A square matrix is invertible or it is not, and so far deciding which has meant row reducing it. The determinant packages that decision into a single number. The same number measures how the linear map scales areas and volumes, and its sign records whether the map preserves or reverses orientation. It also produces the characteristic polynomial, the gateway to eigenvalues in Chapter 8.

This chapter does not start from a formula. It starts from what a signed volume must do. Scaling one edge scales the volume. Sliding one edge along another does not change it. The unit cube has volume 1. We prove that exactly one function has these properties, write it down, and then derive every property of the determinant from that uniqueness: multiplicativity, the transpose rule, cofactor expansion, the inverse formula and Cramer's rule. Nothing is assumed, and no formula is used before it is proved.

What you need. From Chapter 0, permutations and transpositions (Theorem 0.10.4) and the characteristic of a field (Definition 0.7.2). From Chapter 1, linear independence and the Linear Dependence Lemma (Definition 1.4.1, Theorem 1.4.1). From Chapter 2, elementary matrices and the invertible matrix theorem (Definition 2.4.1, Theorem 2.4.4). From Chapter 3, the matrix of a linear map and similarity (Definition 3.6.1, Theorem 3.7.4). From Chapter 4, linear functionals (Definition 4.1.1). From Chapter 5, the root bound for polynomials (Corollary 5.1.4).

6.0.1 Roadmap

- **Signed area and volume.** Three rules that any reasonable notion of signed volume obeys, and the formula $ad - bc$ forced by them.
- **Multilinear alternating forms.** The rules made precise for functions of n vectors, and their first consequences.
- **Permutations and sign.** Counting inversions, and why the parity of a permutation is well defined.
- **Existence and uniqueness of the determinant.** Exactly one alternating form takes the value 1 on the identity; the Leibniz formula.
- **Row operations and multiplicativity.** Computing determinants by elimination, $\det(\mathbf{AB}) = \det \mathbf{A} \det \mathbf{B}$, and the determinant of an operator.
- **Cofactor expansion, the adjugate and Cramer's rule.** Expanding along a row or column, and a formula for the inverse.
- **Minors, rank and Cauchy–Binet.** Rank read off from minors, and the determinant of

a product of rectangular matrices.
- **Special determinants.** Vandermonde, tridiagonal and block triangular matrices, and rank-one updates.
- **Orientation and volume.** The determinant as a volume scaling factor, and the two orientations of $\mathbb{R}^n$.
- **The characteristic polynomial.** $\det(x\mathbf{I} - \mathbf{A})$, its coefficients, and why similar matrices share it.

6.0.2 Named moves

- **Derive from the rules, not the formula.** Prove determinant facts from multilinearity, alternation and normalization, so no property is assumed before it is proved.
- **Uniqueness does the work.** To prove two expressions agree, show both are alternating multilinear in the columns and agree on the identity.
- **Build from elementary matrices.** Check a claim for elementary matrices, then extend it to products.
- **Look-alike matrices.** A matrix with two equal rows has determinant zero; expanding such a matrix proves the adjugate identity.
- **Induct on size.** Expand along a row or column to reduce an $n \times n$ determinant to smaller ones.

6.1 Signed Area and Volume

In Chapter 0 a single number, $ad - bc$, decided whether a 2×2 matrix is invertible (Theorem 0.9.8). For an $n \times n$ matrix, Chapter 2 answered the same question by row reduction, which is a procedure, not a number. Is there one number for every square matrix that does the job of $ad - bc$? This section does not define it yet. Instead it asks what such a number should **mean**, finds the answer in area and volume, and extracts a short list of rules. From the rules alone, $ad - bc$ comes out, with no other choice possible.

6.1.1 Area as a function of two vectors

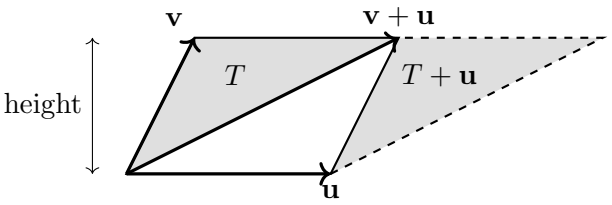
Take two vectors $\mathbf{u}, \mathbf{v} \in \mathbb{R}^2$ and the parallelogram they span,

$$P(\mathbf{u}, \mathbf{v}) = \{s\mathbf{u} + t\mathbf{v} : 0 \le s \le 1,\ 0 \le t \le 1\}.$$

Its corners are $\mathbf{0}$, $\mathbf{u}$, $\mathbf{v}$ and $\mathbf{u} + \mathbf{v}$. We want to understand its area as a **function of the two vectors**, without drawing a coordinate grid and counting squares. Four features are visible without any formula.

Scaling a side scales the area. Replacing $\mathbf{v}$ by $2\mathbf{v}$ stacks two copies of $P(\mathbf{u}, \mathbf{v})$ on top of each other, so the area doubles. Replacing $\mathbf{v}$ by $3\mathbf{v}$ triples it, and replacing $\mathbf{v}$ by $\frac{1}{2}\mathbf{v}$ halves it.

Shearing does not change the area. Replace $\mathbf{v}$ by $\mathbf{v} + c\mathbf{u}$. The top edge slides along its own line, parallel to the base $\mathbf{u}$. The base stays the same, and so does the height, so the area stays the same. The picture shows $c = 1$: the triangle cut off on the left of $P(\mathbf{u}, \mathbf{v})$ reappears, moved by $\mathbf{u}$, on the right of $P(\mathbf{u}, \mathbf{v} + \mathbf{u})$.



The solid outline is $P(\mathbf{u}, \mathbf{v})$ and the dashed one completes $P(\mathbf{u}, \mathbf{v} + \mathbf{u})$. Both consist of the unshaded middle triangle plus a shaded triangle, and the two shaded triangles T and $T + \mathbf{u}$ are translates of each other.

Equal sides give area zero. $P(\mathbf{u}, \mathbf{u})$ is a segment, which has no area. More generally, if $\mathbf{v}$ is a multiple of $\mathbf{u}$, the parallelogram is flat.

The unit square has area one. $P(\mathbf{e}_1, \mathbf{e}_2)$ is the unit square. This fixes the unit of measurement.

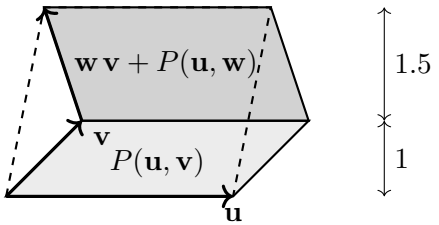
6.1.2 Why the area needs a sign

The first feature is not quite right as stated. Replacing $\mathbf{v}$ by $-\mathbf{v}$ moves the parallelogram to the other side of the line of $\mathbf{u}$ (the point reflection $\mathbf{x} \mapsto \mathbf{u} - \mathbf{x}$ carries $P(\mathbf{u}, \mathbf{v})$ onto $P(\mathbf{u}, -\mathbf{v})$) and does **not** change its area, so ordinary area satisfies $\text{area}(\mathbf{u}, c\mathbf{v}) = |c| \, \text{area}(\mathbf{u}, \mathbf{v})$, with an absolute value. That absolute value spoils a second, very useful property.

Fix the base $\mathbf{u}$ and let the second vector vary. The area is base times height, and heights along a fixed direction add up: if $\mathbf{v}$ reaches height 1 above the line of $\mathbf{u}$ and $\mathbf{w}$ reaches height 1.5, then $\mathbf{v} + \mathbf{w}$ reaches height 2.5. So we expect

$$\text{area}(\mathbf{u}, \mathbf{v} + \mathbf{w}) = \text{area}(\mathbf{u}, \mathbf{v}) + \text{area}(\mathbf{u}, \mathbf{w}).$$

The picture shows it: $P(\mathbf{u}, \mathbf{w})$, moved up by $\mathbf{v}$, sits exactly on top of $P(\mathbf{u}, \mathbf{v})$, and the two together have the same base and total height as $P(\mathbf{u}, \mathbf{v} + \mathbf{w})$ (dashed).



Now take $\mathbf{w} = -\mathbf{v}$. Then $\mathbf{v} + \mathbf{w} = \mathbf{0}$ and the left side is $\text{area}(\mathbf{u}, \mathbf{0}) = 0$, while the right side is $2\,\text{area}(\mathbf{u}, \mathbf{v})$, which is positive. Additivity fails, because $-\mathbf{v}$ points **below** the line of $\mathbf{u}$ and its height should count as negative. The repair is to give area a sign.

Signed area is ordinary area, counted positive when the second vector lies on the counterclockwise side of the first, and negative when it lies on the clockwise side.

So $P(\mathbf{e}_1, \mathbf{e}_2)$ has signed area $+1$, because $\mathbf{e}_2$ is a quarter turn counterclockwise from $\mathbf{e}_1$, and $P(\mathbf{e}_2, \mathbf{e}_1)$ has signed area -1. With the sign in place, scaling holds with c instead of $|c|$, and heights add with their signs, so additivity holds for all $\mathbf{v}, \mathbf{w}$.

Write $D(\mathbf{u},\mathbf{v})$ for the signed area. The pictures suggest that $D\colon \mathbb{R}^2\times\mathbb{R}^2 \to \mathbb{R}$ obeys the following rules, **for all** $\mathbf{u},\mathbf{v},\mathbf{w}\in\mathbb{R}^2$ and **all** $c\in\mathbb{R}$:

(R1) **(Scaling)** $D(c\mathbf{u},\mathbf{v}) = cD(\mathbf{u},\mathbf{v})$ and $D(\mathbf{u},c\mathbf{v}) = cD(\mathbf{u},\mathbf{v})$.
(R2) **(Shear)** $D(\mathbf{u}+c\mathbf{v},\mathbf{v}) = D(\mathbf{u},\mathbf{v})$ and $D(\mathbf{u},\mathbf{v}+c\mathbf{u}) = D(\mathbf{u},\mathbf{v})$.
(R3) **(Equal sides)** $D(\mathbf{u},\mathbf{u}) = 0$.
(R4) **(Normalization)** $D(\mathbf{e}_1,\mathbf{e}_2) = 1$.
(R5) **(Additivity)** $D(\mathbf{u}+\mathbf{w},\mathbf{v}) = D(\mathbf{u},\mathbf{v}) + D(\mathbf{w},\mathbf{v})$ and $D(\mathbf{u},\mathbf{v}+\mathbf{w}) = D(\mathbf{u},\mathbf{v}) + D(\mathbf{u},\mathbf{w})$.

