |c|$ is a norm, and (N2) forces every norm on F to be $\|c\| = |c|\|1\|$, a positive multiple of that one. On the zero space $V = \{\mathbf{0}\}$ the only function to $\mathbb{R}$ is $\|\mathbf{0}\| = 0$, and it is a norm. Both matter: they say that the theory is not empty at the bottom, and the first of them is the model for the general statement that any two norms differ by bounded factors.

Example. (Three near misses)

Change one feature of an example above and watch a single clause break.

(a) **Drop the square root.** On F^n put $N(\mathbf{x}) = |x_1|^2 + \cdots + |x_n|^2$. Then (N1) still holds. But $N(c\mathbf{x}) = |c|^2 N(\mathbf{x})$, so (N2) fails as soon as $|c| \neq 0, 1$: for $\mathbf{x} = \mathbf{e}_1$ and $c = 2$ it gives $N(2\mathbf{e}_1) = 4 \neq 2 = |2|N(\mathbf{e}_1)$. The square root in $\|\cdot\|_2$ is there for exactly this reason.

(b) **Forget a coordinate.** On F^2 put $N(\mathbf{x}) = |x_1|$. Then (N2) and (N3) both hold, inherited from $|\cdot|$ on F. What fails is the word **only** in (N1): $N(\mathbf{e}_2) = 0$ while $\mathbf{e}_2 \neq \mathbf{0}$. A function satisfying (N1) with "only" deleted, together with (N2) and (N3), is called a **seminorm**; it measures a quotient of V rather than V.

(c) **Bend the exponent the other way.** On $\mathbb{R}^2$ put $N(\mathbf{x}) = \left(|x_1|^{1/2} + |x_2|^{1/2}\right)^2$. Then (N1) holds, and (N2) holds because $|c|^{1/2}$ factors out of the inner sum and is squared back to $|c|$. Only (N3) fails: $N(\mathbf{e}_1) = N(\mathbf{e}_2) = 1$ but $N(\mathbf{e}_1 + \mathbf{e}_2) = (1+1)^2 = 4 > 2$.

Item (c) is the one to remember, because it shows the three clauses are genuinely independent: two of them can hold exactly while the third fails, and it is the failing one that carries all the geometry.

Warning. **A norm is not determined by what it does to the standard basis.** Both $\|\cdot\|_1$ and $\|\cdot\|_\infty$ give every $\mathbf{e}_i$ length 1, and so does $\|\cdot\|_2$, yet the three disagree everywhere else: on $\mathbf{1} = (1, \dots, 1)$ they return n, 1 and $\sqrt{n}$. Knowing the lengths of a basis pins down nothing, and this is worth holding on to, because §02's theorem is sometimes misremembered as saying that norms which agree on a basis agree everywhere. It says no such thing.

One small consequence of (N3) will be used twice below and again in §02, so it gets a name here. It is Exercise (B4: A lower bound for a difference of norms) with the inner product removed from the proof.

Lemma 15.1.1 — Reverse Triangle Inequality

Let $\|\cdot\|$ be a norm on V. Then for all $\mathbf{u}, \mathbf{v} \in V$,

$$\big|\, \|\mathbf{u}\| - \|\mathbf{v}\| \,\big| \le \|\mathbf{u} - \mathbf{v}\|.$$

Proof. By (N3) applied to $\mathbf{u} = (\mathbf{u} - \mathbf{v}) + \mathbf{v}$, we have $\|\mathbf{u}\| \le \|\mathbf{u} - \mathbf{v}\| + \|\mathbf{v}\|$, so $\|\mathbf{u}\| - \|\mathbf{v}\| \le \|\mathbf{u} - \mathbf{v}\|$. Swapping the roles of $\mathbf{u}$ and $\mathbf{v}$ gives $\|\mathbf{v}\| - \|\mathbf{u}\| \le \|\mathbf{v} - \mathbf{u}\|$, and $\|\mathbf{v} - \mathbf{u}\| = |-1|\|\mathbf{u} - \mathbf{v}\| = \|\mathbf{u} - \mathbf{v}\|$ by (N2). The number $\big|\|\mathbf{u}\| - \|\mathbf{v}\|\big|$ is one of the two quantities just bounded, so it is at most $\|\mathbf{u} - \mathbf{v}\|$. This proves the inequality. ∎

Read with $\mathbf{v}$ replaced by $\mathbf{v}'$, it says that the function $\|\cdot\|$ changes by at most $\|\mathbf{u} - \mathbf{v}\|$ when its argument moves from $\mathbf{u}$ to $\mathbf{v}$. That is a Lipschitz estimate, and it is the reason a norm is continuous with respect to itself — a fact §02 turns into the main theorem.

15.1.2 Unit balls

The quickest way to see the difference between two norms is to draw the set of vectors they call short.

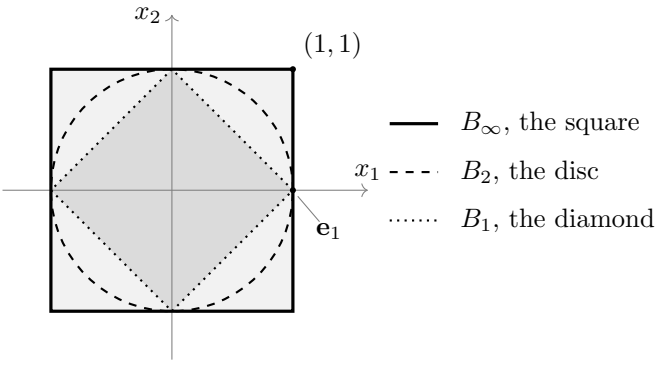
Definition 15.1.2 — Closed Unit Ball

Let $\|\cdot\|$ be a norm on V. Its **closed unit ball** is

$$B_{\|\cdot\|} = \{\mathbf{v} \in V : \|\mathbf{v}\| \le 1\}.$$

In F^n we write B_1, B_2 and B_∞ for the balls of Example (The 1-, 2- and ∞-norms on F^n).

In $\mathbb{R}^2$ the three are a diamond, a disc and a square, and they are nested.



The closed unit balls of the three norms on $\mathbb{R}^2$. A smaller ball belongs to a larger norm: $B_1 \subseteq B_2 \subseteq B_\infty$ says exactly that $\|\mathbf{x}\|_\infty \le \|\mathbf{x}\|_2 \le \|\mathbf{x}\|_1$, and all three agree at $\mathbf{e}_1$

Two features of the picture are general. Each ball is **symmetric**, $\mathbf{v} \in B$ if and only if $-\mathbf{v} \in B$, which is (N2) with $c = -1$; and each is **convex**, since if $\|\mathbf{u}\|, \|\mathbf{v}\| \le 1$ and $0 \le t \le 1$ then

$$\|t\mathbf{u} + (1-t)\mathbf{v}\| \le t\|\mathbf{u}\| + (1-t)\|\mathbf{v}\| \le 1$$

by (N3) and (N2). The diamond has corners and the square has corners; convexity is what the triangle inequality buys, and it is all it buys. The disc is rounder than the other two for a reason that is the subject of the last part of this section.

The nesting in the picture is an inequality, and it holds in every dimension, with a matching chain running the other way.

Proposition 15.1.2 — Comparing the Three Norms

For every $\mathbf{x} \in F^n$,

$$\|\mathbf{x}\|_\infty \le \|\mathbf{x}\|_2 \le \|\mathbf{x}\|_1$$

and

$$\|\mathbf{x}\|_1 \le \sqrt{n}\,\|\mathbf{x}\|_2, \qquad \|\mathbf{x}\|_2 \le \sqrt{n}\,\|\mathbf{x}\|_\infty.$$

Each of the four inequalities is attained: the first two by $\mathbf{x} = \mathbf{e}_1$, the last two by $\mathbf{x} = \mathbf{1}$.

Idea. Four inequalities, two moves. The ones **without** a $\sqrt{n}$ compare a sum against its largest term, or a sum of squares against the square of a sum, and need nothing but non-negativity. The ones **with** a $\sqrt{n}$ are a trade of n terms against one, and the sharp constant comes from Cauchy–Schwarz against the all-ones vector $\mathbf{1}$ — which is exactly why $\mathbf{1}$ is the vector that attains them.

Proof. Write $a_i = |x_i| \ge 0$ and let $a_k = \max_i a_i$. Then $a_k^2 \le \sum_i a_i^2$, and taking non-negative square roots gives $\|\mathbf{x}\|_\infty \le \|\mathbf{x}\|_2$. Next,

$$\|\mathbf{x}\|_1^2 = \Big(\sum_i a_i\Big)^2 = \sum_i a_i^2 + \sum_{i \ne j} a_i a_j \;\ge\; \|\mathbf{x}\|_2^2,$$

since every cross term $a_i a_j$ is ≥ 0; taking square roots gives $\|\mathbf{x}\|_2 \le \|\mathbf{x}\|_1$.

For the third inequality, apply Theorem 10.1.5 in $\mathbb{R}^n$ with the dot product to the vectors

$(a_1, \dots, a_n)$ and $\mathbf{1}$:

$$\|\mathbf{x}\|_1 = \sum_i a_i \cdot 1 \le \Big(\sum_i a_i^2\Big)^{1/2} \Big(\sum_i 1\Big)^{1/2} = \sqrt{n}\,\|\mathbf{x}\|_2.$$

For the fourth, $\sum_i a_i^2 \le n \max_i a_i^2$, and taking square roots gives $\|\mathbf{x}\|_2 \le \sqrt{n}\,\|\mathbf{x}\|_\infty$.

For the equality cases, $\mathbf{e}_1$ has $\|\mathbf{e}_1\|_1 = \|\mathbf{e}_1\|_2 = \|\mathbf{e}_1\|_\infty = 1$, and $\mathbf{1}$ has $\|\mathbf{1}\|_1 = n$, $\|\mathbf{1}\|_2 = \sqrt{n}$ and $\|\mathbf{1}\|_\infty = 1$, so $\|\mathbf{1}\|_1 = \sqrt{n}\,\|\mathbf{1}\|_2$ and $\|\mathbf{1}\|_2 = \sqrt{n}\,\|\mathbf{1}\|_\infty$. This proves the proposition.

■

So the three norms never disagree by a factor worse than $\sqrt{n}$, and the factor $\sqrt{n}$ really occurs. Hold on to both halves of that sentence: §02 proves the first half for *every* pair of norms, and the second half is why its constants cannot be made to forget the dimension.

Quick check. Sketch the set $\{\mathbf{x} \in \mathbb{R}^2 : \|\mathbf{x}\|_w \le 1\}$ for the weighted norm $\|\mathbf{x}\|_w = \max(|x_1|, 2|x_2|)$ of Example (Inner products, weights, and a function space) (b), and find the smallest C with $\|\mathbf{x}\|_\infty \le C\|\mathbf{x}\|_w$ for all $\mathbf{x}$.

Solution. The ball is the rectangle $|x_1| \le 1$, $|x_2| \le \frac{1}{2}$: the square B_∞ squashed vertically by a factor 2. Since $|x_1| \le \|\mathbf{x}\|_w$ and $|x_2| \le \frac{1}{2}\|\mathbf{x}\|_w$, we get $\|\mathbf{x}\|_\infty \le \|\mathbf{x}\|_w$, so $C = 1$ works, and it is smallest because $\mathbf{x} = \mathbf{e}_1$ gives $\|\mathbf{x}\|_\infty = \|\mathbf{x}\|_w = 1$. The other direction costs a factor: $\|\mathbf{x}\|_w \le 2\|\mathbf{x}\|_\infty$, attained at $\mathbf{e}_2$. Squashing a ball inward enlarges the norm, and the largest squash factor is the constant.

15.1.3 Which norms come from an inner product

Chapter 10 §01 closed with a promise. It observed that Theorem 10.1.2 (a), (b) and Corollary 10.1.6 make every induced norm a norm in the general sense, warned that the converse fails, and named the test: the **parallelogram law**

$$\|\mathbf{u}+\mathbf{v}\|^2 + \|\mathbf{u}-\mathbf{v}\|^2 = 2\|\mathbf{u}\|^2 + 2\|\mathbf{v}\|^2. \tag{$*$}$$

It then proved one direction outright — expand both sides with Theorem 10.1.2 (c) and add — and left the converse to Exercise (C1: The parallelogram law characterizes inner-product norms), which carries it out in $\mathbb{R}^2$ while **granting** one step, the homogeneity $\beta(\mathbf{u}, t\mathbf{v}) = t\beta(\mathbf{u}, \mathbf{v})$ for real t. That exercise's own remark says where the gap is: additivity gives homogeneity for rational t by induction, and passing to real t needs a limit.

Here is what this section adds. The dimension 2 in Exercise (C1: The parallelogram law characterizes inner-product norms) was never used, so the computation runs in any real space; the granted step is supplied by a limit, using the completeness of $\mathbb{R}$; and the complex case, which Chapter 10 did not touch at all, is built from the real one. The result is the theorem the promise described, with no hypothesis on the dimension.

Theorem 15.1.3 — The Parallelogram Law Characterizes Inner-Product Norms

Let F be $\mathbb{R}$ or $\mathbb{C}$, let V be a vector space over F, and let $\|\cdot\|$ be a norm on V. Then there

is an inner product on V with $\langle \mathbf{v}, \mathbf{v} \rangle = \|\mathbf{v}\|^2$ for every $\mathbf{v}$ **if and only if** $\|\cdot\|$ satisfies the parallelogram law $(*)$ for all $\mathbf{u}, \mathbf{v} \in V$. When it exists, that inner product is unique.

Idea. The forward direction is Chapter 10's computation. For the converse there is only one candidate for the inner product, because Exercise (C2: Recovering the inner product from the norm) already shows that an inner product is determined by its norm through polarization; so write down the polarization formula and check the axioms. ① Over $\mathbb{R}$ the symmetry and the additivity are the computation of Exercise (C1: The parallelogram law characterizes inner-product norms), which never mentions the dimension. ② Homogeneity comes free for rational scalars and is pushed to real scalars by a limit, which is the one analytic step. ③ Over $\mathbb{C}$, apply ① and ② to V regarded as a real space, then glue the real form β and its twist $\beta(\mathbf{u}, i\mathbf{v})$ into a complex inner product; the single identity $\beta(i\mathbf{u}, i\mathbf{v}) = \beta(\mathbf{u}, \mathbf{v})$ does all the work.

Proof. $(\Rightarrow)$ Suppose $\langle \mathbf{v}, \mathbf{v} \rangle = \|\mathbf{v}\|^2$ for an inner product on V. By Theorem 10.1.2 (c) and the same identity with $-\mathbf{v}$ in place of $\mathbf{v}$,

$$\|\mathbf{u} + \mathbf{v}\|^2 = \|\mathbf{u}\|^2 + 2\,\mathrm{Re}\langle \mathbf{u}, \mathbf{v} \rangle + \|\mathbf{v}\|^2,$$
$$\|\mathbf{u} - \mathbf{v}\|^2 = \|\mathbf{u}\|^2 - 2\,\mathrm{Re}\langle \mathbf{u}, \mathbf{v} \rangle + \|\mathbf{v}\|^2.$$

Adding them gives $(*)$.

$(\Leftarrow)$ Suppose $(*)$ holds. Regard V as a vector space over $\mathbb{R}$, by restricting which scalars are allowed. This changes nothing about $\|\cdot\|$: the vectors, the addition and the values of the norm are the same, and (N2) for real c is a special case of (N2) for $c \in F$. Define

$$\beta(\mathbf{u}, \mathbf{v}) = \tfrac{1}{4}\big(\|\mathbf{u} + \mathbf{v}\|^2 - \|\mathbf{u} - \mathbf{v}\|^2\big).$$

Step 1. β **is symmetric and additive in each slot.** Exercise (C1: The parallelogram law characterizes inner-product norms) runs this computation in $\mathbb{R}^2$; rather than transport an exercise past the hypotheses it was stated under, here it is in full, for an arbitrary V.

Setting $\mathbf{v} = \mathbf{u}$ gives $\beta(\mathbf{u}, \mathbf{u}) = \frac{1}{4}\|2\mathbf{u}\|^2 = \|\mathbf{u}\|^2$ by (N2). Swapping the arguments replaces $\|\mathbf{u} - \mathbf{v}\|$ by $\|\mathbf{v} - \mathbf{u}\|$, equal by (N2) with $c = -1$, so $\beta(\mathbf{u}, \mathbf{v}) = \beta(\mathbf{v}, \mathbf{u})$; and $\beta(\mathbf{u}, \mathbf{0}) = 0$.

For additivity, apply $(*)$ twice. To the pair $\mathbf{u} + \frac{1}{2}(\mathbf{v} + \mathbf{w})$, $\frac{1}{2}(\mathbf{v} - \mathbf{w})$, whose sum is $\mathbf{u} + \mathbf{v}$ and whose difference is $\mathbf{u} + \mathbf{w}$:

$$\|\mathbf{u} + \mathbf{v}\|^2 + \|\mathbf{u} + \mathbf{w}\|^2 = 2\|\mathbf{u} + \tfrac{1}{2}(\mathbf{v} + \mathbf{w})\|^2 + 2\|\tfrac{1}{2}(\mathbf{v} - \mathbf{w})\|^2.$$

Then to the pair $\mathbf{u} - \frac{1}{2}(\mathbf{v} + \mathbf{w})$, $\frac{1}{2}(\mathbf{w} - \mathbf{v})$, whose sum is $\mathbf{u} - \mathbf{v}$ and whose difference is $\mathbf{u} - \mathbf{w}$:

$$\|\mathbf{u} - \mathbf{v}\|^2 + \|\mathbf{u} - \mathbf{w}\|^2 = 2\|\mathbf{u} - \tfrac{1}{2}(\mathbf{v} + \mathbf{w})\|^2 + 2\|\tfrac{1}{2}(\mathbf{w} - \mathbf{v})\|^2.$$

Subtract the second from the first. On the left, the two differences of squares are $4\beta(\mathbf{u}, \mathbf{v})$ and $4\beta(\mathbf{u}, \mathbf{w})$, by the definition of β. On the right, the last terms cancel, since $\|\frac{1}{2}(\mathbf{v} - \mathbf{w})\| = \|\frac{1}{2}(\mathbf{w} - \mathbf{v})\|$ by (N2) with $c = -1$, and the remaining difference of squares is $4\beta\big(\mathbf{u}, \frac{1}{2}(\mathbf{v} + \mathbf{w})\big)$. So $4\beta(\mathbf{u}, \mathbf{v}) + 4\beta(\mathbf{u}, \mathbf{w}) = 8\beta\big(\mathbf{u}, \frac{1}{2}(\mathbf{v} + \mathbf{w})\big)$, that is,

$$\beta(\mathbf{u}, \mathbf{v}) + \beta(\mathbf{u}, \mathbf{w}) = 2\,\beta\big(\mathbf{u}, \tfrac{1}{2}(\mathbf{v} + \mathbf{w})\big).$$

Taking $\mathbf{w} = \mathbf{0}$ and using $\beta(\mathbf{u}, \mathbf{0}) = 0$ turns the right-hand side into $2\beta(\mathbf{u}, \frac{1}{2}\mathbf{v})$, so $\beta(\mathbf{u}, \mathbf{v}) = 2\beta(\mathbf{u}, \frac{1}{2}\mathbf{v})$ for every $\mathbf{v}$; substituting that back with $\mathbf{v} + \mathbf{w}$ in place of $\mathbf{v}$ gives

$$\beta(\mathbf{u}, \mathbf{v}) + \beta(\mathbf{u}, \mathbf{w}) = \beta(\mathbf{u}, \mathbf{v} + \mathbf{w})$$

for all $\mathbf{u}, \mathbf{v}, \mathbf{w} \in V$. Nothing in this argument mentions a dimension. Additivity in the first slot follows from the symmetry.

Step 2. $\beta(\mathbf{u}, t\mathbf{v}) = t\,\beta(\mathbf{u}, \mathbf{v})$ for every real t. This is the step Exercise (C1: The parallelogram law characterizes inner-product norms) granted. First, $\beta(\mathbf{u}, -\mathbf{v}) = -\beta(\mathbf{u}, \mathbf{v})$, directly from the definition of β, since replacing $\mathbf{v}$ by $-\mathbf{v}$ exchanges the two terms. Next, induction on $m \geq 0$ using Step 1 gives $\beta(\mathbf{u}, m\mathbf{v}) = m\beta(\mathbf{u}, \mathbf{v})$, the case $m = 0$ being $\beta(\mathbf{u}, \mathbf{0}) = 0$; combined with the previous sentence this covers every integer m. For a rational $q = m/n$ with $n \geq 1$,

$$n\,\beta\big(\mathbf{u}, q\mathbf{v}\big) = \beta\big(\mathbf{u}, nq\mathbf{v}\big) = \beta(\mathbf{u}, m\mathbf{v}) = m\,\beta(\mathbf{u}, \mathbf{v}),$$

so $\beta(\mathbf{u}, q\mathbf{v}) = q\beta(\mathbf{u}, \mathbf{v})$.

Now fix a real t and put $M = \|\mathbf{u}\| + (|t| + 1)\|\mathbf{v}\|$. For any rational q with $|q - t| \leq 1$, both $\|\mathbf{u} \pm t\mathbf{v}\|$ and $\|\mathbf{u} \pm q\mathbf{v}\|$ are at most M by (N2) and (N3), while Lemma 15.1.1 and (N2) give

$$\big|\,\|\mathbf{u} \pm t\mathbf{v}\| - \|\mathbf{u} \pm q\mathbf{v}\|\,\big| \leq |t - q|\,\|\mathbf{v}\|.$$

Since $|a^2 - b^2| = |a - b|(a + b)$ for $a, b \geq 0$, each of the two squared terms in β moves by at most $2M\|\mathbf{v}\||t - q|$, and therefore

$$\big|\beta(\mathbf{u}, t\mathbf{v}) - \beta(\mathbf{u}, q\mathbf{v})\big| \leq M\|\mathbf{v}\|\,|t - q|.$$

By **the completeness of $\mathbb{R}$, fact (A1) of the chapter introduction**, there is a sequence of rationals $q_k \to t$, and we may assume $|q_k - t| \leq 1$. Then

$$\begin{aligned}
&\big|\beta(\mathbf{u}, t\mathbf{v}) - t\beta(\mathbf{u}, \mathbf{v})\big| \\
&\quad\leq \big|\beta(\mathbf{u}, t\mathbf{v}) - \beta(\mathbf{u}, q_k\mathbf{v})\big| + |q_k - t|\,|\beta(\mathbf{u}, \mathbf{v})| \\
&\quad\leq \big(M\|\mathbf{v}\| + |\beta(\mathbf{u}, \mathbf{v})|\big)|q_k - t|,
\end{aligned}$$

where the middle term used $\beta(\mathbf{u}, q_k\mathbf{v}) = q_k\beta(\mathbf{u}, \mathbf{v})$. The left-hand side does not depend on k, and the right-hand side tends to 0, so the left-hand side is 0.

If $F = \mathbb{R}$, we are done: β is symmetric, bilinear by Steps 1 and 2, and $\beta(\mathbf{v}, \mathbf{v}) = \|\mathbf{v}\|^2 > 0$ for $\mathbf{v} \neq \mathbf{0}$ by (N1), so (IP1), (IP2) and (IP3) of Definition 10.1.1 all hold and the induced norm is $\|\cdot\|$.

Step 3. The complex case. Suppose $F = \mathbb{C}$. Steps 1 and 2 apply to V as a real space, so β is a symmetric $\mathbb{R}$-bilinear form with $\beta(\mathbf{v}, \mathbf{v}) = \|\mathbf{v}\|^2$. Define

$$\langle \mathbf{u}, \mathbf{v} \rangle = \beta(\mathbf{u}, \mathbf{v}) + i\,\beta(\mathbf{u}, i\mathbf{v}).$$

Everything follows from one identity: $\beta(i\mathbf{u}, i\mathbf{v}) = \beta(\mathbf{u}, \mathbf{v})$, which holds because $\|i\mathbf{u} \pm i\mathbf{v}\| = \|i(\mathbf{u} \pm \mathbf{v})\| = |i|\|\mathbf{u} \pm \mathbf{v}\| = \|\mathbf{u} \pm \mathbf{v}\|$ by (N2). Applying it twice, $\beta(i\mathbf{u}, \mathbf{v}) = \beta(i \cdot i\mathbf{u}, i\mathbf{v}) = -\beta(\mathbf{u}, i\mathbf{v})$.

(IP3) and the norm: $\beta(\mathbf{u}, i\mathbf{u}) = \frac{1}{4}(\|\mathbf{u} + i\mathbf{u}\|^2 - \|\mathbf{u} - i\mathbf{u}\|^2)$, and (N2) turns this into $\frac{1}{4}(|1 + i|^2 - |1 - i|^2)\|\mathbf{u}\|^2 = 0$. Hence $\langle \mathbf{u}, \mathbf{u} \rangle = \beta(\mathbf{u}, \mathbf{u}) = \|\mathbf{u}\|^2$, which is > 0 for $\mathbf{u} \neq \mathbf{0}$, and the induced norm is $\|\cdot\|$.

(IP1): additivity in the first slot and homogeneity for real scalars come from Steps 1 and 2 applied to both $\beta(\cdot, \mathbf{v})$ and $\beta(\cdot, i\mathbf{v})$. For the scalar i,

$$\begin{aligned}\langle i\mathbf{u}, \mathbf{v}\rangle &= \beta(i\mathbf{u}, \mathbf{v}) + i\,\beta(i\mathbf{u}, i\mathbf{v}) \\ &= -\beta(\mathbf{u}, i\mathbf{v}) + i\,\beta(\mathbf{u}, \mathbf{v}) = i\,\langle \mathbf{u}, \mathbf{v}\rangle.\end{aligned}$$

Every complex scalar is $a + bi$ with a, b real, so (IP1) follows.

(IP2): using $\beta(\mathbf{v}, i\mathbf{u}) = \beta(i\mathbf{v}, i \cdot i\mathbf{u}) = -\beta(\mathbf{u}, i\mathbf{v})$ and the symmetry of β,

$$\langle \mathbf{v}, \mathbf{u}\rangle = \beta(\mathbf{u}, \mathbf{v}) - i\,\beta(\mathbf{u}, i\mathbf{v}) = \overline{\langle \mathbf{u}, \mathbf{v}\rangle}.$$

So $\langle \cdot, \cdot \rangle$ is an inner product inducing $\|\cdot\|$.

Uniqueness. Suppose $\langle \cdot, \cdot \rangle'$ is any inner product on V with $\langle \mathbf{v}, \mathbf{v}\rangle' = \|\mathbf{v}\|^2$ for every $\mathbf{v}$. The two displays of the ($\Rightarrow$) direction apply to it verbatim, and subtracting them instead of adding them gives

$$\|\mathbf{u} + \mathbf{v}\|^2 - \|\mathbf{u} - \mathbf{v}\|^2 = 4\,\mathrm{Re}\langle \mathbf{u}, \mathbf{v}\rangle',$$

that is, $\mathrm{Re}\langle \mathbf{u}, \mathbf{v}\rangle' = \beta(\mathbf{u}, \mathbf{v})$: the real part of $\langle \cdot, \cdot \rangle'$ is forced to be the β built above. Over $\mathbb{R}$ an inner product is real-valued, so $\langle \mathbf{u}, \mathbf{v}\rangle' = \beta(\mathbf{u}, \mathbf{v})$ and there is nothing left to choose. Over $\mathbb{C}$, apply the same identity to the pair $\mathbf{u}, i\mathbf{v}$. By (IP1) and (IP2) together the form is conjugate-linear in its second slot, so $\langle \mathbf{u}, i\mathbf{v}\rangle' = \bar{i}\,\langle \mathbf{u}, \mathbf{v}\rangle' = -i\,\langle \mathbf{u}, \mathbf{v}\rangle'$, whose real part is $\mathrm{Im}\langle \mathbf{u}, \mathbf{v}\rangle'$. Hence $\mathrm{Im}\langle \mathbf{u}, \mathbf{v}\rangle' = \beta(\mathbf{u}, i\mathbf{v})$, and the two parts together give $\langle \mathbf{u}, \mathbf{v}\rangle' = \beta(\mathbf{u}, \mathbf{v}) + i\,\beta(\mathbf{u}, i\mathbf{v})$, which is exactly the inner product constructed above. So it is the only one. (Exercise (C2: Recovering the inner product from the norm) set this computation as an exercise in Chapter 10; it is carried out here because the theorem rests on it.)

This proves the theorem.

■

The theorem says that the parallelogram law is not one property of induced norms among many — it is the whole difference. A norm either obeys it, and then it is secretly an inner product with an inner product's entire apparatus of angles, orthogonality and adjoints; or it violates it once, and then no inner product will ever produce it.

Warning. **Neither $\|\cdot\|_1$ nor $\|\cdot\|_\infty$ comes from an inner product.** Test $(*)$ on $\mathbf{u} = \mathbf{e}_1$ and $\mathbf{v} = \mathbf{e}_2$ in F^2. Both $\mathbf{u} + \mathbf{v} = (1, 1)$ and $\mathbf{u} - \mathbf{v} = (1, -1)$ have $\|\cdot\|_1 = 2$, so the left side of $(*)$ is $4 + 4 = 8$, while the right side is $2 + 2 = 4$. For $\|\cdot\|_\infty$ both have norm 1, so the left side is 2 and the right side is again 4. One failing pair is enough, and there is no repair: by Theorem 15.1.3 no inner product whatsoever induces these norms, in any dimension ≥ 2. The same two vectors $f(t) = t$ and $g(t) = 1 - t$ in $C[0, 1]$ refute it for the sup norm, since $\|f\|_\infty = \|g\|_\infty = \|f + g\|_\infty = \|f - g\|_\infty = 1$.

Quick check. The function $N(\mathbf{x}) = \left(x_1^2 + 4x_2^2\right)^{1/2}$ is a norm on $\mathbb{R}^2$, and it is lopsided: $N(\mathbf{e}_1) = 1$ while $N(\mathbf{e}_2) = 2$. Does it come from an inner product?

Solution. Yes. It is the norm induced by $\langle \mathbf{x}, \mathbf{y}\rangle = x_1 y_1 + 4x_2 y_2$, which satisfies (IP1) and (IP2) by inspection and (IP3) because $x_1^2 + 4x_2^2 > 0$ for $\mathbf{x} \neq \mathbf{0}$. One may also check

(∗) directly: both sides expand to $2x_1^2 + 8x_2^2 + 2y_1^2 + 8y_2^2$. The lesson is that a norm can be visibly lopsided — its unit ball here is an ellipse, not a circle — and still be an inner-product norm. What matters is not roundness but the parallelogram law.

So the norms of this book split in two. On one side sit $\|\cdot\|_2$, the Frobenius norm and every weighted Euclidean norm, where Chapters 10 to 12 apply in full. On the other sit $\|\cdot\|_1$, $\|\cdot\|_\infty$ and the sup norm, where there is no orthogonality and no adjoint, and the only tools are the three axioms. The next section shows that for questions about convergence the split does not matter at all.

15.1.4 Exercises

15.1.4.1 A. Check your understanding

Exercise A1.

(a) State the three clauses of Definition 15.1.1, and say which one fails for $N(\mathbf{x}) = |x_1|$ on F^2.

(b) Deduce $\|\mathbf{0}\| = 0$ from (N2) alone, and explain why (N1) is therefore stated with the word **only**.

(c) True or false: a function satisfying (N1) and (N3) but not (N2) cannot exist. Justify your answer.

(d) Name the test that decides whether a norm is induced by an inner product, and state what Exercise (C1: The parallelogram law characterizes inner-product norms) had already established before this section.

(e) Order $\|\mathbf{x}\|_1$, $\|\mathbf{x}\|_2$, $\|\mathbf{x}\|_\infty$ for a general $\mathbf{x} \in F^n$, and give a vector for which all three are equal.

Solution.

(a) (N1) positive definiteness, (N2) absolute homogeneity, (N3) the triangle inequality (Definition 15.1.1). For $N(\mathbf{x}) = |x_1|$ only (N1) fails, and only its "only" half: $N(\mathbf{e}_2) = 0$ with $\mathbf{e}_2 \neq \mathbf{0}$ (Example (Three near misses) (b)).

(b) Take $c = 0$ and any $\mathbf{v}$: (N2) gives $\|\mathbf{0}\| = \|0\mathbf{v}\| = |0|\|\mathbf{v}\| = 0$. So "$\mathbf{v} = \mathbf{0} \Rightarrow \|\mathbf{v}\| = 0$" is automatic, and the only content left in (N1) is the converse, which is why it is the clause that is stated.

(c) False. Take $N(\mathbf{x}) = \min(\|\mathbf{x}\|_2, 1)$ on $\mathbb{R}^2$. It is ≥ 0 and vanishes only at $\mathbf{0}$, so (N1) holds. For (N3), note first that $\min(a+b, 1) \leq \min(a, 1) + \min(b, 1)$ for all $a, b \geq 0$: if either $a \geq 1$ or $b \geq 1$ the right side is at least 1, which bounds the left side; and otherwise the right side is $a + b$, which is at least $\min(a + b, 1)$. Applying this to $a = \|\mathbf{u}\|_2$, $b = \|\mathbf{v}\|_2$ and using that $s \mapsto \min(s, 1)$ is increasing gives (N3). But $N(2\mathbf{e}_1) = 1 \neq 2 = 2N(\mathbf{e}_1)$, so (N2) fails.

(d) The parallelogram law (∗): a norm is induced by an inner product exactly when $\|\mathbf{u} + \mathbf{v}\|^2 + \|\mathbf{u} - \mathbf{v}\|^2 = 2\|\mathbf{u}\|^2 + 2\|\mathbf{v}\|^2$ always (Theorem 15.1.3). Before this section, Exercise (C1: The parallelogram law characterizes inner-product norms) had proved the converse direction on $\mathbb{R}^2$, and only modulo the granted homogeneity $\beta(\mathbf{u}, t\mathbf{v}) = t\beta(\mathbf{u}, \mathbf{v})$ for real t; the general dimension, the real homogeneity step and the complex case are what Theorem 15.1.3 adds.

(e) $\|\mathbf{x}\|_\infty \le \|\mathbf{x}\|_2 \le \|\mathbf{x}\|_1$ (Proposition 15.1.2). All three agree at $\mathbf{x} = \mathbf{e}_1$, and more generally at any $\mathbf{x}$ with at most one non-zero coordinate.

15.1.4.2 B. Practice

Exercise B1: Three measurements.

For $\mathbf{x} = (1, -1, 2, -2) \in \mathbb{R}^4$, compute $\|\mathbf{x}\|_1$, $\|\mathbf{x}\|_2$ and $\|\mathbf{x}\|_\infty$, and verify all four inequalities of Proposition 15.1.2. Which of them is closest to being an equality?

Solution. $\|\mathbf{x}\|_1 = 1 + 1 + 2 + 2 = 6$; $\|\mathbf{x}\|_2 = (1 + 1 + 4 + 4)^{1/2} = \sqrt{10}$; $\|\mathbf{x}\|_\infty = 2$. Here $n = 4$, so $\sqrt{n} = 2$. The four inequalities read

$$2 \le \sqrt{10} \le 6, \qquad 6 \le 2\sqrt{10}, \qquad \sqrt{10} \le 4,$$

and $\sqrt{10} \approx 3.162$, so all four hold. The tightest is $\|\mathbf{x}\|_1 \le \sqrt{n}\|\mathbf{x}\|_2$, that is $6 \le 6.32$; this is as expected, since equality there needs all coordinates of equal modulus, and $\mathbf{x}$ has only two distinct moduli.

Exercise B2: Determine which are norms.

Determine which of the following define norms on $\mathbb{R}^2$. For those that do, verify all three clauses of Definition 15.1.1; for those that do not, name the exact clause that fails and give a witness. Justify your answer.

(a) $N(\mathbf{x}) = |x_1| + 2|x_2|$.
(b) $N(\mathbf{x}) = |x_1 - x_2|$.
(c) $N(\mathbf{x}) = \max\big(|x_1|, |x_2|\big) - \frac{1}{4}\min\big(|x_1|, |x_2|\big)$.
(d) $N(\mathbf{x}) = |x_1| + |x_2| - \frac{1}{2}\min\big(|x_1|, |x_2|\big)$.

Solution.

(a) A norm. It is the weighted norm of Example (Inner products, weights, and a function space) (b) in its 1-norm form: (N1) because both terms are ≥ 0 and both vanish only for $\mathbf{x} = \mathbf{0}$; (N2) because $|cx_i| = |c||x_i|$; (N3) coordinatewise, exactly as for $\|\cdot\|_1$.

(b) Not a norm. (N2) and (N3) hold, inherited from $|\cdot|$ on $\mathbb{R}$. **(N1) fails**: $N\big((1,1)\big) = 0$ with $(1,1) \neq \mathbf{0}$.

(c) Not a norm. (N1) holds, since $N(\mathbf{x}) \ge \frac{3}{4}\max(|x_1|, |x_2|)$, which is > 0 for $\mathbf{x} \neq \mathbf{0}$; and (N2) holds because max and min of the scaled moduli both pick up the factor $|c|$. **(N3) fails**: with $\mathbf{u} = (1,1)$ and $\mathbf{v} = (1,-1)$ we get $N(\mathbf{u}) = N(\mathbf{v}) = 1 - \frac{1}{4} = \frac{3}{4}$, while $\mathbf{u} + \mathbf{v} = (2,0)$ has $N(\mathbf{u}+\mathbf{v}) = 2 - 0 = 2 > \frac{3}{2}$. Subtracting from the largest coordinate is exactly what a cancellation in the sum can punish.

(d) A norm, despite the minus sign. Since $|x_1| + |x_2| = \max + \min$, the formula is $N(\mathbf{x}) = \max + \frac{1}{2}\min$, which is

$$N(\mathbf{x}) = \tfrac{1}{2}\|\mathbf{x}\|_1 + \tfrac{1}{2}\|\mathbf{x}\|_\infty.$$

A sum of two norms, each scaled by a positive number, is a norm: (N1), (N2)

and (N3) are each inherited term by term, and (N1) needs only one of the two summands to detect $\mathbf{x} \neq \mathbf{0}$. Compare (c): there the subtracted term was large enough to break (N3), here it is not, and the way to tell is to rewrite the formula rather than to guess.

Exercise B3: Which of these come from an inner product?.

For each norm, determine whether it is induced by an inner product. Justify your answer, using Theorem 15.1.3 in each case.

(a) $\|\mathbf{x}\| = \left(x_1^2 + x_1x_2 + x_2^2\right)^{1/2}$ on $\mathbb{R}^2$.
(b) $\|\mathbf{A}\|_F$ on $M_2(\mathbb{R})$.
(c) $N(\mathbf{A}) = \max_{i,j}|a_{ij}|$ on $M_2(\mathbb{R})$.

Solution.

(a) Yes. Put $\langle \mathbf{x}, \mathbf{y}\rangle = x_1y_1 + \frac{1}{2}(x_1y_2 + x_2y_1) + x_2y_2$. It is bilinear and symmetric by inspection, and $\langle \mathbf{x}, \mathbf{x}\rangle = x_1^2 + x_1x_2 + x_2^2 = (x_1 + \frac{1}{2}x_2)^2 + \frac{3}{4}x_2^2$, which is > 0 unless $x_2 = 0$ and $x_1 = 0$; so (IP3) holds and the induced norm is the given one. (Completing the square is also how one sees that the given function is a norm at all.)

(b) Yes. The Frobenius norm is induced by the Frobenius inner product $\langle \mathbf{A}, \mathbf{B}\rangle = \operatorname{tr}(\mathbf{B}^{\top}\mathbf{A})$ (Example (Inner products, weights, and a function space) (a)), so $(*)$ holds by the forward direction of Theorem 15.1.3.

(c) No. Take $\mathbf{A} = \mathbf{E}_{11}$ and $\mathbf{B} = \mathbf{E}_{12}$, the matrix units. Then $\mathbf{A} \pm \mathbf{B}$ has entries 1 and ± 1 in the first row and zeros elsewhere, so $N(\mathbf{A} + \mathbf{B}) = N(\mathbf{A} - \mathbf{B}) = 1$ and the left side of $(*)$ is 2, while the right side is $2 \cdot 1 + 2 \cdot 1 = 4$. By Theorem 15.1.3 no inner product induces N.

15.1.4.3 C. Going deeper

Exercise C1: Sharpness of the comparison constants.

(a) Prove that $\|\mathbf{x}\|_1 = \sqrt{n}\,\|\mathbf{x}\|_2$ holds if and only if all the numbers $|x_1|, \dots, |x_n|$ are equal. *Hint: the equality case of Theorem 10.1.5.*

(b) Hence deduce that no constant C independent of n satisfies $\|\mathbf{x}\|_1 \leq C\|\mathbf{x}\|_2$ for all n and all $\mathbf{x} \in \mathbb{R}^n$.

Solution.

(a) With $\mathbf{a} = (|x_1|, \dots, |x_n|)$, the proof of Proposition 15.1.2 reads $\|\mathbf{x}\|_1 = \langle \mathbf{a}, \mathbf{1}\rangle \leq \|\mathbf{a}\|_2\|\mathbf{1}\|_2 = \sqrt{n}\|\mathbf{x}\|_2$, an application of Theorem 10.1.5 to $\mathbf{a}$ and $\mathbf{1}$. Equality in Theorem 10.1.5 holds exactly when $(\mathbf{a}, \mathbf{1})$ is dependent. Since $\mathbf{1} \neq \mathbf{0}$, that means $\mathbf{a} = t\mathbf{1}$ for some real t, which is $t \geq 0$ because the entries of $\mathbf{a}$ are; and $\mathbf{a} = t\mathbf{1}$ says precisely that all the $|x_i|$ are equal.

(b) By (a), $\mathbf{x} = \mathbf{1} \in \mathbb{R}^n$ gives $\|\mathbf{1}\|_1 = n$ and $\|\mathbf{1}\|_2 = \sqrt{n}$, so any valid C satisfies $C \geq n/\sqrt{n} = \sqrt{n}$. As n is arbitrary, no single C works for all n. The comparison constants between two norms are genuinely functions of the dimension.

Exercise C2: A real norm that is not a complex norm.

Regard $\mathbb{C}$ as a one-dimensional complex vector space, and also as $\mathbb{R}^2$ by $z = a + bi \leftrightarrow (a, b)$. Define $N(z) = 2|a| + |b|$.

(a) Prove that N is a norm on $\mathbb{R}^2$.

(b) Prove that N is **not** a norm on $\mathbb{C}$ as a complex vector space, and name the exact clause that fails.

(c) Prove that if $\|\cdot\|$ is any norm on a complex vector space V, then it is also a norm on V regarded as a real vector space. Explain why (b) does not contradict this.

Solution.

(a) It is the weighted 1-norm $|x_1| \cdot 2 + |x_2| \cdot 1$ of Exercise (B2: Determine which are norms) (a) with the weights swapped, so all three clauses hold as there.

(b) **(N2) fails** for the complex scalar $c = i$. Indeed $N(1) = 2$ and $N(i) = 1$, while (N2) would demand $N(i \cdot 1) = |i|N(1) = 2$.

(c) Restricting the scalars from $\mathbb{C}$ to $\mathbb{R}$ leaves the vectors, the addition and the zero vector unchanged, so (N1) and (N3) are the same statements. (N2) for real c is a special case of (N2) for complex c, the absolute value of a real number being the same in $\mathbb{R}$ and in $\mathbb{C}$. There is no contradiction with (b) because the implication runs one way only: (N2) over $\mathbb{C}$ is a **strictly stronger** demand than (N2) over $\mathbb{R}$, the extra content being $\|i\mathbf{v}\| = \|\mathbf{v}\|$, and N fails exactly that.

Exercise C3: The ball determines the norm.

Let $\|\cdot\|$ and N be two norms on a vector space V with the **same** closed unit ball, in the sense of Definition 15.1.2:

$$\{\mathbf{v} : \|\mathbf{v}\| \le 1\} = \{\mathbf{v} : N(\mathbf{v}) \le 1\}.$$

(a) Prove that for every $\mathbf{v} \in V$ and every real $t > 0$, we have $\|\mathbf{v}\| \le t$ if and only if $\mathbf{v}/t$ lies in the closed unit ball of $\|\cdot\|$.

(b) Hence prove that $\|\mathbf{v}\| = N(\mathbf{v})$ for every $\mathbf{v} \in V$.

(c) Give two different norms on $\mathbb{R}^2$ whose closed unit balls have the same area, and say why (b) does not apply to them.

Solution.

(a) Since $t > 0$, (N2) gives $\|\mathbf{v}/t\| = \|\mathbf{v}\|/t$. So $\mathbf{v}/t$ lies in the ball exactly when $\|\mathbf{v}\|/t \le 1$, that is, exactly when $\|\mathbf{v}\| \le t$.

(b) For $\mathbf{v} = \mathbf{0}$ both sides are 0 by (N1). Let $\mathbf{v} \neq \mathbf{0}$ and put $t = \|\mathbf{v}\| > 0$. By (a), $\mathbf{v}/t$ lies in the ball of $\|\cdot\|$, hence in the ball of N, hence $N(\mathbf{v}) \le t = \|\mathbf{v}\|$ by (a) applied to N. Swapping the roles of $\|\cdot\|$ and N gives $\|\mathbf{v}\| \le N(\mathbf{v})$. Therefore $\|\mathbf{v}\| = N(\mathbf{v})$.

(c) Take $\|\cdot\|_1$, whose ball is the diamond with vertices $\pm\mathbf{e}_1$ and $\pm\mathbf{e}_2$, of area 2; and $N(\mathbf{x}) = 2|x_1| + \frac{1}{2}|x_2|$, whose ball is the diamond with vertices $\pm\frac{1}{2}\mathbf{e}_1$ and $\pm 2\mathbf{e}_2$, also of area 2. They differ at $\mathbf{e}_1$, where they give 1 and 2. Part (b) does not apply

> because equal **area** is far weaker than equal **set**: the recipe in (a) reads the norm off the ball as a set of vectors, and the area of that set retains almost none of it.

15.2 All Norms Agree

§01 left a worry. There are many norms on F^n, they give different answers, and every statement of the form "this quantity is small" now has to say small in which norm. This section removes the worry in finite dimension, in the strongest way available: any two norms on a finite-dimensional space are trapped between fixed multiples of each other, so they agree about every limit, every bounded set and every continuous function. It also says what the theorem costs — constants that grow with the dimension — and where it stops being true.

15.2.1 Trapped between multiples

Look again at Proposition 15.1.2. Its four inequalities say that on F^n,

$$\tfrac{1}{\sqrt{n}}\,\|\mathbf{x}\|_1 \;\le\; \|\mathbf{x}\|_2 \;\le\; \|\mathbf{x}\|_1,$$

so $\|\cdot\|_2$ never differs from $\|\cdot\|_1$ by a factor worse than $\sqrt{n}$, in either direction. Whatever $\|\cdot\|_1$ calls small, $\|\cdot\|_2$ calls small too, at the cost of a fixed factor. That is a relation worth naming.

Two norms are equivalent when each is sandwiched between two fixed multiples of the other, so that neither can be small while the other is large.

Definition 15.2.1 — Equivalent Norms

Let V be a vector space over $F = \mathbb{R}$ or $\mathbb{C}$, and let $\|\cdot\|_a$ and $\|\cdot\|_b$ be norms on V. They are **equivalent** if there exist real constants $c, C > 0$, **not depending on the vector**, such that

$$c\,\|\mathbf{v}\|_b \;\le\; \|\mathbf{v}\|_a \;\le\; C\,\|\mathbf{v}\|_b \qquad \text{for every } \mathbf{v} \in V.$$

In words. The two inequalities are read separately: the right one says $\|\cdot\|_a$ is *no larger than* a fixed multiple of $\|\cdot\|_b$, and the left one says it is *no smaller than* a fixed positive multiple. The phrase **not depending on the vector** is the whole content, since for each individual $\mathbf{v} \neq \mathbf{0}$ the ratio $\|\mathbf{v}\|_a/\|\mathbf{v}\|_b$ is some positive number and one could always take that number as the constant. What is being asked is that one pair of constants works for all $\mathbf{v}$ at once. Note also that the definition says nothing about the two norms being close; c may be 10^{-6}.

Example. (The three p-norms, with best constants)

On F^n, Proposition 15.1.2 gives

$$\begin{aligned} \|\mathbf{x}\|_\infty \le \|\mathbf{x}\|_2 &\le \sqrt{n}\,\|\mathbf{x}\|_\infty, \\ \|\mathbf{x}\|_\infty \le \|\mathbf{x}\|_1 &\le n\,\|\mathbf{x}\|_\infty, \\ \tfrac{1}{\sqrt{n}}\|\mathbf{x}\|_1 \le \|\mathbf{x}\|_2 &\le \|\mathbf{x}\|_1, \end{aligned}$$

so the three are pairwise equivalent. The middle line's upper constant comes from

$\|\mathbf{x}\|_1 \le \sqrt{n}\|\mathbf{x}\|_2 \le \sqrt{n}\cdot\sqrt{n}\,\|\mathbf{x}\|_\infty$. Every constant shown is attained, so none of them can be improved. On the first two lines the lower constant is attained at $\mathbf{e}_1$ and the upper one at $\mathbf{1}$. **The third line runs the other way**: at $\mathbf{1}$ the lower inequality reads $\frac{1}{\sqrt{n}}\cdot n = \sqrt{n} \le \sqrt{n}$, and at $\mathbf{e}_1$ the upper one reads $1 \le 1$.

Before the theorem, one small fact makes the proof strategy possible: it is enough to compare every norm with a single one of our choosing.

Proposition 15.2.1 — Equivalence of Norms Is an Equivalence Relation

On a fixed vector space V over F, the relation of Definition 15.2.1 is reflexive, symmetric and transitive.

Proof. Reflexive: take $c = C = 1$. Symmetric: if $c\|\mathbf{v}\|_b \le \|\mathbf{v}\|_a \le C\|\mathbf{v}\|_b$ for all $\mathbf{v}$, then dividing through by the positive constants gives $C^{-1}\|\mathbf{v}\|_a \le \|\mathbf{v}\|_b \le c^{-1}\|\mathbf{v}\|_a$. Transitive: if in addition $c'\|\mathbf{v}\|_d \le \|\mathbf{v}\|_b \le C'\|\mathbf{v}\|_d$, then multiplying the first chain's outer inequalities by the positive constants c and C gives

$$cc'\|\mathbf{v}\|_d \le c\|\mathbf{v}\|_b \le \|\mathbf{v}\|_a \le C\|\mathbf{v}\|_b \le CC'\|\mathbf{v}\|_d,$$

and $cc', CC' > 0$. This proves all three properties. ∎

So to prove that *any two* norms on V are equivalent, it suffices to prove that *every* norm is equivalent to one fixed reference norm. We take the reference to be the Euclidean norm of a chosen basis, because that is where compactness lives.

15.2.2 Compactness enters the book

Theorem 15.2.2 — Equivalence of Norms in Finite Dimension

Let V be a vector space over $F = \mathbb{R}$ or $\mathbb{C}$ with $\dim V = n < \infty$. Then **any two** norms on V are equivalent. Explicitly, if $\mathcal{B} = (\mathbf{v}_1, \dots, \mathbf{v}_n)$ is a basis of V, if $\|\cdot\|_2$ denotes the Euclidean norm of the coordinate vector,

$$\Big\|\sum_i x_i\mathbf{v}_i\Big\|_2 := \big(|x_1|^2 + \cdots + |x_n|^2\big)^{1/2},$$

and if N is any norm on V, then there are constants $0 < m \le M$ with

$$m\,\|\mathbf{v}\|_2 \;\le\; N(\mathbf{v}) \;\le\; M\,\|\mathbf{v}\|_2 \qquad \text{for every } \mathbf{v} \in V.$$

Idea. The two inequalities are not symmetric, and it is worth seeing why before starting. The **upper** bound is cheap: write $\mathbf{v}$ in the basis, apply the triangle inequality once, and the constant M is built out of the numbers $N(\mathbf{v}_i)$. The **lower** bound cannot be obtained the same way; there is no inequality running from $N(\sum x_i\mathbf{v}_i)$ down to the individual coordinates, and the temptation to assume that the two norms are comparable on the

basis and then "extend by linearity" is exactly the error the theorem exists to forbid — Example (Agreeing on a basis is not enough) below shows two norms agreeing on a basis and differing by a factor of n elsewhere.

The route is therefore ① upper bound by the triangle inequality; ② use that upper bound to show N is continuous as a function of the coordinates; ③ restrict N to the Euclidean unit sphere, which is compact, so N attains a minimum m there; ④ the minimum is positive because N vanishes only at $\mathbf{0}$, which is not on the sphere; ⑤ scale back. Compactness is what turns the infimum over infinitely many unit vectors into a value attained at a particular unit vector, and a value attained at a vector can be tested for positivity one vector at a time.

Proof. By Proposition 15.2.1 it suffices to prove the displayed two-sided bound, since then any two norms N_1, N_2 are each equivalent to $\|\cdot\|_2$ and hence to each other. If $n = 0$ then $V = \{\mathbf{0}\}$, both norms are the zero function and $m = M = 1$ works; assume $n \geq 1$. The coordinate map $\Phi\colon F^n \to V$, $\mathbf{x} \mapsto \sum_i x_i \mathbf{v}_i$, is an isomorphism (Corollary 3.5.5), and by construction $\|\Phi(\mathbf{x})\|_2 = \|\mathbf{x}\|_2$ is the Euclidean norm of Example (The 1-, 2- and ∞-norms on F^n). It is enough to prove the two bounds for $\mathbf{x} \in F^n$ with N replaced by $f(\mathbf{x}) \coloneqq N(\Phi(\mathbf{x}))$.

Step 1. The upper bound. Let $M = \left(\sum_{i=1}^{n} N(\mathbf{v}_i)^2\right)^{1/2}$. For $\mathbf{x} \in F^n$, the triangle inequality (N3) applied $n-1$ times and then (N2) give

$$f(\mathbf{x}) = N\Big(\sum_i x_i \mathbf{v}_i\Big) \leq \sum_i |x_i|\, N(\mathbf{v}_i),$$

and Theorem 10.1.5 in $\mathbb{R}^n$, applied to the vectors $(|x_1|, \dots, |x_n|)$ and $(N(\mathbf{v}_1), \dots, N(\mathbf{v}_n))$, bounds the right-hand side by $M\|\mathbf{x}\|_2$. Hence $f(\mathbf{x}) \leq M\|\mathbf{x}\|_2$ for every $\mathbf{x}$. Also $M > 0$, since $N(\mathbf{v}_1) > 0$ by (N1) and $\mathbf{v}_1 \neq \mathbf{0}$.

Step 2. f is continuous on F^n for the Euclidean norm. By Lemma 15.1.1 applied to N, and then Step 1 applied to $\mathbf{x} - \mathbf{y}$,

$$|f(\mathbf{x}) - f(\mathbf{y})| \leq N\big(\Phi(\mathbf{x} - \mathbf{y})\big) \leq M\,\|\mathbf{x} - \mathbf{y}\|_2.$$

So f changes by at most M times the distance moved: it is continuous, and the continuity was **deduced** from Step 1 rather than assumed.

Step 3. The minimum on the unit sphere. Let

$$S = \{\mathbf{x} \in F^n : \|\mathbf{x}\|_2 = 1\},$$

which is non-empty because $n \geq 1$ (it contains $\mathbf{e}_1$). It is bounded, and it is closed: if $\|\mathbf{x}_k - \mathbf{x}\|_2 \to 0$ with every $\|\mathbf{x}_k\|_2 = 1$, then Lemma 15.1.1 gives $\big|\|\mathbf{x}\|_2 - 1\big| \leq \|\mathbf{x} - \mathbf{x}_k\|_2 \to 0$, so $\|\mathbf{x}\|_2 = 1$ and $\mathbf{x} \in S$. By **the compactness of closed bounded sets in F^n, fact (A3) of the chapter introduction**, S is compact; by **the extreme value theorem, fact (A4)**, the continuous function f of Step 2 attains a minimum value on S. Say $m = f(\mathbf{x}_0)$ with $\mathbf{x}_0 \in S$.

Step 4. The minimum is positive. Since $\mathbf{x}_0 \in S$ we have $\|\mathbf{x}_0\|_2 = 1 \neq 0$, so $\mathbf{x}_0 \neq \mathbf{0}$ and hence $\Phi(\mathbf{x}_0) \neq \mathbf{0}$, Φ being injective. By (N1) for N, $m = N(\Phi(\mathbf{x}_0)) > 0$. This is the step that needs a minimum rather than an infimum: an infimum of positive numbers can be 0, while a minimum is the value at an actual vector, and there (N1) can be applied.

Step 5. Scaling back. Let $\mathbf{x} \neq \mathbf{0}$. Then $\mathbf{x}/\|\mathbf{x}\|_2 \in S$, so $f(\mathbf{x}/\|\mathbf{x}\|_2) \geq m$, and (N2) for N gives $f(\mathbf{x}) \geq m\|\mathbf{x}\|_2$. For $\mathbf{x} = \mathbf{0}$ both sides are 0. Combining with Step 1,

$$m\,\|\mathbf{x}\|_2 \;\leq\; f(\mathbf{x}) \;\leq\; M\,\|\mathbf{x}\|_2 \qquad (\mathbf{x} \in F^n),$$

and transporting along Φ gives the statement for V. Since $m \leq f(\mathbf{x}_0) \leq M\|\mathbf{x}_0\|_2 = M$, the constants satisfy $0 < m \leq M$. This proves the theorem.

■

The proof used the finite dimension twice, and it is worth saying where: once in Step 1, where the triangle inequality was applied finitely many times to a finite basis expansion, and once in Step 3, where F^n is the space in which closed bounded sets are compact. Remove either and the argument collapses, as the last part of this section shows.

Example. (Agreeing on a basis is not enough)

On F^n, the norms $\|\cdot\|_1$ and $\|\cdot\|_\infty$ both give every standard basis vector the value 1. Yet $\|\mathbf{1}\|_1 = n$ and $\|\mathbf{1}\|_\infty = 1$. So the data "$N_1(\mathbf{v}_i) = N_2(\mathbf{v}_i)$ for every basis vector" implies no inequality between N_1 and N_2 beyond what Theorem 15.2.2 gives for any pair at all.

Quick check. In Step 1 the constant was $M = \left(\sum_i N(\mathbf{v}_i)^2\right)^{1/2}$. Where would the proof break if we tried the symmetric guess $m = \min_i N(\mathbf{v}_i)$ for the lower bound?

Solution. It breaks immediately, and Example (Agreeing on a basis is not enough) is the witness. Take $V = F^2$ with the basis $(\mathbf{e}_1, \mathbf{e}_2)$, $N = \|\cdot\|_\infty$ and $\|\cdot\|_2$ the Euclidean norm. Then $\min_i N(\mathbf{e}_i) = 1$, and the guessed inequality $\|\mathbf{x}\|_\infty \geq \|\mathbf{x}\|_2$ fails at $\mathbf{x} = \mathbf{1}$, where the two sides are 1 and $\sqrt{2}$. The reason is that the triangle inequality only ever bounds $N(\sum x_i\mathbf{v}_i)$ from **above**; there is no lower bound in the axioms, because a sum of long vectors can be short. Getting a lower bound needs a genuinely different mechanism, and compactness is that mechanism.

15.2.3 What the theorem buys

The point of the theorem is that whole sentences may now drop the words "in which norm".

Corollary 15.2.3 — Convergence and Boundedness Do Not Depend on the Norm

Let V be finite-dimensional over $\mathbb{R}$ or $\mathbb{C}$, let $\|\cdot\|_a$ and $\|\cdot\|_b$ be norms on V, and let $(\mathbf{u}_k)$ be a sequence in V with $\mathbf{u} \in V$. Then:

(a) $\|\mathbf{u}_k - \mathbf{u}\|_a \to 0$ if and only if $\|\mathbf{u}_k - \mathbf{u}\|_b \to 0$;
(b) $(\mathbf{u}_k)$ is bounded for $\|\cdot\|_a$ if and only if it is bounded for $\|\cdot\|_b$;
(c) $(\mathbf{u}_k)$ is Cauchy for $\|\cdot\|_a$ if and only if it is Cauchy for $\|\cdot\|_b$.

Proof. By Theorem 15.2.2 there are $c, C > 0$ with $c\|\mathbf{v}\|_b \leq \|\mathbf{v}\|_a \leq C\|\mathbf{v}\|_b$ for every $\mathbf{v} \in V$. For (a), apply this to $\mathbf{v} = \mathbf{u}_k - \mathbf{u}$: if $\|\mathbf{u}_k - \mathbf{u}\|_b \to 0$ then $0 \leq \|\mathbf{u}_k - \mathbf{u}\|_a \leq$

$C\|\mathbf{u}_k-\mathbf{u}\|_b\to 0$, and conversely $\|\mathbf{u}_k-\mathbf{u}\|_b\le c^{-1}\|\mathbf{u}_k-\mathbf{u}\|_a\to 0$. For (b), a bound $\|\mathbf{u}_k\|_b\le K$ for all k gives $\|\mathbf{u}_k\|_a\le CK$, and conversely with c^{-1}. For (c), apply the same two estimates to $\mathbf{v}=\mathbf{u}_k-\mathbf{u}_l$. This proves all three.

■

Now the connection this chapter was built for. Chapter 9 §10 defined convergence of matrices **entrywise** (Definition 9.10.1) and said, in its opening paragraph, that no notion of the size of a matrix was used and that Chapter 15 would supply one. Here is the reconciliation.

Corollary 15.2.4 — Entrywise Convergence Is Convergence in Every Norm

Let $\mathbf{M}_1,\mathbf{M}_2,\dots$ and $\mathbf{M}$ lie in $M_{p\times q}(\mathbb{C})$, and let $\|\cdot\|$ be **any** norm on $M_{p\times q}(\mathbb{C})$. Then $\mathbf{M}_k\to\mathbf{M}$ entrywise in the sense of Definition 9.10.1 if and only if $\|\mathbf{M}_k-\mathbf{M}\|\to 0$. Likewise $(\mathbf{M}_k)$ is bounded in the sense of Definition 9.10.1 if and only if $\big(\|\mathbf{M}_k\|\big)$ is a bounded sequence of real numbers.

Idea. Entrywise convergence is convergence in one particular norm, the entrywise maximum. Theorem 15.2.2 says every other norm is trapped between two multiples of it, and a quantity squeezed between two multiples of something tending to 0 tends to 0 as well. Both directions are that one sentence.

Proof. The space $M_{p\times q}(\mathbb{C})$ is a complex vector space of dimension pq, and

$$N_\infty(\mathbf{M})=\max_{r,s}|m_{rs}|$$

is a norm on it: it is the ∞-norm of Example (The 1-, 2- and ∞-norms on F^n) read on the list of entries, through the coordinate isomorphism of Corollary 3.5.5 that sends a matrix to its pq entries. By Definition 9.10.1 (a), $\mathbf{M}_k\to\mathbf{M}$ entrywise means $(\mathbf{M}_k)_{rs}\to\mathbf{M}_{rs}$ for each of the finitely many positions (r,s), and since a maximum of finitely many non-negative sequences tends to 0 exactly when each of them does, this says precisely $N_\infty(\mathbf{M}_k-\mathbf{M})\to 0$. By Theorem 15.2.2 the norms N_∞ and $\|\cdot\|$ are equivalent, so Corollary 15.2.3 (a) converts this into $\|\mathbf{M}_k-\mathbf{M}\|\to 0$. The statement about boundedness is Definition 9.10.1 (b) together with Corollary 15.2.3 (b), read the same way.

■

Example. (Watching one sequence converge)

In $M_2(\mathbb{R})$ let

$$\mathbf{M}_k=\begin{pmatrix}\frac{1}{k} & 2\\ 0 & 1-\frac{1}{k}\end{pmatrix},\qquad k\ge 1.$$

Entry by entry, $\frac{1}{k}\to 0$, $2\to 2$, $0\to 0$ and $1-\frac{1}{k}\to 1$, so $\mathbf{M}_k\to\mathbf{M}=\left(\begin{smallmatrix}0&2\\0&1\end{smallmatrix}\right)$ in the sense of Definition 9.10.1. The corollary says this is convergence in *every* norm, and here one can see it directly: $\mathbf{M}_k-\mathbf{M}=\operatorname{diag}(\frac{1}{k},-\frac{1}{k})$, so

$$\|\mathbf{M}_k-\mathbf{M}\|_F=\sqrt{\tfrac{1}{k^2}+\tfrac{1}{k^2}}=\frac{\sqrt{2}}{k}\longrightarrow 0,$$

and $\|\mathbf{M}_k - \mathbf{M}\|_\infty$, the largest absolute row sum, is $\frac{1}{k}$. Different norms, different constants, the same verdict — which is the content of the corollary.

So Chapter 9 §10 lost nothing by working entrywise. Its Theorem 9.10.2, Theorem 9.10.3, Theorem 9.10.4 and Theorem 9.10.6 are statements about *the* convergence of matrices, and every norm this chapter introduces — the Frobenius norm, the operator norms of §03, anything at all — measures the same thing. What the norms add is not a new notion of limit but a **rate**: a single number $\|\mathbf{A}^k\|$ that can be bounded, compared and summed, where an entrywise statement gives pq separate sequences and no way to combine them.

One more corollary, which §03 will use to know that the operator norm exists at all.

Corollary 15.2.5 — Closed and Bounded Is Compact, in Every Norm

Let V be finite-dimensional over $\mathbb{R}$ or $\mathbb{C}$. Call a subset $K \subseteq V$ **bounded** for a norm if $K \subseteq \{\mathbf{v} : \|\mathbf{v}\| \le R\}$ for some real R, and **closed** for that norm if whenever $\|\mathbf{u}_k - \mathbf{u}\| \to 0$ with every $\mathbf{u}_k \in K$, also $\mathbf{u} \in K$. Then a subset that is closed and bounded for one norm is closed and bounded for every norm, and is **compact**: every sequence in it has a subsequence converging to a point of it. In particular, when $V \neq \{\mathbf{0}\}$, the unit sphere $\{\mathbf{v} : \|\mathbf{v}\| = 1\}$ of any norm is non-empty and compact, and a continuous real-valued function on it attains a maximum and a minimum.

Idea. Both words in "closed and bounded" are defined by a norm, so the first thing to check is that changing the norm changes neither. That is Theorem 15.2.2 again. Once the words are norm-free, the statement is Theorem 15.2.2's own compactness step read in a coordinate-free way: carry K to F^n by coordinates, apply (A3), and carry the limit back.

Proof. Fix a basis and transport everything to F^n by the coordinate isomorphism (Corollary 3.5.5), as in the proof of Theorem 15.2.2. Let $\|\cdot\|_a$ and $\|\cdot\|_b$ be norms, with $c\|\cdot\|_b \le \|\cdot\|_a \le C\|\cdot\|_b$ from Theorem 15.2.2. A set bounded for one is bounded for the other by the same two estimates as in Corollary 15.2.3 (b). A set closed for one is closed for the other, because by Corollary 15.2.3 (a) the two norms have the same convergent sequences with the same limits, and the notion of closed defined in the statement asks exactly that limits of convergent sequences stay in the set.

For compactness, let $K \subseteq F^n$ be closed and bounded for some norm; by the previous paragraph it is closed and bounded for $\|\cdot\|_2$. By **the compactness of closed bounded sets in F^n, fact (A3) of the chapter introduction**, every sequence in K has a subsequence converging in $\|\cdot\|_2$ to a point of K, and by Corollary 15.2.3 (a) that subsequence converges in every norm to the same point. The unit sphere of a norm N is bounded, and it is closed because $|N(\mathbf{v}) - N(\mathbf{u}_k)| \le N(\mathbf{v} - \mathbf{u}_k)$ by Lemma 15.1.1, so a limit of vectors with $N = 1$ has $N = 1$; it is non-empty when $V \neq \{\mathbf{0}\}$, since $N(\mathbf{v})^{-1}\mathbf{v}$ lies on it for any $\mathbf{v} \neq \mathbf{0}$. The last sentence is then **the extreme value theorem, fact (A4)**, applied to that non-empty compact set. This proves the corollary.

■

15.2.4 Two warnings, and where the theorem stops

The theorem is not permission to forget which norm is in use. Here is the first reason.

Warning. **The constants depend on the dimension, and grow.** Example (The three p-norms, with best constants) gives $\|\mathbf{x}\|_1 \le n\|\mathbf{x}\|_\infty$ on F^n, and Exercise (C1: Sharpness of the comparison constants) shows the constant $\sqrt{n}$ in $\|\mathbf{x}\|_1 \le \sqrt{n}\|\mathbf{x}\|_2$ is attained, hence best possible. So a statement such as "the error is at most 10^{-6} in the ∞-norm" translates into the 1-norm as "at most $n \cdot 10^{-6}$", which is a different statement when n is a million. Theorem 15.2.2 says the two norms cannot disagree about **whether** something tends to zero; it says nothing about **how fast**, and every quantitative estimate in the rest of this chapter names its norm for that reason.

The second reason is that the theorem is false without the finite dimension, and not by a narrow margin.

Example. (Two inequivalent norms on a space of polynomials)

Let $V = \mathbb{R}[x]$, the real polynomials — equivalently, the sequences of real coefficients with only finitely many non-zero terms. For $p = a_0 + a_1 x + \cdots + a_d x^d$ put

$$\|p\|_1 = |a_0| + \cdots + |a_d|, \qquad \|p\|_\infty = \max_i |a_i|.$$

Both are norms, by the same coordinatewise checks as in Example (The 1-, 2- and ∞-norms on F^n); the only difference is that the number of coordinates is unbounded. One inequality survives: $\|p\|_\infty \le \|p\|_1$ always. The other fails completely. Put

$$p_k = 1 + x + x^2 + \cdots + x^{k-1}.$$

Then $\|p_k\|_1 = k$ while $\|p_k\|_\infty = 1$, so a constant C with $\|p\|_1 \le C\|p\|_\infty$ for all p would have to satisfy $C \ge k$ for every k. No such C exists, and the two norms are not equivalent.

Look at what the sequence $\left(\frac{1}{k}p_k\right)$ does: it tends to 0 in $\|\cdot\|_\infty$, since $\|\frac{1}{k}p_k\|_\infty = 1/k$, while $\|\frac{1}{k}p_k\|_1 = 1$ for every k. So the two norms disagree about which sequences converge — not about the rate, about the fact. Everything in Corollary 15.2.3 and Corollary 15.2.5 fails here at once, and it fails because Step 3 of the proof of Theorem 15.2.2 has nothing to stand on. The general reason is recorded, and not proved, in the warning below.

Warning. **Infinite dimension is outside the scope of this book.** The closed unit ball of a normed space is compact **only** when the space is finite-dimensional. That is a genuine theorem, due to Riesz, and it is **recorded here, not proved**: it lies outside the four imported facts of the chapter introduction, this book never uses it as a step in an argument, and it is stated only so that Example (Two inequivalent norms on a space of polynomials) is not mistaken for an accident of a badly chosen pair. Every result of this chapter carries the hypothesis $\dim V < \infty$, and on $C[0,1]$ or $\mathbb{R}[x]$ none of them is available. The study of norms on infinite-dimensional spaces is functional analysis, and there the choice of norm is the main content rather than an irrelevance.

Quick check. On $C[0,1]$, compare the sup norm $\|f\|_\infty$ of Example (Inner products, weights, and a function space) (c) with $\|f\|_1 = \int_0^1 |f|$, which is a norm because a contin-

uous $f \geq 0$ with $\int_0^1 f = 0$ is the zero function — the one fact from analysis that Chapter 10 §01 recorded when it put an inner product on $C[0,1]$, quoted again here. Which of the two inequalities of Definition 15.2.1 holds, and which fails?

Solution. The inequality $\|f\|_1 \leq \|f\|_\infty$ holds, since $\int_0^1 |f| \leq \int_0^1 \|f\|_\infty = \|f\|_\infty$. The other fails. Take $f_k(t) = \max(0, 1 - kt)$ for $k \geq 1$, the spike that drops from 1 to 0 on $[0, 1/k]$. Then $\|f_k\|_\infty = f_k(0) = 1$, while

$$\|f_k\|_1 = \int_0^{1/k} (1 - kt)\,\mathrm{d}t = \frac{1}{2k},$$

the area of a triangle of base $1/k$ and height 1, so no integration theory is needed to evaluate it. A constant C with $\|f\|_\infty \leq C\|f\|_1$ would need $C \geq 2k$ for every k. A tall thin spike has small integral and large maximum, and in infinite dimension nothing stops it from being arbitrarily thin.

With the choice of norm made harmless in finite dimension, the next section can measure matrices without apologizing for which measurement it uses — and then, when the estimates start to matter, name the norm on purpose.

15.2.5 Exercises

15.2.5.1 A. Check your understanding

Exercise A1.

(a) State Definition 15.2.1, and explain why the phrase "not depending on the vector" cannot be dropped.