These are rules read off from pictures, not yet a definition. The question is what they force.

6.1.3 The rules force $ad - bc$

A 2×2 matrix $\mathbf{A} = \begin{pmatrix} a & b \\ c & d \end{pmatrix}$ has columns $\mathbf{u} = (a,c)$ and $\mathbf{v} = (b,d)$, and $P(\mathbf{u},\mathbf{v})$ is the image of the unit square under $\mathbf{x}\mapsto\mathbf{A}\mathbf{x}$. We now show that the first four rules leave no freedom at all. The method is the column version of elimination: use shears to clear entries until the parallelogram becomes a rectangle.

Example. ($ad - bc$ from the Rules)

Let $D\colon \mathbb{R}^2\times\mathbb{R}^2 \to \mathbb{R}$ be **any** function satisfying (R1)–(R4). Show that $D((a,c),(b,d)) = ad - bc$ for all $a,b,c,d\in\mathbb{R}$.

Solution. Write $\mathbf{u} = (a,c)$ and $\mathbf{v} = (b,d)$. Two consequences of (R1) come first. Taking the scalar 0 in (R1) gives $D(\mathbf{u},\mathbf{0}) = D(\mathbf{u},0\mathbf{v}) = 0\cdot D(\mathbf{u},\mathbf{v}) = 0$, and likewise $D(\mathbf{0},\mathbf{v}) = 0$. Using (R1) twice and then (R4),

$$\begin{aligned} D((p,0),(0,q)) &= D(p\mathbf{e}_1, q\mathbf{e}_2) = pq\, D(\mathbf{e}_1,\mathbf{e}_2) \\ &= pq \qquad \text{for all } p,q\in\mathbb{R}. \end{aligned} \tag{$*$}$$

Case 1: $a\neq 0$. By the second shear rule with scalar $-b/a$,

$$D(\mathbf{u},\mathbf{v}) = D\big(\mathbf{u},\mathbf{v}-\tfrac{b}{a}\mathbf{u}\big) = D\big(\mathbf{u},(0,d')\big), \qquad \text{where } d' = d - \tfrac{bc}{a}.$$

If $d' = 0$, this is $D(\mathbf{u},\mathbf{0}) = 0 = ad'$. If $d'\neq 0$, the first shear rule with scalar $-c/d'$ clears the second entry of $\mathbf{u}$:

$$D\big(\mathbf{u},(0,d')\big) = D\big(\mathbf{u}-\tfrac{c}{d'}(0,d'),(0,d')\big) = D\big((a,0),(0,d')\big) = ad'$$

by $(*)$. In both sub-cases $D(\mathbf{u},\mathbf{v}) = ad' = ad - bc$.

Case 2: $a = 0$ *and* $b\neq 0$. By the first shear rule with scalar 1, $D(\mathbf{u},\mathbf{v}) = D(\mathbf{u}+\mathbf{v},\mathbf{v})$, and $\mathbf{u}+\mathbf{v} = (b,c+d)$ has first entry $b\neq 0$. Case 1, applied to the columns $(b,c+d)$ and (b,d), gives

$$D(\mathbf{u},\mathbf{v}) = bd - b(c+d) = -bc = ad - bc,$$

since $a = 0$.

Case 3: $a = b = 0$. If $c = 0$, then $\mathbf{u} = \mathbf{0}$ and $D(\mathbf{u}, \mathbf{v}) = 0$. If $c \neq 0$, the second shear rule with scalar $-d/c$ gives $D(\mathbf{u}, \mathbf{v}) = D(\mathbf{u}, \mathbf{v} - \frac{d}{c}\mathbf{u}) = D(\mathbf{u}, \mathbf{0}) = 0$. In both sub-cases $D(\mathbf{u}, \mathbf{v}) = 0 = ad - bc$.

The three cases cover all a, b, c, d, so $D((a, c), (b, d)) = ad - bc$, as claimed.

So **at most one** function obeys (R1)–(R4). Conversely, $(a, c), (b, d) \mapsto ad - bc$ obeys all five rules; for instance, for the second shear rule, replacing (b, d) by $(b+ta, d+tc)$ gives $a(d+tc)-(b+ta)c = ad - bc$. The other checks are just as short. Hence **exactly one** function satisfies (R1)–(R4), and it satisfies (R5) as well.

Two things in this computation are worth noticing. First, (R3) was never used. It follows from the others: $D(\mathbf{u}, \mathbf{u}) = D(\mathbf{u}, \mathbf{u} - \mathbf{u}) = D(\mathbf{u}, \mathbf{0}) = 0$, by a shear and then scaling by 0. Second, the argument used only addition, subtraction, multiplication and division by non-zero numbers. So over **any** field F, exactly one function $F^2 \times F^2 \to F$ satisfies (R1)–(R4), namely $ad - bc$. The picture needs $\mathbb{R}$; the algebra does not.

There is also a shorter route, if we allow additivity. Expanding $\mathbf{u} = a\mathbf{e}_1 + c\mathbf{e}_2$ and $\mathbf{v} = b\mathbf{e}_1 + d\mathbf{e}_2$ with (R5) and (R1) gives four terms:

$$D(\mathbf{u}, \mathbf{v}) = ab\, D(\mathbf{e}_1, \mathbf{e}_1) + ad\, D(\mathbf{e}_1, \mathbf{e}_2) + cb\, D(\mathbf{e}_2, \mathbf{e}_1) + cd\, D(\mathbf{e}_2, \mathbf{e}_2).$$

The first and last vanish by (R3), $D(\mathbf{e}_1, \mathbf{e}_2) = 1$ by (R4), and $D(\mathbf{e}_2, \mathbf{e}_1) = -1$ (see the Quick check below). This expansion is the route that generalizes to n vectors later in the chapter, while the elimination route of Example ($ad - bc$ from the Rules) becomes the practical way to compute.

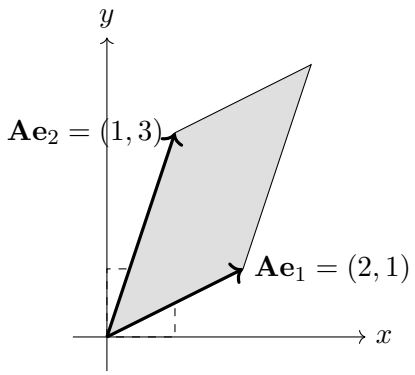
Quick check. Using only (R1) and (R2), show that $D(\mathbf{u}, \mathbf{v}) = -D(\mathbf{v}, \mathbf{u})$ for all $\mathbf{u}, \mathbf{v}$. Deduce $D(\mathbf{e}_2, \mathbf{e}_1)$.

Solution. Apply shears and one scaling:

$$\begin{aligned} D(\mathbf{u}, \mathbf{v}) &\overset{(R2)}{=} D(\mathbf{u} + \mathbf{v}, \mathbf{v}) \\ &\overset{(R2)}{=} D\big(\mathbf{u} + \mathbf{v}, \mathbf{v} - (\mathbf{u} + \mathbf{v})\big) = D(\mathbf{u} + \mathbf{v}, -\mathbf{u}) \\ &\overset{(R2)}{=} D\big((\mathbf{u} + \mathbf{v}) + (-\mathbf{u}), -\mathbf{u}\big) = D(\mathbf{v}, -\mathbf{u}) \\ &\overset{(R1)}{=} -D(\mathbf{v}, \mathbf{u}). \end{aligned}$$

With $\mathbf{u} = \mathbf{e}_1$, $\mathbf{v} = \mathbf{e}_2$ and (R4), $D(\mathbf{e}_2, \mathbf{e}_1) = -D(\mathbf{e}_1, \mathbf{e}_2) = -1$. This agrees with $ad - bc = 0 \cdot 0 - 1 \cdot 1$ for the columns $(0, 1), (1, 0)$.

Now compare with Chapter 0. By Theorem 0.9.8, $\mathbf{A}$ is invertible **if and only if** $ad - bc \neq 0$. In the language of this section: $\mathbf{A}$ is invertible exactly when the parallelogram spanned by its columns is **not flat**, that is, when the columns do not lie on a common line through the origin. The number that decides invertibility and the signed area of the image of the unit square are the same number. Drag the images of $\mathbf{e}_1$ and $\mathbf{e}_2$ below and watch the signed area pass through 0 exactly when the two columns line up.



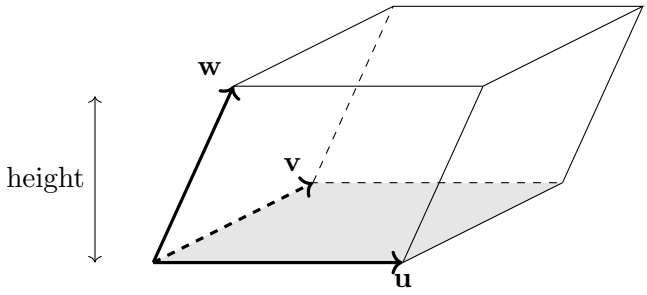
The unit square (dashed) and its image under $\mathbf{A} = \begin{pmatrix} 2 & 1 \\ 1 & 3 \end{pmatrix}$, a parallelogram of signed area $2 \cdot 3 - 1 \cdot 1 = 5$. The second column lies counterclockwise from the first, so the sign is positive.

6.1.4 Volume in three dimensions

The same story plays out one dimension up. Three vectors $\mathbf{u}, \mathbf{v}, \mathbf{w} \in \mathbb{R}^3$ span a **parallelepiped**

$$P(\mathbf{u}, \mathbf{v}, \mathbf{w}) = \{r\mathbf{u} + s\mathbf{v} + t\mathbf{w} : 0 \leq r, s, t \leq 1\},$$

a slanted box whose faces are parallelograms.