(b) State Theorem 15.2.2, including its hypothesis on V.

(c) Which two of the four imported analysis facts does the proof of Theorem 15.2.2 use, and at which step is each used?

(d) True or false: if two norms on $\mathbb{R}^n$ are equivalent, then some sequence converges in one and not the other. Justify your answer.

(e) True or false: equivalent norms give the same value to every vector. Justify your answer.

Solution.

(a) Two norms $\|\cdot\|_a, \|\cdot\|_b$ on V are equivalent if there are constants $c, C > 0$, independent of the vector, with $c\|\mathbf{v}\|_b \leq \|\mathbf{v}\|_a \leq C\|\mathbf{v}\|_b$ for every $\mathbf{v} \in V$ (Definition 15.2.1). Without the phrase the condition is vacuous: for each $\mathbf{v} \neq \mathbf{0}$ the number $\|\mathbf{v}\|_a/\|\mathbf{v}\|_b$ is positive and could be taken as both c and C at that one vector, so every pair of norms would qualify.

(b) On a finite-dimensional vector space over $\mathbb{R}$ or $\mathbb{C}$, any two norms are equivalent (Theorem 15.2.2). Finite dimension is essential — see Example (Two inequivalent norms on a space of polynomials).

(c) Fact (A3), the compactness of closed bounded sets in F^n, at Step 3, to know the Euclidean unit sphere is compact; and fact (A4), the extreme value theorem, also

at Step 3, to know that the continuous function f attains a minimum there rather than merely approaching an infimum.

(d) False, and this is the content of Corollary 15.2.3 (a): equivalent norms have exactly the same convergent sequences with exactly the same limits.

(e) False. $\|\cdot\|_1$ and $\|\cdot\|_\infty$ on $\mathbb{R}^2$ are equivalent by Example (The three p-norms, with best constants), yet $\|\mathbf{1}\|_1 = 2 \neq 1 = \|\mathbf{1}\|_\infty$. Equivalence constrains ratios, not values.

15.2.5.2 B. Practice

Exercise B1: Best constants for a weighted norm.

On $\mathbb{R}^2$ let $N(\mathbf{x}) = \left(x_1^2 + 4x_2^2\right)^{1/2}$. Find the **best** constants $c, C > 0$ with

$$c\,\|\mathbf{x}\|_\infty \le N(\mathbf{x}) \le C\,\|\mathbf{x}\|_\infty \qquad (\mathbf{x} \in \mathbb{R}^2),$$

and give a vector attaining each. Hence deduce that N and $\|\cdot\|_\infty$ are equivalent.

Solution. Write $a = |x_1|$, $b = |x_2|$ and $M = \max(a, b) = \|\mathbf{x}\|_\infty$. Then $N(\mathbf{x})^2 = a^2 + 4b^2$.

Upper: $a^2 + 4b^2 \le M^2 + 4M^2 = 5M^2$, so $N(\mathbf{x}) \le \sqrt{5}\,\|\mathbf{x}\|_\infty$. Equality needs $a = b = M$, and $\mathbf{x} = (1, 1)$ gives $N(\mathbf{x}) = \sqrt{5}$ and $\|\mathbf{x}\|_\infty = 1$. So $C = \sqrt{5}$ and it cannot be lowered.

Lower: if $M = a$ then $a^2 + 4b^2 \ge a^2 = M^2$, and if $M = b$ then $a^2 + 4b^2 \ge 4b^2 \ge M^2$. Either way $N(\mathbf{x}) \ge \|\mathbf{x}\|_\infty$, so $c = 1$ works, and $\mathbf{x} = \mathbf{e}_1$ gives $N(\mathbf{x}) = \|\mathbf{x}\|_\infty = 1$, so it cannot be raised.

Since 1 and $\sqrt{5}$ are positive constants independent of $\mathbf{x}$, the two norms are equivalent by Definition 15.2.1.

Exercise B2: Reading a convergence off the entries.

In $M_2(\mathbb{R})$ let

$$\mathbf{M}_k = \begin{pmatrix} 1 + \frac{1}{k} & \frac{(-1)^k}{k^2} \\ \frac{1}{2^k} & 3 - \frac{5}{k} \end{pmatrix}.$$

Determine $\lim_k \mathbf{M}_k$ in the sense of Definition 9.10.1, and compute $\|\mathbf{M}_k - \mathbf{M}\|_F$ explicitly. Hence confirm Corollary 15.2.4 for this sequence and the Frobenius norm.

Solution. Each entry converges: $1 + 1/k \to 1$, $(-1)^k/k^2 \to 0$, $2^{-k} \to 0$, $3 - 5/k \to 3$. So $\mathbf{M}_k \to \mathbf{M} = \begin{pmatrix} 1 & 0 \\ 0 & 3 \end{pmatrix}$ entrywise. Then

$$\|\mathbf{M}_k - \mathbf{M}\|_F = \left(\tfrac{1}{k^2} + \tfrac{1}{k^4} + \tfrac{1}{4^k} + \tfrac{25}{k^2}\right)^{1/2},$$

which is at most $\left(28/k^2\right)^{1/2} = \sqrt{28}/k$ for $k \ge 1$, since $1/k^4 \le 1/k^2$ and $4^{-k} \le 1/k^2$ for $k \ge 1$. Hence $\|\mathbf{M}_k - \mathbf{M}\|_F \to 0$, as Corollary 15.2.4 predicts. Note what the norm added: a single sequence $\sqrt{28}/k$ bounding the whole matrix, where the entrywise statement gave four unrelated sequences.

Exercise B3: An equivalence with the constants written down.

Let $V = \mathbb{R}[x]_{\le 2}$ with basis $\mathcal{B} = (1, x, x^2)$. For $p \in V$ let $\|p\|_{\mathcal{B}}$ be the Euclidean norm of the coefficient vector, and let $N(p) = |p(0)| + |p(1)| + |p(-1)|$.

(a) Prove that N is a norm on V.

(b) Find an explicit M with $N(p) \le M\|p\|_{\mathcal{B}}$, following Step 1 of the proof of Theorem 15.2.2.

(c) Explain, without computing it, why a constant $m > 0$ with $N(p) \ge m\|p\|_{\mathcal{B}}$ exists.

Solution.

(a) (N2) and (N3) are inherited pointwise from $|\cdot|$ on $\mathbb{R}$, exactly as for $\|\cdot\|_1$ in Example (The 1-, 2- and ∞-norms on F^n). For (N1): $N(p) = 0$ forces $p(0) = p(1) = p(-1) = 0$, so p has three distinct roots while $\deg p \le 2$, hence $p = 0$. This is the only clause with any content, and it is where $\dim V = 3$ and the three sample points match up.

(b) Step 1 takes $M = \big(\sum_i N(\mathbf{v}_i)^2\big)^{1/2}$ over the basis. Here $N(1) = 1 + 1 + 1 = 3$, $N(x) = 0 + 1 + 1 = 2$ and $N(x^2) = 0 + 1 + 1 = 2$, so

$$M = \big(9 + 4 + 4\big)^{1/2} = \sqrt{17}.$$

(c) V is finite-dimensional, so Theorem 15.2.2 applies to the pair N, $\|\cdot\|_{\mathcal{B}}$ and delivers both constants at once. Only the upper one is computable by hand from the basis; the lower one comes from compactness and the proof gives no formula for it.

15.2.5.3 C. Going deeper

Exercise C1: Every linear map out of a finite-dimensional space is continuous.

Let V be finite-dimensional over F with norm $\|\cdot\|_V$, let W be a normed space over F with norm $\|\cdot\|_W$, and let $T\colon V \to W$ be linear. Fix a basis $\mathcal{B} = (\mathbf{v}_1, \dots, \mathbf{v}_n)$ of V and write $\|\cdot\|_1$ for the 1-norm of the coordinate vector in the basis $\mathcal{B}$.

(a) Prove that $\|T\mathbf{v}\|_W \le K\|\mathbf{v}\|_1$ for every $\mathbf{v} \in V$, where $K = \max_i \|T\mathbf{v}_i\|_W$.

(b) Hence prove that there is a constant L with $\|T\mathbf{u} - T\mathbf{v}\|_W \le L\|\mathbf{u} - \mathbf{v}\|_V$ for all $\mathbf{u}, \mathbf{v} \in V$.

(c) Explain why (b) may fail when V is infinite-dimensional, using Example (Two inequivalent norms on a space of polynomials).

Solution.

(a) Write $\mathbf{v} = \sum_i x_i \mathbf{v}_i$. By linearity of T, then (N3) and (N2) in W,

$$\|T\mathbf{v}\|_W = \Big\|\sum_i x_i T\mathbf{v}_i\Big\|_W \le \sum_i |x_i|\,\|T\mathbf{v}_i\|_W \le K\|\mathbf{v}\|_1.$$

(b) The function $\|\cdot\|_1$ is a norm on V (it is $\|\cdot\|_1$ of Example (The 1-, 2- and ∞-norms on F^n) transported by the coordinate isomorphism Corollary 3.5.5), and V is finite-

dimensional, so by Theorem 15.2.2 there is $C > 0$ with $\|\mathbf{v}\|_1 \le C\|\mathbf{v}\|_V$ for all $\mathbf{v}$. Put $L = KC$. By linearity, $T\mathbf{u} - T\mathbf{v} = T(\mathbf{u} - \mathbf{v})$, so (a) gives

$$\|T\mathbf{u} - T\mathbf{v}\|_W \le K\|\mathbf{u} - \mathbf{v}\|_1 \le L\|\mathbf{u} - \mathbf{v}\|_V.$$

(c) Part (a) needs a **finite** basis expansion, and part (b) needs Theorem 15.2.2, which is false in infinite dimension. Concretely, take $V = \mathbb{R}[x]$ with the coefficient norm $\|\cdot\|_\infty$ of Example (Two inequivalent norms on a space of polynomials), $W = \mathbb{R}$ with $|\cdot|$, and the linear functional $T(p) = p(1)$, which adds up the coefficients. With $p_k = 1 + x + \cdots + x^{k-1}$ as there, the polynomials $q_k = \frac{1}{k}p_k$ satisfy $\|q_k\|_\infty = 1/k \to 0$ while $T(q_k) = 1$ for every k. So T sends a sequence tending to 0 to a sequence that does not, and no constant L can exist.

Exercise C2: No dimension-free constants.

For each $n \ge 1$ let $c_n, C_n > 0$ be the best constants with

$$c_n\|\mathbf{x}\|_\infty \le \|\mathbf{x}\|_1 \le C_n\|\mathbf{x}\|_\infty \qquad (\mathbf{x} \in F^n).$$

(a) Determine c_n and C_n, with a vector attaining each.

(b) Deduce that there is no pair of constants $c, C > 0$ working simultaneously for every n.

(c) A statement about $\mathbb{R}^n$ says "the error $\mathbf{e}$ satisfies $\|\mathbf{e}\|_\infty \le 10^{-6}$". What is the strongest bound on $\|\mathbf{e}\|_1$ that follows, and for which n does it stop being informative if the entries of $\mathbf{e}$ are themselves of size about 10^{-6}?

Solution.

(a) $c_n = 1$ and $C_n = n$. Indeed $\|\mathbf{x}\|_\infty = |x_k|$ for some k, and $|x_k| \le \sum_i |x_i| = \|\mathbf{x}\|_1$, with equality at $\mathbf{x} = \mathbf{e}_1$; and $\|\mathbf{x}\|_1 = \sum_i |x_i| \le n \max_i |x_i| = n\|\mathbf{x}\|_\infty$, with equality at $\mathbf{x} = \mathbf{1}$. Both constants are therefore attained and cannot be improved.

(b) A dimension-free C would need $C \ge C_n = n$ for every n, which is impossible. (The constant $c = 1$ does happen to work for all n; it is the upper constant that blows up, and one blown-up constant is enough.)

(c) The strongest bound is $\|\mathbf{e}\|_1 \le n \cdot 10^{-6}$, by (a), and it is attained when all entries have modulus 10^{-6} — which is exactly the situation described. So for $n = 10^6$ the bound reads $\|\mathbf{e}\|_1 \le 1$, which says nothing useful about a quantity that is itself of order 1. The two norms agree that the error tends to 0 as the computation improves; they disagree, by a factor of n, about whether it is currently small.

Exercise C3: A finite-dimensional subspace is closed.

Let W be a normed space over F with norm $\|\cdot\|$, and let $U \subseteq W$ be a **finite-dimensional** subspace. Let $(\mathbf{u}_k)$ be a sequence in U with $\|\mathbf{u}_k - \mathbf{w}\| \to 0$ for some $\mathbf{w} \in W$.

(a) Prove that $(\mathbf{u}_k)$ is bounded in U for the restricted norm.

(b) Using Corollary 15.2.5, produce a subsequence $(\mathbf{u}_{k_j})$ converging to some $\mathbf{u} \in U$.

(c) Deduce that $\mathbf{w} = \mathbf{u}$, so that U contains the limit of every convergent sequence of its own elements. *Hint: the triangle inequality, through* $\mathbf{u}_{k_j}$.

Solution.

(a) By Lemma 15.1.1, $\big|\|\mathbf{u}_k\| - \|\mathbf{w}\|\big| \le \|\mathbf{u}_k - \mathbf{w}\|$, and the right side tends to 0. So there is K with $\|\mathbf{u}_k - \mathbf{w}\| \le 1$ for $k \ge K$, whence $\|\mathbf{u}_k\| \le \|\mathbf{w}\| + 1$ for those k; the finitely many earlier terms are bounded by their maximum. Hence $(\mathbf{u}_k)$ is bounded.

(b) The restriction of $\|\cdot\|$ to U is a norm on U, and U is finite-dimensional. The set $K = \{\mathbf{u} \in U : \|\mathbf{u}\| \le R\}$, with R the bound from (a), is closed and bounded in U, hence compact by Corollary 15.2.5. The sequence $(\mathbf{u}_k)$ lies in K, so some subsequence $(\mathbf{u}_{k_j})$ converges to a point $\mathbf{u} \in K \subseteq U$.

(c) For every j, by (N3),

$$\|\mathbf{w} - \mathbf{u}\| \le \|\mathbf{w} - \mathbf{u}_{k_j}\| + \|\mathbf{u}_{k_j} - \mathbf{u}\|.$$

Both terms on the right tend to 0 as $j \to \infty$: the first because $(\mathbf{u}_k)$ converges to $\mathbf{w}$ and a subsequence of a convergent sequence has the same limit, the second by (b). The left side does not depend on j, so $\|\mathbf{w} - \mathbf{u}\| = 0$, and (N1) gives $\mathbf{w} = \mathbf{u} \in U$. Hence U contains every such limit, which is what it means for U to be closed in W. Note that W itself was never assumed finite-dimensional; only U was, and that is exactly where Corollary 15.2.5 was applied.

15.3 Measuring a Matrix

Chapter 11 §11 gave the Frobenius norm its own symbol and explained the subscript: a bare $\|\cdot\|$ already meant the norm of a *vector*, and a matrix, it warned, would shortly be asked to carry both kinds of measurement. This is that moment. A matrix is a list of mn numbers, and it is also a map; measuring the list is easy, measuring the map is what we usually want, and the two answers are not the same number. This section builds the second measurement, computes it in the three cases anyone computes, and says exactly where the first one fails.

Throughout, F is $\mathbb{R}$ or $\mathbb{C}$, all spaces are finite-dimensional, and $\|\cdot\|$ with no subscript is a norm in the sense of Definition 15.1.1.

15.3.1 What a matrix norm has to do

Chapter 9 §10 decided whether $\mathbf{A}^m \to 0$ by looking at one entry of one Jordan block at a time. A single number attached to $\mathbf{A}$ would be a far better instrument — but only if it interacts with matrix multiplication, because the questions we want to answer are questions about products: $\mathbf{A}^m$, $\sum_k \mathbf{A}^k$, $e^{\mathbf{A}}$. A norm that satisfies

$$\|\mathbf{AB}\| \le \|\mathbf{A}\|\,\|\mathbf{B}\|$$

immediately gives $\|\mathbf{A}^m\| \le \|\mathbf{A}\|^m$, and with that one line a geometric series is in reach. A norm that does not satisfy it gives nothing at all about powers. So the property is not a technical nicety; it is the entire reason for the definition.

A matrix norm is a norm on matrices that never lets a product be bigger than the product of the sizes.

Definition 15.3.1 — Matrix Norm

Let $n \geq 1$. A **matrix norm** on $M_n(F)$ is a function $\|\cdot\| : M_n(F) \to \mathbb{R}$ which is a norm on $M_n(F)$ as a vector space (Definition 15.1.1) and which is in addition **submultiplicative**: for **all** $\mathbf{A}, \mathbf{B} \in M_n(F)$,

$$\|\mathbf{AB}\| \leq \|\mathbf{A}\| \, \|\mathbf{B}\|.$$

In words: the first requirement is the ordinary one — clauses (N1), (N2), (N3) of Definition 15.1.1 — and it sees $M_n(F)$ only as the vector space F^{n^2} in disguise. The second requirement is the one that notices the multiplication. Note that submultiplicativity is an inequality, not an equality: it is easy for a norm to make $\|\mathbf{AB}\|$ far smaller than $\|\mathbf{A}\|\|\mathbf{B}\|$, and impossible for a matrix norm to make it larger.

The condition needs a square matrix only so that $\mathbf{AB}$ is defined for every pair; nothing else in the definition cares about the shape.

Example. (The Frobenius norm is submultiplicative)

Show that $\|\mathbf{AB}\|_F \leq \|\mathbf{A}\|_F \|\mathbf{B}\|_F$ for all $\mathbf{A}, \mathbf{B} \in M_n(F)$, so that $\|\cdot\|_F$ is a matrix norm.

Solution. The entry $(\mathbf{AB})_{ij} = \sum_k a_{ik} b_{kj}$ is the inner product in F^n of the i-th row of $\mathbf{A}$ with the j-th column of $\mathbf{B}$ (up to a conjugation, which does not change moduli). By Theorem 10.1.5,

$$|(\mathbf{AB})_{ij}|^2 \leq \Big(\sum_k |a_{ik}|^2\Big)\Big(\sum_k |b_{kj}|^2\Big).$$

Summing over all i and j, and noting that the two bracketed factors depend only on i and only on j respectively,

$$\|\mathbf{AB}\|_F^2 \leq \Big(\sum_{i,k} |a_{ik}|^2\Big)\Big(\sum_{k,j} |b_{kj}|^2\Big) = \|\mathbf{A}\|_F^2 \, \|\mathbf{B}\|_F^2.$$

Both sides are non-negative, so taking square roots gives the claim. That $\|\cdot\|_F$ is a norm was settled in Chapter 10: it is the norm induced by the Frobenius inner product (Definition 10.1.3), so Theorem 10.1.2 and Corollary 10.1.6 apply.

Now the minimal change that breaks it. Keep the idea "read the matrix as a list of numbers" but measure the list with the maximum instead of the Euclidean length.

Example. (The entrywise maximum is not submultiplicative)

For $\mathbf{A} \in M_n(F)$ put $N(\mathbf{A}) = \max_{i,j} |a_{ij}|$. Show that N is a norm on $M_n(F)$ but not a matrix norm for $n \geq 2$.

Solution. N is the ∞-norm of the list of n^2 entries, so it is a norm (Definition 15.1.1): it vanishes only on the zero matrix, $N(c\mathbf{A}) = |c|N(\mathbf{A})$, and (N3) holds entry by entry.

Submultiplicativity fails already for $n = 2$. Take $\mathbf{A} = \mathbf{B} = \mathbf{J} = \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix}$. Then $N(\mathbf{J}) = 1$, while

$$\mathbf{J}^2 = \begin{pmatrix} 2 & 2 \\ 2 & 2 \end{pmatrix}, \qquad N(\mathbf{J}^2) = 2 > 1 = N(\mathbf{J})N(\mathbf{J}).$$

The mechanism is plain: an entry of a product is a sum of n terms, each as large as the largest entry, and a maximum taken entry by entry has no way of charging for the length of that sum. For $n \times n$ the same matrix gives $N(\mathbf{J}^2) = n$.

Warning. **Submultiplicativity is a property of the norm, not of matrices.** The failure above is not caused by $\mathbf{J}$ being special; it is caused by N being the wrong yardstick. Exercise (C2: Repairing the entrywise maximum) shows that the single rescaling $\mathbf{A} \mapsto nN(\mathbf{A})$ repairs it, which is a good way to see that nothing deep is being violated — only a normalization.

15.3.2 The norm a vector norm induces

The definition above is a filter, not a construction: it says which norms are usable, not where to find one. The construction comes from remembering what $\mathbf{A}$ is for. It sends vectors to vectors, and if both are already measured, we can ask how much $\mathbf{A}$ magnifies.

This is exactly the question Chapter 12 §08 asked of the singular value decomposition, and the question Chapter 12 §12 asked of an oblique projection, in each case computing $\max\{\|\mathbf{Ax}\| : \|\mathbf{x}\| = 1\}$ and then promising that the number would get a name here.

Before naming it, we must know that the maximum exists. "Take the largest value of a function over infinitely many vectors" is not something one may write without a reason, and the reason is compactness, already packaged for us in Corollary 15.2.5.

Lemma 15.3.1 — The Largest Stretch Is Attained

Let $n, m \geq 1$, let $\|\cdot\|$ be a norm on F^n and also a norm on F^m, and let $\mathbf{A} \in M_{m\times n}(F)$. Then the function $\mathbf{x} \mapsto \|\mathbf{Ax}\|$ attains a maximum on the unit sphere $S = \{\mathbf{x} \in F^n : \|\mathbf{x}\| = 1\}$.

Idea. Two steps, and the second is already packaged for us. ① The function is Lipschitz, hence continuous: Lemma 15.1.1 converts a difference of norms into the norm of a difference, and a crude expansion in the standard basis bounds $\|\mathbf{Az}\|$ by a constant times $\|\mathbf{z}\|$. ② The unit sphere is closed and bounded, hence compact, and a continuous real function on it attains its bounds — which is exactly what Corollary 15.2.5 says.

Proof. **Step 1: a Lipschitz bound.** Write $\mathbf{z} = \sum_{j=1}^{n} z_j \mathbf{e}_j$. By subadditivity and homogeneity,

$$\|\mathbf{Az}\| \le \sum_{j=1}^{n} |z_j| \, \|\mathbf{Ae}_j\| \le \Big(\max_j \|\mathbf{Ae}_j\|\Big) \|\mathbf{z}\|_1.$$

By Theorem 15.2.2, applied on F^n to the norms $\|\cdot\|_1$ and $\|\cdot\|$, there is a constant $c > 0$ with $\|\mathbf{z}\|_1 \le c\|\mathbf{z}\|$ for every $\mathbf{z}$. Hence $\|\mathbf{Az}\| \le M\|\mathbf{z}\|$ with $M = c \max_j \|\mathbf{Ae}_j\|$, a constant depending on $\mathbf{A}$ but not on $\mathbf{z}$.

Step 2: continuity. Let $\mathbf{x}, \mathbf{y} \in F^n$. By Lemma 15.1.1, applied to the vectors $\mathbf{Ax}$ and $\mathbf{Ay}$ of F^m, and then by Step 1,

$$\big|\, \|\mathbf{Ax}\| - \|\mathbf{Ay}\| \,\big| \le \|\mathbf{A}(\mathbf{x} - \mathbf{y})\| \le M\|\mathbf{x} - \mathbf{y}\|.$$

So $\mathbf{x} \mapsto \|\mathbf{Ax}\|$ is Lipschitz with constant M, and in particular continuous.

Step 3: compactness. The set S is non-empty, since $n \ge 1$ and $\mathbf{e}_1/\|\mathbf{e}_1\| \in S$, the division being legal because $\mathbf{e}_1 \ne \mathbf{0}$. By Corollary 15.2.5 the unit sphere of any norm on a finite-dimensional space is compact, and a continuous real-valued function on it attains a maximum. That corollary is where this chapter's imported facts (A3), the compactness of closed bounded sets, and (A4), the extreme value theorem, are cashed in; here we only apply it, to the continuous function of Step 2. This proves the lemma.

■

The operator norm of a matrix is the worst stretching it can do to a unit vector.

Definition 15.3.2 — Operator Norm

Let $n, m \ge 1$ and let a norm $\|\cdot\|$ be given on F^n and on F^m; we write both with the same symbol, the argument saying which is meant. The **operator norm** of $\mathbf{A} \in M_{m\times n}(F)$ **induced by** those norms is

$$\|\mathbf{A}\| := \max\{\, \|\mathbf{Ax}\| : \mathbf{x} \in F^n,\ \|\mathbf{x}\| = 1 \,\},$$

which exists by Lemma 15.3.1. When the vector norm is $\|\cdot\|_p$ on both sides we write $\|\mathbf{A}\|_p$, and $\|\mathbf{A}\|_2$ is also called the **spectral norm**.

Clause by clause: the maximum is over **unit** vectors only, so a matrix that stretches one long vector enormously is not thereby given a large norm — what counts is the *factor*. The norm on the source and the norm on the target may be different, and then $\|\mathbf{A}\|$ depends on both; the notation hides that, which is why the vector norm must always be named. And the word **induced** is doing real work: not every matrix norm arises this way, as the end of this section shows.

Three equivalent descriptions are worth having at once. For $\mathbf{A} \ne 0$,

$$\|\mathbf{A}\| = \max_{\|\mathbf{x}\|=1} \|\mathbf{Ax}\| = \max_{\mathbf{x}\ne\mathbf{0}} \frac{\|\mathbf{Ax}\|}{\|\mathbf{x}\|} = \max_{\|\mathbf{x}\|\le 1} \|\mathbf{Ax}\|.$$

The middle expression equals the first because $\|\mathbf{Ax}\|/\|\mathbf{x}\| = \|\mathbf{A}(\mathbf{x}/\|\mathbf{x}\|)\|$ by homogeneity, and $\mathbf{x}/\|\mathbf{x}\|$ runs over S as $\mathbf{x}$ runs over the non-zero vectors. The third equals the first because scaling any $\mathbf{x}$ with $0 < \|\mathbf{x}\| \le 1$ up to the sphere only increases $\|\mathbf{Ax}\|$, and $\mathbf{x} = \mathbf{0}$ contributes 0.

The smallest cases are worth seeing before any real example, because they pin the scale. For $\mathbf{A} = \mathbf{0}$ every $\mathbf{Ax}$ is $\mathbf{0}$, so $\|\mathbf{0}\| = 0$, as (N1) demands. For $m = n = 1$, a matrix is a scalar (a), the only unit vectors are the scalars of modulus 1, and $\|(a)\| = |a|$: the operator norm of a number is its absolute value, so the definition extends the one-dimensional case rather than replacing it. And for $\mathbf{A} = \mathbf{I}$, every unit vector satisfies $\|\mathbf{Ix}\| = \|\mathbf{x}\| = 1$, so $\|\mathbf{I}\| = 1$ **for every choice of vector norm** — a fact used so often below that it is worth fixing now.

> *Quick check.* Why is the maximum in Definition 15.3.2 taken over $\|\mathbf{x}\| = 1$ rather than over all $\mathbf{x}$? What would the supremum over all $\mathbf{x} \in F^n$ be?

> *Solution.* For a non-zero $\mathbf{A}$ it would be infinite: pick $\mathbf{x}_0$ with $\mathbf{Ax}_0 \neq \mathbf{0}$; then $\|\mathbf{A}(t\mathbf{x}_0)\| = t\|\mathbf{Ax}_0\| \to \infty$ as $t \to \infty$. Restricting to unit vectors measures the *ratio* of output size to input size, which is what "how much does $\mathbf{A}$ magnify?" means, and by homogeneity the ratio is already known on all of F^n once it is known on the sphere.

Theorem 15.3.2 — Properties of the Operator Norm

Let $\|\cdot\|$ be a norm on each of F^n, F^m, F^ℓ, and let $\mathbf{A} \in M_{m\times n}(F)$. Then:

(a) $\|\mathbf{Ax}\| \le \|\mathbf{A}\|\,\|\mathbf{x}\|$ for **every** $\mathbf{x} \in F^n$, and $\|\mathbf{A}\|$ is the smallest constant with this property;

(b) $\|\cdot\|$ is a norm on the vector space $M_{m\times n}(F)$;

(c) $\|\mathbf{I}_n\| = 1$;

(d) $\|\mathbf{AB}\| \le \|\mathbf{A}\|\,\|\mathbf{B}\|$ for every $\mathbf{B} \in M_{n\times \ell}(F)$. In particular the operator norm induced on $M_n(F)$ by a single norm on F^n is a matrix norm in the sense of Definition 15.3.1.

> *Idea.* Everything is the definition plus homogeneity. The one move worth naming is in (a): a general $\mathbf{x} \neq \mathbf{0}$ is $\|\mathbf{x}\|$ times a unit vector, so the inequality on the sphere upgrades to an inequality everywhere; and once (a) is available, (d) is two applications of it.

> *Proof.*
>
> (a) For $\mathbf{x} = \mathbf{0}$ both sides are 0. For $\mathbf{x} \neq \mathbf{0}$, the vector $\mathbf{u} = \mathbf{x}/\|\mathbf{x}\|$ satisfies $\|\mathbf{u}\| = 1$, so $\|\mathbf{Au}\| \le \|\mathbf{A}\|$ by Definition 15.3.2; multiplying by $\|\mathbf{x}\|$ and using homogeneity gives $\|\mathbf{Ax}\| \le \|\mathbf{A}\|\|\mathbf{x}\|$. If K is any constant with $\|\mathbf{Ax}\| \le K\|\mathbf{x}\|$ for all $\mathbf{x}$, then taking a unit $\mathbf{x}_0$ at which the maximum is attained (Lemma 15.3.1) gives $\|\mathbf{A}\| = \|\mathbf{Ax}_0\| \le K$.
>
> (b) Each value is a maximum of non-negative numbers, so $\|\mathbf{A}\| \ge 0$. If $\|\mathbf{A}\| = 0$ then $\mathbf{Au} = \mathbf{0}$ for every unit $\mathbf{u}$, hence $\mathbf{Ax} = \mathbf{0}$ for every $\mathbf{x}$ by (a), hence $\mathbf{A} = 0$. For a scalar c, $\|c\mathbf{A}\| = \max_{\|\mathbf{x}\|=1}|c|\|\mathbf{Ax}\| = |c|\|\mathbf{A}\|$. For subadditivity, let $\mathbf{x}$ be a unit vector; then $\|(\mathbf{A}+\mathbf{B})\mathbf{x}\| \le \|\mathbf{Ax}\| + \|\mathbf{Bx}\| \le \|\mathbf{A}\| + \|\mathbf{B}\|$, and taking the maximum over $\mathbf{x}$ gives $\|\mathbf{A}+\mathbf{B}\| \le \|\mathbf{A}\| + \|\mathbf{B}\|$.
>
> (c) $\|\mathbf{I}_n\mathbf{x}\| = \|\mathbf{x}\| = 1$ for every unit $\mathbf{x}$, so the maximum is 1.
>
> (d) Let $\mathbf{x} \in F^\ell$ be a unit vector. By (a) applied twice, first to $\mathbf{A}$ and then to $\mathbf{B}$,

$$\|\mathbf{ABx}\| \le \|\mathbf{A}\|\,\|\mathbf{Bx}\| \le \|\mathbf{A}\|\,\|\mathbf{B}\|\,\|\mathbf{x}\| = \|\mathbf{A}\|\,\|\mathbf{B}\|.$$

Taking the maximum over unit $\mathbf{x}$ gives $\|\mathbf{AB}\| \le \|\mathbf{A}\|\|\mathbf{B}\|$. This proves the theorem.

■

Part (c) is small and will do a large amount of work: it is the single property that separates the operator norms from the rest of the matrix norms.

15.3.3 The three formulas

A definition by maximization is not yet a computation. For the three standard vector norms the maximization can be carried out completely, and in two of the three cases the answer is read straight off the entries.

Theorem 15.3.3 — Computing the 1-, 2- and Infinity-Norms

Let $\mathbf{A} = (a_{ij}) \in M_{m\times n}(F)$ with $m, n \ge 1$. Then

(a) $\|\mathbf{A}\|_1 = \max\limits_{1\le j\le n} \sum\limits_{i=1}^{m} |a_{ij}|$, the largest absolute column sum;

(b) $\|\mathbf{A}\|_\infty = \max\limits_{1\le i\le m} \sum\limits_{j=1}^{n} |a_{ij}|$, the largest absolute row sum;

(c) $\|\mathbf{A}\|_2 = \sigma_1(\mathbf{A})$, the largest singular value of $\mathbf{A}$ (Definition 12.8.1).

Idea. Each part is an upper bound and a witness. ① For $\|\cdot\|_1$ the upper bound is subadditivity of the modulus with the column sums pulled out, and the witness is a standard basis vector $\mathbf{e}_k$ selecting the heaviest column. ② For $\|\cdot\|_\infty$ the upper bound is the same estimate read along a row, and the witness is a vector of unimodular entries chosen to rotate every term of the heaviest row into the positive reals, so that no cancellation occurs. ③ For $\|\cdot\|_2$ the witness is the first right singular vector, and the upper bound is the singular value decomposition: unitary factors are invisible to the Euclidean norm, so only the diagonal matrix $\mathbf{\Sigma}$ is left, and a diagonal matrix stretches most along its largest entry, because it scales each coordinate separately.

Proof. Write $C = \max_j \sum_i |a_{ij}|$ and $R = \max_i \sum_j |a_{ij}|$.

(a). Let $\|\mathbf{x}\|_1 = 1$. Then

$$\|\mathbf{Ax}\|_1 = \sum_i \Big|\sum_j a_{ij}x_j\Big| \le \sum_j |x_j| \sum_i |a_{ij}| \le C \sum_j |x_j| = C,$$

where the first inequality is subadditivity of the modulus together with an exchange of two finite sums. So $\|\mathbf{A}\|_1 \le C$. For the reverse, choose k with $\sum_i |a_{ik}| = C$. The vector $\mathbf{e}_k$ has $\|\mathbf{e}_k\|_1 = 1$ and $\mathbf{Ae}_k$ is the k-th column of $\mathbf{A}$, so $\|\mathbf{Ae}_k\|_1 = C$. Hence $\|\mathbf{A}\|_1 \ge C$.

(b). Let $\|\mathbf{x}\|_\infty = 1$. For each i,

$$\left|\sum_j a_{ij}x_j\right| \le \sum_j |a_{ij}|\,|x_j| \le \sum_j |a_{ij}| \le R,$$

so $\|\mathbf{Ax}\|_\infty \le R$ and $\|\mathbf{A}\|_\infty \le R$. For the reverse, choose k with $\sum_j |a_{kj}| = R$ and define $\mathbf{x}$ by $x_j = \overline{a_{kj}}/|a_{kj}|$ when $a_{kj} \neq 0$ and $x_j = 1$ otherwise. Every x_j has modulus 1, so $\|\mathbf{x}\|_\infty = 1$; and $a_{kj}x_j = |a_{kj}|$ for every j, the choice being legal exactly because we checked $a_{kj} \neq 0$ before dividing. Hence the k-th entry of $\mathbf{Ax}$ is $\sum_j |a_{kj}| = R$, giving $\|\mathbf{Ax}\|_\infty \ge R$.

(c). Let $\mathbf{A} = \mathbf{U\Sigma V}^*$ be a singular value decomposition (Theorem 12.8.1), with $\mathbf{U}, \mathbf{V}$ unitary and $\mathbf{\Sigma}$ carrying $\sigma_1 \ge \cdots \ge \sigma_p \ge 0$ on its diagonal, $p = \min(m, n)$. Let $\|\mathbf{x}\|_2 = 1$ and put $\mathbf{y} = \mathbf{V}^*\mathbf{x}$. A unitary matrix is an isometry for $\|\cdot\|_2$ (Theorem 10.7.3, (a) and (f)), so $\|\mathbf{y}\|_2 = 1$ and $\|\mathbf{Ax}\|_2 = \|\mathbf{U\Sigma y}\|_2 = \|\mathbf{\Sigma y}\|_2$. The vector $\mathbf{\Sigma y}$ has entries $\sigma_i y_i$ for $i \le p$ and zeros below, so

$$\|\mathbf{Ax}\|_2^2 = \sum_{i=1}^{p} \sigma_i^2 |y_i|^2 \le \sigma_1^2 \sum_{i=1}^{n} |y_i|^2 = \sigma_1^2.$$

Hence $\|\mathbf{A}\|_2 \le \sigma_1$. For the reverse, take $\mathbf{x} = \mathbf{v}_1$, the first column of $\mathbf{V}$; then $\mathbf{y} = \mathbf{V}^*\mathbf{v}_1 = \mathbf{e}_1$, so $\|\mathbf{Av}_1\|_2 = \|\mathbf{\Sigma e}_1\|_2 = \sigma_1$, and $\|\mathbf{v}_1\|_2 = 1$ because the columns of a unitary matrix are orthonormal. This proves the theorem.