Its volume is the area of the base $P(\mathbf{u}, \mathbf{v})$ (shaded) times the height of $\mathbf{w}$ above the plane of the base. Each feature from the plane has a counterpart:

- scaling one edge scales the volume;
- replacing $\mathbf{w}$ by $\mathbf{w} + a\mathbf{u} + b\mathbf{v}$ slides the top face within its own plane, so the base and height, hence the volume, are unchanged, and similarly for shears of $\mathbf{u}$ or $\mathbf{v}$;
- if two edges are equal, the box is flat and the volume is 0;
- the unit cube $P(\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3)$ has volume 1;
- with a sign attached, heights add, so the signed volume is additive in each edge.

The sign in three dimensions records whether $(\mathbf{u}, \mathbf{v}, \mathbf{w})$ is arranged like $(\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3)$, the right-hand rule. We make this precise as orientation later in the chapter. For now the point is that the rules are **the same rules**, now for a function $D(\mathbf{u}, \mathbf{v}, \mathbf{w})$ of three vectors. The Quick check above also carries over word for word: shearing and scaling two of the arguments while the third stays fixed shows that swapping two arguments changes the sign.

6.1.5 What we will prove

Here is the goal for the next three sections. Let F be a field and $n \geq 1$.

> There is **exactly one** function D of n vectors in F^n that is linear in each argument separately, is 0 whenever two arguments are equal, and takes the value 1 at $(\mathbf{e}_1, \ldots, \mathbf{e}_n)$.

Its value on the columns of a matrix $\mathbf{A}$ will be the determinant $\det \mathbf{A}$. The plan follows the shorter route for $n = 2$. Expanding every argument in the standard basis gives n^n terms. The rule for equal arguments kills every term with a repeated basis vector, which leaves one term for each rearrangement $(\mathbf{e}_{\sigma(1)}, \ldots, \mathbf{e}_{\sigma(n)})$ of the standard basis. Each surviving value is ± 1, reached from $D(\mathbf{e}_1, \ldots, \mathbf{e}_n) = 1$ by swaps, with one sign change per swap. That creates two tasks:

1. Name and study functions of several vectors with these rules. This is the next section, on multilinear alternating forms.
2. Make sure the sign of a rearrangement is well defined, even though it can be reached by different sequences of swaps. This is the section on permutations and sign.

The existence and uniqueness theorem itself comes after both.

Warning. **Sarrus's rule is a 3×3 coincidence.** For a 3×3 matrix, the "diagonals" shortcut (add the three products along the down-right diagonals of the array with its first two columns copied to the right, subtract the three along the up-right diagonals) gives the correct six terms, because there are exactly $3! = 6$ rearrangements. The same picture for 4×4 gives $4 + 4 = 8$ products, while the expansion above has $4! = 24$ terms. It fails already for the matrix with columns $\mathbf{e}_2, \mathbf{e}_1, \mathbf{e}_3, \mathbf{e}_4$: every one of the eight wrapped diagonals passes through a zero entry, so the shortcut returns 0, but the swap rule gives $D(\mathbf{e}_2, \mathbf{e}_1, \mathbf{e}_3, \mathbf{e}_4) = -D(\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3, \mathbf{e}_4) = -1$. Never use Sarrus's rule beyond 3×3, and never use it as a proof tool.

6.1.6 Exercises

6.1.6.1 A. Check your understanding

Exercise A1.

(a) State the four rules (R1)–(R4) for signed area.

(b) True or false: ordinary (unsigned) area satisfies $\text{area}(\mathbf{u}, \mathbf{v} + \mathbf{w}) = \text{area}(\mathbf{u}, \mathbf{v}) + \text{area}(\mathbf{u}, \mathbf{w})$ for all $\mathbf{u}, \mathbf{v}, \mathbf{w} \in \mathbb{R}^2$. Justify your answer.

(c) Find the signed area of $P((1,3),(2,4))$. Is $\begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix}$ invertible?

(d) Explain why any D satisfying (R1) and (R2) has $D(\mathbf{u}, 5\mathbf{u}) = 0$.

(e) How many terms does the full expansion for 4×4 matrices have, and how many products does the 4×4 analogue of Sarrus's rule use?

Solution.

(a) For all $\mathbf{u}, \mathbf{v} \in \mathbb{R}^2$ and $c \in \mathbb{R}$: $D(c\mathbf{u}, \mathbf{v}) = cD(\mathbf{u}, \mathbf{v}) = D(\mathbf{u}, c\mathbf{v})$; $D(\mathbf{u} + c\mathbf{v}, \mathbf{v}) = D(\mathbf{u}, \mathbf{v}) = D(\mathbf{u}, \mathbf{v} + c\mathbf{u})$; $D(\mathbf{u}, \mathbf{u}) = 0$; $D(\mathbf{e}_1, \mathbf{e}_2) = 1$.

(b) False. Take $\mathbf{u} = \mathbf{e}_1$, $\mathbf{v} = \mathbf{e}_2$, $\mathbf{w} = -\mathbf{e}_2$. The left side is the area of $P(\mathbf{e}_1, \mathbf{0})$, which is 0; the right side is $1 + 1 = 2$.

(c) With $a = 1$, $b = 2$, $c = 3$, $d = 4$, the signed area is $ad - bc = 4 - 6 = -2$. Since $-2 \neq 0$, the matrix is invertible by Theorem 0.9.8.

(d) By the second shear rule with scalar -5, $D(\mathbf{u}, 5\mathbf{u}) = D(\mathbf{u}, 5\mathbf{u} - 5\mathbf{u}) = D(\mathbf{u}, \mathbf{0})$, and $D(\mathbf{u}, \mathbf{0}) = D(\mathbf{u}, 0 \cdot \mathbf{u}) = 0 \cdot D(\mathbf{u}, \mathbf{u}) = 0$ by (R1).

(e) The expansion has $4! = 24$ terms, one for each rearrangement of $\mathbf{e}_1, \ldots, \mathbf{e}_4$. The Sarrus-type diagram has only 8 products, so it must miss 16 of them.

6.1.6.2 B. Practice

Exercise B1: Signed Areas from the Rules.

Using only (R1)–(R4), in the manner of Example ($ad - bc$ from the Rules), compute the following. Then check each answer against $ad - bc$.

(a) $D((2, 1), (4, 5))$.

(b) $D((1, 2), (3, 6))$.

(c) $D((0, 3), (2, 0))$.

Solution.

(a) By the second shear rule with scalar -2, $D((2, 1), (4, 5)) = D((2, 1), (4, 5) - 2(2, 1)) = D((2, 1), (0, 3))$. By the first shear rule with scalar $-\frac{1}{3}$, this equals $D((2, 1) - \frac{1}{3}(0, 3), (0, 3)) = D((2, 0), (0, 3))$. By (R1) twice and (R4), $D(2\mathbf{e}_1, 3\mathbf{e}_2) = 6D(\mathbf{e}_1, \mathbf{e}_2) = 6$. Check: $2 \cdot 5 - 4 \cdot 1 = 6$.

(b) By the second shear rule with scalar -3, $D((1, 2), (3, 6)) = D((1, 2), (0, 0))$, and $D(\mathbf{u}, \mathbf{0}) = D(\mathbf{u}, 0 \cdot \mathbf{u}) = 0$ by (R1). So the value is 0. Check: $1 \cdot 6 - 3 \cdot 2 = 0$. The columns lie on one line, and the parallelogram is flat.

(c) By (R1) twice, $D(3\mathbf{e}_2, 2\mathbf{e}_1) = 6D(\mathbf{e}_2, \mathbf{e}_1)$. By the Quick check (which uses only (R1) and (R2)), $D(\mathbf{e}_2, \mathbf{e}_1) = -D(\mathbf{e}_1, \mathbf{e}_2) = -1$ by (R4). So the value is -6. Check: with columns $(0, 3)$ and $(2, 0)$, $a = 0$, $b = 2$, $c = 3$, $d = 0$, and $ad - bc = -6$. The sign is negative because $(2, 0)$ lies clockwise from $(0, 3)$.

Exercise B2: Equal Sides Force the Swap Rule.

Let $D\colon \mathbb{R}^2 \times \mathbb{R}^2 \to \mathbb{R}$ satisfy (R1), (R3) and (R5), but not necessarily (R2).

(a) Prove that $D(\mathbf{u}, \mathbf{v}) = -D(\mathbf{v}, \mathbf{u})$ for all $\mathbf{u}, \mathbf{v} \in \mathbb{R}^2$.

(b) Suppose moreover that (R4) holds. Deduce that $D((a, c), (b, d)) = ad - bc$.

Hint: expand $D(\mathbf{u} + \mathbf{v}, \mathbf{u} + \mathbf{v})$.

Solution.

(a) Let $\mathbf{u}, \mathbf{v} \in \mathbb{R}^2$. By (R3), $D(\mathbf{u}+\mathbf{v}, \mathbf{u}+\mathbf{v}) = 0$. Expanding with (R5) in the first argument and then in the second,

$$0 = D(\mathbf{u},\mathbf{u}) + D(\mathbf{u},\mathbf{v}) + D(\mathbf{v},\mathbf{u}) + D(\mathbf{v},\mathbf{v}) = D(\mathbf{u},\mathbf{v}) + D(\mathbf{v},\mathbf{u}),$$

where the second equality uses (R3) twice. Hence $D(\mathbf{u},\mathbf{v}) = -D(\mathbf{v},\mathbf{u})$.

(b) Write $(a,c) = a\mathbf{e}_1 + c\mathbf{e}_2$ and $(b,d) = b\mathbf{e}_1 + d\mathbf{e}_2$. By (R5) and (R1) in each argument,

$$D((a,c),(b,d)) = ab\,D(\mathbf{e}_1,\mathbf{e}_1) + ad\,D(\mathbf{e}_1,\mathbf{e}_2) + cb\,D(\mathbf{e}_2,\mathbf{e}_1) + cd\,D(\mathbf{e}_2,\mathbf{e}_2).$$

By (R3) the first and last terms are 0. By (R4), $D(\mathbf{e}_1,\mathbf{e}_2) = 1$, and by (a), $D(\mathbf{e}_2,\mathbf{e}_1) = -1$. Hence $D((a,c),(b,d)) = ad - bc$.

6.1.6.3 C. Going deeper

Exercise C1: Area of a Triangle.

Let $\mathbf{p}, \mathbf{q}, \mathbf{r} \in \mathbb{R}^2$.

(a) Explain why the triangle with vertices $\mathbf{p}, \mathbf{q}, \mathbf{r}$ has area $\frac{1}{2}|D(\mathbf{q}-\mathbf{p}, \mathbf{r}-\mathbf{p})|$, where $D(\mathbf{u},\mathbf{v})$ is the signed area.

(b) Find the area of the triangle with vertices $(1,2)$, $(4,3)$, $(2,6)$.

(c) Hence decide whether the points $(0,1)$, $(2,4)$, $(6,10)$ lie on a line. Justify your answer.

Solution.

(a) Translating by $-\mathbf{p}$ does not change areas, so the triangle has the same area as the triangle with vertices $\mathbf{0}$, $\mathbf{u} = \mathbf{q}-\mathbf{p}$, $\mathbf{v} = \mathbf{r}-\mathbf{p}$. That triangle is half of the parallelogram $P(\mathbf{u},\mathbf{v})$: the diagonal from $\mathbf{u}$ to $\mathbf{v}$ cuts $P(\mathbf{u},\mathbf{v})$ into the triangle with vertices $\mathbf{0},\mathbf{u},\mathbf{v}$ and the triangle with vertices $\mathbf{u}+\mathbf{v},\mathbf{v},\mathbf{u}$, and the point reflection $\mathbf{x} \mapsto \mathbf{u}+\mathbf{v}-\mathbf{x}$ maps the first onto the second, so they have equal area. The area of $P(\mathbf{u},\mathbf{v})$ is $|D(\mathbf{u},\mathbf{v})|$, since the signed area differs from the area only by its sign. Hence the triangle has area $\frac{1}{2}|D(\mathbf{q}-\mathbf{p}, \mathbf{r}-\mathbf{p})|$.

(b) Here $\mathbf{q}-\mathbf{p} = (3,1)$ and $\mathbf{r}-\mathbf{p} = (1,4)$, so $D = 3\cdot 4 - 1\cdot 1 = 11$ and the area is $\frac{11}{2}$.

(c) With $\mathbf{p} = (0,1)$, $\mathbf{q}-\mathbf{p} = (2,3)$ and $\mathbf{r}-\mathbf{p} = (6,9)$, so $D = 2\cdot 9 - 6\cdot 3 = 0$ and the "triangle" has area 0. Indeed $(6,9) = 3(2,3)$, so $\mathbf{r}-\mathbf{p}$ is a multiple of $\mathbf{q}-\mathbf{p}$, and all three points lie on the line through $(0,1)$ with direction $(2,3)$. Yes, they are collinear.

Exercise C2: The 1×1 Case.

For $n = 1$, the rules ask for a function $f\colon F \to F$ of one vector in $F^1 = F$.

(a) Explain why the rule "zero whenever two arguments are equal" imposes no condition when $n = 1$.

(b) Prove that the only function $f\colon F \to F$ that is linear with $f(1) = 1$ is $f(a) = a$. Hence the determinant of a 1×1 matrix (a) must be a.

Solution.

(a) The rule speaks about two **different** positions $i \neq j$ holding equal vectors. With one argument there is no pair of positions, so the condition is vacuously true (Example (A vacuously true implication)).

(b) Let f be linear with $f(1) = 1$, and let $a \in F$. Since $a = a \cdot 1$, homogeneity gives $f(a) = f(a \cdot 1) = af(1) = a$. Conversely, $a \mapsto a$ is linear and sends 1 to 1. Hence $f(a) = a$ is the only such function.

6.2 Multilinear Alternating Forms

The previous section found that signed area obeys a few rules: it is linear in each side separately, it vanishes when two sides are equal, and swapping the sides changes its sign. This section gives these rules names for functions of k vectors in an arbitrary vector space, and derives everything that follows from them before any formula exists. The main result is that "zero on equal arguments" already implies the swap rule, the shear rule and vanishing on dependent lists. The swap rule, in turn, gives back "zero on equal arguments" only when $1 + 1 \neq 0$ in the field.

Throughout, V is a vector space over a field F, $k \geq 1$ is an integer, and $V^k = V \times \cdots \times V$ is the set of k-tuples of vectors (Definition 0.3.11).

6.2.1 Multilinear forms

Signed area is not a linear function of the pair $(\mathbf{u}, \mathbf{v})$: doubling both sides multiplies the area by four, not by two. What it does have is linearity in $\mathbf{u}$ when $\mathbf{v}$ is held fixed, and linearity in $\mathbf{v}$ when $\mathbf{u}$ is held fixed. This "one slot at a time" linearity recurs throughout the book: in the dot product, later in inner products and bilinear forms, and in the determinant. So we give it a name.

A multilinear form is a function of several vectors that is linear in each vector while the others are held fixed.

Definition 6.2.1 — Multilinear Form

A function $f\colon V^k \to F$ is **k-linear**, or a **multilinear form** on V, if **for every** position $i \in \{1, \ldots, k\}$ and **every** choice of $\mathbf{v}_1, \ldots, \mathbf{v}_{i-1}, \mathbf{v}_{i+1}, \ldots, \mathbf{v}_k \in V$, the function

$$V \to F, \qquad \mathbf{x} \mapsto f(\mathbf{v}_1, \ldots, \mathbf{v}_{i-1}, \mathbf{x}, \mathbf{v}_{i+1}, \ldots, \mathbf{v}_k)$$

is linear. A 2-linear form is called **bilinear**.

In words: fix all arguments except the one in position i. What remains is a function of one vector, and it must be a linear functional (Definition 4.1.1). Written out, for all $\mathbf{x}, \mathbf{y} \in V$ and

$c \in F$,

$$f(\dots, \mathbf{x}+\mathbf{y}, \dots) = f(\dots, \mathbf{x}, \dots) + f(\dots, \mathbf{y}, \dots),$$
$$f(\dots, c\mathbf{x}, \dots) = c\, f(\dots, \mathbf{x}, \dots),$$

where the dots stand for the same fixed vectors on both sides. The condition is imposed for **every** position i, one at a time.

Some examples:

- **Signed area.** On F^2, $f(\mathbf{u}, \mathbf{v}) = u_1v_2 - u_2v_1$ is bilinear. For fixed $\mathbf{v}$, the map $\mathbf{u} \mapsto v_2u_1 - v_1u_2$ is a linear functional on F^2, and for fixed $\mathbf{u}$, so is $\mathbf{v} \mapsto u_1v_2 - u_2v_1$.
- **The dot product.** On F^n, $(\mathbf{u}, \mathbf{v}) \mapsto u_1v_1 + \cdots + u_nv_n$ is bilinear, by the same one-slot check.
- **Products of functionals.** If $\varphi_1, \dots, \varphi_k \in V^*$, then $f(\mathbf{v}_1, \dots, \mathbf{v}_k) = \varphi_1(\mathbf{v}_1)\varphi_2(\mathbf{v}_2)\cdots\varphi_k(\mathbf{v}_k)$ is k-linear: in position i it is the linear functional φ_i multiplied by the fixed scalar $\prod_{j\neq i} \varphi_j(\mathbf{v}_j)$. For instance, on $F[x]$, $(p, q) \mapsto p(0)q(1)$ is bilinear, since evaluation at a point is linear (Theorem 0.8.5).
- **The degenerate case $k = 1$.** A 1-linear form is exactly a linear functional on V. So multilinear forms generalize the dual space of Chapter 4.

> *Warning.* **Multilinear is not linear.** A bilinear form is **not** a linear function of the pair. For the signed area $f(\mathbf{u}, \mathbf{v}) = u_1v_2 - u_2v_1$ on $\mathbb{R}^2$, scaling both arguments by 2 gives $f(2\mathbf{e}_1, 2\mathbf{e}_2) = 4$, not $2f(\mathbf{e}_1, \mathbf{e}_2) = 2$. Adding in both slots at once is not allowed either: $f(\mathbf{e}_1 + \mathbf{0}, \mathbf{e}_1 + \mathbf{e}_2) = f(\mathbf{e}_1, \mathbf{e}_1 + \mathbf{e}_2) = 1$, while $f(\mathbf{e}_1, \mathbf{e}_1) + f(\mathbf{0}, \mathbf{e}_2) = 0$. Pull out scalars and split sums **one slot at a time**.

6.2.2 Alternating and skew-symmetric forms

The second rule of signed area was geometric: if two edges coincide, the parallelogram or box is flat. There are two natural ways to put this into algebra. One says the value is **zero** when two arguments are equal. The other says the value **changes sign** when two arguments are swapped. They look like two phrasings of one idea, but they are not the same, and we must choose.

An alternating form vanishes as soon as two of its arguments coincide.

Definition 6.2.2 — Alternating Form

A k-linear form $f\colon V^k \to F$ is **alternating** if $f(\mathbf{v}_1, \dots, \mathbf{v}_k) = 0$ **whenever** $\mathbf{v}_i = \mathbf{v}_j$ for **some** pair of positions $i \neq j$.

Definition 6.2.3 — Skew-Symmetric Form

A k-linear form $f\colon V^k \to F$ is **skew-symmetric** if, **for all** $\mathbf{v}_1, \dots, \mathbf{v}_k \in V$ and **all** positions $i < j$, swapping the arguments in positions i and j multiplies the value by -1:

$$f(\mathbf{v}_1, \dots, \mathbf{v}_j, \dots, \mathbf{v}_i, \dots, \mathbf{v}_k) = -f(\mathbf{v}_1, \dots, \mathbf{v}_i, \dots, \mathbf{v}_j, \dots, \mathbf{v}_k),$$

where on the left $\mathbf{v}_j$ sits in position i, $\mathbf{v}_i$ sits in position j, and all other positions are unchanged.