■

Part (c) is the promise this section was written to keep. Chapter 12 §08 computed $\sigma_1 = \max\{\|\mathbf{Ax}\| : \|\mathbf{x}\| = 1\}$ and said that Chapter 15 would give that quantity a name, the operator norm $\|\mathbf{A}\|_2$, "and this computation is why $\|\mathbf{A}\|_2 = \sigma_1$". The name is Definition 15.3.2; the reason has now been separated from the name, so that the equality is a theorem about two independently defined numbers rather than a definition dressed up as one. Chapter 12 §12 measured an oblique projection by the same maximum and deferred the word twice; Example (The oblique projection, finally measured) below supplies it. And Chapter 11 §11, when it wrote $\|\mathbf{A}\|_F$ with an obligatory subscript, explained that the bare symbol was reserved because a matrix would soon be asked to be measured both as a list and as a map: parts (a)–(c) are that second measurement, and the rest of this section is the difference between the two.

Example. (One matrix, four numbers)

For $\mathbf{A} = \begin{pmatrix} 3 & 0 \\ 4 & 5 \end{pmatrix} \in M_2(\mathbb{R})$, compute $\|\mathbf{A}\|_1$, $\|\mathbf{A}\|_\infty$, $\|\mathbf{A}\|_F$ and $\|\mathbf{A}\|_2$.

Solution. The column sums of absolute values are $3+4=7$ and $0+5=5$, so $\|\mathbf{A}\|_1 = 7$ by Theorem 15.3.3 (a). The row sums are 3 and 9, so $\|\mathbf{A}\|_\infty = 9$ by (b). The Frobenius norm is $\sqrt{9+16+25} = 5\sqrt{2}$.

For the spectral norm, form

$$\mathbf{A}^\top\mathbf{A} = \begin{pmatrix} 25 & 20 \\ 20 & 25 \end{pmatrix}.$$

This matrix is $25\mathbf{I} + 20\left(\begin{smallmatrix}0&1\\1&0\end{smallmatrix}\right)$, whose eigenvalues are 25 ± 20, namely 45 and 5. So the singular values are $\sigma_1 = 3\sqrt{5}$ and $\sigma_2 = \sqrt{5}$, and $\|\mathbf{A}\|_2 = 3\sqrt{5} \approx 6.708$ by (c).

Two checks come for free. The product $\sigma_1\sigma_2 = 15$ equals $|\det \mathbf{A}| = 15$, and $\sigma_1^2 + \sigma_2^2 = 50 = \|\mathbf{A}\|_F^2$. The four numbers 7, 9, $5\sqrt{2} \approx 7.071$ and $3\sqrt{5} \approx 6.708$ are all different, which is the point: "the size of $\mathbf{A}$" is not a well-posed phrase until the norm is named.

Example. (The oblique projection, finally measured)

Chapter 12 §12 studied a projection P of F^2 onto a line, with matrix $\left(\begin{smallmatrix}1&x\\0&0\end{smallmatrix}\right)$ in a suitable orthonormal basis, and found that the largest value of $\|P\mathbf{v}\|$ over unit $\mathbf{v}$ is $\sqrt{1+|x|^2}$, which over $\mathbb{R}$ is $1/\sin\theta$ for the angle θ between image and kernel. Confirm this with Theorem 15.3.3 (c) for $x = -1$, the matrix $\mathbf{P}' = \left(\begin{smallmatrix}1&-1\\0&0\end{smallmatrix}\right)$ of Example (Two Oblique Projections, Measured).

Solution. $(\mathbf{P}')^{\top}\mathbf{P}' = \left(\begin{smallmatrix}1&-1\\-1&1\end{smallmatrix}\right)$, with eigenvalues 2 and 0; so $\sigma_1 = \sqrt{2}$ and $\|\mathbf{P}'\|_2 = \sqrt{2}$. This agrees with $\sqrt{1+|-1|^2} = \sqrt{2}$, and with $1/\sin\theta$ for $\theta = \pi/4$, the angle between the two lines. An orthogonal projection, by contrast, has $\|P_U\|_2 = 1$ whenever $U \neq \{\mathbf{0}\}$, since it fixes every unit vector of U and shortens the rest.

The two matrix norms now in play compare in a way worth recording, because the Frobenius norm is far cheaper to compute and the spectral norm is usually the one wanted.

Proposition 15.3.4 — Frobenius Against Spectral

Let $\mathbf{A} \in M_{m\times n}(F)$ be non-zero, of rank r. Then

$$\|\mathbf{A}\|_2 \le \|\mathbf{A}\|_F \le \sqrt{r}\,\|\mathbf{A}\|_2,$$

and the left inequality is an equality if and only if $r = 1$.

Idea. Write both norms in terms of the singular values: $\|\mathbf{A}\|_2 = \sigma_1$ and $\|\mathbf{A}\|_F^2 = \sigma_1^2 + \cdots + \sigma_r^2$. The claim is then the statement that one term of a sum of r non-negative numbers is at most the sum, which is at most r times the largest — and that the first is an equality exactly when there is only one term.

Proof. By Lemma 11.11.1 and $\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^*$ (Theorem 12.8.1), $\|\mathbf{A}\|_F = \|\mathbf{\Sigma}\|_F$, so $\|\mathbf{A}\|_F^2 = \sum_{i=1}^{p}\sigma_i^2$. Exactly r of the σ_i are non-zero (Theorem 12.8.1), and each satisfies $\sigma_i \le \sigma_1$. Hence

$$\sigma_1^2 \le \sum_{i=1}^{p}\sigma_i^2 \le r\sigma_1^2,$$

which is the displayed chain after taking square roots and using $\|\mathbf{A}\|_2 = \sigma_1$ (Theorem 15.3.3 (c)). The left inequality is an equality exactly when $\sigma_i = 0$ for all $i \ge 2$, that

is, when $r = 1$.

■

So the two norms never differ by a factor worse than $\sqrt{r} \le \sqrt{\min(m,n)}$, and they agree exactly on the rank-one matrices. What they do *not* agree on is more interesting.

15.3.4 What submultiplicativity does not buy

The Frobenius norm is a matrix norm: Example (The Frobenius norm is submultiplicative) proved it submultiplicative. It is tempting to conclude that it is therefore the operator norm induced by some vector norm — perhaps a cleverly chosen one. It is not, and the obstruction is a single line.

Warning. **Submultiplicative does not mean induced.** Every operator norm satisfies $\|\mathbf{I}_n\| = 1$ by Theorem 15.3.2 (c), whereas

$$\|\mathbf{I}_n\|_F = \sqrt{\underbrace{1 + 1 + \cdots + 1}_{n}} = \sqrt{n}.$$

So for $n \ge 2$ the Frobenius norm is **not** induced by any norm on F^n whatsoever — not by a bad choice, but by no choice at all. It is a matrix norm and not an operator norm, and the two phrases must be kept apart.

The identity is the cheapest witness, and it is decisive because $\|\mathbf{I}\| = 1$ is forced: the identity stretches nothing, so a norm that measures stretching must give it 1. A norm that assigns the identity the value $\sqrt{n}$ is measuring something else — the amount of material in the matrix, which for $\mathbf{I}_n$ grows with n.

Warning. **Two different objects are called $\|\mathbf{A}\|_\infty$ in the wild.** In this book $\|\mathbf{A}\|_\infty$ is the operator norm induced by $\|\cdot\|_\infty$ on vectors, that is, the largest row sum. The entrywise maximum $N(\mathbf{A}) = \max_{i,j}|a_{ij}|$ of Example (The entrywise maximum is not submultiplicative) is a different function, and it is not even submultiplicative. Whenever a source writes $\|\mathbf{A}\|_\infty$, check which one is meant by evaluating it at $\mathbf{I}_2$: the row-sum norm gives 1, the entrywise maximum gives 1 as well — so evaluate instead at $\mathbf{J}$, where the row-sum norm gives 2 and the entrywise maximum gives 1.

Quick check. The Frobenius norm satisfies $\|\mathbf{Ax}\|_2 \le \|\mathbf{A}\|_F\|\mathbf{x}\|_2$ for every $\mathbf{x}$, by Proposition 15.3.4 and Theorem 15.3.2 (a). Does that make it an operator norm?

Solution. No. Being *compatible* with a vector norm — satisfying $\|\mathbf{Ax}\| \le \|\mathbf{A}\|\|\mathbf{x}\|$ — is weaker than being induced by it. The induced norm is the **smallest** constant that works (Theorem 15.3.2 (a)), and for $\mathbf{A} = \mathbf{I}_n$ with $n \ge 2$ the smallest constant is 1 while $\|\mathbf{I}_n\|_F = \sqrt{n}$. Compatibility says the number is big enough; being induced says it is exactly right.

Where this leaves us: we have a supply of matrix norms (Definition 15.3.1), among them a distinguished family, the induced ones (Definition 15.3.2), and inside that family three that are computable (Theorem 15.3.3). The next section asks which quantity all of these norms are

simultaneously bounding from above, and finds that the answer is the spectral radius.

15.3.5 Exercises

15.3.5.1 A. Check your understanding

Exercise A1.

(a) Define a **matrix norm** on $M_n(F)$, and define the **operator norm** induced by a vector norm.

(b) State the three formulas of Theorem 15.3.3.

(c) Which analysis facts make Definition 15.3.2 legitimate, and where is each used?

(d) Determine whether the following statement is correct, and justify your answer: every matrix norm on $M_n(\mathbb{R})$ is the operator norm induced by some norm on $\mathbb{R}^n$.

(e) Determine whether the following statement is correct, and justify your answer: for every $\mathbf{A} \in M_n(F)$ and every operator norm, $\|\mathbf{A}^2\| = \|\mathbf{A}\|^2$.

Solution.

(a) A matrix norm is a norm on the vector space $M_n(F)$ that also satisfies $\|\mathbf{AB}\| \leq \|\mathbf{A}\|\|\mathbf{B}\|$ for all $\mathbf{A}, \mathbf{B}$ (Definition 15.3.1). Given norms on F^n and F^m, the operator norm of $\mathbf{A} \in M_{m\times n}(F)$ is $\|\mathbf{A}\| = \max\{\|\mathbf{Ax}\| : \|\mathbf{x}\| = 1\}$ (Definition 15.3.2).

(b) $\|\mathbf{A}\|_1$ is the largest absolute column sum, $\|\mathbf{A}\|_\infty$ the largest absolute row sum, and $\|\mathbf{A}\|_2 = \sigma_1(\mathbf{A})$.

(c) Two: the compactness of closed bounded sets, fact (A3) of the chapter introduction, used for the unit sphere S; and the extreme value theorem, fact (A4), used for $\mathbf{x} \mapsto \|\mathbf{Ax}\|$. Both enter through Corollary 15.2.5, quoted in Step 3 of Lemma 15.3.1. The continuity needed for the second is proved, not imported, and rests on Theorem 15.2.2 and Lemma 15.1.1.

(d) Incorrect. The Frobenius norm is a matrix norm, and $\|\mathbf{I}_n\|_F = \sqrt{n} \neq 1$ for $n \geq 2$, whereas every operator norm has $\|\mathbf{I}_n\| = 1$ by Theorem 15.3.2 (c).

(e) Incorrect; only $\leq$ holds, by Theorem 15.3.2 (d). Take $\mathbf{A} = \left(\begin{smallmatrix} 0 & 1 \\ 0 & 0 \end{smallmatrix}\right)$, for which $\|\mathbf{A}\|_2 = 1$ but $\mathbf{A}^2 = 0$, so $\|\mathbf{A}^2\|_2 = 0$.

15.3.5.2 B. Practice

Exercise B1: Four numbers for one matrix.

Let $\mathbf{A} = \begin{pmatrix} 2 & -1 \\ 2 & 2 \end{pmatrix} \in M_2(\mathbb{R})$. Compute $\|\mathbf{A}\|_1$, $\|\mathbf{A}\|_\infty$, $\|\mathbf{A}\|_F$ and $\|\mathbf{A}\|_2$, and verify that $\|\mathbf{A}\|_2 \leq \|\mathbf{A}\|_F$.

Solution. Absolute column sums: $2 + 2 = 4$ and $1 + 2 = 3$, so $\|\mathbf{A}\|_1 = 4$. Absolute row sums: $2 + 1 = 3$ and $2 + 2 = 4$, so $\|\mathbf{A}\|_\infty = 4$. Also $\|\mathbf{A}\|_F = \sqrt{4 + 1 + 4 + 4} = \sqrt{13}$.

For the spectral norm,

$$\mathbf{A}^{\top}\mathbf{A} = \begin{pmatrix} 8 & 2 \\ 2 & 5 \end{pmatrix},$$

with trace 13 and determinant $40 - 4 = 36$, so its eigenvalues solve $\lambda^2 - 13\lambda + 36 = 0$, giving $\lambda = 9$ and $\lambda = 4$. Hence $\sigma_1 = 3$, $\sigma_2 = 2$ and $\|\mathbf{A}\|_2 = 3$ by Theorem 15.3.3 (c). Finally $3 \le \sqrt{13}$, as Proposition 15.3.4 requires; the inequality is strict because $\operatorname{rank}\mathbf{A} = 2$.

Exercise B2: A rank-one matrix.

Let $\mathbf{u} \in F^m$ and $\mathbf{v} \in F^n$ be non-zero and put $\mathbf{A} = \mathbf{u}\mathbf{v}^*$.

(a) Prove that $\|\mathbf{A}\|_2 = \|\mathbf{u}\|_2\|\mathbf{v}\|_2$.

(b) Verify the formula for $\mathbf{u} = (1, 2)$ and $\mathbf{v} = (2, -1)$ in $\mathbb{R}^2$ by computing $\sigma_1(\mathbf{A})$ directly.

Solution.

(a) For $\mathbf{x} \in F^n$ we have $\mathbf{A}\mathbf{x} = (\mathbf{v}^*\mathbf{x})\mathbf{u}$, so $\|\mathbf{A}\mathbf{x}\|_2 = |\mathbf{v}^*\mathbf{x}|\,\|\mathbf{u}\|_2$. By Theorem 10.1.5, $|\mathbf{v}^*\mathbf{x}| = |\langle \mathbf{x}, \mathbf{v}\rangle| \le \|\mathbf{x}\|_2\|\mathbf{v}\|_2$, with equality when $\mathbf{x} = \mathbf{v}/\|\mathbf{v}\|_2$. Hence for unit $\mathbf{x}$ the quantity $\|\mathbf{A}\mathbf{x}\|_2$ is at most $\|\mathbf{u}\|_2\|\mathbf{v}\|_2$ and attains that value, so $\|\mathbf{A}\|_2 = \|\mathbf{u}\|_2\|\mathbf{v}\|_2$.

(b) Here $\mathbf{A} = \left(\begin{smallmatrix} 2 & -1 \\ 4 & -2 \end{smallmatrix}\right)$ and $\mathbf{A}^{\top}\mathbf{A} = \left(\begin{smallmatrix} 20 & -10 \\ -10 & 5 \end{smallmatrix}\right)$, of trace 25 and determinant $100 - 100 = 0$. So the eigenvalues are 25 and 0, giving $\sigma_1 = 5$. And $\|\mathbf{u}\|_2\|\mathbf{v}\|_2 = \sqrt{5}\cdot\sqrt{5} = 5$, in agreement. Note also $\|\mathbf{A}\|_F = 5 = \|\mathbf{A}\|_2$, as Proposition 15.3.4 predicts for a rank-one matrix.

Exercise B3: The star trick.

Let $\mathbf{A} \in M_{m\times n}(F)$. Prove that $\|\mathbf{A}^*\mathbf{A}\|_2 = \|\mathbf{A}\|_2^2$. *Hint: the eigenvalues of* $\mathbf{A}^*\mathbf{A}$.

Solution. By Definition 12.8.1 the eigenvalues of $\mathbf{A}^*\mathbf{A}$ are $\sigma_1^2 \ge \cdots \ge \sigma_n^2 \ge 0$, where the σ_i are the singular values of $\mathbf{A}$ padded with zeros if $n > m$. The matrix $\mathbf{A}^*\mathbf{A}$ is positive semidefinite, hence Hermitian, so by Corollary 11.4.3 it is $\mathbf{W}\mathbf{D}\mathbf{W}^*$ with $\mathbf{W}$ unitary and $\mathbf{D} = \operatorname{diag}(\sigma_1^2, \dots, \sigma_n^2)$. Then $(\mathbf{A}^*\mathbf{A})^*(\mathbf{A}^*\mathbf{A}) = \mathbf{W}\mathbf{D}^2\mathbf{W}^*$, whose eigenvalues are σ_i^4, so the singular values of $\mathbf{A}^*\mathbf{A}$ are the σ_i^2 and its largest is σ_1^2. By Theorem 15.3.3 (c), applied to $\mathbf{A}^*\mathbf{A}$ and then to $\mathbf{A}$,

$$\|\mathbf{A}^*\mathbf{A}\|_2 = \sigma_1^2 = \|\mathbf{A}\|_2^2.$$

This proves the claim. Notice that it is an equality, whereas Theorem 15.3.2 (d) alone would give only $\|\mathbf{A}^*\mathbf{A}\|_2 \le \|\mathbf{A}^*\|_2\|\mathbf{A}\|_2$.

15.3.5.3 C. Going deeper

Exercise C1: The spectral norm between the other two.

Let $\mathbf{A} \in M_{m\times n}(F)$.

(a) Prove that $\|\mathbf{A}\|_2 \le \sqrt{\|\mathbf{A}\|_1 \|\mathbf{A}\|_\infty}$.

(b) Check the inequality on the matrix of Example (One matrix, four numbers), and say how far it is from equality.

Hint for (a): apply Theorem 10.1.5 to the splitting $|a_{ij}| = |a_{ij}|^{1/2} \cdot |a_{ij}|^{1/2}|x_j|$ inside one row.

Solution.

(a) Write $C = \|\mathbf{A}\|_1$ and $R = \|\mathbf{A}\|_\infty$ for the largest column and row sums (Theorem 15.3.3). Let $\|\mathbf{x}\|_2 = 1$. For each i, Theorem 10.1.5 applied to the vectors with entries $|a_{ij}|^{1/2}$ and $|a_{ij}|^{1/2}|x_j|$ gives

$$\Big|\sum_j a_{ij}x_j\Big|^2 \le \Big(\sum_j |a_{ij}|\Big)\Big(\sum_j |a_{ij}|\,|x_j|^2\Big) \le R\sum_j |a_{ij}|\,|x_j|^2.$$

Summing over i and exchanging the two finite sums,

$$\|\mathbf{A}\mathbf{x}\|_2^2 \le R\sum_j |x_j|^2 \sum_i |a_{ij}| \le RC\sum_j |x_j|^2 = RC.$$

Taking the maximum over unit $\mathbf{x}$ gives $\|\mathbf{A}\|_2^2 \le RC$, as claimed.

(b) There $\|\mathbf{A}\|_1 = 7$ and $\|\mathbf{A}\|_\infty = 9$, so the bound is $\sqrt{63} \approx 7.937$, while $\|\mathbf{A}\|_2 = 3\sqrt{5} \approx 6.708$. The bound overestimates by about 18 per cent. It is sharp in general: for $\mathbf{A} = \mathbf{I}_n$ all three numbers are 1.

Exercise C2: Repairing the entrywise maximum.

For $\mathbf{A} \in M_n(F)$ let $N(\mathbf{A}) = \max_{i,j}|a_{ij}|$, as in Example (The entrywise maximum is not submultiplicative).

(a) Prove that $N(\mathbf{AB}) \le nN(\mathbf{A})N(\mathbf{B})$, and deduce that $\mathbf{A} \mapsto nN(\mathbf{A})$ **is** a matrix norm.

(b) Deduce that $nN(\cdot)$ is not an operator norm for any $n \ge 2$.

(c) Explain why (a) and (b) together show that submultiplicativity and $\|\mathbf{I}\| = 1$ are independent requirements.

Solution.

(a) For all i, j,

$$|(\mathbf{AB})_{ij}| = \Big|\sum_k a_{ik}b_{kj}\Big| \le \sum_k |a_{ik}|\,|b_{kj}| \le n\,N(\mathbf{A})N(\mathbf{B}),$$

so $N(\mathbf{AB}) \le nN(\mathbf{A})N(\mathbf{B})$. Put $\|\mathbf{A}\| = nN(\mathbf{A})$. It is a norm, being a positive multiple of the norm N, and

$$\|\mathbf{AB}\| = nN(\mathbf{AB}) \le n^2 N(\mathbf{A})N(\mathbf{B}) = \|\mathbf{A}\|\,\|\mathbf{B}\|.$$

(b) $\|\mathbf{I}_n\| = nN(\mathbf{I}_n) = n \ne 1$ for $n \ge 2$, while every operator norm gives the identity the value 1 (Theorem 15.3.2 (c)).

(c) N itself is a norm with $N(\mathbf{I}_n) = 1$ that is not submultiplicative; nN is submulti-

plicative with $nN(\mathbf{I}_n) = n$. So neither property implies the other, and an operator norm is precisely a matrix norm that also passes the identity test — a necessary condition which, as $\|\cdot\|_F$ already showed, is still not sufficient on its own for n large.

Exercise C3: When is a bound an equality?.

Let $\mathbf{A} \in M_{m\times n}(F)$ be non-zero.

(a) Prove that $\|\mathbf{A}\|_2 = \|\mathbf{A}\|_F$ if and only if $\operatorname{rank}\mathbf{A} = 1$.

(b) Give an example with $m = n = 2$ where $\|\mathbf{A}\|_F = \sqrt{2}\,\|\mathbf{A}\|_2$, the worst case allowed by Proposition 15.3.4.

(c) Is there a non-zero $\mathbf{A}$ with $\|\mathbf{A}\|_F < \|\mathbf{A}\|_2$? Justify your answer.

Solution.

(a) This is the equality case of Proposition 15.3.4, proved there: $\|\mathbf{A}\|_F^2 = \sum_i \sigma_i^2$ and $\|\mathbf{A}\|_2^2 = \sigma_1^2$, so the two agree exactly when $\sigma_i = 0$ for every $i \geq 2$, which by Theorem 12.8.1 says $\operatorname{rank}\mathbf{A} = 1$.

(b) Take $\mathbf{A} = \mathbf{I}_2$. Its singular values are $1, 1$, so $\|\mathbf{A}\|_2 = 1$ and $\|\mathbf{A}\|_F = \sqrt{2}$. Any matrix with two equal non-zero singular values does the same, for instance any 2×2 unitary matrix.

(c) No. $\|\mathbf{A}\|_2 = \sigma_1 \leq \left(\sum_i \sigma_i^2\right)^{1/2} = \|\mathbf{A}\|_F$ always, since every term of the sum is non-negative. The Frobenius norm counts all the singular values and the spectral norm only the largest, so the Frobenius norm can never be the smaller of the two.

15.4 The Spectral Radius

Every criterion in Chapter 9 §10 began by looking at the largest modulus of an eigenvalue, and that section gave the number a name in passing — the spectral radius — without a numbered definition and without a single norm available to compare it with. It also left a note: "Chapter 15 measures matrices by norms, proves that the spectral radius never exceeds the norm of $\mathbf{A}$ induced by any vector norm, and recovers $\rho(\mathbf{A})$ as a limit built from the norms of the powers $\mathbf{A}^m$." This section pays that note in full, and is careful about what is new when it does.

Throughout, matrices are complex. A real matrix is read inside $M_n(\mathbb{C})$, exactly as Chapter 9 §10 read it when it counted eigenvalues; over $\mathbb{R}$ a matrix may have no eigenvalue at all, and then there is nothing to take the largest modulus of.

15.4.1 The number Chapter 9 named

The spectral radius is the radius of the smallest disk about the origin that holds the whole spectrum.

Definition 15.4.1 — Spectral Radius

Let $\mathbf{A} \in M_n(\mathbb{C})$ with $n \geq 1$. The **spectral radius** of $\mathbf{A}$ is

$$\rho(\mathbf{A}) \coloneqq \max\{\, |\lambda| : \lambda \in \operatorname{spec}(\mathbf{A}) \,\}.$$

For an operator T on a non-zero finite-dimensional complex vector space, $\rho(T)$ is defined by the same formula with $\operatorname{spec}(T)$ in place of $\operatorname{spec}(\mathbf{A})$.

The maximum is over a **finite non-empty** set, so it exists with no analysis at all: $\operatorname{spec}(\mathbf{A})$ is the root set of the characteristic polynomial $p_{\mathbf{A}}$, which is non-empty by the Fundamental Theorem of Algebra (Theorem 5.5.1) and has at most n elements. It is the largest modulus of an eigenvalue, **not** the largest eigenvalue: over $\mathbb{C}$ there is no order to take a largest in, and even for a real spectrum $\rho(\operatorname{diag}(-5, 1)) = 5$, not 1. This is the number Chapter 9 §10 introduced in prose, now with a label so that later sections can cite it.

Some values, simplest first.

- **Diagonal or triangular.** The eigenvalues of a triangular matrix are its diagonal entries (Theorem 8.7.4 (b)), so ρ is the largest modulus on the diagonal. For $\operatorname{diag}(d_1, \dots, d_n)$ it is $\max_i |d_i|$.
- **Normal.** If $\mathbf{A}$ is normal then $\mathbf{A} = \mathbf{U}\mathbf{D}\mathbf{U}^*$ with $\mathbf{D} = \operatorname{diag}(\lambda_1, \dots, \lambda_n)$ (Corollary 11.4.3), so $\mathbf{A}^*\mathbf{A} = \mathbf{U} \operatorname{diag}(|\lambda_i|^2)\mathbf{U}^*$ and the singular values of $\mathbf{A}$ are the moduli $|\lambda_i|$. Hence $\rho(\mathbf{A}) = \sigma_1(\mathbf{A}) = \|\mathbf{A}\|_2$ by Theorem 15.3.3 (c). For a normal matrix the spectral radius **is** the spectral norm, which is where the second name comes from.
- **A rotation.** $\left(\begin{smallmatrix} 0 & -1 \\ 1 & 0 \end{smallmatrix}\right)$ has eigenvalues $\pm i$, so $\rho = 1$, although no real vector is left in place.
- **Nilpotent.** $\mathbf{J}_k(0)$ is triangular with zero diagonal, so by the first bullet $\rho(\mathbf{J}_k(0)) = 0$. The matrix itself is not 0 when $k \geq 2$.

The last entry is the degenerate case, and it is the important one: it says at once that ρ is not a norm.

Warning. **ρ is not a norm, and it is neither subadditive nor submultiplicative.** Take

$$\mathbf{A} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}, \qquad \mathbf{B} = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix}.$$

Both are nilpotent, so $\rho(\mathbf{A}) = \rho(\mathbf{B}) = 0$ although neither is the zero matrix. Their sum $\left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$ has eigenvalues ± 1 and their product $\mathbf{AB} = \left(\begin{smallmatrix} 1 & 0 \\ 0 & 0 \end{smallmatrix}\right)$ has eigenvalues 1 and 0. So $\rho(\mathbf{A} + \mathbf{B}) = 1 > 0 = \rho(\mathbf{A}) + \rho(\mathbf{B})$ and $\rho(\mathbf{AB}) = 1 > 0 = \rho(\mathbf{A})\rho(\mathbf{B})$. So positive definiteness and subadditivity both fail, and so does submultiplicativity, all on the same small pair. Only absolute homogeneity survives, since $\rho(c\mathbf{A}) = |c|\rho(\mathbf{A})$ for every scalar c.

So ρ is a genuinely different kind of measurement from the ones of the previous section. The relation between the two is the subject of the rest of this section, and it is one-sided.

15.4.2 Every norm dominates the spectral radius

Theorem 15.4.1 — The Spectral Radius Is a Lower Bound for Every Norm

Let $\mathbf{A} \in M_n(\mathbb{C})$.

(a) If $\|\cdot\|$ is the operator norm on $M_n(\mathbb{C})$ induced by a norm on $\mathbb{C}^n$ (Definition 15.3.2), then $\rho(\mathbf{A}) \le \|\mathbf{A}\|$.

(b) More generally, $\rho(\mathbf{A}) \le \|\mathbf{A}\|$ for **every** matrix norm $\|\cdot\|$ on $M_n(\mathbb{C})$ (Definition 15.3.1).

Idea. For (a) there is nothing to do but write down the eigenvalue equation: an eigenvector is a vector on which $\mathbf{A}$ acts by multiplication by λ, so the stretching factor $|\lambda|$ is one of the factors the maximum in Definition 15.3.2 ranges over. For (b) there is no vector to feed the norm, only matrices — so manufacture one: fill an $n \times n$ matrix with copies of the eigenvector, and the eigenvalue equation becomes a matrix equation that submultiplicativity can be applied to.

Proof.

(a) Let $\lambda \in \operatorname{spec}(\mathbf{A})$ and let $\mathbf{x} \neq \mathbf{0}$ with $\mathbf{A}\mathbf{x} = \lambda\mathbf{x}$. Then $\|\mathbf{A}\mathbf{x}\| = |\lambda|\,\|\mathbf{x}\|$ by homogeneity, while $\|\mathbf{A}\mathbf{x}\| \le \|\mathbf{A}\|\|\mathbf{x}\|$ by Theorem 15.3.2 (a). Since $\mathbf{x} \neq \mathbf{0}$ we have $\|\mathbf{x}\| > 0$ and may divide, giving $|\lambda| \le \|\mathbf{A}\|$. This holds for every eigenvalue, so it holds for the largest modulus.

(b) Let λ and $\mathbf{x}$ be as above, and let $\mathbf{X} \in M_n(\mathbb{C})$ be the matrix all of whose n columns equal $\mathbf{x}$. Then $\mathbf{X} \neq 0$, so $\|\mathbf{X}\| > 0$. Computing column by column, $\mathbf{A}\mathbf{X}$ has every column equal to $\mathbf{A}\mathbf{x} = \lambda\mathbf{x}$, that is,

$$\mathbf{A}\mathbf{X} = \lambda\mathbf{X}.$$

Taking norms and using homogeneity on the left and submultiplicativity on the right,

$$|\lambda|\,\|\mathbf{X}\| = \|\mathbf{A}\mathbf{X}\| \le \|\mathbf{A}\|\,\|\mathbf{X}\|.$$

Dividing by $\|\mathbf{X}\| > 0$ gives $|\lambda| \le \|\mathbf{A}\|$, and again the largest modulus obeys the same bound. This proves the theorem.

■

This is the inequality Chapter 9 §10 promised: the spectral radius never exceeds the norm of $\mathbf{A}$ induced by any vector norm. Part (b) says more than was promised, and costs one extra line.

The immediate use is that every computable norm is a computable *upper bound* for every eigenvalue — and two of the three formulas of Theorem 15.3.3 need no arithmetic beyond adding up moduli.

Corollary 15.4.2 — Cheap Bounds on the Spectrum

Let $\mathbf{A} \in M_n(\mathbb{C})$. Then every eigenvalue λ of $\mathbf{A}$ satisfies

$$|\lambda| \le \rho(\mathbf{A}) \le \min\bigl\{\|\mathbf{A}\|_1,\ \|\mathbf{A}\|_\infty,\ \|\mathbf{A}\|_F\bigr\},$$

that is, $\rho(\mathbf{A})$ is at most the largest absolute column sum, at most the largest absolute row sum, and at most $\|\mathbf{A}\|_F$.

Proof. The first two are operator norms (Theorem 15.3.3 (a), (b)), so Theorem 15.4.1 (a) applies; $\|\cdot\|_F$ is a matrix norm (Example (The Frobenius norm is submultiplicative)), so Theorem 15.4.1 (b) applies. A minimum of upper bounds is an upper bound. ∎

Remark. The bound $\rho(\mathbf{A}) \le \|\mathbf{A}\|_2 = \sigma_1(\mathbf{A})$ is the same crude inequality $|\lambda| \le \sigma_1$ that Chapter 12 §08 obtained directly from $\mathbf{Ax} = \lambda\mathbf{x}$. It is now one instance of a general principle rather than an isolated computation, and Theorem 15.4.1 (a) is that computation with the norm left unnamed.

Example. (Bounding a spectrum without finding it)

Let $\mathbf{A} = \frac{1}{10}\begin{pmatrix} 2 & 5 & 1 \\ 3 & 1 & 4 \\ 1 & 2 & 5 \end{pmatrix}$. Show that $\rho(\mathbf{A}) \le \frac{4}{5}$, and hence that $\mathbf{A}^m \to 0$.

Solution. Every row of $\mathbf{A}$ sums to $\frac{8}{10} = \frac{4}{5}$, so $\|\mathbf{A}\|_\infty = \frac{4}{5}$ by Theorem 15.3.3 (b), and $\rho(\mathbf{A}) \le \frac{4}{5}$ by Corollary 15.4.2. Since $\frac{4}{5} < 1$, every eigenvalue has modulus less than 1 and $\mathbf{A}^m \to 0$ by Theorem 9.10.2. No characteristic polynomial was computed.

The column sums are $\frac{6}{10}$, $\frac{8}{10}$ and 1, so $\|\mathbf{A}\|_1 = 1$ and the column bound gives nothing. It is worth computing both and keeping the smaller. In fact $\rho(\mathbf{A}) = \frac{4}{5}$ exactly, because the constant row sums make $\mathbf{1}$ an eigenvector with eigenvalue $\frac{4}{5}$, so the row bound here is attained.

Quick check. Theorem 15.4.1 says $\rho(\mathbf{A}) \le \|\mathbf{A}\|$ for every matrix norm. Why does it not follow that ρ is the smallest matrix norm?

Solution. Because ρ is not a matrix norm at all: ρ vanishes on every non-zero nilpotent matrix, and it fails both subadditivity and submultiplicativity, as the warning above showed. The correct statement is that $\rho(\mathbf{A})$ is a lower bound for the *values* $\|\mathbf{A}\|$, one matrix at a time, and the next theorem shows it is the greatest such lower bound.

15.4.3 A norm as close to the spectral radius as we like

Theorem 15.4.1 leaves open how large the gap can be. It can be enormous for a fixed norm: $\mathbf{J}_2(0)$ has $\rho = 0$ and $\|\mathbf{J}_2(0)\|_2 = 1$, and multiplying the corner entry by 10^6 leaves $\rho = 0$ while the norm becomes 10^6. But the norm may be chosen after the matrix, and then the gap can be made as small as we please.

Theorem 15.4.3 — Norms Close to the Spectral Radius

Let $\mathbf{A} \in M_n(\mathbb{C})$ and let $\varepsilon > 0$. Then there is a norm $\|\cdot\|_t$ on $\mathbb{C}^n$ whose induced operator norm satisfies

$$\rho(\mathbf{A}) \le \|\mathbf{A}\|_t \le \rho(\mathbf{A}) + \varepsilon.$$

Idea. Schur-triangularize and then squash. ① By Corollary 11.1.3, $\mathbf{A} = \mathbf{U}\mathbf{T}\mathbf{U}^*$ with $\mathbf{T}$ upper triangular carrying the eigenvalues on its diagonal; the row sums of $\mathbf{T}$ are the diagonal entry plus the off-diagonal junk. ② Conjugating $\mathbf{T}$ by $\mathbf{D}_t = \operatorname{diag}(1, t, \dots, t^{n-1})$ multiplies the entry in position (i, j) by t^{i-j}, which leaves the diagonal alone and, for large t, shrinks everything strictly above it, because $i - j < 0$ there. ③ Choose t so that every off-diagonal row sum is below ε; the largest row sum is then below $\rho(\mathbf{A}) + \varepsilon$, and the largest row sum is a norm we can compute, by Theorem 15.3.3 (b). ④ Transport that norm back to $\mathbb{C}^n$ along the invertible matrix $\mathbf{D}_t\mathbf{U}^*$.