In words: "alternating" asks for the value 0 as soon as **any two** positions, adjacent or not, hold the same vector, whatever the remaining arguments are. It is a condition on the inputs where two entries coincide, and says nothing directly about other inputs. "Skew-symmetric" is a condition on **every** input: it compares the value at a list with the value at the list with two entries exchanged.

Example. (Alternating Forms)

Check that each of the following is an alternating form.

(a) On F^2, for a fixed $c \in F$: $f_c(\mathbf{u}, \mathbf{v}) = c(u_1v_2 - u_2v_1)$.
(b) On F^3, for fixed coordinate indices $1 \le r < s \le 3$: $g_{rs}(\mathbf{u}, \mathbf{v}) = u_rv_s - u_sv_r$.
(c) On $F[x]$: $h(p, q) = p(0)q(1) - p(1)q(0)$.
(d) On any V, with $k = 1$: any linear functional $\varphi \in V^*$.

Solution.

(a) Bilinearity is the one-slot check above, multiplied by the constant c. With $k = 2$ the only pair of positions is $(1, 2)$, and $f_c(\mathbf{u}, \mathbf{u}) = c(u_1u_2 - u_2u_1) = 0$ by commutativity in F. So f_c is alternating. For $c = 0$ it is the zero form, which is alternating for the silly reason that it is zero everywhere; for $c = 1$ it is the signed area of the previous section.
(b) In each slot g_{rs} is a linear functional, as in (a), and $g_{rs}(\mathbf{u}, \mathbf{u}) = u_ru_s - u_su_r = 0$. Over $\mathbb{R}$ these three forms are, up to sign and order, the components of the cross product: $\mathbf{u} \times \mathbf{v} = \big(g_{23}(\mathbf{u}, \mathbf{v}), -g_{13}(\mathbf{u}, \mathbf{v}), g_{12}(\mathbf{u}, \mathbf{v})\big)$. This example shows that the number of arguments need not equal the dimension: here $k = 2$ and $\dim F^3 = 3$.
(c) Evaluation at 0 and at 1 are linear in p (Theorem 0.8.5), so for fixed q the map $p \mapsto q(1)\,p(0) - q(0)\,p(1)$ is linear, and similarly in q. Also $h(p, p) = p(0)p(1) - p(1)p(0) = 0$. It is not the zero form: $h(1, x) = 1 \cdot 1 - 1 \cdot 0 = 1$.
(d) A linear functional is 1-linear. With a single position there is **no** pair $i \neq j$, so the alternating condition holds vacuously (Example (A vacuously true implication)). This degenerate case matters because it shows that "alternating" is purely a condition about **pairs** of positions; the interesting content starts at $k = 2$.

Now a non-example, by a minimal change of (a). Over $\mathbb{R}$, replace the minus sign by a plus: $s(\mathbf{u}, \mathbf{v}) = u_1v_2 + u_2v_1$. Bilinearity survives, by the same one-slot check. But $s(\mathbf{e}_1 + \mathbf{e}_2, \mathbf{e}_1 + \mathbf{e}_2) = 1 + 1 = 2 \neq 0$, so the alternating clause fails. The dot product fails in the same way, $\mathbf{e}_1 \cdot \mathbf{e}_1 = 1$. A different minimal change keeps the alternating clause and breaks the other one. The unsigned area $|u_1v_2 - u_2v_1|$ on $\mathbb{R}^2$ is still 0 whenever $\mathbf{u} = \mathbf{v}$, but it is not linear in $\mathbf{u}$: at $\mathbf{v} = \mathbf{e}_2$ it sends $\mathbf{e}_1 \mapsto 1$ and $-\mathbf{e}_1 \mapsto 1 \neq -1$. This is the failure that forced a sign onto area in the previous section.

Quick check. Is $f(\mathbf{u}, \mathbf{v}) = u_1v_2$ on F^2 alternating? Is it skew-symmetric?

Solution. It is bilinear, but neither. With $\mathbf{u} = \mathbf{v} = \mathbf{e}_1 + \mathbf{e}_2$, $f(\mathbf{u}, \mathbf{u}) = 1 \cdot 1 = 1 \neq 0$, so it is not alternating. And $f(\mathbf{e}_1, \mathbf{e}_2) = 1$ while $f(\mathbf{e}_2, \mathbf{e}_1) = 0$; skew-symmetry would need $0 = -1$, which fails in every field.

Why this definition. We chose "zero when two arguments are equal" as the basic notion, and in the form "**any** two positions". There are two reasons. First, it is what the picture says

directly: two equal edges make a flat box. Second, as we prove next, it implies the swap rule over **every** field, while the swap rule implies it only when $1 + 1 \neq 0$. Allowing any pair of positions, not just adjacent ones, also spares us a separate argument moving equal entries next to each other.

6.2.3 Consequences of the alternating condition

Everything that elimination does to a determinant will come from the following theorem. Its four parts are the column operations of Chapter 2 seen through a form: swap two arguments, add a multiple of one to another, scale one, and the extreme case of a dependent list.

Theorem 6.2.1 — Properties of Alternating Forms

Let $f\colon V^k \to F$ be an alternating k-linear form, let $\mathbf{v}_1, \dots, \mathbf{v}_k \in V$, and let $i \neq j$ be positions in $\{1, \dots, k\}$.

(a) **(Swap)** Exchanging the arguments in positions i and j multiplies $f(\mathbf{v}_1, \dots, \mathbf{v}_k)$ by -1. In particular, f is skew-symmetric.

(b) **(Shear)** For every $c \in F$, replacing $\mathbf{v}_i$ by $\mathbf{v}_i + c\mathbf{v}_j$ does not change $f(\mathbf{v}_1, \dots, \mathbf{v}_k)$.

(c) **(Scaling)** For every $c \in F$, replacing $\mathbf{v}_i$ by $c\mathbf{v}_i$ multiplies $f(\mathbf{v}_1, \dots, \mathbf{v}_k)$ by c.

(d) **(Dependence)** If the list $(\mathbf{v}_1, \dots, \mathbf{v}_k)$ is linearly dependent, then $f(\mathbf{v}_1, \dots, \mathbf{v}_k) = 0$. In particular, $f(\mathbf{v}_1, \dots, \mathbf{v}_k) = 0$ if some $\mathbf{v}_i = \mathbf{0}$.

Idea. Parts (a)–(c) involve at most the two slots i and j, so freeze the other $k - 2$ arguments. What is left is a bilinear form $g(\mathbf{x}, \mathbf{y})$ with $g(\mathbf{x}, \mathbf{x}) = 0$, and the k-argument statements become two-argument statements about g. For the swap, the move is to feed g a sum in both slots, $g(\mathbf{x} + \mathbf{y}, \mathbf{x} + \mathbf{y}) = 0$, and expand: the two "square" terms die and the two cross terms must cancel. For (d), write one vector as a combination of the others and expand in its slot: every resulting term has a repeated argument.

Proof. Suppose first $i < j$; the case $i > j$ is the same with the roles of i and j exchanged. For $\mathbf{x}, \mathbf{y} \in V$, let

$$g(\mathbf{x}, \mathbf{y}) = f(\mathbf{v}_1, \dots, \mathbf{v}_{i-1}, \mathbf{x}, \mathbf{v}_{i+1}, \dots, \mathbf{v}_{j-1}, \mathbf{y}, \mathbf{v}_{j+1}, \dots, \mathbf{v}_k),$$

the value of f with $\mathbf{x}$ in position i, $\mathbf{y}$ in position j, and $\mathbf{v}_m$ in every other position m. Since f is k-linear, g is bilinear, and since f is alternating, $g(\mathbf{x}, \mathbf{x}) = 0$ for every $\mathbf{x} \in V$. In this notation $f(\mathbf{v}_1, \dots, \mathbf{v}_k) = g(\mathbf{v}_i, \mathbf{v}_j)$.

(c) This is linearity of f in position i: $g(c\mathbf{v}_i, \mathbf{v}_j) = c\, g(\mathbf{v}_i, \mathbf{v}_j)$.

(d) By linearity in the first slot of g and $g(\mathbf{v}_j, \mathbf{v}_j) = 0$,

$$g(\mathbf{v}_i + c\mathbf{v}_j, \mathbf{v}_j) = g(\mathbf{v}_i, \mathbf{v}_j) + c\, g(\mathbf{v}_j, \mathbf{v}_j) = g(\mathbf{v}_i, \mathbf{v}_j).$$

(e) By bilinearity of g,

$$\begin{aligned} 0 &= g(\mathbf{v}_i + \mathbf{v}_j, \mathbf{v}_i + \mathbf{v}_j) \\ &= g(\mathbf{v}_i, \mathbf{v}_i) + g(\mathbf{v}_i, \mathbf{v}_j) + g(\mathbf{v}_j, \mathbf{v}_i) + g(\mathbf{v}_j, \mathbf{v}_j) \\ &= g(\mathbf{v}_i, \mathbf{v}_j) + g(\mathbf{v}_j, \mathbf{v}_i), \end{aligned}$$

where the first and last equalities use $g(\mathbf{x},\mathbf{x}) = 0$. Hence $g(\mathbf{v}_j,\mathbf{v}_i) = -g(\mathbf{v}_i,\mathbf{v}_j)$, which is the swap statement. Since $\mathbf{v}_1,\dots,\mathbf{v}_k$ and $i < j$ were arbitrary, f is skew-symmetric (Definition 6.2.3).