Proof. By Corollary 11.1.3 there are a unitary $\mathbf{U}$ and an upper triangular $\mathbf{T} = (t_{ij})$ with $\mathbf{A} = \mathbf{U}\mathbf{T}\mathbf{U}^*$ and $t_{ii} = \lambda_i$, the eigenvalues of $\mathbf{A}$. For $t \ge 1$ put $\mathbf{D}_t = \operatorname{diag}(1, t, t^2, \dots, t^{n-1})$, an invertible matrix, and $\mathbf{T}_t = \mathbf{D}_t\mathbf{T}\mathbf{D}_t^{-1}$. Multiplying out,

$$(\mathbf{T}_t)_{ij} = t^{\,i-1}\, t_{ij}\, t^{-(j-1)} = t^{\,i-j} t_{ij}.$$

So $\mathbf{T}_t$ is again upper triangular with the same diagonal $\lambda_1, \dots, \lambda_n$, while for $i < j$ the entry is scaled by $t^{i-j} \le t^{-1}$, using $t \ge 1$ and $j - i \ge 1$. Let $M = \max_{i<j} |t_{ij}|$ if $n \ge 2$, and $M = 0$ if $n = 1$. Then the i-th absolute row sum of $\mathbf{T}_t$ is at most

$$|\lambda_i| + \sum_{j>i} t^{-1}|t_{ij}| \le \rho(\mathbf{A}) + \frac{(n-1)M}{t}.$$

Choose $t = \max\bigl(1,\ (n-1)M/\varepsilon\bigr)$. Then every absolute row sum of $\mathbf{T}_t$ is at most $\rho(\mathbf{A}) + \varepsilon$, so $\|\mathbf{T}_t\|_\infty \le \rho(\mathbf{A}) + \varepsilon$ by Theorem 15.3.3 (b).

Now define, for $\mathbf{x} \in \mathbb{C}^n$,

$$\|\mathbf{x}\|_t := \|\mathbf{D}_t\mathbf{U}^*\mathbf{x}\|_\infty.$$

This is a norm: it is non-negative, homogeneous and subadditive because $\|\cdot\|_\infty$ is and $\mathbf{x} \mapsto \mathbf{D}_t\mathbf{U}^*\mathbf{x}$ is linear, and it vanishes only at $\mathbf{x} = \mathbf{0}$ because $\mathbf{D}_t\mathbf{U}^*$ is invertible.

It remains to compute the induced operator norm. Put $\mathbf{Q} = \mathbf{D}_t\mathbf{U}^*$, so $\|\mathbf{x}\|_t = \|\mathbf{Q}\mathbf{x}\|_\infty$. As $\mathbf{x}$ runs over $\{\|\mathbf{x}\|_t = 1\}$, the vector $\mathbf{y} = \mathbf{Q}\mathbf{x}$ runs over $\{\|\mathbf{y}\|_\infty = 1\}$, since $\mathbf{Q}$ is a bijection. Moreover $\mathbf{Q}\mathbf{A}\mathbf{Q}^{-1} = \mathbf{D}_t\mathbf{U}^*\mathbf{A}\mathbf{U}\mathbf{D}_t^{-1} = \mathbf{D}_t\mathbf{T}\mathbf{D}_t^{-1} = \mathbf{T}_t$, so

$$\|\mathbf{A}\mathbf{x}\|_t = \|\mathbf{Q}\mathbf{A}\mathbf{x}\|_\infty = \|\mathbf{T}_t\,\mathbf{y}\|_\infty.$$

Taking maxima over the two matching sets gives $\|\mathbf{A}\|_t = \|\mathbf{T}_t\|_\infty \le \rho(\mathbf{A}) + \varepsilon$. The lower bound $\rho(\mathbf{A}) \le \|\mathbf{A}\|_t$ is Theorem 15.4.1 (a). This proves the theorem.

■

Read together, the last two theorems say

$$\rho(\mathbf{A}) = \inf\{\|\mathbf{A}\| : \|\cdot\| \text{ an induced matrix norm}\}.$$

Remark. The infimum need not be attained. If $\mathbf{A} \neq 0$ is nilpotent then $\rho(\mathbf{A}) = 0$ while $\|\mathbf{A}\| > 0$ for every norm, so no norm achieves the value. At the other extreme, for a normal $\mathbf{A}$ the spectral norm achieves it exactly: $\|\mathbf{A}\|_2 = \rho(\mathbf{A})$, as computed at the start of this section. The gap between ρ and the norms is a measure of how far $\mathbf{A}$ is from being normal, which is the theme Chapter 11 §11 opened with the departure from normality.

15.4.4 Gelfand's formula

The infimum above is over norms, and to use it we must choose one. There is a second description of $\rho(\mathbf{A})$ that needs no choice: fix any norm at all, and let the powers of $\mathbf{A}$ tell you the answer.

Theorem 15.4.4 — Gelfand's Formula

Let $\mathbf{A} \in M_n(\mathbb{C})$ and let $\|\cdot\|$ be any matrix norm on $M_n(\mathbb{C})$. Then

$$\lim_{k\to\infty} \|\mathbf{A}^k\|^{1/k} = \rho(\mathbf{A}).$$

In particular the limit exists and does not depend on which matrix norm is used.

Idea. Two inequalities, one for each direction, and they come from opposite ends of the chapter. ① The lower bound $\rho(\mathbf{A}) \le \|\mathbf{A}^k\|^{1/k}$ is Theorem 15.4.1 applied to $\mathbf{A}^k$, once we know $\rho(\mathbf{A}^k) = \rho(\mathbf{A})^k$ — which is the Spectral Mapping Theorem. This holds for every k, with no limit taken. ② For the upper bound, scale $\mathbf{A}$ down by a whisker more than $\rho(\mathbf{A})$. The scaled matrix has spectral radius below 1, so Chapter 9 §10's criterion makes its powers tend to 0, and once they are below 1 in norm the inequality we want has been written down. Theorem 15.4.3 says the same decay is geometric, which is what the corollary below extracts.

Proof. **Lower bound.** Fix $k \ge 1$. By Theorem 8.10.1 applied to $q(x) = x^k$, $\operatorname{spec}(\mathbf{A}^k) = \{\lambda^k : \lambda \in \operatorname{spec}(\mathbf{A})\}$, so

$$\rho(\mathbf{A}^k) = \max_{\lambda \in \operatorname{spec}(\mathbf{A})} |\lambda|^k = \rho(\mathbf{A})^k.$$

By Theorem 15.4.1 (b) applied to $\mathbf{A}^k$, $\rho(\mathbf{A})^k = \rho(\mathbf{A}^k) \le \|\mathbf{A}^k\|$. Taking k-th roots of these non-negative reals,

$$\rho(\mathbf{A}) \le \|\mathbf{A}^k\|^{1/k} \qquad \text{for every } k \ge 1.$$

Upper bound. Let $\varepsilon > 0$, put $s = \rho(\mathbf{A}) + \varepsilon > 0$ and $\mathbf{B} = s^{-1}\mathbf{A}$. Every eigenvalue of $\mathbf{B}$ is λ/s for some $\lambda \in \operatorname{spec}(\mathbf{A})$ (Theorem 8.10.1 with $q(x) = x/s$), so

$$\rho(\mathbf{B}) = \frac{\rho(\mathbf{A})}{\rho(\mathbf{A}) + \varepsilon} < 1.$$

By Theorem 9.10.2, $\mathbf{B}^k \to 0$ entrywise. Entrywise convergence of matrices is convergence in **every** norm on $M_n(\mathbb{C})$, by Corollary 15.2.4, so $\|\mathbf{B}^k\| \to 0$. A real sequence tending to 0 is eventually below 1: there is K with $\|\mathbf{B}^k\| \le 1$ for all $k \ge K$. Since $\mathbf{B}^k = s^{-k}\mathbf{A}^k$, homogeneity gives $\|\mathbf{A}^k\| \le s^k$, that is,

$$\|\mathbf{A}^k\|^{1/k} \le \rho(\mathbf{A}) + \varepsilon \qquad (k \ge K).$$

Conclusion. Combining, for every $\varepsilon > 0$ there is K with

$$\rho(\mathbf{A}) \le \|\mathbf{A}^k\|^{1/k} \le \rho(\mathbf{A}) + \varepsilon \qquad (k \ge K),$$

which is the definition of $\|\mathbf{A}^k\|^{1/k} \to \rho(\mathbf{A})$. The independence of the norm is automatic, since the limit equals $\rho(\mathbf{A})$ whichever matrix norm was fixed at the start. This proves the theorem.

■

Remark. **Which analysis was used.** The lower bound used none. The upper bound used Theorem 9.10.2, which is a theorem of this book, and Corollary 15.2.4, likewise; the only analysis is that a real sequence tending to 0 is eventually less than 1, and that a sequence trapped between $\rho(\mathbf{A})$ and $\rho(\mathbf{A}) + \varepsilon$ for every $\varepsilon > 0$ converges to $\rho(\mathbf{A})$. Neither is an extra import: both are the definition of a limit of a real sequence, read forwards and backwards. Nothing from the list (A1)–(A4) of the chapter introduction is needed here, and nothing outside it is used.

The formula is a genuine computation rule as well as a theorem. For a fixed k the number $\|\mathbf{A}^k\|^{1/k}$ is an *upper* estimate of $\rho(\mathbf{A})$ — that is the lower bound above, read the other way — and the estimates improve as k grows.

Example. (Watching the limit converge)

Let $\mathbf{A} = \begin{pmatrix} 1/2 & 10 \\ 0 & 1/3 \end{pmatrix}$. Compute $\|\mathbf{A}^k\|_\infty$ exactly and confirm Gelfand's formula.

Solution. $\mathbf{A}$ is upper triangular, so $\rho(\mathbf{A}) = \max(\frac{1}{2}, \frac{1}{3}) = \frac{1}{2}$ and the powers are upper triangular with diagonal $2^{-k}, 3^{-k}$. For the corner entry, induction on k gives

$$(\mathbf{A}^k)_{12} = 10 \sum_{j=0}^{k-1} 2^{-j} 3^{-(k-1-j)} = 60\big(2^{-k} - 3^{-k}\big),$$

the last step by summing the geometric series with ratio $3/2$. The two absolute row sums are $2^{-k} + 60(2^{-k} - 3^{-k})$ and 3^{-k}, the first being the larger, so by Theorem 15.3.3 (b)

$$\|\mathbf{A}^k\|_\infty = 61 \cdot 2^{-k} - 60 \cdot 3^{-k}.$$

At $k = 1$ this is 10.5, which overestimates $\rho(\mathbf{A}) = \frac{1}{2}$ by a factor of 21; the k-th roots run $10.5,\ 2.93,\ 1.75,\ 1.32,\ 1.11,\ 0.98, \ldots$ and settle toward $\frac{1}{2}$, which is what Theorem 15.4.4 guarantees. The convergence is slow, and it has to be: the single number $\|\mathbf{A}\|_\infty$ cannot know that the entry 10 sits above the diagonal rather than on it.

15.4.5 What is new, and what is not

Corollary 15.4.5 — Powers Tending to Zero, with a Rate

Let $\mathbf{A} \in M_n(\mathbb{C})$ and let $\|\cdot\|$ be any matrix norm on $M_n(\mathbb{C})$.

(a) $\mathbf{A}^k \to 0$ if and only if $\rho(\mathbf{A}) < 1$, and this holds if and only if $\|\mathbf{A}^k\| \to 0$.

(b) If $\rho(\mathbf{A}) < 1$, then for every q with $\rho(\mathbf{A}) < q < 1$ there is a constant $C \geq 1$, depending on $\mathbf{A}$, on q and on the norm, such that $\|\mathbf{A}^k\| \leq C\, q^k$ for **every** $k \geq 0$.

Idea. Part (a) is Theorem 9.10.2 translated into norms by Corollary 15.2.4; nothing is proved that was not proved in Chapter 9. Part (b) is the new content, and it is Theorem 15.4.3 doing what it was built for: choose a norm in which $\mathbf{A}$ itself is already smaller than q, take powers there, and pay one fixed constant to return to the norm we were given.

Proof.

(a) The first equivalence is Theorem 9.10.2, since $\rho(\mathbf{A}) < 1$ says exactly that every eigenvalue has modulus less than 1. The second is Corollary 15.2.4: entrywise convergence of matrices and convergence in the norm $\|\cdot\|$ are the same thing.

(b) Let $\varepsilon = q - \rho(\mathbf{A}) > 0$. By Theorem 15.4.3 there is an induced matrix norm $\|\cdot\|_t$ on $M_n(\mathbb{C})$ with $\|\mathbf{A}\|_t \leq \rho(\mathbf{A}) + \varepsilon = q$. Submultiplicativity (Theorem 15.3.2 (d)) gives $\|\mathbf{A}^k\|_t \leq \|\mathbf{A}\|_t^k \leq q^k$ for every $k \geq 0$. By Theorem 15.2.2, applied to the two norms $\|\cdot\|$ and $\|\cdot\|_t$ on the finite-dimensional space $M_n(\mathbb{C})$, there is $C_0 > 0$ with $\|\mathbf{M}\| \leq C_0 \|\mathbf{M}\|_t$ for every $\mathbf{M}$. Taking $C = \max(C_0, 1)$,

$$\|\mathbf{A}^k\| \le C_0 \|\mathbf{A}^k\|_t \le C\, q^k.$$

This proves the corollary.

■

It is worth being exact about the accounting. Part (a) is **not** new. Chapter 9 §10 proved that $\mathbf{A}^m \to 0$ if and only if every eigenvalue has modulus less than 1, and it proved it with the Jordan form and no norms whatsoever; all that has happened here is that the conclusion has been restated in a language where "small" is a number. What is new is part (b): a **rate**. Chapter 9 could say that the powers die; it could not say how fast, because it had nothing to measure a matrix with. Now every decaying matrix comes with a geometric envelope Cq^k for every q above its spectral radius, and that envelope is what later sections integrate, sum and differentiate.

Two honest limitations of the envelope deserve saying out loud.

Warning. $\rho(\mathbf{A}) < 1$ **promises eventual decay, not immediate decay.** The constant C in Corollary 15.4.5 (b) is generally larger than 1 and grows as q approaches $\rho(\mathbf{A})$. For

$$\mathbf{A} = \begin{pmatrix} 9/10 & 10 \\ 0 & 9/10 \end{pmatrix}, \qquad \mathbf{A}^k = \begin{pmatrix} (9/10)^k & 10k(9/10)^{k-1} \\ 0 & (9/10)^k \end{pmatrix},$$

we have $\rho(\mathbf{A}) = 9/10 < 1$, yet $\|\mathbf{A}^k\|_\infty = (9/10)^{k-1}(9/10 + 10k)$ **rises** from 10.9 at $k = 1$ to about 39.13 at $k = 9$ before beginning its decay, and does not fall below 1 until $k = 63$. A transient hump of this kind is invisible to the spectral radius and is exactly what the constant C is paying for.

Quick check. For which matrices can one take $C = 1$ and $q = \rho(\mathbf{A})$ in the bound of Corollary 15.4.5 (b), with the spectral norm?

Solution. For normal $\mathbf{A}$, among others. If $\mathbf{A}$ is normal then so is $\mathbf{A}^k$ (its adjoint is $(\mathbf{A}^*)^k$, and powers of commuting matrices commute), so $\|\mathbf{A}^k\|_2 = \rho(\mathbf{A}^k) = \rho(\mathbf{A})^k$ by the computation at the start of this section together with Theorem 8.10.1. There is then no transient at all: the norm of the powers is exactly geometric. The hump in the warning is possible only because that matrix is far from normal, with departure from normality 10 in the sense of Definition 11.11.1.

15.4.6 Exercises

15.4.6.1 A. Check your understanding

Exercise A1.

(a) Define the **spectral radius**, and say why the maximum in the definition exists.

(b) State Theorem 15.4.1 and Theorem 15.4.4.

(c) Determine whether the following statement is correct, and justify your answer: ρ

is a matrix norm on $M_n(\mathbb{C})$.

(d) Determine whether the following statement is correct, and justify your answer: if $\rho(\mathbf{A}) < 1$ then $\|\mathbf{A}\|_2 < 1$.

(e) Chapter 9 §10 already proved that $\mathbf{A}^m \to 0$ exactly when $\rho(\mathbf{A}) < 1$. What does Corollary 15.4.5 add to that?

Solution.

(a) $\rho(\mathbf{A}) = \max\{|\lambda| : \lambda \in \operatorname{spec}(\mathbf{A})\}$ (Definition 15.4.1). The set $\operatorname{spec}(\mathbf{A})$ is finite and non-empty — it is the root set of $p_{\mathbf{A}}$, non-empty by Theorem 5.5.1 — so the maximum of the finitely many moduli exists.

(b) For every matrix norm on $M_n(\mathbb{C})$, $\rho(\mathbf{A}) \le \|\mathbf{A}\|$; and for every matrix norm, $\|\mathbf{A}^k\|^{1/k} \to \rho(\mathbf{A})$ as $k \to \infty$.

(c) Incorrect. ρ vanishes on non-zero nilpotent matrices, so it is not even a norm, and it is neither subadditive nor submultiplicative: see the warning after Definition 15.4.1.

(d) Incorrect. $\mathbf{A} = \left(\begin{smallmatrix} 0 & 10 \\ 0 & 0 \end{smallmatrix}\right)$ has $\rho(\mathbf{A}) = 0$ and $\|\mathbf{A}\|_2 = 10$. The correct statement is that *some* norm has $\|\mathbf{A}\| < 1$, by Theorem 15.4.3.

(e) Nothing about the criterion, which is Theorem 9.10.2 restated; what it adds is the quantitative envelope $\|\mathbf{A}^k\| \le Cq^k$ for every $q \in (\rho(\mathbf{A}), 1)$, a rate of decay rather than the bare fact of it.

15.4.6.2 B. Practice

Exercise B1: Four numbers again.

Let $\mathbf{A} = \begin{pmatrix} 0 & 2 \\ 1/4 & 0 \end{pmatrix}$. Compute $\rho(\mathbf{A})$, $\|\mathbf{A}\|_1$, $\|\mathbf{A}\|_\infty$ and $\|\mathbf{A}\|_2$, and verify Theorem 15.4.1 in each case.

Solution. $p_{\mathbf{A}}(x) = x^2 - \frac{1}{2}$, so $\operatorname{spec}(\mathbf{A}) = \{\pm 1/\sqrt{2}\}$ and $\rho(\mathbf{A}) = 1/\sqrt{2} \approx 0.707$.

The absolute column sums are $\frac{1}{4}$ and 2, so $\|\mathbf{A}\|_1 = 2$; the absolute row sums are 2 and $\frac{1}{4}$, so $\|\mathbf{A}\|_\infty = 2$. For the spectral norm, $\mathbf{A}^\top\mathbf{A} = \operatorname{diag}(\frac{1}{16}, 4)$, whose eigenvalues are $\frac{1}{16}$ and 4; hence $\sigma_1 = 2$ and $\|\mathbf{A}\|_2 = 2$ by Theorem 15.3.3 (c).

So $\rho(\mathbf{A}) = 0.707\cdots \le 2$ in all three cases, and the gap is a factor of nearly 3 even though $\mathbf{A}$ is a very small matrix. The reason is the mismatch between the two off-diagonal entries: $\mathbf{A}$ is far from normal.

Exercise B2: Gelfand exactly.

With $\mathbf{A}$ as in Exercise (B1: Four numbers again), compute $\mathbf{A}^k$ for every k and evaluate $\lim_k \|\mathbf{A}^k\|_\infty^{1/k}$ directly.

Solution. $\mathbf{A}^2 = \frac{1}{2}\mathbf{I}$, so by induction $\mathbf{A}^{2l} = 2^{-l}\mathbf{I}$ and $\mathbf{A}^{2l+1} = 2^{-l}\mathbf{A}$. Hence

$$\|\mathbf{A}^{2l}\|_\infty = 2^{-l}, \qquad \|\mathbf{A}^{2l+1}\|_\infty = 2^{-l}\cdot 2 = 2^{1-l}.$$

For even $k = 2l$, $\|\mathbf{A}^k\|_\infty^{1/k} = (2^{-l})^{1/(2l)} = 2^{-1/2}$, exactly $\rho(\mathbf{A})$ for every l. For odd $k = 2l+1$, $\|\mathbf{A}^k\|_\infty^{1/k} = 2^{(1-l)/(2l+1)}$, and $(1-l)/(2l+1) \to -\frac{1}{2}$, so this too tends to $2^{-1/2}$. Both subsequences converge to $1/\sqrt{2} = \rho(\mathbf{A})$, confirming Theorem 15.4.4.

Exercise B3: Deciding convergence without eigenvalues.

For each matrix, decide whether $\mathbf{A}^m \to 0$, using only Corollary 15.4.2 and Theorem 9.10.2.

(a) $\mathbf{A} = \frac{1}{4}\begin{pmatrix} 1 & 2 & 0 \\ 0 & 1 & 1 \\ 2 & 0 & 1 \end{pmatrix}$.

(b) $\mathbf{A} = \begin{pmatrix} 1/2 & 3 \\ 0 & 2 \end{pmatrix}$.

Solution.

(a) The absolute row sums are $\frac{3}{4}$, $\frac{1}{2}$ and $\frac{3}{4}$, so $\|\mathbf{A}\|_\infty = \frac{3}{4}$ and $\rho(\mathbf{A}) \le \frac{3}{4} < 1$. By Theorem 9.10.2, $\mathbf{A}^m \to 0$.

(b) Here the row sums are $\frac{7}{2}$ and 2 and the column sums are $\frac{1}{2}$ and 5, so the bounds give only $\rho(\mathbf{A}) \le \frac{7}{2}$ and decide nothing. But the bound is an upper bound, and here the matrix is triangular, so the eigenvalues are visible: $\frac{1}{2}$ and 2, giving $\rho(\mathbf{A}) = 2 > 1$. By Theorem 9.10.2 the powers do **not** tend to 0. The moral is that Corollary 15.4.2 can only ever certify convergence, never rule it out.

15.4.6.3 C. Going deeper

Exercise C1: A norm that sees the decay.

Let $\mathbf{A} \in M_n(\mathbb{C})$.

(a) Prove that if $\|\mathbf{A}\| < 1$ for **some** matrix norm, then $\mathbf{A}^k \to 0$.

(b) Give a matrix with $\mathbf{A}^k \to 0$ and $\|\mathbf{A}\|_2 > 1$, so that the converse of (a) fails for a fixed norm.

(c) Prove that the converse of (a) nevertheless holds if the norm is allowed to depend on $\mathbf{A}$.

Solution.

(a) Submultiplicativity gives $\|\mathbf{A}^k\| \le \|\mathbf{A}\|^k$ by induction on k. With $r = \|\mathbf{A}\| < 1$ the right-hand side tends to 0, so $\|\mathbf{A}^k\| \to 0$, and by Corollary 15.2.4 this is the same as $\mathbf{A}^k \to 0$ entrywise.

(b) $\mathbf{A} = \left(\begin{smallmatrix} 0 & 10 \\ 0 & 0 \end{smallmatrix}\right)$ satisfies $\mathbf{A}^2 = 0$, so certainly $\mathbf{A}^k \to 0$; but $\|\mathbf{A}\|_2 = 10 > 1$. The same happens for $\left(\begin{smallmatrix} 1/2 & 10 \\ 0 & 1/2 \end{smallmatrix}\right)$, which is not even nilpotent.

(c) Suppose $\mathbf{A}^k \to 0$. By Theorem 9.10.2, $\rho(\mathbf{A}) < 1$. Apply Theorem 15.4.3 with $\varepsilon = \frac{1}{2}(1 - \rho(\mathbf{A})) > 0$: it produces an induced matrix norm $\|\cdot\|_t$ with

$$\|\mathbf{A}\|_t \le \rho(\mathbf{A}) + \varepsilon = \tfrac{1}{2}\big(1 + \rho(\mathbf{A})\big) < 1.$$

So a norm witnessing the decay always exists, though it must be chosen after $\mathbf{A}$.

Exercise C2: Spectral radius zero.

Let $\mathbf{A} \in M_n(\mathbb{C})$.

(a) Prove that $\rho(\mathbf{A}) = 0$ if and only if $\mathbf{A}$ is nilpotent.

(b) Deduce that for a nilpotent $\mathbf{A}$ and any matrix norm, $\|\mathbf{A}^k\|^{1/k} \to 0$, and verify this directly for $\mathbf{A} = \mathbf{J}_n(0)$.

(c) Explain why (a) shows that no inequality of the form $\|\mathbf{A}\| \le c\,\rho(\mathbf{A})$, with c depending only on n, can hold.

Solution.

(a) ($\Rightarrow$) If $\rho(\mathbf{A}) = 0$ then every eigenvalue is 0, so $p_{\mathbf{A}}(x) = x^n$ because $p_{\mathbf{A}}$ is monic of degree n and splits over $\mathbb{C}$ with all roots 0 (Theorem 5.5.1). By the Cayley–Hamilton theorem (Theorem 8.6.1), $\mathbf{A}^n = p_{\mathbf{A}}(\mathbf{A}) = 0$, so $\mathbf{A}$ is nilpotent (Definition 9.2.1).
($\Leftarrow$) If $\mathbf{A}^d = 0$ and $\mathbf{A}\mathbf{x} = \lambda\mathbf{x}$ with $\mathbf{x} \neq \mathbf{0}$, then $\mathbf{0} = \mathbf{A}^d\mathbf{x} = \lambda^d\mathbf{x}$, so $\lambda^d = 0$ and $\lambda = 0$. Hence $\operatorname{spec}(\mathbf{A}) = \{0\}$ and $\rho(\mathbf{A}) = 0$.

(b) By Theorem 15.4.4 the limit is $\rho(\mathbf{A}) = 0$. Directly for $\mathbf{A} = \mathbf{J}_n(0)$: $\mathbf{A}^k = 0$ for $k \ge n$, so $\|\mathbf{A}^k\|^{1/k} = 0$ for all $k \ge n$, and the sequence is eventually constant at 0.

(c) Such an inequality would force $\|\mathbf{A}\| = 0$, hence $\mathbf{A} = 0$, for every nilpotent $\mathbf{A}$. But $\mathbf{J}_2(0) \neq 0$ is nilpotent. So the two quantities cannot be compared in that direction at all; Theorem 15.4.3 is the best available substitute, and it buys its conclusion by changing the norm.

Exercise C3: When the infimum is attained.

Call $\mathbf{A} \in M_n(\mathbb{C})$ **radius-attaining** if $\|\mathbf{A}\| = \rho(\mathbf{A})$ for some matrix norm.

(a) Prove that every normal $\mathbf{A}$ is radius-attaining.

(b) Prove that a non-zero nilpotent $\mathbf{A}$ is not.

(c) Deduce that $\left(\begin{smallmatrix} 1 & 1 \\ 0 & 1 \end{smallmatrix}\right)$ is not radius-attaining, even though it is invertible.

Hint for (c): consider $\mathbf{A} - \mathbf{I}$.

Solution.

(a) Let $\mathbf{A}$ be normal, so $\mathbf{A} = \mathbf{U}\mathbf{D}\mathbf{U}^*$ with $\mathbf{U}$ unitary and $\mathbf{D} = \operatorname{diag}(\lambda_1, \dots, \lambda_n)$ (Corollary 11.4.3). Then $\mathbf{A}^*\mathbf{A} = \mathbf{U}\operatorname{diag}(|\lambda_i|^2)\mathbf{U}^*$, so the singular values of $\mathbf{A}$ are the $|\lambda_i|$ in decreasing order and $\|\mathbf{A}\|_2 = \sigma_1 = \max_i |\lambda_i| = \rho(\mathbf{A})$ by Theorem 15.3.3 (c).

(b) If $\mathbf{A} \neq 0$ is nilpotent then $\rho(\mathbf{A}) = 0$ by Exercise (C2: Spectral radius zero) (a), while $\|\mathbf{A}\| > 0$ for every norm, since a norm vanishes only at 0 (Definition 15.1.1).

So no norm can give $\|\mathbf{A}\| = \rho(\mathbf{A})$.

(c) Put $\mathbf{A} = \left(\begin{smallmatrix} 1 & 1 \\ 0 & 1 \end{smallmatrix}\right)$, whose only eigenvalue is 1, so $\rho(\mathbf{A}) = 1$. Suppose some matrix norm had $\|\mathbf{A}\| = 1$. Then $\|\mathbf{A}^k\| \le \|\mathbf{A}\|^k = 1$ for every k, so the sequence $(\mathbf{A}^k)$ is bounded in that norm, hence bounded entrywise by Corollary 15.2.4, whose second sentence covers boundedness. But $\mathbf{A}^k = \left(\begin{smallmatrix} 1 & k \\ 0 & 1 \end{smallmatrix}\right)$, whose $(1,2)$-entry is unbounded. Contradiction. (The hint points at the same phenomenon: $\mathbf{A} - \mathbf{I}$ is a non-zero nilpotent, so $\mathbf{A}$ is a unipotent matrix, and it is the nilpotent part that the spectral radius cannot see.)

15.5 Inverting a Perturbation of the Identity

Chapter 9 §10 summed the series $\mathbf{I} + \mathbf{A} + \mathbf{A}^2 + \dots$ and identified its sum as $(\mathbf{I} - \mathbf{A})^{-1}$, under the exact hypothesis that every eigenvalue of $\mathbf{A}$ has modulus less than 1. What it could not say is how large that inverse is. This section reruns the argument with a norm in hand. The hypothesis becomes cruder — $\|\mathbf{A}\| < 1$ instead of $\rho(\mathbf{A}) < 1$ — and the conclusion becomes quantitative, which is the trade this chapter keeps making. The payoff is immediate: the invertible matrices turn out to form an open set, inversion turns out to be continuous, and a first estimate appears for how far the solution of $\mathbf{A}\mathbf{x} = \mathbf{b}$ moves when $\mathbf{A}$ and $\mathbf{b}$ are disturbed.

Throughout, $\|\cdot\|$ is the operator norm on $M_n(\mathbb{C})$ induced by a norm on $\mathbb{C}^n$ (Definition 15.3.2), so that $\|\mathbf{I}\| = 1$ and $\|\mathbf{X}\mathbf{Y}\| \le \|\mathbf{X}\|\|\mathbf{Y}\|$ by Theorem 15.3.2 (c) and (d). Both properties are used in every proof below, and the first of them is not free: the closing warning shows what happens without it.

15.5.1 The geometric series, with a number attached

The scalar identity behind everything here is $1 + r + r^2 + \cdots = 1/(1-r)$ for $0 \le r < 1$. Chapter 9 §10 gave the matrix version of the *identity*. What a norm adds is the matrix version of the *inequality* $|1 + r + \dots| \le 1/(1-r)$: a ceiling on the inverse, expressed in the data.

Theorem 15.5.1 — Neumann Series with a Bound

Let $\mathbf{A} \in M_n(\mathbb{C})$ with $\|\mathbf{A}\| < 1$, and write $a = \|\mathbf{A}\|$. Then:

(a) $\mathbf{I} - \mathbf{A}$ is invertible, and $\sum_{k \ge 0} \mathbf{A}^k = (\mathbf{I} - \mathbf{A})^{-1}$;

(b) $\|(\mathbf{I} - \mathbf{A})^{-1}\| \le \dfrac{1}{1 - a}$;

(c) for every $K \ge 0$, the partial sum $\mathbf{S}_K = \sum_{k=0}^{K} \mathbf{A}^k$ satisfies

$$\|(\mathbf{I} - \mathbf{A})^{-1} - \mathbf{S}_K\| \le \frac{a^{K+1}}{1 - a};$$

(d) $\|(\mathbf{I} - \mathbf{A})^{-1}\| \ge \dfrac{1}{1 + a}$.

Idea. Part (a) is not new work: $\|\mathbf{A}\| < 1$ forces $\rho(\mathbf{A}) < 1$ by Theorem 15.4.1, which is exactly the hypothesis of Chapter 9's Theorem 9.10.6. Everything else is the tail-

bounding move. Submultiplicativity turns $\|\mathbf{A}^k\|$ into a^k, so each partial sum is bounded by a scalar geometric sum; the bound then has to be carried across the limit, and what carries it is the fact that a norm is continuous. For (c), the tail of the series factors as $\mathbf{A}^{K+1}$ times the whole series again, so (b) bounds it. For (d), read $\mathbf{I} = (\mathbf{I}-\mathbf{A})(\mathbf{I}-\mathbf{A})^{-1}$ through submultiplicativity.

Proof.

(a) By Theorem 15.4.1 (a), $\rho(\mathbf{A}) \le \|\mathbf{A}\| = a < 1$, so every eigenvalue of $\mathbf{A}$ has modulus less than 1. That is the hypothesis of Theorem 9.10.6, which gives both the invertibility of $\mathbf{I}-\mathbf{A}$ and the value of the sum.

(b) Submultiplicativity (Theorem 15.3.2 (d)) gives $\|\mathbf{A}^k\| \le a^k$ for every $k \ge 1$, by induction on k; and $\|\mathbf{A}^0\| = \|\mathbf{I}\| = 1 = a^0$ by part (c) of the same theorem. Hence, by subadditivity applied K times,

$$\|\mathbf{S}_K\| \le \sum_{k=0}^{K} \|\mathbf{A}^k\| \le \sum_{k=0}^{K} a^k = \frac{1-a^{K+1}}{1-a} \le \frac{1}{1-a},$$

the last step because $a^{K+1} \ge 0$ and $1-a > 0$. By (a) the sequence $(\mathbf{S}_K)$ converges entrywise to $(\mathbf{I}-\mathbf{A})^{-1}$, so $\|\mathbf{S}_K - (\mathbf{I}-\mathbf{A})^{-1}\| \to 0$ by Corollary 15.2.4. Then Lemma 15.1.1 gives

$$\big|\, \|\mathbf{S}_K\| - \|(\mathbf{I}-\mathbf{A})^{-1}\| \,\big| \le \|\mathbf{S}_K - (\mathbf{I}-\mathbf{A})^{-1}\| \to 0,$$

so $\|\mathbf{S}_K\| \to \|(\mathbf{I}-\mathbf{A})^{-1}\|$. A non-strict inequality survives a limit, so a limit of numbers each at most $1/(1-a)$ is at most $1/(1-a)$, which proves (b).

(c) Fix K. For every $M \ge 1$, multiplying out and canceling,

$$\mathbf{S}_{K+M} - \mathbf{S}_K = \sum_{k=K+1}^{K+M} \mathbf{A}^k = \mathbf{A}^{K+1}\,\mathbf{S}_{M-1}.$$

Let $M \to \infty$. The left-hand side tends to $(\mathbf{I}-\mathbf{A})^{-1} - \mathbf{S}_K$ by (a). The right-hand side tends to $\mathbf{A}^{K+1}(\mathbf{I}-\mathbf{A})^{-1}$, because

$$\|\mathbf{A}^{K+1}\mathbf{S}_{M-1} - \mathbf{A}^{K+1}(\mathbf{I}-\mathbf{A})^{-1}\| \le \|\mathbf{A}^{K+1}\|\,\|\mathbf{S}_{M-1} - (\mathbf{I}-\mathbf{A})^{-1}\|,$$

which tends to 0 by (a) and Corollary 15.2.4 again. A sequence has at most one limit, so

$$(\mathbf{I}-\mathbf{A})^{-1} - \mathbf{S}_K = \mathbf{A}^{K+1}(\mathbf{I}-\mathbf{A})^{-1}.$$

Taking norms and using submultiplicativity together with (b),

$$\|(\mathbf{I}-\mathbf{A})^{-1} - \mathbf{S}_K\| \le \|\mathbf{A}^{K+1}\|\,\|(\mathbf{I}-\mathbf{A})^{-1}\| \le \frac{a^{K+1}}{1-a}.$$

(d) $1 = \|\mathbf{I}\| = \|(\mathbf{I}-\mathbf{A})(\mathbf{I}-\mathbf{A})^{-1}\| \le \|\mathbf{I}-\mathbf{A}\|\,\|(\mathbf{I}-\mathbf{A})^{-1}\|$, and $\|\mathbf{I}-\mathbf{A}\| \le \|\mathbf{I}\| + \|\mathbf{A}\| = 1 + a$ by subadditivity. Since $1 + a > 0$ we may divide, which proves (d). This proves the theorem.

■

Parts (b) and (d) together pin the inverse between two numbers computed from a alone:

$$\frac{1}{1+a} \le \|(\mathbf{I}-\mathbf{A})^{-1}\| \le \frac{1}{1-a}.$$

As a approaches 1 the upper bound escapes to infinity while the lower one stays near $\frac{1}{2}$, and the gap is real rather than an artifact of the proof: $\mathbf{A} = a\mathbf{I}$ attains the upper bound, and $\mathbf{A} = -a\mathbf{I}$ attains the lower one.

Example. (The bound and the truth)

Let

$$\mathbf{A} = \begin{pmatrix} 0 & 1/2 \\ 1/3 & 0 \end{pmatrix}.$$

Using the ∞-norm, check the hypothesis, compute $(\mathbf{I}-\mathbf{A})^{-1}$ exactly, and compare it with the bound of Theorem 15.5.1 (b). Then compare $\mathbf{S}_3$ with the true inverse and with the tail bound of (c).

Solution. The hypothesis. The absolute row sums are $\frac{1}{2}$ and $\frac{1}{3}$, so $\|\mathbf{A}\|_\infty = \frac{1}{2} < 1$ by Theorem 15.3.3 (b). So Theorem 15.5.1 applies with $a = \frac{1}{2}$.

The inverse. $\mathbf{I}-\mathbf{A} = \left(\begin{smallmatrix} 1 & -1/2 \\ -1/3 & 1 \end{smallmatrix}\right)$ has determinant $1 - \frac{1}{6} = \frac{5}{6}$, so by Theorem 0.9.8

$$(\mathbf{I}-\mathbf{A})^{-1} = \tfrac{6}{5}\begin{pmatrix} 1 & 1/2 \\ 1/3 & 1 \end{pmatrix} = \begin{pmatrix} 6/5 & 3/5 \\ 2/5 & 6/5 \end{pmatrix},$$

whose largest absolute row sum is $\frac{6}{5} + \frac{3}{5} = \frac{9}{5} = 1.8$. The bound is $1/(1-\frac{1}{2}) = 2$. So the estimate is correct and loses only ten percent.

The partial sum. Here $\mathbf{A}^2 = \frac{1}{6}\mathbf{I}$, so $\mathbf{A}^3 = \frac{1}{6}\mathbf{A}$ and

$$\mathbf{S}_3 = (1+\tfrac{1}{6})(\mathbf{I}+\mathbf{A}) = \tfrac{7}{6}\begin{pmatrix} 1 & 1/2 \\ 1/3 & 1 \end{pmatrix}.$$

Hence $(\mathbf{I}-\mathbf{A})^{-1} - \mathbf{S}_3 = (\frac{6}{5} - \frac{7}{6})(\mathbf{I}+\mathbf{A}) = \frac{1}{30}(\mathbf{I}+\mathbf{A})$, with ∞-norm $\frac{1}{30}\cdot\frac{3}{2} = \frac{1}{20} = 0.05$. The bound of (c) with $K = 3$ is $(\frac{1}{2})^4/(1-\frac{1}{2}) = \frac{1}{8} = 0.125$. Again correct, and this time loose by a factor of 2.5 — the price of replacing four matrices by four copies of one number.

15.5.2 Which theorem is stronger

The two Neumann theorems must be compared honestly, because neither contains the other.

Chapter 9's Theorem 9.10.6 assumes $\rho(\mathbf{A}) < 1$ and concludes that the series converges, with sum $(\mathbf{I}-\mathbf{A})^{-1}$; and its hypothesis is **sharp**, since the statement is an "if and only if". Theorem 15.5.1 assumes $\|\mathbf{A}\| < 1$, which by Theorem 15.4.1 is a **strictly stronger** demand: $\rho(\mathbf{A}) \le \|\mathbf{A}\|$ always, and the inequality is often strict. For

$$\mathbf{A} = \begin{pmatrix} 0 & 2 \\ 0 & 0 \end{pmatrix}$$

we have $\rho(\mathbf{A}) = 0$, so Chapter 9's theorem applies and returns $\sum_k \mathbf{A}^k = \mathbf{I}+\mathbf{A}$; but $\|\mathbf{A}\| = 2$ in each of the 1-, 2- and ∞-norms, so this section's theorem says nothing at all about it.

In the other direction, when this section's theorem does apply it says strictly more: a ceiling on the inverse, a rate at which the partial sums approach it, and a floor as well. Chapter 9 could not have stated any of the three, having no way to measure a matrix.

There is a third thing to say, and it dissolves most of the apparent conflict. If $\rho(\mathbf{A}) < 1$, then by Theorem 15.4.3 there is a norm $\|\cdot\|_t$ with $\|\mathbf{A}\|_t \le \rho(\mathbf{A}) + \varepsilon < 1$, and Theorem 15.5.1 applies **in that norm**. For the matrix above, taking $\mathbf{D} = \operatorname{diag}(1, 4)$ and $\|\mathbf{x}\|_t = \|\mathbf{D}\mathbf{x}\|_\infty$ gives $\|\mathbf{A}\|_t = \|\mathbf{D}\mathbf{A}\mathbf{D}^{-1}\|_\infty = \frac{1}{2}$, so the bound reads $\|(\mathbf{I} - \mathbf{A})^{-1}\|_t \le 2$; and indeed $\mathbf{D}(\mathbf{I} + \mathbf{A})\mathbf{D}^{-1} = \left(\begin{smallmatrix} 1 & 1/2 \\ 0 & 1 \end{smallmatrix}\right)$ has ∞-norm $\frac{3}{2} \le 2$. So the quantitative theorem can always be brought to bear on a matrix Chapter 9 accepts — at the cost of changing the norm, and the bound it then produces is a bound in that new norm, which may be a strange unit of measurement.

> *Quick check.* Both theorems need a hypothesis. Which of the two hypotheses, $\rho(\mathbf{A}) < 1$ and $\|\mathbf{A}\| < 1$, can be checked by looking at the entries of $\mathbf{A}$ and doing no linear algebra?

> *Solution.* The second, for a suitable norm: $\|\mathbf{A}\|_1$ and $\|\mathbf{A}\|_\infty$ are the largest absolute column and row sums (Theorem 15.3.3), read straight off the entries. Deciding $\rho(\mathbf{A}) < 1$ requires the eigenvalues, that is, the roots of a degree-n polynomial. This is the practical reason the cruder hypothesis is worth having: it is the one a reader can verify at a glance, and Corollary 15.4.2 is the same observation used in the other direction.

> *Warning.* **The hypothesis $\|\mathbf{A}\| < 1$ is sufficient and never necessary.** A matrix can be as far from $\mathbf{I}$ as one likes and still have $\mathbf{I}-\mathbf{A}$ invertible: $\mathbf{A} = 5\mathbf{I}$ gives $(\mathbf{I}-\mathbf{A})^{-1} = -\frac{1}{4}\mathbf{I}$. What fails when $\|\mathbf{A}\| \ge 1$ is not the invertibility but the *argument*, and with it the bound. Read $\|\mathbf{A}\| < 1$ as "$\mathbf{A}$ is a small perturbation", not as a criterion.

15.5.3 The invertible matrices form an open set

The theorem above concerns perturbations of $\mathbf{I}$. Every invertible matrix can be moved to $\mathbf{I}$ by multiplication, so the general statement follows at once, and it is the statement several earlier arguments wanted: a matrix near an invertible matrix is invertible, and its inverse is near.

Corollary 15.5.2 — Invertibility Is an Open Condition, and Inversion Is Continuous

Let $\mathbf{B} \in M_n(\mathbb{C})$ be invertible and let $\mathbf{E} \in M_n(\mathbb{C})$ satisfy

$$\|\mathbf{E}\| < \frac{1}{\|\mathbf{B}^{-1}\|}.$$

Write $r = \|\mathbf{B}^{-1}\|\|\mathbf{E}\| < 1$. Then:

(a) $\mathbf{B} + \mathbf{E}$ is invertible, and $\|(\mathbf{B} + \mathbf{E})^{-1}\| \le \dfrac{\|\mathbf{B}^{-1}\|}{1 - r}$;

(b) $\|(\mathbf{B} + \mathbf{E})^{-1} - \mathbf{B}^{-1}\| \le \dfrac{\|\mathbf{B}^{-1}\|^2\|\mathbf{E}\|}{1 - r}$.

Consequently $\mathrm{GL}_n(\mathbb{C})$ is an open subset of $M_n(\mathbb{C})$: around every invertible $\mathbf{B}$ the ball

of radius $1/\|\mathbf{B}^{-1}\|$ consists of invertible matrices. And inversion is continuous on it: if $\mathbf{B}_m \to \mathbf{B}$ with $\mathbf{B}$ invertible, then $\mathbf{B}_m$ is invertible for all large m and $\mathbf{B}_m^{-1} \to \mathbf{B}^{-1}$.

Idea. Factor the perturbed matrix as $\mathbf{B}+\mathbf{E} = \mathbf{B}(\mathbf{I}+\mathbf{B}^{-1}\mathbf{E})$ — legitimate because $\mathbf{B}$ is invertible — and notice that $\|\mathbf{B}^{-1}\mathbf{E}\| \le r < 1$, so the second factor is a perturbation of the identity of exactly the kind Theorem 15.5.1 handles, with $\mathbf{A} = -\mathbf{B}^{-1}\mathbf{E}$. For (b), the difference of two inverses always factors as $\mathbf{X}^{-1} - \mathbf{Y}^{-1} = \mathbf{X}^{-1}(\mathbf{Y}-\mathbf{X})\mathbf{Y}^{-1}$, and both inverses are now bounded.

Proof. Put $\mathbf{A} = -\mathbf{B}^{-1}\mathbf{E}$. By submultiplicativity, $\|\mathbf{A}\| \le \|\mathbf{B}^{-1}\|\|\mathbf{E}\| = r < 1$.

(a) Since $\mathbf{B}$ is invertible, $\mathbf{B}+\mathbf{E} = \mathbf{B}(\mathbf{I}+\mathbf{B}^{-1}\mathbf{E}) = \mathbf{B}(\mathbf{I}-\mathbf{A})$. By Theorem 15.5.1 (a) the factor $\mathbf{I}-\mathbf{A}$ is invertible, so $\mathbf{B}+\mathbf{E}$ is a product of invertible matrices and is invertible, with

$$(\mathbf{B}+\mathbf{E})^{-1} = (\mathbf{I}-\mathbf{A})^{-1}\mathbf{B}^{-1}.$$

By submultiplicativity and Theorem 15.5.1 (b),

$$\|(\mathbf{B}+\mathbf{E})^{-1}\| \le \|(\mathbf{I}-\mathbf{A})^{-1}\|\,\|\mathbf{B}^{-1}\| \le \frac{\|\mathbf{B}^{-1}\|}{1-\|\mathbf{A}\|} \le \frac{\|\mathbf{B}^{-1}\|}{1-r},$$

the last step because $\|\mathbf{A}\| \le r$ and $t \mapsto 1/(1-t)$ increases on $[0,1)$.

(b) Multiplying the identity $\mathbf{B} - (\mathbf{B}+\mathbf{E}) = -\mathbf{E}$ on the left by $(\mathbf{B}+\mathbf{E})^{-1}$ and on the right by $\mathbf{B}^{-1}$ gives

$$(\mathbf{B}+\mathbf{E})^{-1} - \mathbf{B}^{-1} = -(\mathbf{B}+\mathbf{E})^{-1}\mathbf{E}\,\mathbf{B}^{-1}.$$

Taking norms and applying submultiplicativity twice and then (a),

$$\|(\mathbf{B}+\mathbf{E})^{-1} - \mathbf{B}^{-1}\| \le \frac{\|\mathbf{B}^{-1}\|}{1-r}\,\|\mathbf{E}\|\,\|\mathbf{B}^{-1}\| = \frac{\|\mathbf{B}^{-1}\|^2\|\mathbf{E}\|}{1-r}.$$

For the two consequences: openness is the statement of (a) with $\mathbf{E}$ ranging over the ball of radius $1/\|\mathbf{B}^{-1}\|$. For continuity, let $\mathbf{B}_m \to \mathbf{B}$ with $\mathbf{B}$ invertible, and put $\mathbf{E}_m = \mathbf{B}_m - \mathbf{B}$. By Corollary 15.2.4, $\|\mathbf{E}_m\| \to 0$, so $\|\mathbf{E}_m\| < 1/(2\|\mathbf{B}^{-1}\|)$ for all large m; for those m, part (a) applies with $r \le \frac{1}{2}$ and $\mathbf{B}_m$ is invertible, and part (b) gives

$$\|\mathbf{B}_m^{-1} - \mathbf{B}^{-1}\| \le 2\|\mathbf{B}^{-1}\|^2\|\mathbf{E}_m\| \to 0.$$

This proves the corollary.

■

Example. (How far an invertible matrix can be pushed)

Take $\mathbf{B} = \left(\begin{smallmatrix} 2 & 1 \\ 0 & 2 \end{smallmatrix}\right)$ and work with $\|\cdot\|_\infty$. Then $\mathbf{B}^{-1} = \left(\begin{smallmatrix} \frac{1}{2} & -\frac{1}{4} \\ 0 & \frac{1}{2} \end{smallmatrix}\right)$, whose largest absolute row sum is $\frac{1}{2}+\frac{1}{4} = \frac{3}{4}$, so $\|\mathbf{B}^{-1}\|_\infty = \frac{3}{4}$. Corollary 15.5.2 therefore keeps $\mathbf{B}+\mathbf{E}$ invertible for every $\mathbf{E}$ with

$$\|\mathbf{E}\|_\infty < \frac{1}{\|\mathbf{B}^{-1}\|_\infty} = \frac{4}{3}.$$

For a perturbation of size $\|\mathbf{E}\|_\infty \le \frac{1}{2}$ we get $r = \frac{3}{4}\cdot\frac{1}{2} = \frac{3}{8}$, and part (a) bounds

$$\|(\mathbf{B}+\mathbf{E})^{-1}\|_\infty \;\le\; \frac{3/4}{1-3/8} \;=\; \frac{6}{5}.$$

The bound is honest rather than tight: pushing every entry of $\mathbf{E}$ to $\pm\frac{1}{4}$ gives at worst $\|(\mathbf{B}+\mathbf{E})^{-1}\|_\infty = \frac{12}{11} \approx 1.09$, against the promised 1.2. What the corollary buys is not the sharpest constant but a radius inside which no invertibility check is needed at all.

Part (a) has a reading worth recording, since the relative-error theorem of §08 is the same sentence with the constant named: **the distance from an invertible $\mathbf{B}$ to the nearest singular matrix is at least $1/\|\mathbf{B}^{-1}\|$.** A large $\|\mathbf{B}^{-1}\|$ is therefore not an abstract complaint; it says that $\mathbf{B}$ is close, in the literal sense of the norm, to a matrix that cannot be inverted at all.

Remark. Chapter 11 §01 proved that every matrix has diagonalizable matrices arbitrarily close to it (Corollary 11.1.6) and used the word "close" before this chapter existed. Corollary 15.5.2 is the first of the two facts that argument needs; the second is the continuity of the eigenvalues, and the two are put together in §07.

15.5.4 Perturbing a solve

The question the rest of the chapter circles is this. A linear system $\mathbf{A}\mathbf{x} = \mathbf{b}$ is solved; the data $\mathbf{A}$ and $\mathbf{b}$ were only known approximately; how wrong can $\mathbf{x}$ be? With Corollary 15.5.2 available the answer is three lines, and it already contains the quantity §08 will name.

Theorem 15.5.3 — Relative Error in a Perturbed Solve

Let $\mathbf{A} \in M_n(\mathbb{C})$ be invertible, let $\mathbf{b} \neq \mathbf{0}$, and let $\mathbf{x}$ be the solution of $\mathbf{A}\mathbf{x} = \mathbf{b}$. Let $\mathbf{E} \in M_n(\mathbb{C})$ and $\mathbf{f} \in \mathbb{C}^n$ be perturbations with

$$r = \|\mathbf{A}^{-1}\|\|\mathbf{E}\| < 1,$$

and let $\widetilde{\mathbf{x}}$ be the solution of $(\mathbf{A}+\mathbf{E})\widetilde{\mathbf{x}} = \mathbf{b}+\mathbf{f}$, which exists and is unique by Corollary 15.5.2. Then

$$\frac{\|\widetilde{\mathbf{x}}-\mathbf{x}\|}{\|\mathbf{x}\|} \le \frac{\|\mathbf{A}\|\,\|\mathbf{A}^{-1}\|}{1-r}\left(\frac{\|\mathbf{E}\|}{\|\mathbf{A}\|}+\frac{\|\mathbf{f}\|}{\|\mathbf{b}\|}\right).$$

Idea. Subtract the two equations to isolate $\mathbf{A}(\widetilde{\mathbf{x}}-\mathbf{x})$; what is left on the other side is $\mathbf{f}-\mathbf{E}\widetilde{\mathbf{x}}$. Apply $\mathbf{A}^{-1}$ and take norms. The one awkward term is $\|\widetilde{\mathbf{x}}\|$, which is not data; write $\widetilde{\mathbf{x}} = \mathbf{x} + (\widetilde{\mathbf{x}}-\mathbf{x})$ and move the resulting copy of $\|\widetilde{\mathbf{x}}-\mathbf{x}\|$ to the left, which is where the factor $1/(1-r)$ comes from. Finally $\|\mathbf{b}\| \le \|\mathbf{A}\|\|\mathbf{x}\|$ converts $1/\|\mathbf{x}\|$ into $\|\mathbf{A}\|/\|\mathbf{b}\|$, and the two perturbations appear only through their relative sizes.

Proof. Write $\mathbf{d} = \widetilde{\mathbf{x}}-\mathbf{x}$. Subtracting $\mathbf{A}\mathbf{x} = \mathbf{b}$ from $(\mathbf{A}+\mathbf{E})\widetilde{\mathbf{x}} = \mathbf{b}+\mathbf{f}$ gives $\mathbf{A}\widetilde{\mathbf{x}}+\mathbf{E}\widetilde{\mathbf{x}}-\mathbf{A}\mathbf{x} = \mathbf{f}$, that is, $\mathbf{A}\mathbf{d} = \mathbf{f}-\mathbf{E}\widetilde{\mathbf{x}}$. Since $\mathbf{A}$ is invertible, $\mathbf{d} = \mathbf{A}^{-1}(\mathbf{f}-\mathbf{E}\widetilde{\mathbf{x}})$, and Theorem 15.3.2 (a) with subadditivity gives

$$\|\mathbf{d}\| \le \|\mathbf{A}^{-1}\|\big(\|\mathbf{f}\| + \|\mathbf{E}\|\,\|\widetilde{\mathbf{x}}\|\big).$$

Now $\|\widetilde{\mathbf{x}}\| \le \|\mathbf{x}\| + \|\mathbf{d}\|$, so

$$\|\mathbf{d}\| \le \|\mathbf{A}^{-1}\|\|\mathbf{f}\| + \|\mathbf{A}^{-1}\|\|\mathbf{E}\|\|\mathbf{x}\| + r\|\mathbf{d}\|,$$

using $\|\mathbf{A}^{-1}\|\|\mathbf{E}\| = r$ on the last term. Since $r < 1$ we may subtract $r\|\mathbf{d}\|$ and divide by $1 - r > 0$:

$$\|\mathbf{d}\| \le \frac{\|\mathbf{A}^{-1}\|}{1-r}\bigl(\|\mathbf{f}\| + \|\mathbf{E}\|\|\mathbf{x}\|\bigr).$$

Divide by $\|\mathbf{x}\|$, which is non-zero because $\mathbf{b} \neq \mathbf{0}$:

$$\frac{\|\mathbf{d}\|}{\|\mathbf{x}\|} \le \frac{\|\mathbf{A}^{-1}\|}{1-r}\left(\frac{\|\mathbf{f}\|}{\|\mathbf{x}\|} + \|\mathbf{E}\|\right).$$

Finally $\|\mathbf{b}\| = \|\mathbf{A}\mathbf{x}\| \le \|\mathbf{A}\|\|\mathbf{x}\|$, so $1/\|\mathbf{x}\| \le \|\mathbf{A}\|/\|\mathbf{b}\|$. Substituting this in the first term and writing $\|\mathbf{E}\| = \|\mathbf{A}\| \cdot \|\mathbf{E}\|/\|\mathbf{A}\|$ in the second gives the stated inequality. This proves the theorem.

■

The shape of the conclusion is the point. On the right, the two perturbations appear only as **relative** sizes, $\|\mathbf{E}\|/\|\mathbf{A}\|$ and $\|\mathbf{f}\|/\|\mathbf{b}\|$; on the left is the relative size of the error. Between them stands one number built from $\mathbf{A}$ alone,

$$\|\mathbf{A}\|\,\|\mathbf{A}^{-1}\|,$$

inflated slightly by $1/(1-r)$, which is close to 1 whenever the perturbation of $\mathbf{A}$ is small. That number is the condition number of §08. Everything that section does is to give it a name, compute it for the 2-norm, and show that the bound is attained.

Example. (A perturbation of the matrix)

Let

$$\mathbf{A} = \begin{pmatrix} 2 & 1 \\ 1 & 1 \end{pmatrix}, \quad \mathbf{b} = \begin{pmatrix} 3 \\ 2 \end{pmatrix}, \quad \mathbf{E} = \begin{pmatrix} 0 & 0 \\ 0 & 1/10 \end{pmatrix}, \quad \mathbf{f} = \mathbf{0}.$$

Solve both systems in the ∞-norm, compute the relative error, and compare it with Theorem 15.5.3.

Solution. The two solutions. $\det \mathbf{A} = 1$, so $\mathbf{A}^{-1} = \left(\begin{smallmatrix} 1 & -1 \\ -1 & 2 \end{smallmatrix}\right)$ by Theorem 0.9.8, and $\mathbf{x} = \mathbf{A}^{-1}\mathbf{b} = (3-2,\ -3+4) = (1, 1)$. For the perturbed matrix, $\mathbf{A} + \mathbf{E} = \left(\begin{smallmatrix} 2 & 1 \\ 1 & 11/10 \end{smallmatrix}\right)$ has determinant $\frac{22}{10} - 1 = \frac{6}{5}$, so

$$\widetilde{\mathbf{x}} = \tfrac{5}{6}\begin{pmatrix} 11/10 & -1 \\ -1 & 2 \end{pmatrix}\begin{pmatrix} 3 \\ 2 \end{pmatrix} = \tfrac{5}{6}\begin{pmatrix} 13/10 \\ 1 \end{pmatrix} = \begin{pmatrix} 13/12 \\ 5/6 \end{pmatrix}.$$

The error. $\widetilde{\mathbf{x}} - \mathbf{x} = (\frac{1}{12}, -\frac{1}{6})$, so $\|\widetilde{\mathbf{x}} - \mathbf{x}\|_\infty = \frac{1}{6}$ and, since $\|\mathbf{x}\|_\infty = 1$, the relative error is $\frac{1}{6} \approx 0.167$.

The bound. The absolute row sums give $\|\mathbf{A}\|_\infty = 3$ and $\|\mathbf{A}^{-1}\|_\infty = 3$, so $\|\mathbf{A}\|_\infty\|\mathbf{A}^{-1}\|_\infty = 9$. Also $\|\mathbf{E}\|_\infty = \frac{1}{10}$ and $r = 3 \cdot \frac{1}{10} = \frac{3}{10} < 1$. With $\mathbf{f} = \mathbf{0}$ the bound is

$$\frac{9}{1 - \frac{3}{10}} \cdot \frac{1/10}{3} = \frac{9}{7/10} \cdot \frac{1}{30} = \frac{3}{7} \approx 0.429.$$

So $0.167 \le 0.429$: correct, and loose by a factor of about 2.6. Note the accounting. The matrix was disturbed by 3.3% of its size and the answer moved by 16.7%, an amplification of about 5; the theorem promised at most $9/(1-0.3) \approx 12.9$.

Warning. **All four bounds of this section need $\|\mathbf{I}\| = 1$, which is a property of *induced* norms only.** The Frobenius norm is submultiplicative (Example (The Frobenius norm is submultiplicative)) but has $\|\mathbf{I}_n\|_F = \sqrt{n}$. Take $\mathbf{A} = 0$ in $M_2(\mathbb{C})$: then $\|\mathbf{A}\|_F = 0 < 1$, while

$$\|(\mathbf{I}-\mathbf{A})^{-1}\|_F = \|\mathbf{I}_2\|_F = \sqrt{2} > 1 = \frac{1}{1-\|\mathbf{A}\|_F},$$

so Theorem 15.5.1 (b) is false for it. The repair is easy — Exercise (C3: Without $\|\mathbf{I}\| = 1$) — but it is not the same inequality, and using the Frobenius norm here is the most common way to arrive at a wrong constant.

15.5.5 Exercises

15.5.5.1 A. Check your understanding

Exercise A1.

(a) State Theorem 15.5.1 in full, including which kind of norm it assumes.

(b) Chapter 9 §10 already proved that $\sum_k \mathbf{A}^k$ converges to $(\mathbf{I}-\mathbf{A})^{-1}$ when $\rho(\mathbf{A}) < 1$. Say precisely what this section adds, and what it gives up.

(c) Determine whether the following statement is correct, and justify your answer: if $\mathbf{I}-\mathbf{A}$ is invertible then $\|\mathbf{A}\| < 1$.

(d) Where in the proof of Theorem 15.5.1 is $\|\mathbf{I}\| = 1$ used?

(e) State what Corollary 15.5.2 says about the distance from an invertible matrix to the singular matrices.

Solution.

(a) If $\|\cdot\|$ is the operator norm induced by a vector norm and $\|\mathbf{A}\| = a < 1$, then $\mathbf{I}-\mathbf{A}$ is invertible with $\sum_{k\ge 0}\mathbf{A}^k = (\mathbf{I}-\mathbf{A})^{-1}$; moreover $\|(\mathbf{I}-\mathbf{A})^{-1}\| \le 1/(1-a)$, the partial sums satisfy $\|(\mathbf{I}-\mathbf{A})^{-1} - \mathbf{S}_K\| \le a^{K+1}/(1-a)$, and $\|(\mathbf{I}-\mathbf{A})^{-1}\| \ge 1/(1+a)$.

(b) It adds three numbers: a ceiling on the inverse, a geometric rate for the partial sums, and a floor. It gives up sharpness of the hypothesis: $\rho(\mathbf{A}) < 1$ is necessary and sufficient for convergence, whereas $\|\mathbf{A}\| < 1$ is only sufficient, and strictly stronger by Theorem 15.4.1.

(c) Incorrect. $\mathbf{A} = 5\mathbf{I}$ has $\mathbf{I}-\mathbf{A} = -4\mathbf{I}$, invertible, while $\|\mathbf{A}\| = 5$ in every induced norm. Invertibility of $\mathbf{I}-\mathbf{A}$ says only $1 \notin \operatorname{spec}(\mathbf{A})$.

(d) Twice, and both times to make a geometric sum start at 1: in (b), where $\|\mathbf{A}^0\| = \|\mathbf{I}\| = 1$ is the $k = 0$ term of $\sum_k a^k$; and in (d), where $1 = \|\mathbf{I}\|$ is the left-hand side of the estimate.

(e) It is at least $1/\|\mathbf{B}^{-1}\|$: every $\mathbf{E}$ with $\|\mathbf{E}\| < 1/\|\mathbf{B}^{-1}\|$ leaves $\mathbf{B}+\mathbf{E}$ invertible.

15.5.5.2 B. Practice

Exercise B1: Check, sum, compare.

Let $\mathbf{A} = \begin{pmatrix} 1/4 & 1/4 \\ 0 & 1/2 \end{pmatrix}$.

(a) Verify the hypothesis of Theorem 15.5.1 for $\|\cdot\|_\infty$.

(b) Compute $(\mathbf{I}-\mathbf{A})^{-1}$ exactly and compare $\|(\mathbf{I}-\mathbf{A})^{-1}\|_\infty$ with the bound of (b) and with the lower bound of (d).

Solution.

(a) The absolute row sums are $\frac{1}{2}$ and $\frac{1}{2}$, so $\|\mathbf{A}\|_\infty = \frac{1}{2} < 1$ by Theorem 15.3.3 (b).

(b) $\mathbf{I} - \mathbf{A} = \begin{pmatrix} 3/4 & -1/4 \\ 0 & 1/2 \end{pmatrix}$, upper triangular with determinant $\frac{3}{8}$, so by Theorem 0.9.8

$$(\mathbf{I} - \mathbf{A})^{-1} = \tfrac{8}{3}\begin{pmatrix} 1/2 & 1/4 \\ 0 & 3/4 \end{pmatrix} = \begin{pmatrix} 4/3 & 2/3 \\ 0 & 2 \end{pmatrix}.$$

The absolute row sums are 2 and 2, so $\|(\mathbf{I} - \mathbf{A})^{-1}\|_\infty = 2$. The upper bound is $1/(1 - \frac{1}{2}) = 2$, attained exactly; the lower bound is $1/(1 + \frac{1}{2}) = \frac{2}{3}$, comfortably satisfied. The upper bound is attained because both rows of $\mathbf{A}$ have the same absolute sum and no cancellation occurs anywhere in the geometric series.

Exercise B2: A perturbed right-hand side.

Let $\mathbf{A} = \begin{pmatrix} 3 & 1 \\ 1 & 2 \end{pmatrix}$, $\mathbf{b} = (4, 3)$ and $\mathbf{f} = (1/10, 0)$, with $\mathbf{E} = 0$. Solve both systems, compute the relative error in the ∞-norm, and compare with Theorem 15.5.3.

Solution. $\det \mathbf{A} = 5$, so $\mathbf{A}^{-1} = \frac{1}{5}\left(\begin{smallmatrix} 2 & -1 \\ -1 & 3 \end{smallmatrix}\right)$ by Theorem 0.9.8, and $\mathbf{x} = \mathbf{A}^{-1}\mathbf{b} = \frac{1}{5}(8 - 3, -4 + 9) = (1, 1)$.

With $\mathbf{b} + \mathbf{f} = (\frac{41}{10}, 3)$ we get $\widetilde{\mathbf{x}} = \frac{1}{5}(\frac{82}{10} - 3, -\frac{41}{10} + 9) = (\frac{52}{50}, \frac{49}{50})$. Hence $\widetilde{\mathbf{x}} - \mathbf{x} = (\frac{2}{50}, -\frac{1}{50})$ and $\|\widetilde{\mathbf{x}} - \mathbf{x}\|_\infty = \frac{1}{25} = 0.04$, a relative error of 0.04 since $\|\mathbf{x}\|_\infty = 1$.

For the bound: $\|\mathbf{A}\|_\infty = 4$, $\|\mathbf{A}^{-1}\|_\infty = \frac{4}{5}$, so $\|\mathbf{A}\|_\infty\|\mathbf{A}^{-1}\|_\infty = \frac{16}{5}$. Here $\mathbf{E} = 0$, so $r = 0$, and $\|\mathbf{f}\|_\infty / \|\mathbf{b}\|_\infty = \frac{1/10}{4} = \frac{1}{40}$. The bound is $\frac{16}{5} \cdot \frac{1}{40} = \frac{2}{25} = 0.08$. So $0.04 \le 0.08$, loose by a factor of exactly 2.

Exercise B3: Staying invertible.

Let $\mathbf{B} = \begin{pmatrix} 2 & 0 \\ 0 & 1/2 \end{pmatrix}$. Using $\|\cdot\|_\infty$, find a radius $\delta > 0$ such that every $\mathbf{E}$ with $\|\mathbf{E}\|_\infty < \delta$ leaves $\mathbf{B} + \mathbf{E}$ invertible, and bound $\|(\mathbf{B} + \mathbf{E})^{-1}\|_\infty$ for $\|\mathbf{E}\|_\infty \le \frac{1}{4}$. Is your δ the largest possible?

Solution. $\mathbf{B}^{-1} = \operatorname{diag}(\frac{1}{2}, 2)$, so $\|\mathbf{B}^{-1}\|_\infty = 2$ and Corollary 15.5.2 gives $\delta = 1/\|\mathbf{B}^{-1}\|_\infty = \frac{1}{2}$.

For $\|\mathbf{E}\|_\infty \le \frac{1}{4}$ we get $r = 2 \cdot \frac{1}{4} = \frac{1}{2}$, so part (a) of the corollary gives

$$\|(\mathbf{B}+\mathbf{E})^{-1}\|_\infty \le \frac{2}{1-\frac{1}{2}} = 4.$$

It is the largest possible here. Taking $\mathbf{E} = \operatorname{diag}(0, -\frac{1}{2})$ gives $\|\mathbf{E}\|_\infty = \frac{1}{2}$ and $\mathbf{B}+\mathbf{E} = \operatorname{diag}(2,0)$, which is singular. So no radius larger than $\frac{1}{2}$ works, and the estimate $1/\|\mathbf{B}^{-1}\|$ is attained by this $\mathbf{B}$. (It is not attained by every $\mathbf{B}$ in every norm; Exercise (C2: Distance to the singular matrices) returns to this.)

15.5.5.3 C. Going deeper

Exercise C1: The inverse to first order.

Let $\|\mathbf{A}\| < 1$.

(a) Prove that $\|(\mathbf{I}-\mathbf{A})^{-1} - \mathbf{I} - \mathbf{A}\| \le \dfrac{\|\mathbf{A}\|^2}{1-\|\mathbf{A}\|}$.

(b) Deduce that for a fixed $\mathbf{M} \in M_n(\mathbb{C})$ and small real t,

$$(\mathbf{I}-t\mathbf{M})^{-1} = \mathbf{I} + t\mathbf{M} + \mathbf{R}(t), \qquad \|\mathbf{R}(t)\|/|t| \to 0$$

as $t \to 0$.

Hint for (a): this is Theorem 15.5.1 (c) with a particular K.

Solution.

(a) Take $K = 1$ in Theorem 15.5.1 (c): $\mathbf{S}_1 = \mathbf{I} + \mathbf{A}$, so

$$\|(\mathbf{I}-\mathbf{A})^{-1} - \mathbf{I} - \mathbf{A}\| \le \frac{\|\mathbf{A}\|^{1+1}}{1-\|\mathbf{A}\|} = \frac{\|\mathbf{A}\|^2}{1-\|\mathbf{A}\|}.$$

(b) If $\mathbf{M} = 0$ the claim is trivial, so assume $\mathbf{M} \neq 0$ and let $|t| < 1/(2\|\mathbf{M}\|)$. Then $\|t\mathbf{M}\| = |t|\|\mathbf{M}\| < \frac{1}{2}$, so (a) applies with $\mathbf{A} = t\mathbf{M}$ and gives, with $\mathbf{R}(t) = (\mathbf{I}-t\mathbf{M})^{-1} - \mathbf{I} - t\mathbf{M}$,

$$\|\mathbf{R}(t)\| \le \frac{t^2\|\mathbf{M}\|^2}{1-|t|\|\mathbf{M}\|} \le 2t^2\|\mathbf{M}\|^2,$$

using $1 - |t|\|\mathbf{M}\| > \frac{1}{2}$. Hence $\|\mathbf{R}(t)\|/|t| \le 2|t|\|\mathbf{M}\|^2 \to 0$ as $t \to 0$. So $t \mapsto (\mathbf{I}-t\mathbf{M})^{-1}$ is differentiable at $t = 0$ with derivative $\mathbf{M}$, which is the case $\mathbf{A}(t) = \mathbf{I} - t\mathbf{M}$ of the general formula for differentiating an inverse, proved in §06.

Exercise C2: Distance to the singular matrices.

Let $\mathbf{B} \in M_n(\mathbb{C})$ be invertible and let $\|\cdot\|$ be an induced matrix norm.

(a) Prove that every singular $\mathbf{S} \in M_n(\mathbb{C})$ satisfies $\|\mathbf{B}-\mathbf{S}\| \ge 1/\|\mathbf{B}^{-1}\|$.

(b) For $\mathbf{B} = \operatorname{diag}(1, \varepsilon)$ with $0 < \varepsilon < 1$ and the 2-norm, exhibit a singular $\mathbf{S}$ attaining

the bound.

(c) Hence say what $\|\mathbf{B}^{-1}\|_2$ measures.

Solution.

(a) Suppose $\|\mathbf{B}-\mathbf{S}\| < 1/\|\mathbf{B}^{-1}\|$. Apply Corollary 15.5.2 with $\mathbf{E} = \mathbf{S}-\mathbf{B}$: since $\|\mathbf{E}\| < 1/\|\mathbf{B}^{-1}\|$, the matrix $\mathbf{B}+\mathbf{E} = \mathbf{S}$ is invertible, contradicting the assumption that $\mathbf{S}$ is singular. Hence $\|\mathbf{B}-\mathbf{S}\| \geq 1/\|\mathbf{B}^{-1}\|$ for every singular $\mathbf{S}$.

(b) $\mathbf{B}^{-1} = \operatorname{diag}(1, 1/\varepsilon)$, a normal matrix, so its singular values are the moduli of its eigenvalues and $\|\mathbf{B}^{-1}\|_2 = 1/\varepsilon$ by Theorem 15.3.3 (c). The bound is therefore ε. Take $\mathbf{S} = \operatorname{diag}(1, 0)$, which is singular; then $\mathbf{B}-\mathbf{S} = \operatorname{diag}(0, \varepsilon)$ and $\|\mathbf{B}-\mathbf{S}\|_2 = \varepsilon$. So the bound is attained.