(f) Suppose $(\mathbf{v}_1,\dots,\mathbf{v}_k)$ is linearly dependent. By the Linear Dependence Lemma (Theorem 1.4.1), there is an index j with $\mathbf{v}_j \in \operatorname{span}(\mathbf{v}_1,\dots,\mathbf{v}_{j-1})$. If $j = 1$, then $\mathbf{v}_1 = \mathbf{0} = 0\cdot\mathbf{v}_1$, and by (c) with $c = 0$, $f(\mathbf{v}_1,\dots,\mathbf{v}_k) = 0\cdot f(\mathbf{v}_1,\dots,\mathbf{v}_k) = 0$. If $j \geq 2$, write $\mathbf{v}_j = a_1\mathbf{v}_1 + \cdots + a_{j-1}\mathbf{v}_{j-1}$ with $a_m \in F$. By linearity of f in position j,

$$f(\mathbf{v}_1,\dots,\mathbf{v}_k) = \sum_{m=1}^{j-1} a_m\, f(\mathbf{v}_1,\dots,\mathbf{v}_{j-1},\mathbf{v}_m,\mathbf{v}_{j+1},\dots,\mathbf{v}_k).$$

In the m-th term, the vector $\mathbf{v}_m$ sits both in position m and in position $j \neq m$, so the term is 0 because f is alternating. Hence $f(\mathbf{v}_1,\dots,\mathbf{v}_k) = 0$. The last sentence of (d) holds because a list containing $\mathbf{0}$ is dependent. This proves the theorem.

■

For the determinant, (a)–(c) will be the rules for column operations, and (d) explains at once why a matrix with dependent columns must have determinant 0. Part (d) also bounds the number of arguments: on a space of dimension n, any $k > n$ vectors are dependent, so a non-zero alternating form needs $k \leq n$ (Exercise C1).

6.2.4 Alternating versus skew-symmetric

Part (a) says alternating forms are skew-symmetric. The converse depends on the field.

Theorem 6.2.2 — Skew-Symmetric and Alternating Forms

Let $f\colon V^k \to F$ be a k-linear form.

(a) If f is alternating, then f is skew-symmetric.

(b) If f is skew-symmetric and the characteristic of F is **not** 2, then f is alternating.

Proof.

(a) is Theorem 6.2.1 (a).

(b) Suppose $\mathbf{v}_i = \mathbf{v}_j$ for some $i < j$. Exchanging the arguments in positions i and j does not change the list, so skew-symmetry gives $f(\mathbf{v}_1,\dots,\mathbf{v}_k) = -f(\mathbf{v}_1,\dots,\mathbf{v}_k)$, that is, $(1+1)\,f(\mathbf{v}_1,\dots,\mathbf{v}_k) = 0$. If $1+1 = 0$ in F, then $2\cdot 1 = 0$ while $1\cdot 1 = 1 \neq 0$, so the smallest positive n with $n\cdot 1 = 0$ would be 2, and the characteristic of F would be 2 (Definition 0.7.2). So $1+1 \neq 0$, and multiplying by $(1+1)^{-1}$ gives $f(\mathbf{v}_1,\dots,\mathbf{v}_k) = 0$. Hence f is alternating.

■

Warning. **Skew-symmetric does not imply alternating over $\mathbb{F}_2$.** In $\mathbb{F}_2$ we have $-1 = 1$, so "skew-symmetric" just means "symmetric". Take $f(\mathbf{u},\mathbf{v}) = u_1v_1$ on $\mathbb{F}_2^2$. It is bilinear, and $f(\mathbf{v},\mathbf{u}) = v_1u_1 = u_1v_1 = -f(\mathbf{u},\mathbf{v})$, so it is skew-symmetric. But

$f(\mathbf{e}_1, \mathbf{e}_1) = 1 \neq 0$, so it is **not** alternating. Checking all 16 pairs $(\mathbf{u}, \mathbf{v})$ confirms both claims: $f(\mathbf{u}, \mathbf{v}) = f(\mathbf{v}, \mathbf{u})$ always, and $f(\mathbf{u}, \mathbf{u}) = u_1$ is 1 for $\mathbf{u} = (1, 0)$ and $\mathbf{u} = (1, 1)$. This is why the determinant is built on alternating forms, not skew-symmetric ones: the construction must work over $\mathbb{F}_2$ too.

6.2.5 The space of alternating forms

Alternating forms can be added and scaled, and the result is again alternating. This is what makes the uniqueness question later in the chapter a question about dimension.

Theorem 6.2.3 — Alternating Forms Form a Vector Space

The k-linear forms on V form a subspace of the vector space F^{V^k} of all functions $V^k \to F$, with the pointwise operations of Example (The Standard Vector Spaces) (d). The alternating k-linear forms on V form a subspace of it. In particular, both are vector spaces over F.

Proof. We use the Subspace Test (Theorem 1.2.1) twice.

The zero function is k-linear, since in each position it is the zero functional, and it is alternating, since all its values are 0.

Let f and g be k-linear and $a \in F$. Fix a position i and vectors in the other positions, and write $f(\dots, \mathbf{x}, \dots)$ for the value with $\mathbf{x}$ in position i. For $\mathbf{x}, \mathbf{y} \in V$ and $c \in F$, the pointwise definition and linearity of f and g in position i give

$$\begin{aligned}(f+g)(\dots, \mathbf{x}+\mathbf{y}, \dots) &= f(\dots, \mathbf{x}, \dots) + f(\dots, \mathbf{y}, \dots) \\ &\quad + g(\dots, \mathbf{x}, \dots) + g(\dots, \mathbf{y}, \dots) \\ &= (f+g)(\dots, \mathbf{x}, \dots) + (f+g)(\dots, \mathbf{y}, \dots)\end{aligned}$$

and

$$(f+g)(\dots, c\mathbf{x}, \dots) = c\, f(\dots, \mathbf{x}, \dots) + c\, g(\dots, \mathbf{x}, \dots) = c\,(f+g)(\dots, \mathbf{x}, \dots).$$

So $f+g$ is k-linear. In the same way $(af)(\dots, \mathbf{x}+\mathbf{y}, \dots) = af(\dots, \mathbf{x}, \dots) + af(\dots, \mathbf{y}, \dots)$ and $(af)(\dots, c\mathbf{x}, \dots) = c\,(af)(\dots, \mathbf{x}, \dots)$, using commutativity in F, so af is k-linear.

If moreover f and g are alternating and $\mathbf{v}_i = \mathbf{v}_j$ for some $i \neq j$, then $(f+g)(\mathbf{v}_1, \dots, \mathbf{v}_k) = 0 + 0 = 0$ and $(af)(\mathbf{v}_1, \dots, \mathbf{v}_k) = a \cdot 0 = 0$. So the alternating forms are closed under both operations. This proves the theorem. ∎

For $V = F^2$ and $k = 2$, Exercise B2 shows that every alternating bilinear form is one of the forms f_c of Example (Alternating Forms) (a), with $c = f(\mathbf{e}_1, \mathbf{e}_2)$. So that space is spanned by the single non-zero form f_1, and has dimension 1. Later in this chapter we prove the same for all n: the alternating n-linear forms on F^n form a space of dimension exactly 1, spanned by the determinant. The missing ingredient is how the value of an alternating form changes when its arguments are rearranged by more than one swap, which is the subject of the next section.

6.2.6 Exercises

6.2.6.1 A. Check your understanding

Exercise A1.

(a) Define an alternating k-linear form on a vector space V over F.

(b) True or false: a bilinear form f on $\mathbb{R}^2$ with $f(\mathbf{e}_1, \mathbf{e}_1) = f(\mathbf{e}_2, \mathbf{e}_2) = 0$ is alternating. Justify your answer.

(c) True or false: every skew-symmetric bilinear form on $\mathbb{R}^5$ is alternating. Justify your answer.

(d) Let f be an alternating 3-linear form on $\mathbb{R}^3$ and $\mathbf{u}, \mathbf{v} \in \mathbb{R}^3$. What is $f(\mathbf{u}, \mathbf{v}, 2\mathbf{u}-\mathbf{v})$?

(e) Name the move that proves an alternating form changes sign under a swap.

Solution.

(a) A function $f\colon V^k \to F$ that is linear in each argument when the others are fixed (Definition 6.2.1), and satisfies $f(\mathbf{v}_1, \dots, \mathbf{v}_k) = 0$ whenever $\mathbf{v}_i = \mathbf{v}_j$ for some $i \neq j$ (Definition 6.2.2).

(b) False. The form $s(\mathbf{u}, \mathbf{v}) = u_1 v_2 + u_2 v_1$ is bilinear with $s(\mathbf{e}_1, \mathbf{e}_1) = s(\mathbf{e}_2, \mathbf{e}_2) = 0$, but $s(\mathbf{e}_1 + \mathbf{e}_2, \mathbf{e}_1 + \mathbf{e}_2) = 2 \neq 0$. Checking the basis vectors is not enough, because the alternating condition is about **all** vectors.

(c) True. $\mathbb{R}$ has characteristic 0, so Theorem 6.2.2 (b) applies.

(d) 0. The list $(\mathbf{u}, \mathbf{v}, 2\mathbf{u} - \mathbf{v})$ is linearly dependent, since $2\mathbf{u} - \mathbf{v} - (2\mathbf{u} - \mathbf{v}) = \mathbf{0}$ with coefficients $2, -1, -1$ not all zero. By Theorem 6.2.1 (d) the value is 0.

(e) Put the sum of the two arguments into both positions, use $f(\dots, \mathbf{x} + \mathbf{y}, \dots, \mathbf{x} + \mathbf{y}, \dots) = 0$, and expand by linearity in both positions; the terms with equal arguments vanish and the two cross terms must cancel.

6.2.6.2 B. Practice

Exercise B1: Multilinear or Alternating?.

Determine which of the following functions are multilinear, and which of those are alternating. Justify your answer.

(a) $\mathbb{R}^2 \times \mathbb{R}^2 \to \mathbb{R}$, $(\mathbf{u}, \mathbf{v}) \mapsto 3u_1 v_2 - 3u_2 v_1$.

(b) $\mathbb{R}^2 \times \mathbb{R}^2 \to \mathbb{R}$, $(\mathbf{u}, \mathbf{v}) \mapsto u_1 v_2 - u_2 v_1 + 1$.

(c) $\mathbb{R}^3 \times \mathbb{R}^3 \times \mathbb{R}^3 \to \mathbb{R}$, $(\mathbf{u}, \mathbf{v}, \mathbf{w}) \mapsto u_1 v_2 w_3$.