(c) The reciprocal $1/\|\mathbf{B}^{-1}\|_2$ is a lower bound for the distance from $\mathbf{B}$ to the singular matrices, attained in the example. So $\|\mathbf{B}^{-1}\|_2$ is large exactly when $\mathbf{B}$ is close to being singular, which is the geometric content behind the condition number of §08.

Exercise C3: Without $\|\mathbf{I}\| = 1$.

Let $\|\cdot\|$ be any matrix norm on $M_n(\mathbb{C})$ in the sense of Definition 15.3.1, not necessarily induced, and let $\|\mathbf{A}\| < 1$.

(a) Prove that $\mathbf{I}-\mathbf{A}$ is invertible and that

$$\|(\mathbf{I}-\mathbf{A})^{-1}\| \leq \|\mathbf{I}\| + \frac{\|\mathbf{A}\|}{1-\|\mathbf{A}\|}.$$

(b) Verify that this bound is correct for the Frobenius norm on $M_2(\mathbb{C})$ with $\mathbf{A} = 0$, where the bound of Theorem 15.5.1 (b) fails.

(c) Explain why the argument of (a) cannot be improved to $1/(1-\|\mathbf{A}\|)$ for a general matrix norm.

Solution.

(a) By Theorem 15.4.1 (b), which holds for every matrix norm, $\rho(\mathbf{A}) \leq \|\mathbf{A}\| < 1$; so Theorem 9.10.6 applies and gives both the invertibility of $\mathbf{I}-\mathbf{A}$ and $\mathbf{S}_K \to (\mathbf{I}-\mathbf{A})^{-1}$. Submultiplicativity gives $\|\mathbf{A}^k\| \leq \|\mathbf{A}\|^k$ for $k \geq 1$, so separating the term $k = 0$,

$$\|\mathbf{S}_K\| \leq \|\mathbf{I}\| + \sum_{k=1}^{K} \|\mathbf{A}\|^k \leq \|\mathbf{I}\| + \frac{\|\mathbf{A}\|}{1-\|\mathbf{A}\|}.$$

As in the proof of Theorem 15.5.1 (b), Corollary 15.2.4 and Lemma 15.1.1 let the bound pass to the limit.

(b) With $\mathbf{A} = 0$, the right-hand side is $\|\mathbf{I}_2\|_F + 0 = \sqrt{2}$, and the left-hand side is $\|\mathbf{I}_2\|_F = \sqrt{2}$. The bound holds, with equality; the bound $1/(1-0) = 1$ of Theorem 15.5.1 (b) does not.

(c) The case $\mathbf{A} = 0$ already decides it: the left-hand side is $\|\mathbf{I}\|$, so any valid bound must be at least $\|\mathbf{I}\|$, and $1/(1-\|\mathbf{A}\|) = 1$ there. A norm with $\|\mathbf{I}\| > 1$ therefore falsifies the sharper form at once, and by Theorem 15.3.2 (c) an induced norm

never has $\|\mathbf{I}\| > 1$. This is exactly the difference between a matrix norm and an induced one.

15.6 Bounds for the Exponential, and Two Derivatives

Chapter 9 §09 built $e^{\mathbf{A}}$ out of a series and closed with a promise: "Chapter 15 will return to $e^{\mathbf{A}}$ with norms available, which give quantitative bounds instead of exact formulas." That is what this section does. It does not rebuild the exponential; Definition 9.9.2 and Theorem 9.9.3 stand as they are, and the Jordan form is not touched. What is new is that the series now has a size, so its sum has a ceiling, its truncation has an error bound, and its behavior as $t \to \infty$ has a rate.

The second half takes the other step Chapter 9 could not: it differentiates. The derivative of the determinant and the derivative of the inverse are both needed later in the book, and both require one fact from calculus that linear algebra does not supply. That fact is stated before it is used.

Throughout, $\|\cdot\|$ is the operator norm on $M_n(\mathbb{C})$ induced by a norm on $\mathbb{C}^n$ (Definition 15.3.2), so $\|\mathbf{I}\| = 1$ and $\|\mathbf{XY}\| \le \|\mathbf{X}\|\|\mathbf{Y}\|$ (Theorem 15.3.2 (c), (d)).

15.6.1 How big is the exponential

Chapter 9 §10's criteria answered *whether*; the norm answers *how much*. The bound to aim at is the one the scalar case suggests: $|e^z| \le e^{|z|}$, because the series has non-negative terms once every term is replaced by its modulus. The matrix proof is the same sentence with submultiplicativity in place of $|zw| = |z||w|$.

One scalar fact is needed and is not on the chapter's list of imports. We name it here rather than let it in quietly.

Remark. **A quoted fact.** For every real $s \ge 0$ the series $\sum_{m \ge 0} s^m/m!$ converges, with sum e^s. This is fact (A1) of Chapter 9 §09, quoted there and quoted again here; this book does not prove it. Because its terms are non-negative, its partial sums increase to e^s, so every partial sum is at most e^s — that last step is **(A2), monotone convergence**, from the list in this chapter's introduction.

Theorem 15.6.1 — Bounds for the Exponential

Let $\mathbf{A} \in M_n(\mathbb{C})$ and write $a = \|\mathbf{A}\|$. Then

(a) $\|e^{\mathbf{A}}\| \le e^a$;

(b) $\|e^{\mathbf{A}} - \mathbf{I}\| \le e^a - 1$;

(c) $\|e^{\mathbf{A}} - \mathbf{I} - \mathbf{A}\| \le e^a - 1 - a \le \dfrac{a^2 e^a}{2}$.

In particular $\|e^{t\mathbf{A}}\| \le e^{|t|a}$ for every real t.

Idea. All three are the same computation stopped at a different place: bound the norm of a partial sum by the corresponding partial sum of $\sum s^m/m!$, then let the partial sums converge. The only thing that needs care is the passage to the limit, and Lemma 15.1.1 does it, exactly as in Theorem 15.5.1. For the second inequality in (c), compare $m!$ with $2\,(m-2)!$.

Proof. Write $\mathbf{S}_M = \sum_{m=0}^{M} \mathbf{A}^m/m!$. By Theorem 9.9.3 the sequence $(\mathbf{S}_M)$ converges entrywise to $e^{\mathbf{A}}$, hence $\|\mathbf{S}_M - e^{\mathbf{A}}\| \to 0$ by Corollary 15.2.4, hence $\|\mathbf{S}_M\| \to \|e^{\mathbf{A}}\|$ by Lemma 15.1.1. The same three steps apply to $\mathbf{S}_M - \mathbf{I}$ and to $\mathbf{S}_M - \mathbf{I} - \mathbf{A}$. So in each part it suffices to bound the partial sums, uniformly in M.

(a) Submultiplicativity gives $\|\mathbf{A}^m\| \le a^m$ for $m \ge 1$, by induction, and $\|\mathbf{A}^0\| = \|\mathbf{I}\| = 1$. By subadditivity and the quoted fact above,

$$\|\mathbf{S}_M\| \le \sum_{m=0}^{M} \frac{\|\mathbf{A}^m\|}{m!} \le \sum_{m=0}^{M} \frac{a^m}{m!} \le e^a.$$

Letting $M \to \infty$ gives $\|e^{\mathbf{A}}\| \le e^a$.

(b) The same estimate with the term $m = 0$ removed:

$$\|\mathbf{S}_M - \mathbf{I}\| \le \sum_{m=1}^{M} \frac{a^m}{m!} \le e^a - 1,$$

since the partial sums of $\sum_{m\ge1} a^m/m!$ increase to $e^a - 1$.

(c) Removing the terms $m = 0$ and $m = 1$ in the same way gives

$$\|e^{\mathbf{A}} - \mathbf{I} - \mathbf{A}\| \le \sum_{m\ge2} \frac{a^m}{m!} = e^a - 1 - a.$$

For the second inequality, note that $m! = m(m-1)\,(m-2)! \ge 2\,(m-2)!$ for every $m \ge 2$, so $a^m/m! \le \frac{1}{2}a^2 \cdot a^{m-2}/(m-2)!$. Summing over $m \ge 2$ and substituting $l = m - 2$,

$$\sum_{m\ge2} \frac{a^m}{m!} \le \frac{a^2}{2} \sum_{l\ge0} \frac{a^l}{l!} = \frac{a^2 e^a}{2}.$$

The final claim is (a) applied to $t\mathbf{A}$, whose norm is $|t|a$ by homogeneity. This proves the theorem.

■

Part (c) is the statement that $e^{\mathbf{A}}$ agrees with $\mathbf{I} + \mathbf{A}$ to second order in $\|\mathbf{A}\|$, with an explicit constant. It is the bound one uses when $\mathbf{A}$ is a small perturbation, and it is the counterpart, for the exponential, of Theorem 15.5.1 (c).

Example. (Where the bound is exact, and where it is useless)

Compare $\|e^{\mathbf{A}}\|_2$ with $e^{\|\mathbf{A}\|_2}$ for

(a) $\mathbf{A} = \operatorname{diag}(2, 1)$;

(b) $\mathbf{A} = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}$, and more generally $t\mathbf{A}$ for $t > 0$.

Solution.

(a) $\mathbf{A}$ is Hermitian, hence normal, so its singular values are the moduli of its eigenvalues and $\|\mathbf{A}\|_2 = 2$ by Theorem 15.3.3 (c). By Definition 9.9.1 (or directly from the series, entry by entry) $e^{\mathbf{A}} = \operatorname{diag}(e^2, e)$, again normal, so $\|e^{\mathbf{A}}\|_2 = e^2$. The bound $e^{\|\mathbf{A}\|_2} = e^2$ is attained exactly. The same happens for every $\mathbf{A} = c\mathbf{I}$ with $c > 0$, so no constant smaller than 1 can be inserted in Theorem 15.6.1 (a).

(b) $\mathbf{A}^2 = -\mathbf{I}$, so $\mathbf{A}^3 = -\mathbf{A}$, $\mathbf{A}^4 = \mathbf{I}$, and grouping the series by parity gives, using fact (A1) of Chapter 9 §09 for the series of cos and sin and its (A3) to rearrange a convergent series into its even and odd parts,

$$e^{t\mathbf{A}} = (\cos t)\mathbf{I} + (\sin t)\mathbf{A} = \begin{pmatrix} \cos t & \sin t \\ -\sin t & \cos t \end{pmatrix},$$

a real orthogonal matrix. Hence $\|e^{t\mathbf{A}}\|_2 = 1$ for every t, while $\|t\mathbf{A}\|_2 = t$ and the bound reads e^t. At $t = 10$ the bound is about 22026 and the truth is 1.

Warning. **The bound sees only the size of A, never the direction of its spectrum.** Part (b) above is the extreme case: $\|e^{t\mathbf{A}}\|$ stays at 1 while $e^{t\|\mathbf{A}\|}$ runs away. The reason is that Theorem 15.6.1 throws away every cancellation in the series at the first step, when $\|\mathbf{A}^m\|$ is replaced by $\|\mathbf{A}\|^m$. Any statement about $e^{t\mathbf{A}}$ for **large** t must come from the eigenvalues instead, which is the subject of the next subsection.

Quick check. Why does Theorem 15.6.1 (a) fail for the Frobenius norm, and what is the correct statement for it?

Solution. Because $\|\mathbf{I}_n\|_F = \sqrt{n}$, so already at $\mathbf{A} = 0$ the claim reads $\sqrt{n} \le 1$. Repeating the proof with the term $m = 0$ kept separate gives the correct version for any matrix norm: $\|e^{\mathbf{A}}\| \le \|\mathbf{I}\| + e^{\|\mathbf{A}\|} - 1$. This is the same correction as in Exercise (C3: Without $\|\mathbf{I}\| = 1$), and it comes from the same place: only an induced norm has $\|\mathbf{I}\| = 1$.

15.6.2 Decay in the stable case

The warning above says the bound $e^{t\|\mathbf{A}\|}$ is the wrong instrument for large t. The right one reads the eigenvalues, and the bridge to the discrete theory of §04 is the observation that the exponential turns the *real part* of an eigenvalue into a *modulus*.

Lemma 15.6.2 — The Spectrum of the Exponential

Let $\mathbf{A} \in M_n(\mathbb{C})$. Then $\operatorname{spec}(e^{\mathbf{A}}) = \{e^{\lambda} : \lambda \in \operatorname{spec}(\mathbf{A})\}$, and

$$\rho(e^{\mathbf{A}}) = e^{\mu}, \qquad \mu = \max\{\operatorname{Re}\lambda : \lambda \in \operatorname{spec}(\mathbf{A})\}.$$

Idea. The eigenvalues of $e^{\mathbf{A}}$ are the numbers e^{λ} for $\lambda \in \operatorname{spec}(\mathbf{A})$, which the Jordan form makes visible. Taking moduli turns e^{λ} into $e^{\operatorname{Re}\lambda}$, and the largest of finitely many such numbers is the one with the largest exponent.

Proof. By Theorem 9.3.1 there are an invertible $\mathbf{P}$ and a Jordan matrix $\mathbf{J}$ with $\mathbf{A} = \mathbf{P}\mathbf{J}\mathbf{P}^{-1}$, and the diagonal of $\mathbf{J}$ lists the eigenvalues $\lambda_1, \dots, \lambda_n$ of $\mathbf{A}$ with multiplicity. By Theorem 9.9.4 (a), $e^{\mathbf{J}} = e^{\mathbf{P}^{-1}\mathbf{A}\mathbf{P}} = \mathbf{P}^{-1}e^{\mathbf{A}}\mathbf{P}$. By Theorem 9.9.3 each block $e^{\mathbf{J}_k(\lambda)}$ is upper triangular with e^{λ} on its diagonal, so $e^{\mathbf{J}}$ is upper triangular with diagonal $e^{\lambda_1}, \dots, e^{\lambda_n}$; hence $\operatorname{spec}(e^{\mathbf{J}}) = \{e^{\lambda_i}\}$ by Theorem 8.7.4 (b). Similar matrices have the same characteristic polynomial (Theorem 6.10.3), so $\operatorname{spec}(e^{\mathbf{A}}) = \operatorname{spec}(e^{\mathbf{J}})$, which is the first claim.

For the second, $|e^{\lambda}| = e^{\operatorname{Re}\lambda}$ by fact (A1) of Chapter 9 §09, and $s \mapsto e^{s}$ is non-decreasing on $\mathbb{R}$ — for $h \geq 0$, $e^{s+h} = e^{s}e^{h} \geq e^{s}$ by fact (A1) of Chapter 9 §09 — so the largest of the finitely many numbers $e^{\operatorname{Re}\lambda_i}$ is e^{μ}. This proves the lemma.

■

Chapter 11 §10 called $\mathbf{A}$ **stable** when every $\lambda \in \operatorname{spec}(\mathbf{A})$ has $\operatorname{Re}\lambda < 0$ (Definition 11.10.2). In the language of the lemma, $\mathbf{A}$ is stable exactly when $\rho(e^{\mathbf{A}}) < 1$ — the continuous-time condition and Chapter 9 §10's discrete-time condition are the same condition, read through the exponential.

Theorem 15.6.3 — Exponential Decay of a Stable System

Let $\mathbf{A} \in M_n(\mathbb{C})$, let $\mu = \max\{\operatorname{Re}\lambda : \lambda \in \operatorname{spec}(\mathbf{A})\}$, and let $\nu > \mu$ be real. Then there is a constant $C \geq 1$, depending on $\mathbf{A}$, on ν and on the norm, with

$$\|e^{t\mathbf{A}}\| \leq C\, e^{\nu t} \qquad \text{for every } t \geq 0.$$

In particular, if $\mathbf{A}$ is **stable** then ν may be taken negative, and every solution of $\mathbf{x}' = \mathbf{A}\mathbf{x}$ satisfies

$$\|\mathbf{x}(t)\| \leq Ce^{\nu t}\|\mathbf{x}(0)\| \xrightarrow[t\to\infty]{} 0.$$

Idea. Sample the flow at integer times and use §04. The matrix $\mathbf{M} = e^{-\nu}e^{\mathbf{A}}$ has $\rho(\mathbf{M}) = e^{\mu-\nu} < 1$ by Lemma 15.6.2, so Corollary 15.4.5 bounds all of its powers by one constant; unwinding the powers gives $\|e^{k\mathbf{A}}\| \leq C_0 e^{\nu k}$ at every integer k. Between the integers, $e^{t\mathbf{A}} = e^{(t-k)\mathbf{A}}e^{k\mathbf{A}}$ with $0 \leq t-k < 1$, and the crude bound Theorem 15.6.1 (a) is more than enough to cover a gap of length 1. The whole point is that the crude bound is applied only on a bounded interval, where crudeness costs a constant and not a rate.

Proof. Put $\mathbf{M} = e^{-\nu}e^{\mathbf{A}}$. Multiplying a matrix by a scalar c multiplies every eigenvalue by c, so by Lemma 15.6.2,

$$\rho(\mathbf{M}) = e^{-\nu}\rho(e^{\mathbf{A}}) = e^{-\nu}e^{\mu} = e^{\mu-\nu} < 1,$$

using $\mu - \nu < 0$. Fix any q with $\rho(\mathbf{M}) < q < 1$. By Corollary 15.4.5 (b) there is $C_0 \geq 1$ with $\|\mathbf{M}^k\| \leq C_0 q^k \leq C_0$ for every integer $k \geq 0$.

Since $\mathbf{A}$ commutes with itself, Theorem 9.9.4 (d) gives $e^{(s+u)\mathbf{A}} = e^{s\mathbf{A}}e^{u\mathbf{A}}$ for all real s, u;

in particular $(e^{\mathbf{A}})^k = e^{k\mathbf{A}}$ by induction on k. Hence $\mathbf{M}^k = e^{-\nu k} e^{k\mathbf{A}}$, and

$$\|e^{k\mathbf{A}}\| = e^{\nu k}\|\mathbf{M}^k\| \le C_0\, e^{\nu k} \qquad (k = 0, 1, 2, \dots).$$

Now let $t \ge 0$ and let k be the integer part of t, so that $k \ge 0$ and $0 \le t - k < 1$. Then $e^{t\mathbf{A}} = e^{(t-k)\mathbf{A}} e^{k\mathbf{A}}$, so by submultiplicativity and Theorem 15.6.1 (a),

$$\|e^{t\mathbf{A}}\| \le \|e^{(t-k)\mathbf{A}}\|\, \|e^{k\mathbf{A}}\| \le e^{(t-k)\|\mathbf{A}\|}\, C_0 e^{\nu k} \le C_0\, e^{\|\mathbf{A}\|}\, e^{\nu k},$$

using $0 \le t - k < 1$ in the last step. Finally $e^{\nu k} = e^{\nu t} e^{-\nu(t-k)} \le e^{\nu t} e^{|\nu|}$, again because $0 \le t - k < 1$. So the constant

$$C = C_0\, e^{\|\mathbf{A}\| + |\nu|} \ge 1$$

works for every $t \ge 0$.

For the last statement, suppose $\mathbf{A}$ is stable, so $\mu < 0$, and choose $\nu \in (\mu, 0)$. By Theorem 9.9.6 the unique solution with the given initial value is $\mathbf{x}(t) = e^{t\mathbf{A}}\mathbf{x}(0)$, so $\|\mathbf{x}(t)\| \le \|e^{t\mathbf{A}}\|\|\mathbf{x}(0)\| \le Ce^{\nu t}\|\mathbf{x}(0)\|$ by Theorem 15.3.2 (a). Since $\nu < 0$, $e^{\nu t} \to 0$ as $t \to \infty$ — this is fact (A5) of Chapter 9 §09 with $j = 0$, quoted there and quoted again here — so $\|\mathbf{x}(t)\| \to 0$, and by Corollary 15.2.4 the vectors $\mathbf{x}(t)$ tend to $\mathbf{0}$. This proves the theorem.

■

Example. (Decay after a detour)

Let $\mathbf{A} = \begin{pmatrix} -1 & 5 \\ 0 & -1 \end{pmatrix}$. Find μ, compute $\|e^{t\mathbf{A}}\|_\infty$ exactly, and find the smallest constant C that works in Theorem 15.6.3 for $\nu = -\frac{1}{2}$.

Solution. The eigenvalues. $\mathbf{A}$ is upper triangular with both diagonal entries -1, so $\operatorname{spec}(\mathbf{A}) = \{-1\}$ (Theorem 8.7.4 (b)) and $\mu = -1 < 0$: the matrix is stable.

The exponential. Write $\mathbf{A} = -\mathbf{I} + 5\mathbf{N}$ with $\mathbf{N} = \left(\begin{smallmatrix} 0 & 1 \\ 0 & 0 \end{smallmatrix}\right)$. The two summands commute and $\mathbf{N}^2 = 0$, so Corollary 9.9.5 gives

$$e^{t\mathbf{A}} = e^{-t}(\mathbf{I} + 5t\mathbf{N}) = e^{-t} \begin{pmatrix} 1 & 5t \\ 0 & 1 \end{pmatrix}.$$

The absolute row sums are $e^{-t}(1 + 5t)$ and e^{-t}, so $\|e^{t\mathbf{A}}\|_\infty = e^{-t}(1 + 5t)$ for $t \ge 0$ by Theorem 15.3.3 (b).

The transient. The function $t \mapsto e^{-t}(1 + 5t)$ has derivative $e^{-t}(4 - 5t)$, so it **rises** from 1 at $t = 0$ to $5e^{-4/5} \approx 2.247$ at $t = \frac{4}{5}$, and only then decays. A stable matrix does not decay from the start.

The constant. We need the smallest C with $e^{-t}(1 + 5t) \le Ce^{-t/2}$ for all $t \ge 0$, that is, $C = \max_{t \ge 0}(1 + 5t)e^{-t/2}$. The derivative of $(1 + 5t)e^{-t/2}$ is $e^{-t/2}\big(5 - \frac{1}{2}(1 + 5t)\big)$, which is positive for $t < \frac{9}{5}$ and negative for $t > \frac{9}{5}$, so by fact (A6) of the chapter introduction the maximum is at $t = \frac{9}{5}$ and

$$C = 10\, e^{-9/10} \approx 4.066.$$

The rate $e^{-t/2}$ is honest and the constant pays for the hump.

Remark. **What this settles from Chapter 11 §10, and what it does not.** That section introduced the Lyapunov equation $\mathbf{AX} + \mathbf{XA}^* = -\mathbf{Q}$ and the word *stable* (Definition 11.10.2). It then stated, without proof, that a stable $\mathbf{A}$ and a positive definite $\mathbf{Q}$ produce a positive definite solution $\mathbf{X}$, and conversely; it assigned the positivity half to Chapter 12, and assigned to this chapter "the consequence for differential equations — that a stable $\mathbf{A}$ makes every solution of $\dot{\mathbf{x}} = \mathbf{Ax}$ decay, with $\mathbf{x}^*\mathbf{Xx}$ as the quantity that measures the decay".

Theorem 15.6.3 delivers the decay, with a rate, and does so without the Lyapunov equation at all. What it does not deliver is the existence of a positive definite $\mathbf{X}$ for a stable $\mathbf{A}$: that statement is not proved anywhere in this book, and nothing here depends on it. What can be said cheaply is the other half of the connection: **any** positive definite $\mathbf{X}$ satisfying $\mathbf{A}^*\mathbf{X} + \mathbf{XA} = -\mathbf{Q}$ with $\mathbf{Q} \succ 0$ does measure the decay, in the sense that $\mathbf{x}^*\mathbf{Xx}$ is strictly decreasing along every non-zero solution of $\mathbf{x}' = \mathbf{Ax}$. That is Exercise (C3: A quantity that measures the decay), and it is three lines once the product rule below is available. Note the transpose: the equation the decay computation wants is Definition 11.10.2 for the pair $(\mathbf{A}^*, \mathbf{Q})$, and $\mathbf{A}$ is stable if and only if $\mathbf{A}^*$ is, since the eigenvalues of $\mathbf{A}^*$ are the conjugates of those of $\mathbf{A}$.

15.6.3 Differentiating a matrix-valued function

A matrix whose entries vary — a family $\mathbf{A}(t)$, a curve in $M_n(F)$ — is differentiated entrywise, exactly as Chapter 9 §09 differentiated $t \mapsto e^{t\mathbf{A}}$. The two derivatives this book needs later, of det and of inversion, are algebraic facts with one analytic ingredient, and the ingredient is named first.

Definition 15.6.1 — Derivative of a Matrix-Valued Function

Let $I \subseteq \mathbb{R}$ be an open interval and $\mathbf{A}\colon I \to M_{m\times n}(\mathbb{C})$, written $\mathbf{A}(t) = (a_{ij}(t))$. Call $\mathbf{A}$ **differentiable** at $t_0 \in I$ if every entry function $a_{ij}\colon I \to \mathbb{C}$ is differentiable at t_0, and then set

$$\mathbf{A}'(t_0) := \big(a_{ij}'(t_0)\big) \in M_{m\times n}(\mathbb{C}).$$

The prime here always means the derivative in t; no dual map (Definition 4.4.1) appears anywhere in this section, so the notation cannot collide. By Corollary 15.2.4 the definition can be restated without coordinates: $\mathbf{A}$ is differentiable at t_0 with derivative $\mathbf{B}$ exactly when

$$\Big\| \frac{\mathbf{A}(t) - \mathbf{A}(t_0)}{t - t_0} - \mathbf{B} \Big\| \longrightarrow 0 \qquad (t \to t_0),$$

in any norm at all. Both readings are used below, the entrywise one to import calculus and the norm one to take limits.

Remark. **The calculus this section quotes.** Let $f, g\colon I \to \mathbb{C}$ be differentiable at t_0.

(D1) *(Linearity and the product rule.)* $f+g$ and fg are differentiable at t_0, with $(f+g)' = f' + g'$ and $(fg)' = f'g + fg'$; a constant function has derivative 0.

(D2) *(Differentiable implies continuous.)* f is continuous at t_0.

Neither is proved here. (D1) is Chapter 9 §09's fact (A3), read for complex-valued functions of a real variable; (D2) is one more standard fact of the same kind, quoted here for the first time in this book. Both are of a piece with Chapter 13 §06's Taylor assumption: standard one-variable calculus, quoted so that the theorems below have hypotheses to stand on. Everything that follows them is linear algebra.

Lemma 15.6.4 — Product Rule for Matrices

Let $\mathbf{A}\colon I \to M_{m\times n}(\mathbb{C})$ and $\mathbf{B}\colon I \to M_{n\times p}(\mathbb{C})$ be differentiable at t_0. Then so is $t \mapsto \mathbf{A}(t)\mathbf{B}(t)$, with

$$(\mathbf{AB})'(t_0) = \mathbf{A}'(t_0)\mathbf{B}(t_0) + \mathbf{A}(t_0)\mathbf{B}'(t_0).$$

Proof. Fix a position (i,k). The entry function is $t \mapsto \sum_{j=1}^{n} a_{ij}(t)b_{jk}(t)$, a finite sum of products of functions differentiable at t_0. By (D1) it is differentiable at t_0 with derivative

$$\sum_{j=1}^{n}\big(a'_{ij}(t_0)b_{jk}(t_0) + a_{ij}(t_0)b'_{jk}(t_0)\big),$$

which is the (i,k)-entry of $\mathbf{A}'(t_0)\mathbf{B}(t_0) + \mathbf{A}(t_0)\mathbf{B}'(t_0)$. Since this holds at every position, Definition 15.6.1 gives the claim. Note that the order of the factors is preserved throughout: matrices do not commute, and the product rule must not be written $2\mathbf{AA}'$ even for $\mathbf{B} = \mathbf{A}$. This proves the lemma.

■

15.6.4 The derivative of the inverse

Nothing so far says that $t \mapsto \mathbf{A}(t)^{-1}$ is even defined near t_0, let alone differentiable. Both come from §05.

Theorem 15.6.5 — Derivative of the Inverse

Let $\mathbf{A}\colon I \to M_n(\mathbb{C})$ be differentiable at $t_0 \in I$, with $\mathbf{A}(t_0)$ invertible. Then $\mathbf{A}(t)$ is invertible for all t in some open interval around t_0, the function $t \mapsto \mathbf{A}(t)^{-1}$ is differentiable at t_0, and

$$\big(\mathbf{A}^{-1}\big)'(t_0) = -\,\mathbf{A}(t_0)^{-1}\,\mathbf{A}'(t_0)\,\mathbf{A}(t_0)^{-1}.$$

Idea. The formula is what one gets by differentiating $\mathbf{AA}^{-1} = \mathbf{I}$ with Lemma 15.6.4 and solving — but that argument presupposes what has to be proved, namely that $\mathbf{A}^{-1}$ is differentiable. So run it in the honest order. The difference of two inverses factors as $\mathbf{X}^{-1} - \mathbf{Y}^{-1} = \mathbf{X}^{-1}(\mathbf{Y} - \mathbf{X})\mathbf{Y}^{-1}$; divide by $t - t_0$ and the middle factor becomes a difference quotient, which converges by hypothesis, while the outer factor converges because inversion is continuous (Corollary 15.5.2). The limit of the product is the product of the limits, and that is the formula.

Proof. Write $\mathbf{A}_0 = \mathbf{A}(t_0)$. By (D2) every entry of $\mathbf{A}$ is continuous at t_0, so $\mathbf{A}(t) \to \mathbf{A}_0$ entrywise as $t \to t_0$, hence $\|\mathbf{A}(t) - \mathbf{A}_0\| \to 0$ by Corollary 15.2.4. By Corollary 15.5.2 there is therefore an open interval $J \ni t_0$ on which $\|\mathbf{A}(t) - \mathbf{A}_0\| < 1/\|\mathbf{A}_0^{-1}\|$, so that $\mathbf{A}(t)$ is invertible for $t \in J$, and on which $\|\mathbf{A}(t)^{-1} - \mathbf{A}_0^{-1}\| \to 0$ as $t \to t_0$.

Let $t \in J$ with $t \neq t_0$. Multiplying $\mathbf{A}_0 - \mathbf{A}(t)$ on the left by $\mathbf{A}(t)^{-1}$ and on the right by $\mathbf{A}_0^{-1}$,

$$\mathbf{A}(t)^{-1} - \mathbf{A}_0^{-1} = -\,\mathbf{A}(t)^{-1}\big(\mathbf{A}(t) - \mathbf{A}_0\big)\mathbf{A}_0^{-1}.$$

Divide by $t - t_0$:

$$\frac{\mathbf{A}(t)^{-1} - \mathbf{A}_0^{-1}}{t - t_0} = -\,\mathbf{A}(t)^{-1}\,\frac{\mathbf{A}(t) - \mathbf{A}_0}{t - t_0}\,\mathbf{A}_0^{-1}.$$

As $t \to t_0$ the middle factor tends to $\mathbf{A}'(t_0)$, by Definition 15.6.1. The left factor tends to $\mathbf{A}_0^{-1}$, by the first paragraph. Products of convergent matrix families converge to the product of the limits: if $\|\mathbf{X}(t) - \mathbf{X}\| \to 0$ and $\|\mathbf{Y}(t) - \mathbf{Y}\| \to 0$ then

$$\|\mathbf{X}(t)\mathbf{Y}(t) - \mathbf{X}\mathbf{Y}\| \le \|\mathbf{X}(t) - \mathbf{X}\|\|\mathbf{Y}(t)\| + \|\mathbf{X}\|\|\mathbf{Y}(t) - \mathbf{Y}\|,$$

and $\|\mathbf{Y}(t)\|$ is bounded near t_0 because $\|\mathbf{Y}(t)\| \le \|\mathbf{Y}\| + \|\mathbf{Y}(t) - \mathbf{Y}\|$. Applying this twice, the right-hand side converges to $-\mathbf{A}_0^{-1}\mathbf{A}'(t_0)\mathbf{A}_0^{-1}$. Hence the difference quotient on the left converges, which by Definition 15.6.1 is exactly the differentiability of $t \mapsto \mathbf{A}(t)^{-1}$ at t_0, with the stated derivative. This proves the theorem.

■

Warning. **The two copies of $\mathbf{A}^{-1}$ sit on either side and cannot be combined.** The scalar formula $(1/a)' = -a'/a^2$ tempts one to write $-\mathbf{A}^{-2}\mathbf{A}'$, and that is wrong unless $\mathbf{A}'(t_0)$ commutes with $\mathbf{A}(t_0)$. For $\mathbf{A}(t) = \left(\begin{smallmatrix} 1 & t \\ 0 & 2 \end{smallmatrix}\right)$ at $t = 0$: we have $\mathbf{A}(0)^{-1} = \operatorname{diag}(1, \tfrac{1}{2})$ and $\mathbf{A}'(0) = \left(\begin{smallmatrix} 0 & 1 \\ 0 & 0 \end{smallmatrix}\right)$, so the correct answer is $-\operatorname{diag}(1, \tfrac{1}{2})\left(\begin{smallmatrix} 0 & 1 \\ 0 & 0 \end{smallmatrix}\right)\operatorname{diag}(1, \tfrac{1}{2}) = \left(\begin{smallmatrix} 0 & -1/2 \\ 0 & 0 \end{smallmatrix}\right)$, whereas $-\mathbf{A}(0)^{-2}\mathbf{A}'(0) = -\left(\begin{smallmatrix} 1 & 0 \\ 0 & 1/4 \end{smallmatrix}\right)\left(\begin{smallmatrix} 0 & 1 \\ 0 & 0 \end{smallmatrix}\right) = \left(\begin{smallmatrix} 0 & -1 \\ 0 & 0 \end{smallmatrix}\right)$.

15.6.5 Jacobi's formula

The determinant is a polynomial in the entries, so differentiating it needs no analysis beyond (D1); the work is in recognizing the answer.

Theorem 15.6.6 — Jacobi's Formula

Let $\mathbf{A}\colon I \to M_n(\mathbb{C})$ be differentiable at $t_0 \in I$. Then $t \mapsto \det \mathbf{A}(t)$ is differentiable at t_0, with

$$\frac{d}{dt}\Big|_{t_0} \det \mathbf{A}(t) = \operatorname{tr}\big(\operatorname{adj} \mathbf{A}(t_0)\, \mathbf{A}'(t_0)\big).$$

If moreover $\mathbf{A}(t_0)$ is invertible, this equals $\det \mathbf{A}(t_0)\, \operatorname{tr}\big(\mathbf{A}(t_0)^{-1}\mathbf{A}'(t_0)\big)$.

Idea. Use the Leibniz formula, which writes det as a sum of $n!$ products of n entries, one from each column. The product rule differentiates each such product into n terms, the j-th of which has column j differentiated and the rest untouched. Collecting by j gives n determinants, the j-th being $\mathbf{A}$ with its j-th column replaced by $\mathbf{a}_j'$. Expanding that

determinant along column j (Theorem 6.6.1) produces $\sum_i a'_{ij}C_{ij}$, and summing over j gives a double sum which is precisely a trace against the adjugate.

Proof. For $n = 1$ the statement reads $\frac{d}{dt}\big|_{t_0} a_{11}(t) = a'_{11}(t_0)$, since $\operatorname{adj}\mathbf{A} = (1)$ by Definition 6.6.2, so assume $n \geq 2$; that is what lets us speak of cofactors. Write $\mathbf{A}(t) = (a_{ij}(t))$ with columns $\mathbf{a}_1(t), \dots, \mathbf{a}_n(t)$, and write C_{ij} for the cofactors of $\mathbf{A}(t_0)$ (Definition 6.6.1). By Theorem 6.4.3,

$$\det \mathbf{A}(t) = \sum_{\sigma \in S_n} \operatorname{sgn}(\sigma)\, a_{\sigma(1)1}(t) \cdots a_{\sigma(n)n}(t),$$

a finite sum of products of n functions each differentiable at t_0. By (D1), applied $n-1$ times to each product and then to the sum, $\det \mathbf{A}$ is differentiable at t_0 with

$$\frac{d}{dt}\Big|_{t_0} \det \mathbf{A} = \sum_{j=1}^{n} \sum_{\sigma \in S_n} \operatorname{sgn}(\sigma)\, a'_{\sigma(j)j}(t_0) \prod_{l \neq j} a_{\sigma(l)l}(t_0),$$

where the outer sum collects, for each j, the terms in which the j-th factor was the one differentiated. By Theorem 6.4.3 read backwards, the inner sum is the determinant of the matrix $\mathbf{A}_j$ obtained from $\mathbf{A}(t_0)$ by replacing its j-th column with $\mathbf{a}'_j(t_0)$. Expanding $\det \mathbf{A}_j$ along that column with Theorem 6.6.1 (a), and using that the cofactors of column j do not involve column j and are therefore the cofactors C_{ij} of $\mathbf{A}(t_0)$ itself,

$$\det \mathbf{A}_j = \sum_{i=1}^{n} a'_{ij}(t_0)\, C_{ij}.$$

Summing over j,

$$\frac{d}{dt}\Big|_{t_0} \det \mathbf{A} = \sum_{j=1}^{n} \sum_{i=1}^{n} C_{ij}\, a'_{ij}(t_0).$$

It remains to recognize the right-hand side. By Definition 6.6.2, $(\operatorname{adj}\mathbf{A}(t_0))_{ji} = C_{ij}$, so

$$\operatorname{tr}\big(\operatorname{adj}\mathbf{A}(t_0)\, \mathbf{A}'(t_0)\big) = \sum_{j=1}^{n} \sum_{i=1}^{n} (\operatorname{adj}\mathbf{A}(t_0))_{ji}\, a'_{ij}(t_0),$$

which is the same double sum. For the last claim, if $\mathbf{A}(t_0)$ is invertible then $\operatorname{adj}\mathbf{A}(t_0) = \det \mathbf{A}(t_0)\, \mathbf{A}(t_0)^{-1}$ by Theorem 6.6.2, and the trace is linear (Theorem 0.9.6), so the scalar $\det \mathbf{A}(t_0)$ comes out in front. This proves the theorem.

■

Corollary 15.6.7 — The Determinant's Derivative at the Identity Is the Trace

For every $\mathbf{B} \in M_n(\mathbb{C})$,

$$\frac{d}{dt}\Big|_{t=0} \det(\mathbf{I} + t\mathbf{B}) = \operatorname{tr}\mathbf{B}.$$

Proof. Apply Theorem 15.6.6 to $\mathbf{A}(t) = \mathbf{I} + t\mathbf{B}$, which is differentiable with $\mathbf{A}'(t) = \mathbf{B}$ and $\mathbf{A}(0) = \mathbf{I}$. Since $\mathbf{I}$ is invertible with $\mathbf{I}^{-1} = \mathbf{I}$ and $\det \mathbf{I} = 1$, the second form of the

formula gives $\operatorname{tr}(\mathbf{IB}) = \operatorname{tr}\mathbf{B}$.

■

So the determinant, which is a product of n numbers, has the trace, a sum of n numbers, as its linearization at $\mathbf{I}$. That is the honest source of the identity $\det e^{\mathbf{A}} = e^{\operatorname{tr}\mathbf{A}}$ of Theorem 9.9.4 (e), and Exercise (C1: The determinant of the exponential, again) reproves that identity along these lines.

Example. (Both derivatives on one family)

Let $\mathbf{A}(t) = \begin{pmatrix} 1+t & t^2 \\ t & 1 \end{pmatrix}$.

(a) Compute $\frac{d}{dt}\det\mathbf{A}(t)$ directly and by Theorem 15.6.6.

(b) Compute $(\mathbf{A}^{-1})'(0)$ by Theorem 15.6.5, and check it against a direct expansion.

Solution.

(a) *Directly.* $\det\mathbf{A}(t) = (1+t)\cdot 1 - t^2\cdot t = 1 + t - t^3$, so the derivative is $1 - 3t^2$.
By the formula. $\operatorname{adj}\mathbf{A}(t) = \left(\begin{smallmatrix} 1 & -t^2 \\ -t & 1+t \end{smallmatrix}\right)$ (Definition 6.6.2) and $\mathbf{A}'(t) = \left(\begin{smallmatrix} 1 & 2t \\ 1 & 0 \end{smallmatrix}\right)$, so

$$\operatorname{adj}\mathbf{A}(t)\,\mathbf{A}'(t) = \begin{pmatrix} 1-t^2 & 2t \\ 1 & -2t^2 \end{pmatrix},$$

whose trace is $1 - t^2 - 2t^2 = 1 - 3t^2$. The two agree.

(b) $\mathbf{A}(0) = \mathbf{I}$ and $\mathbf{A}'(0) = \left(\begin{smallmatrix} 1 & 0 \\ 1 & 0 \end{smallmatrix}\right)$, so Theorem 15.6.5 gives

$$(\mathbf{A}^{-1})'(0) = -\mathbf{I}\begin{pmatrix} 1 & 0 \\ 1 & 0 \end{pmatrix}\mathbf{I} = \begin{pmatrix} -1 & 0 \\ -1 & 0 \end{pmatrix}.$$

Check. $\mathbf{A}(t)^{-1} = \dfrac{1}{1+t-t^3}\left(\begin{smallmatrix} 1 & -t^2 \\ -t & 1+t \end{smallmatrix}\right)$. Near $t = 0$ the scalar factor is $1 - t + (\text{terms in } t^2)$, so

$$\mathbf{A}(t)^{-1} = \begin{pmatrix} 1-t & 0 \\ -t & 1 \end{pmatrix} + (\text{terms in } t^2),$$

whose derivative at 0 is $\left(\begin{smallmatrix} -1 & 0 \\ -1 & 0 \end{smallmatrix}\right)$, as predicted. The formula did the work that the quotient rule would otherwise have had to do four times.

Quick check. Theorem 15.6.6 holds with no invertibility hypothesis, yet the second form of the formula has one. Where exactly is invertibility used, and what does the formula say at a t_0 where $\det\mathbf{A}(t_0) = 0$?

Solution. Only in the last line, where $\operatorname{adj}\mathbf{A}(t_0)$ is rewritten as $\det\mathbf{A}(t_0)\mathbf{A}(t_0)^{-1}$. The adjugate itself is defined for every square matrix (Definition 6.6.2), so the first form survives. At a t_0 with $\det\mathbf{A}(t_0) = 0$ it still gives a number: for $\mathbf{A}(t) = \operatorname{diag}(t, t)$ at $t_0 = 0$ we get $\operatorname{adj}\mathbf{A}(0) = 0$, so the derivative of $\det\mathbf{A}(t) = t^2$ is 0 there, which is correct. The second form would read "0 times something undefined".

15.6.6 Exercises

15.6.6.1 A. Check your understanding

Exercise A1.

(a) State the three bounds of Theorem 15.6.1, and say which property of the norm each one needs.

(b) Determine whether the following statement is correct, and justify your answer: if $\|\mathbf{A}\|_2$ is large then $\|e^{\mathbf{A}}\|_2$ is large.

(c) State Theorem 15.6.3, and say what the constant C is paying for.

(d) State Jacobi's formula (Theorem 15.6.6), and name the fact from calculus its proof quotes.

(e) Write down the derivative of $t \mapsto \mathbf{A}(t)^{-1}$ and explain in one sentence why it is not $-\mathbf{A}^{-2}\mathbf{A}'$.

Solution.

(a) $\|e^{\mathbf{A}}\| \le e^{\|\mathbf{A}\|}$, $\|e^{\mathbf{A}}-\mathbf{I}\| \le e^{\|\mathbf{A}\|}-1$, and $\|e^{\mathbf{A}}-\mathbf{I}-\mathbf{A}\| \le e^{\|\mathbf{A}\|}-1-\|\mathbf{A}\| \le \|\mathbf{A}\|^2 e^{\|\mathbf{A}\|}/2$. All three need subadditivity (to bound a sum term by term) and submultiplicativity (to get $\|\mathbf{A}^m\| \le \|\mathbf{A}\|^m$); the first also needs $\|\mathbf{I}\| = 1$, which is what makes the $m = 0$ term equal 1.

(b) Incorrect. For $\mathbf{A} = t\left(\begin{smallmatrix} 0 & 1 \\ -1 & 0 \end{smallmatrix}\right)$ we have $\|\mathbf{A}\|_2 = t$, arbitrarily large, while $e^{\mathbf{A}}$ is a rotation matrix and $\|e^{\mathbf{A}}\|_2 = 1$ (Example (Where the bound is exact, and where it is useless)).

(c) If μ is the largest real part of an eigenvalue of $\mathbf{A}$ and $\nu > \mu$, there is $C \ge 1$ with $\|e^{t\mathbf{A}}\| \le Ce^{\nu t}$ for all $t \ge 0$. The constant pays for the transient: $\|e^{t\mathbf{A}}\|$ may first grow, as in Example (Decay after a detour), and it also pays for the gap between ν and μ.

(d) $\frac{d}{dt}\det \mathbf{A}(t) = \operatorname{tr}(\operatorname{adj} \mathbf{A}(t)\, \mathbf{A}'(t))$, for a matrix-valued $\mathbf{A}$ differentiable at t. The quoted fact is (D1): the linearity of differentiation and the product rule for complex-valued functions of a real variable.

(e) $(\mathbf{A}^{-1})' = -\mathbf{A}^{-1}\mathbf{A}'\mathbf{A}^{-1}$. The two copies of $\mathbf{A}^{-1}$ sit on opposite sides of $\mathbf{A}'$, and matrices do not commute, so they may not be collected into $\mathbf{A}^{-2}$ unless $\mathbf{A}'$ commutes with $\mathbf{A}$.

15.6.6.2 B. Practice

Exercise B1: Bound against truth.

For each matrix, compute $\|e^{\mathbf{A}}\|_\infty$ exactly and compare with $e^{\|\mathbf{A}\|_\infty}$.

(a) $\mathbf{A} = \begin{pmatrix} 0 & 3 \\ 0 & 0 \end{pmatrix}$.

(b) $\mathbf{A} = \operatorname{diag}(1, -4)$.

Solution.

(a) $\mathbf{A}^2 = 0$, so the series stops: $e^{\mathbf{A}} = \mathbf{I} + \mathbf{A} = \left(\begin{smallmatrix} 1 & 3 \\ 0 & 1 \end{smallmatrix}\right)$, with $\|e^{\mathbf{A}}\|_\infty = 4$. Also $\|\mathbf{A}\|_\infty = 3$, so the bound is $e^3 \approx 20.09$. Correct, and loose by a factor of about 5.

(b) $e^{\mathbf{A}} = \operatorname{diag}(e, e^{-4})$, so $\|e^{\mathbf{A}}\|_\infty = e \approx 2.718$. Here $\|\mathbf{A}\|_\infty = 4$ and the bound is $e^4 \approx 54.6$. The bound is governed by the entry of largest modulus, -4, while the exponential is governed by the largest **real part**, 1. This is the discrepancy Theorem 15.6.3 exists to remove.

Exercise B2: A rate for a stable matrix.

Let $\mathbf{A} = \begin{pmatrix} -2 & 4 \\ 0 & -2 \end{pmatrix}$.

(a) Compute μ and $e^{t\mathbf{A}}$, and give $\|e^{t\mathbf{A}}\|_\infty$ for $t \geq 0$.

(b) Find the largest value of $\|e^{t\mathbf{A}}\|_\infty$ on $t \geq 0$.

(c) Find the smallest C that works in Theorem 15.6.3 for $\nu = -1$.

Solution.

(a) $\mathbf{A}$ is upper triangular with diagonal $-2, -2$, so $\operatorname{spec}(\mathbf{A}) = \{-2\}$ (Theorem 8.7.4 (b)) and $\mu = -2$. Writing $\mathbf{A} = -2\mathbf{I} + 4\mathbf{N}$ with $\mathbf{N} = \left(\begin{smallmatrix} 0 & 1 \\ 0 & 0 \end{smallmatrix}\right)$, the summands commute and $\mathbf{N}^2 = 0$, so by Corollary 9.9.5

$$e^{t\mathbf{A}} = e^{-2t}\begin{pmatrix} 1 & 4t \\ 0 & 1 \end{pmatrix}, \qquad \|e^{t\mathbf{A}}\|_\infty = e^{-2t}(1 + 4t).$$

(b) The derivative of $e^{-2t}(1+4t)$ is $e^{-2t}(4 - 2 - 8t) = e^{-2t}(2 - 8t)$, which is positive for $t < \frac{1}{4}$ and negative after, so by fact (A6) the maximum is at $t = \frac{1}{4}$. The value there is $2e^{-1/2} \approx 1.213$.

(c) We need the smallest C with $e^{-2t}(1+4t) \leq Ce^{-t}$, that is, $C = \max_{t \geq 0}(1+4t)e^{-t}$. Its derivative is $e^{-t}(4 - 1 - 4t) = e^{-t}(3 - 4t)$, positive for $t < \frac{3}{4}$ and negative after, so by fact (A6) the maximum is at $t = \frac{3}{4}$ and $C = 4e^{-3/4} \approx 1.890$.

Exercise B3: Two derivatives.

Let $\mathbf{A}(t) = \begin{pmatrix} \cos t & -\sin t \\ \sin t & \cos t \end{pmatrix}$.

(a) Compute $\frac{d}{dt} \det \mathbf{A}(t)$ by Theorem 15.6.6 and check it against the exact value of $\det \mathbf{A}(t)$.

(b) Compute $(\mathbf{A}^{-1})'(t)$ by Theorem 15.6.5 and check it by differentiating $\mathbf{A}(t)^{-1}$ directly.

Solution.

(a) $\det \mathbf{A}(t) = \cos^2 t + \sin^2 t = 1$, so the derivative is 0. By the formula: $\operatorname{adj} \mathbf{A}(t) = \left(\begin{smallmatrix} \cos t & \sin t \\ -\sin t & \cos t \end{smallmatrix}\right)$ and $\mathbf{A}'(t) = \left(\begin{smallmatrix} -\sin t & -\cos t \\ \cos t & -\sin t \end{smallmatrix}\right)$, so

$$\operatorname{adj} \mathbf{A}(t)\mathbf{A}'(t) = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix},$$

whose trace is 0. The two agree. (The diagonal entries are $-\cos t \sin t + \sin t \cos t$ and $\sin t \cos t - \cos t \sin t$, both zero.)

(b) Since $\det \mathbf{A}(t) = 1$, $\mathbf{A}(t)^{-1} = \operatorname{adj} \mathbf{A}(t) = \left(\begin{smallmatrix} \cos t & \sin t \\ -\sin t & \cos t \end{smallmatrix}\right)$, whose entrywise derivative is $\left(\begin{smallmatrix} -\sin t & \cos t \\ -\cos t & -\sin t \end{smallmatrix}\right)$. By the formula, using the product $\operatorname{adj} \mathbf{A}(t)\mathbf{A}'(t)$ computed in (a),

$$-\mathbf{A}^{-1}\mathbf{A}'\mathbf{A}^{-1} = -\begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}\begin{pmatrix} \cos t & \sin t \\ -\sin t & \cos t \end{pmatrix} = \begin{pmatrix} -\sin t & \cos t \\ -\cos t & -\sin t \end{pmatrix}.$$

The two agree.

15.6.6.3 C. Going deeper

Exercise C1: The determinant of the exponential, again.

Let $\mathbf{A} \in M_n(\mathbb{C})$ and put $\varphi(t) = \det e^{t\mathbf{A}}$.

(a) Prove that φ is differentiable with $\varphi'(t) = (\operatorname{tr} \mathbf{A})\varphi(t)$.

(b) Hence deduce $\det e^{\mathbf{A}} = e^{\operatorname{tr} \mathbf{A}}$, recovering Theorem 9.9.4 (e).

Hint for (b): consider $\psi(t) = e^{-t \operatorname{tr} \mathbf{A}}\varphi(t)$.

Solution.

(a) The function $t \mapsto e^{t\mathbf{A}}$ is differentiable with derivative $\mathbf{A}e^{t\mathbf{A}}$ (Theorem 9.9.4 (b)), and $e^{t\mathbf{A}}$ is invertible with inverse $e^{-t\mathbf{A}}$ (Theorem 9.9.4 (c)). So Theorem 15.6.6 applies in its second form:

$$\varphi'(t) = \det(e^{t\mathbf{A}}) \operatorname{tr}\big(e^{-t\mathbf{A}}\mathbf{A}e^{t\mathbf{A}}\big).$$

By Theorem 0.9.6 (3) with the two factors $e^{-t\mathbf{A}}$ and $\mathbf{A}e^{t\mathbf{A}}$, we get $\operatorname{tr}(e^{-t\mathbf{A}}\mathbf{A}e^{t\mathbf{A}}) = \operatorname{tr}(\mathbf{A}e^{t\mathbf{A}}e^{-t\mathbf{A}}) = \operatorname{tr} \mathbf{A}$, giving $\varphi'(t) = (\operatorname{tr} \mathbf{A})\varphi(t)$.

(b) Put $c = \operatorname{tr} \mathbf{A}$ and $\psi(t) = e^{-ct}\varphi(t)$. By the product rule (D1) and (a),

$$\psi'(t) = -c\, e^{-ct}\varphi(t) + e^{-ct} c\, \varphi(t) = 0$$

for every t, where $\frac{d}{dt}e^{-ct} = -ce^{-ct}$ is Theorem 9.9.4 (b) in the case $n = 1$. A differentiable function with vanishing derivative is constant — fact (A4) of Chapter 9 §09 — so $\psi(t) = \psi(0) = \det(e^0) = \det \mathbf{I} = 1$. Hence $\varphi(t) = e^{ct}$, and $t = 1$ gives $\det e^{\mathbf{A}} = e^{\operatorname{tr} \mathbf{A}}$.

Exercise C2: Comparing two exponentials.

Let $\mathbf{A}, \mathbf{B} \in M_n(\mathbb{C})$ with $\mathbf{AB} = \mathbf{BA}$.

(a) Prove that $\|e^{\mathbf{A}} - e^{\mathbf{B}}\| \le e^{\|\mathbf{B}\|}\big(e^{\|\mathbf{A}-\mathbf{B}\|} - 1\big)$.

(b) Deduce that $\mathbf{M} \mapsto e^{\mathbf{M}}$ is continuous at every $\mathbf{M}$ that commutes with a neighborhood of itself, and identify those $\mathbf{M}$: they are exactly the scalar matrices $c\mathbf{I}$.

(c) Say exactly where the commuting hypothesis is used, and why the argument cannot simply be dropped.

Solution.

(a) Since $\mathbf{A}$ and $\mathbf{B}$ commute, so do $\mathbf{B}$ and $\mathbf{A}-\mathbf{B}$. By Theorem 9.9.4 (d), $e^{\mathbf{A}} = e^{\mathbf{B}+(\mathbf{A}-\mathbf{B})} = e^{\mathbf{B}}e^{\mathbf{A}-\mathbf{B}}$. Hence

$$e^{\mathbf{A}} - e^{\mathbf{B}} = e^{\mathbf{B}}\big(e^{\mathbf{A}-\mathbf{B}} - \mathbf{I}\big),$$

and submultiplicativity with Theorem 15.6.1 (a) and (b) gives

$$\|e^{\mathbf{A}} - e^{\mathbf{B}}\| \le \|e^{\mathbf{B}}\|\,\|e^{\mathbf{A}-\mathbf{B}} - \mathbf{I}\| \le e^{\|\mathbf{B}\|}\big(e^{\|\mathbf{A}-\mathbf{B}\|} - 1\big).$$

(b) Take $\mathbf{B} = c\mathbf{I}$, which commutes with every matrix. For $\mathbf{A}$ with $\|\mathbf{A} - c\mathbf{I}\| = \delta$, part (a) gives $\|e^{\mathbf{A}} - e^{c}\mathbf{I}\| \le e^{|c|}(e^{\delta} - 1)$, and $e^{\delta} - 1 \to 0$ as $\delta \to 0$, because $t \mapsto e^{t}$ is differentiable by fact (A2) of Chapter 9 §09 and so continuous at 0. So $e^{\mathbf{A}} \to e^{c\mathbf{I}}$ as $\mathbf{A} \to c\mathbf{I}$.

(c) Only in the first line, where $e^{\mathbf{B}+(\mathbf{A}-\mathbf{B})}$ is split as $e^{\mathbf{B}}e^{\mathbf{A}-\mathbf{B}}$; Theorem 9.9.4 (d) has commutation as a hypothesis, and Chapter 9 §09 exhibits matrices with $e^{\mathbf{A}+\mathbf{B}} \neq e^{\mathbf{A}}e^{\mathbf{B}}$. Without it there is no factorization to take norms of, and a different argument is needed. (The inequality itself is in fact true in general, but proving it needs an integral representation of $e^{\mathbf{A}} - e^{\mathbf{B}}$, which this book does not have.)

Exercise C3: A quantity that measures the decay.

Let $\mathbf{A}, \mathbf{X}, \mathbf{Q} \in M_n(\mathbb{C})$ with $\mathbf{X}$ and $\mathbf{Q}$ positive definite (Definition 12.1.1) and

$$\mathbf{A}^{*}\mathbf{X} + \mathbf{X}\mathbf{A} = -\mathbf{Q}.$$

Let $\mathbf{x}\colon \mathbb{R} \to \mathbb{C}^n$ be differentiable with $\mathbf{x}' = \mathbf{A}\mathbf{x}$, and put $V(t) = \mathbf{x}(t)^{*}\mathbf{X}\mathbf{x}(t)$.

(a) Prove that V is real-valued and differentiable, with $V'(t) = \mathbf{x}(t)^{*}(\mathbf{A}^{*}\mathbf{X}+\mathbf{X}\mathbf{A})\mathbf{x}(t)$.

(b) Deduce that if $\mathbf{x}(0) \neq \mathbf{0}$, then V is strictly decreasing.

(c) Explain how this relates to the Lyapunov equation of Definition 11.10.2, whose unknown sits between $\mathbf{A}$ and $\mathbf{A}^{*}$ the other way round.

Hint for (a): $\mathbf{x}^{*}$ is a $1 \times n$ matrix-valued function, and $\overline{f}' = \overline{f'}$ for a differentiable $f\colon \mathbb{R} \to \mathbb{C}$.

Solution.

(a) $V(t)$ is a 1×1 matrix, and $V(t)^{*} = \mathbf{x}^{*}\mathbf{X}^{*}\mathbf{x} = \mathbf{x}^{*}\mathbf{X}\mathbf{x} = V(t)$ since $\mathbf{X}$ is Hermitian, so $V(t)$ is real. Each entry of $t \mapsto \mathbf{x}(t)^{*}$ is the conjugate of an entry of $\mathbf{x}$, hence differentiable with $(\mathbf{x}^{*})' = (\mathbf{x}')^{*} = (\mathbf{A}\mathbf{x})^{*} = \mathbf{x}^{*}\mathbf{A}^{*}$. By Lemma 15.6.4, applied twice to the product $\mathbf{x}^{*} \cdot \mathbf{X} \cdot \mathbf{x}$ and using $\mathbf{X}' = 0$,

$$V'(t) = \mathbf{x}^{*}\mathbf{A}^{*}\mathbf{X}\mathbf{x} + \mathbf{x}^{*}\mathbf{X}\mathbf{A}\mathbf{x} = \mathbf{x}^{*}(\mathbf{A}^{*}\mathbf{X} + \mathbf{X}\mathbf{A})\mathbf{x}.$$

(b) By hypothesis $V'(t) = -\mathbf{x}(t)^{*}\mathbf{Q}\mathbf{x}(t)$. If $\mathbf{x}(t_1) = \mathbf{0}$ for some t_1, then by Theorem 9.9.6 $\mathbf{x}(t) = e^{t\mathbf{A}}\mathbf{x}(0)$ for every t, and $e^{t_1\mathbf{A}}$ is invertible by Theorem 9.9.4 (c), so $\mathbf{x}(0) = \mathbf{0}$, contradicting the hypothesis. So $\mathbf{x}(t) \neq \mathbf{0}$ for every t, and $\mathbf{Q} \succ 0$ gives $\mathbf{x}(t)^{*}\mathbf{Q}\mathbf{x}(t) > 0$, hence $V'(t) < 0$ for every t. A differentiable real function with everywhere negative derivative is strictly decreasing; that last step is the mean value theorem, one more fact of one-variable calculus quoted here and not proved.

(c) Definition 11.10.2 writes the equation as $\mathbf{AX} + \mathbf{XA}^* = -\mathbf{Q}$; the equation used here is that one for the pair $(\mathbf{A}^*, \mathbf{Q})$. The two are interchanged by replacing $\mathbf{A}$ with $\mathbf{A}^*$, which changes nothing about stability, since the eigenvalues of $\mathbf{A}^*$ are the complex conjugates of those of $\mathbf{A}$ and conjugation preserves real parts. So the decay of V is exactly the statement Chapter 11 §10 pointed forward to, for whichever of the two conventions one adopts — granted a positive definite solution $\mathbf{X}$, whose existence is not proved in this book.

15.7 Eigenvalues Move Continuously

Chapter 11 §01 proved that every complex matrix has diagonalizable matrices arbitrarily close to it (Corollary 11.1.6), then admitted that the word "close" was doing work no definition supported, and handed the repair to this chapter. The repair is now in place: a norm on $M_n(\mathbb{C})$ says how close two matrices are, and Corollary 15.2.4 says that it does not matter which norm. This section asks the question that could not even be posed before that point. If the matrix moves a little, how far do its eigenvalues move?

The answer has two halves, and the second is the one worth remembering. The eigenvalues do move only a little — provided they are read as an unordered list, which is the only way they can be read. But "a little" is not proportional to the movement of the matrix, and for a matrix with a large Jordan block it is spectacularly larger.

Throughout, matrices are complex, as in Section 4, so that an $n \times n$ matrix always has exactly n eigenvalues counted with algebraic multiplicity (Corollary 5.5.5).

15.7.1 From matrices to polynomials

The eigenvalues of $\mathbf{A}$ are the roots of $p_{\mathbf{A}}$ (Theorem 8.2.1), with algebraic multiplicity meaning multiplicity as a root (Definition 8.3.1). So the question splits in two: do the coefficients of $p_{\mathbf{A}}$ move a little when $\mathbf{A}$ does, and do the roots of a polynomial move a little when its coefficients do? The first half is easy and we do it now; the whole difficulty is in the second.

The reason the first half is easy is that everything in sight is a polynomial in the entries. It is worth isolating that observation once, because it will be used four times in this section.

Lemma 15.7.1 — Polynomial Maps of the Entries Are Continuous

Let $\Phi\colon M_{p\times q}(\mathbb{C}) \to M_{r\times s}(\mathbb{C})$ be a map each of whose output entries is given by a fixed polynomial, with complex coefficients, in the pq entries of the input. Fix any norm on the source and any norm on the target. Then Φ is **continuous**: whenever $\|\mathbf{A}_k - \mathbf{A}\| \to 0$ we have $\|\Phi(\mathbf{A}_k) - \Phi(\mathbf{A})\| \to 0$, and equivalently, for every $\mathbf{A}$ and every $\varepsilon > 0$ there is $\delta > 0$ such that $\|\mathbf{B} - \mathbf{A}\| < \delta$ forces $\|\Phi(\mathbf{B}) - \Phi(\mathbf{A})\| < \varepsilon$. The same holds for a map into $\mathbb{C}$.

Idea. Two reductions and one piece of arithmetic. Convergence in any norm is entrywise convergence, by Corollary 15.2.4, in the source and in the target alike; so the claim is about pq complex sequences producing rs complex sequences. That reduces it to the statement that a polynomial in finitely many complex variables respects limits, which is

the algebra of limits.

Proof. Suppose $\|\mathbf{A}_k - \mathbf{A}\| \to 0$. By Corollary 15.2.4, each entry $(\mathbf{A}_k)_{ij} \to a_{ij}$. Sums and products of convergent complex sequences converge to the sum and the product of the limits: for sums this is Theorem 0.6.4, and for products it follows from

$$|z_k w_k - z w| \le |z_k|\,|w_k - w| + |w|\,|z_k - z|$$

together with the fact that a convergent sequence is bounded. A polynomial is built from its variables and constants by finitely many sums and products, so each entry of $\Phi(\mathbf{A}_k)$ converges to the corresponding entry of $\Phi(\mathbf{A})$. Applying Corollary 15.2.4 in $M_{r\times s}(\mathbb{C})$ gives $\|\Phi(\mathbf{A}_k) - \Phi(\mathbf{A})\| \to 0$.

For the equivalence of the two formulations, suppose the ε–δ statement failed at some $\mathbf{A}$ for some $\varepsilon > 0$. Then for each $k \ge 1$ the value $\delta = 1/k$ is not good enough, so there is $\mathbf{B}_k$ with $\|\mathbf{B}_k - \mathbf{A}\| < 1/k$ and $\|\Phi(\mathbf{B}_k) - \Phi(\mathbf{A})\| \ge \varepsilon$. The sequence $(\mathbf{B}_k)$ contradicts the sequential statement just proved. This proves the lemma. ∎

Now the first half of the question is answered. Write $p_{\mathbf{A}}(x) = x^n + c_{n-1}(\mathbf{A})x^{n-1} + \cdots + c_0(\mathbf{A})$, which is legitimate because $p_{\mathbf{A}}$ is monic of degree n (Theorem 6.10.2). Each c_j is a polynomial in the entries of $\mathbf{A}$: the Leibniz sum of Definition 6.10.1 expresses $\det(x\mathbf{I} - \mathbf{A})$ as a signed sum of products of the entries of $x\mathbf{I} - \mathbf{A}$, each of which is $x - a_{jj}$ or $-a_{ij}$, and collecting the powers of x leaves every coefficient a polynomial with integer coefficients in the a_{ij}. So $\mathbf{A} \mapsto (c_0(\mathbf{A}), \dots, c_{n-1}(\mathbf{A}))$ is continuous by Lemma 15.7.1.

That leaves the second half: roots against coefficients. Before stating what is true there, we settle what cannot be true.

15.7.2 Why the answer must be about the multiset

The statement a reader would write down first is *"each eigenvalue is a continuous function of the matrix"*. It is not merely unproved; it is meaningless as written, because the eigenvalues come with no numbering — and the natural repair, "there is a way of numbering them that makes each one continuous", is false. One two-by-two family shows it, and the failure is the ordinary square root.

Proposition 15.7.2 — There Is No Continuous Choice of a Single Eigenvalue

For $t \in \mathbb{C}$ put

$$\mathbf{A}(t) = \begin{pmatrix} 0 & 1 \\ t & 0 \end{pmatrix},$$

so that $p_{\mathbf{A}(t)}(x) = x^2 - t$ and the eigenvalues of $\mathbf{A}(t)$ are the two square roots of t. Then there is **no** continuous function $\lambda\colon D \to \mathbb{C}$ on the closed unit disc $D = \{t \in \mathbb{C} : |t| \le 1\}$ such that $\lambda(t)$ is an eigenvalue of $\mathbf{A}(t)$ for every $t \in D$. Consequently there is no continuous $\Lambda\colon M_2(\mathbb{C}) \to \mathbb{C}$ with $\Lambda(\mathbf{B}) \in \operatorname{spec}(\mathbf{B})$ for every $\mathbf{B}$.

Idea. Walk t once around the unit circle. The two roots $\pm\sqrt{t}$ trade places on the way round, so a choice that is continuous along the walk comes home as the *other* root. The bookkeeping is done by dividing the chosen root by one fixed root, which turns the walk into a continuous function with only the two values 1 and -1; on an interval such a function cannot jump, and it must.

Proof. The characteristic polynomial is $\det\left(\begin{smallmatrix} x & -1 \\ -t & x \end{smallmatrix}\right) = x^2 - t$, so μ is an eigenvalue of $\mathbf{A}(t)$ if and only if $\mu^2 = t$ (Theorem 8.2.1).

Suppose such a λ exists, so $\lambda(t)^2 = t$ for all $|t| \le 1$. Define $g\colon [0, 2\pi] \to \mathbb{C}$ by

$$g(\theta) = \lambda\big(e^{i\theta}\big)\, e^{-i\theta/2}.$$

It is continuous, being a composite and a product of continuous functions — the elementary algebra of limits recorded in the chapter introduction, applied to $\theta \mapsto e^{i\theta}$, to λ, and to $\theta \mapsto e^{-i\theta/2}$. Squaring,

$$g(\theta)^2 = \lambda\big(e^{i\theta}\big)^2 e^{-i\theta} = e^{i\theta}e^{-i\theta} = 1,$$

so $g(\theta) \in \{1, -1\}$ for every θ. In particular g is real-valued, and a continuous real-valued function on an interval taking only the values 1 and -1 is constant: if it took both, the intermediate value theorem would produce a θ with $g(\theta) = 0$. Hence $g(2\pi) = g(0)$.

But $e^{i\cdot 0} = e^{i\cdot 2\pi} = 1$, so $g(0) = \lambda(1)$ while $g(2\pi) = \lambda(1)e^{-i\pi} = -\lambda(1)$. Therefore $\lambda(1) = -\lambda(1)$, that is $\lambda(1) = 0$, contradicting $\lambda(1)^2 = 1$. So no such λ exists.

For the last sentence, if Λ were such a function then $t \mapsto \Lambda(\mathbf{A}(t))$ would be continuous, because $t \mapsto \mathbf{A}(t)$ is continuous by Lemma 15.7.1, and it would select an eigenvalue of $\mathbf{A}(t)$ for each t. This proves the proposition. ∎

The intermediate value theorem is quoted here, and it is the only place in this chapter that uses it; it is fact (A5) of the chapter introduction, borrowed and not proved.

Two things are worth reading off the argument. First, the obstruction is not exotic: $\mathbf{A}(0) = \mathbf{J}_2(0)$ is the standard nilpotent matrix, and the trouble happens exactly at the parameter where the two eigenvalues collide. Second, nothing is wrong with the *pair* $\{\sqrt{t}, -\sqrt{t}\}$, which shrinks to $\{0, 0\}$ as $t \to 0$ in any reasonable sense. It is only the attempt to call one of them "the first" that fails. This is why the correct statement speaks of the roots as a **multiset**: a list with multiplicities and no order.

15.7.3 The imported fact

Here is what is true. It is the one statement in this chapter that the chapter does not prove.

Theorem 15.7.3 — Continuous Dependence of the Roots on the Coefficients

Let $n \geq 1$ and let

$$p(x) = x^n + c_{n-1}x^{n-1} + \cdots + c_1 x + c_0 \in \mathbb{C}[x]$$

be monic, with roots $\mu_1, \ldots, \mu_n \in \mathbb{C}$ listed with multiplicity (Corollary 5.5.5). Let $\varepsilon > 0$. Then there is $\delta > 0$ with the following property. If

$$q(x) = x^n + b_{n-1}x^{n-1} + \cdots + b_1 x + b_0$$

is monic of the **same degree** n and $|b_j - c_j| < \delta$ for every j, then the roots $\nu_1, \ldots, \nu_n$ of q, listed with multiplicity, can be **numbered** so that

$$|\nu_i - \mu_i| < \varepsilon \qquad (i = 1, \ldots, n).$$

This chapter quotes this theorem, and Chapter 19 proves it. The classical proof uses complex analysis: one encircles each root of p by a small circle on which p does not vanish, counts the roots inside by a contour integral, and observes that an integer-valued quantity depending continuously on the coefficients cannot change. The book never develops that machinery, and it does not need to: compactness, fact (A3), together with unique factorization in $\mathbb{C}[x]$, is enough, and Chapter 19 §03 gives that proof. It is postponed there because it belongs with the quantitative bounds on how far roots move. Until then the statement is recorded in the manner this book has used before — Chapter 13 §06 with Taylor's theorem, Chapter 10 with the theorem of Abel and Ruffini: named at the point of use, never buried inside a proof that presents itself as self-contained, and never strengthened in passing. What *can* be proved with the tools at hand is that the numbering in the statement has to be chosen afresh for each q, and that was Proposition 15.7.2.

Two clauses of the statement carry weight. **Monic of the same degree** is essential: the roots of $\delta x^2 + x$ are 0 and $-1/\delta$, which runs off to infinity as $\delta \to 0$, while the limit polynomial x has the single root 0. Allowing the leading coefficient to vanish destroys everything, and monic polynomials of a fixed degree are exactly the family where it cannot. And **numbered so that** is the multiset formulation: the permutation matching up the two lists depends on q, and Proposition 15.7.2 says it must.

15.7.4 Eigenvalues, and the spectral radius

Now the two halves are assembled.

Corollary 15.7.4 — Eigenvalues Depend Continuously on the Matrix

Let $\mathbf{A} \in M_n(\mathbb{C})$ with eigenvalues $\lambda_1, \ldots, \lambda_n$ listed with algebraic multiplicity, let $\|\cdot\|$ be any norm on $M_n(\mathbb{C})$, and let $\varepsilon > 0$. Then there is $\delta > 0$ such that every $\mathbf{B} \in M_n(\mathbb{C})$ with $\|\mathbf{B} - \mathbf{A}\| < \delta$ has eigenvalues $\mu_1, \ldots, \mu_n$, listed with algebraic multiplicity, which can be numbered so that $|\mu_i - \lambda_i| < \varepsilon$ for every i.

Idea. The characteristic polynomial's coefficients are polynomials in the entries, so they move continuously with $\mathbf{A}$; the quoted root theorem then moves the roots. The only work is composing the two estimates, choosing the tolerance for the coefficients small enough that the roots come out within ε.