(d) $M_2(\mathbb{R}) \times M_2(\mathbb{R}) \to \mathbb{R}$, $(\mathbf{A}, \mathbf{B}) \mapsto \operatorname{tr}(\mathbf{AB}) - \operatorname{tr}(\mathbf{BA})$.

(e) $\mathbb{R}[x] \times \mathbb{R}[x] \to \mathbb{R}$, $(p, q) \mapsto p(1)q'(1) - p'(1)q(1)$.

Solution.

(a) Multilinear and alternating: it is f_3 from Example (Alternating Forms) (a) with $c = 3$.

(b) Not multilinear. A linear functional sends $\mathbf{0}$ to 0, but at $\mathbf{u} = \mathbf{0}$ the map $\mathbf{v} \mapsto$

$0-0+1=1$ does not. So it is not an alternating form either; in any case its value at $(\mathbf{u},\mathbf{u})$ is $1\neq 0$.

(c) Multilinear: in each position it is a coordinate functional times a fixed scalar, as for products of functionals. Not alternating: with $\mathbf{u}=\mathbf{v}=\mathbf{e}_1+\mathbf{e}_2$ and $\mathbf{w}=\mathbf{e}_3$, the value is $1\cdot 1\cdot 1=1\neq 0$.

(d) By Theorem 0.9.6, $\operatorname{tr}(\mathbf{AB})=\operatorname{tr}(\mathbf{BA})$, so this is the zero function. The zero function is multilinear and alternating (Theorem 6.2.3). This is the degenerate case.

(e) Multilinear: $p\mapsto p(1)$ and $p\mapsto p'(1)$ are linear, the second as a composition of differentiation (Example (Differentiation)) with evaluation (Theorem 0.8.5). So for fixed q, $p\mapsto q'(1)\,p(1)-q(1)\,p'(1)$ is linear, and similarly in q. Alternating: $p(1)p'(1)-p'(1)p(1)=0$.

Exercise B2: Alternating Bilinear Forms on F^2.

Let f be an alternating bilinear form on F^2. Prove that

$$f(\mathbf{u},\mathbf{v})=f(\mathbf{e}_1,\mathbf{e}_2)\,(u_1v_2-u_2v_1)\qquad\text{for all }\mathbf{u},\mathbf{v}\in F^2.$$

Hence show that the alternating bilinear forms on F^2 form a space of dimension 1.

Solution. Write $\mathbf{u}=u_1\mathbf{e}_1+u_2\mathbf{e}_2$ and $\mathbf{v}=v_1\mathbf{e}_1+v_2\mathbf{e}_2$. By linearity in the first and then in the second argument,

$$f(\mathbf{u},\mathbf{v})=u_1v_1f(\mathbf{e}_1,\mathbf{e}_1)+u_1v_2f(\mathbf{e}_1,\mathbf{e}_2)+u_2v_1f(\mathbf{e}_2,\mathbf{e}_1)+u_2v_2f(\mathbf{e}_2,\mathbf{e}_2).$$

Since f is alternating, $f(\mathbf{e}_1,\mathbf{e}_1)=f(\mathbf{e}_2,\mathbf{e}_2)=0$, and by Theorem 6.2.1 (a), $f(\mathbf{e}_2,\mathbf{e}_1)=-f(\mathbf{e}_1,\mathbf{e}_2)$. Hence $f(\mathbf{u},\mathbf{v})=f(\mathbf{e}_1,\mathbf{e}_2)(u_1v_2-u_2v_1)$.

By Theorem 6.2.3 these forms form a vector space, and we have just shown $f=f(\mathbf{e}_1,\mathbf{e}_2)\,f_1$, where $f_1(\mathbf{u},\mathbf{v})=u_1v_2-u_2v_1$ is alternating by Example (Alternating Forms) (a). So (f_1) spans the space. It is non-zero, since $f_1(\mathbf{e}_1,\mathbf{e}_2)=1$, so the list (f_1) is linearly independent and hence a basis. The dimension is 1.

Exercise B3: The Triple Product.

For $\mathbf{v},\mathbf{w}\in\mathbb{R}^3$ let $\mathbf{v}\times\mathbf{w}=(v_2w_3-v_3w_2,\ v_3w_1-v_1w_3,\ v_1w_2-v_2w_1)$, and define $f(\mathbf{u},\mathbf{v},\mathbf{w})=u_1(\mathbf{v}\times\mathbf{w})_1+u_2(\mathbf{v}\times\mathbf{w})_2+u_3(\mathbf{v}\times\mathbf{w})_3$. Show that f is an alternating 3-linear form on $\mathbb{R}^3$ with $f(\mathbf{e}_1,\mathbf{e}_2,\mathbf{e}_3)=1$.

Solution. Multilinear. Each component of $\mathbf{v}\times\mathbf{w}$ is $g_{rs}(\mathbf{v},\mathbf{w})$ or $-g_{rs}(\mathbf{v},\mathbf{w})$ for a form of Example (Alternating Forms) (b), hence bilinear in $(\mathbf{v},\mathbf{w})$. For fixed $\mathbf{v},\mathbf{w}$, f is a linear functional of $\mathbf{u}$ with coefficients $(\mathbf{v}\times\mathbf{w})_m$. For fixed $\mathbf{u}$ and $\mathbf{w}$, $f=\sum_m u_m(\mathbf{v}\times\mathbf{w})_m$ is a combination of linear functionals of $\mathbf{v}$, hence linear in $\mathbf{v}$; likewise in $\mathbf{w}$.

Alternating. There are three pairs of positions. If $\mathbf{v}=\mathbf{w}$, every component $v_rv_s-v_sv_r$ is 0, so $\mathbf{v}\times\mathbf{v}=\mathbf{0}$ and $f=0$. If $\mathbf{u}=\mathbf{v}$,

$$f(\mathbf{u},\mathbf{u},\mathbf{w})=u_1(u_2w_3-u_3w_2)+u_2(u_3w_1-u_1w_3)+u_3(u_1w_2-u_2w_1)=0,$$

since the six terms cancel in pairs: $u_1u_2w_3$ with $-u_2u_1w_3$, $-u_1u_3w_2$ with $u_3u_1w_2$, and $u_2u_3w_1$ with $-u_3u_2w_1$. If $\mathbf{u} = \mathbf{w}$, the same expansion $u_1(v_2u_3 - v_3u_2) + u_2(v_3u_1 - v_1u_3) + u_3(v_1u_2 - v_2u_1)$ cancels in pairs in the same way.

Value. $\mathbf{e}_2 \times \mathbf{e}_3 = (1 \cdot 1 - 0 \cdot 0,\ 0 \cdot 0 - 0 \cdot 1,\ 0 \cdot 0 - 1 \cdot 0) = (1, 0, 0)$, so $f(\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3) = 1$.

6.2.6.3 C. Going deeper

Exercise C1: Too Many Arguments.

Let V be finite-dimensional with $\dim V = n$.

(a) Prove that every alternating k-linear form on V with $k > n$ is the zero form.

(b) Deduce that the only alternating 3-linear form on F^2 is zero, and give a non-zero alternating 2-linear form on F^2 to show that the bound in (a) cannot be lowered to $k \geq n$.

Solution.

(a) Let f be an alternating k-linear form with $k > n$, and let $\mathbf{v}_1, \ldots, \mathbf{v}_k \in V$. By Theorem 1.6.3 (a), a list of length $k > \dim V$ is linearly dependent. By Theorem 6.2.1 (d), $f(\mathbf{v}_1, \ldots, \mathbf{v}_k) = 0$. Since the vectors were arbitrary, f is the zero form.

(b) Here $\dim F^2 = 2 < 3$, so (a) applies. For $k = n = 2$, the form $f_1(\mathbf{u}, \mathbf{v}) = u_1v_2 - u_2v_1$ of Example (Alternating Forms) (a) is alternating with $f_1(\mathbf{e}_1, \mathbf{e}_2) = 1 \neq 0$.

Exercise C2: Bilinear Forms over $\mathbb{F}_2$.

(a) Let f be a bilinear form on F^2 and write $b_{rs} = f(\mathbf{e}_r, \mathbf{e}_s)$. Show that $f(\mathbf{u}, \mathbf{v}) = \sum_{r,s=1}^{2} b_{rs}u_rv_s$, and that conversely every choice of four scalars b_{rs} defines a bilinear form this way. Hence there are exactly 16 bilinear forms on $\mathbb{F}_2^2$.

(b) Prove that a bilinear form on $\mathbb{F}_2^2$ is skew-symmetric if and only if $b_{12} = b_{21}$. How many are there?

(c) Prove that a bilinear form on $\mathbb{F}_2^2$ is alternating if and only if $b_{11} = b_{22} = 0$ and $b_{12} = b_{21}$. How many are there?

(d) Over $\mathbb{R}$, how do the analogous two sets of bilinear forms on $\mathbb{R}^2$ compare? Justify your answer.

Solution.

(a) Expanding $\mathbf{u} = u_1\mathbf{e}_1 + u_2\mathbf{e}_2$ and $\mathbf{v} = v_1\mathbf{e}_1 + v_2\mathbf{e}_2$ by linearity in each argument gives $f(\mathbf{u}, \mathbf{v}) = \sum_{r,s} u_rv_sf(\mathbf{e}_r, \mathbf{e}_s) = \sum_{r,s} b_{rs}u_rv_s$. Conversely, for any scalars b_{rs}, the function $\sum_{r,s} b_{rs}u_rv_s$ is linear in $\mathbf{u}$ for fixed $\mathbf{v}$ (a combination of the coordinates u_r with coefficients $\sum_s b_{rs}v_s$) and similarly in $\mathbf{v}$, and it takes the value b_{rs} at $(\mathbf{e}_r, \mathbf{e}_s)$. So bilinear forms on F^2 correspond exactly to quadruples $(b_{11}, b_{12}, b_{21}, b_{22})$, and over $\mathbb{F}_2$ there are $2^4 = 16$.

(b) In $\mathbb{F}_2$, $-a = a$ for every a, so f is skew-symmetric exactly when $f(\mathbf{v}, \mathbf{u}) = f(\mathbf{u}, \mathbf{v})$ for all $\mathbf{u}, \mathbf{v}$. ($\Rightarrow$) Taking $\mathbf{u} = \mathbf{e}_1$, $\mathbf{v} = \mathbf{e}_2$ gives $b_{21} = b_{12}$. ($\Leftarrow$) If $b_{12} = b_{21}$, then $b_{rs} = b_{sr}$ for all r, s, and $f(\mathbf{v}, \mathbf{u}) = \sum_{r,s} b_{rs}v_ru_s = \sum_{r,s} b_{sr}u_sv_r = f(\mathbf{u}, \mathbf{v})$. The entries b_{11}, b_{22} and the common value $b_{12} = b_{21}$ are free, so there are $2^3 = 8$

skew-symmetric forms.

(c) ($\Rightarrow$) If f is alternating, then $b_{11} = f(\mathbf{e}_1, \mathbf{e}_1) = 0$ and $b_{22} = 0$, and $0 = f(\mathbf{e}_1 + \mathbf{e}_2, \mathbf{e}_1 + \mathbf{e}_2) = b_{11} + b_{12} + b_{21} + b_{22} = b_{12} + b_{21}$, so $b_{21} = -b_{12} = b_{12}$. ($\Leftarrow$) With $b_{11} = b_{22} = 0$ and $b_{12} = b_{21} = b$, $f(\mathbf{u}, \mathbf{u}) = b(u_1u_2 + u_2u_1) = (1 + 1)\, b\, u_1u_2 = 0$. Only $b \in \{0, 1\}$ is free, so there are 2 alternating forms. Hence $8 - 2 = 6$ skew-symmetric forms over $\mathbb{F}_2$ are not alternating; u_1v_1 (with $b_{11} = 1$, all others 0) is one of them, as in the warning. A brute-force check of all 16 forms against all pairs in $\mathbb{F}_2^2$ gives the same counts, 8 and 2.

(d) Over $\mathbb{R}$ the two sets are **equal**. Alternating forms are skew-symmetric by Theorem 6.2.2 (a), and since $\mathbb{R}$ has characteristic 0, skew-symmetric forms are alternating by part (b) of that theorem. Concretely, both conditions say $b_{11} = b_{22} = 0$ and $b_{21} = -b_{12}$.

6.3 Permutations and Sign

An alternating form changes sign when two of its arguments are swapped (Theorem 6.2.1). To compare $f(\mathbf{v}_3, \mathbf{v}_1, \mathbf{v}_2)$ with $f(\mathbf{v}_1, \mathbf{v}_2, \mathbf{v}_3)$, we reach one list from the other by swaps and collect a factor -1 per swap. But the same rearrangement can be reached by different sequences of swaps, and Chapter 0 showed that even their number is not unique. If one route used an even number of swaps and another an odd number, we would get $f(\mathbf{v}_1, \mathbf{v}_2, \mathbf{v}_3) = -f(\mathbf{v}_1, \mathbf{v}_2, \mathbf{v}_3)$ for every alternating form, which is absurd for signed volume. This section rules that out. It attaches to each permutation a sign defined without any choices, proves that the sign is multiplicative, and deduces that the parity of the number of transpositions is well defined, as Chapter 0 promised.

6.3.1 Permutations, recalled

Recall from Chapter 0 that S_n is the group of bijections $\{1, \dots, n\} \to \{1, \dots, n\}$, with $n!$ elements. A permutation can be written in two-line notation, with $\sigma(i)$ below i, or as a product of cycles. The product $\sigma\tau$ is the composition $\sigma \circ \tau$: **first** τ**, then** σ, so products of cycles are read from right to left (Example (Computing with cycles)). A transposition $(i\ j)$ swaps i and j and fixes everything else, and for $n \geq 2$ every permutation is a product of transpositions (Theorem 0.10.4). The product is far from unique, since

$$(1\ 2\ 3) = (1\ 3)(1\ 2) = (1\ 2)(2\ 3) = (1\ 3)(1\ 2)(1\ 2)(1\ 2).$$

Here the numbers of transpositions are $2, 2, 4$, all even. The goal is to show this is no accident.

Why can we not simply **define** the sign of σ as $(-1)^r$, where σ is a product of r transpositions? Because that definition depends on a choice of product, and we would have to prove that every choice gives the same answer. That is the statement we are trying to prove. We need a definition that involves no choice at all.

6.3.2 Inversions and the sign

To measure how much a permutation scrambles $1, 2, \dots, n$, look at the bottom row $\sigma(1), \sigma(2), \dots, \sigma(n)$ of its two-line notation and count the pairs of entries that are in the wrong order. A sorted row

has none, and each swap of two neighboring entries changes the count by exactly one. So the count is a natural candidate for tracking the parity of swaps.

The sign of a permutation records whether it puts an even or an odd number of pairs out of order.

Definition 6.3.1 — Inversion

Let $\sigma \in S_n$. An **inversion** of σ is a pair (i, j) of positions with $1 \le i < j \le n$ **and** $\sigma(i) > \sigma(j)$. We write $\mathrm{inv}(\sigma)$ for the number of inversions of σ.

Definition 6.3.2 — Sign of a Permutation

The **sign** of $\sigma \in S_n$ is

$$\operatorname{sgn}\sigma = (-1)^{\mathrm{inv}(\sigma)} \in \{1, -1\}.$$

The permutation σ is **even** if $\operatorname{sgn}\sigma = 1$ and **odd** if $\operatorname{sgn}\sigma = -1$.

In words: an inversion is a pair of positions whose order σ **reverses**. The condition $i < j$ makes each pair of positions count once, and $\sigma(i) > \sigma(j)$ says the values come out in the opposite order. Since $\mathrm{inv}(\sigma)$ is the size of a subset of the finite set of pairs $i < j$, it is a well-defined integer between 0 and $n(n-1)/2$, and there is nothing to choose. That is the whole reason for this definition.

The identity. Its bottom row is sorted, so $\mathrm{inv}(\mathrm{id}) = 0$ and id is even. In $S_1 = \{\mathrm{id}\}$ this is the only permutation, with sign 1. The degenerate case matters: the identity is the empty product of transpositions, and its sign $1 = (-1)^0$ is what a product of 0 swaps should give.

All of S_3. Here is each permutation with its bottom row and inversions.

σ	id	(1 2)	(2 3)	(1 3)	(1 2 3)	(1 3 2)
bottom row	1 2 3	2 1 3	1 3 2	3 2 1	2 3 1	3 1 2
inversions	none	$(1,2)$	$(2,3)$	$(1,2),(1,3),(2,3)$	$(1,3),(2,3)$	$(1,2),(1,3)$
sgn	1	-1	-1	-1	1	1

For (1 2 3), the bottom row is $\sigma(1), \sigma(2), \sigma(3) = 2, 3, 1$, and the out-of-order pairs of positions are $(1, 3)$, since $2 > 1$, and $(2, 3)$, since $3 > 1$.

Two things stand out. The three transpositions are odd, although (1 3) has three inversions, not one. And the two 3-cycles are even, consistent with (1 2 3) = (1 3)(1 2) being a product of two transpositions.

Why all pairs, not just neighbors. A tempting shortcut counts only **adjacent** positions $(i, i+1)$ with $\sigma(i) > \sigma(i+1)$. For (1 3), with bottom row $3, 2, 1$, this count is 2, which would make (1 3) "even". But (1 3) = (1 2)(2 3)(1 2), as one checks by following $1 \mapsto 2 \mapsto 3 \mapsto 3$, $2 \mapsto 1 \mapsto 1 \mapsto 2$, $3 \mapsto 3 \mapsto 2 \mapsto 1$, and each factor has adjacent count 1. A count that is to be multiplicative must give $(-1)^3 = -1$ here, so the adjacent count is the wrong one.

> *Quick check.* Find $\operatorname{sgn}(1\ 4)$ in S_4 by counting inversions.

Solution. The bottom row is $4, 2, 3, 1$. The pairs of positions in the wrong order are $(1, 2), (1, 3), (1, 4)$, since 4 is larger than everything after it, and $(2, 4), (3, 4)$, since $2 > 1$ and $3 > 1$. The pair $(2, 3)$ is in order. So $\operatorname{inv}(1\ 4) = 5$ and $\operatorname{sgn}(1\ 4) = -1$.

6.3.3 The sign is multiplicative

The key property is that signs multiply when permutations are composed.

Theorem 6.3.1 — The Sign Is Multiplicative

For all $\sigma, \tau \in S_n$,

$$\operatorname{sgn}(\sigma\tau) = \operatorname{sgn}\sigma \cdot \operatorname{sgn}\tau.$$

Idea. Count inversions one pair at a time, and record each pair as $+1$ (order kept) or -1 (order reversed). The sign is the product of these ± 1's. Applying τ and then σ moves a pair of positions $\{i, j\}$ to $\{\tau(i), \tau(j)\}$ and then to $\{\sigma\tau(i), \sigma\tau(j)\}$. The order is reversed overall exactly when it is reversed at one of the two stages but not both, which is multiplication of ± 1's. Finally, as $\{i, j\}$ runs over all pairs, so does $\{\tau(i), \tau(j)\}$, so the contributions of σ multiply to $\operatorname{sgn}\sigma$, just in a different order.

Proof. For a non-zero integer m let $s(m) = 1$ if $m > 0$ and $s(m) = -1$ if $m < 0$. Then $s(mm') = s(m)s(m')$ for non-zero integers m, m', by the sign rules for products of integers.

Let $\mathcal{P}$ be the set of 2-element subsets $\{i, j\}$ of $\{1, \dots, n\}$. For $\rho \in S_n$ and $\{i, j\} \in \mathcal{P}$, define

$$\varepsilon_\rho(\{i, j\}) = s\big((\rho(i) - \rho(j))(i - j)\big).$$

This is defined: $i \neq j$ and $\rho(i) \neq \rho(j)$ since ρ is injective, so the product is non-zero; and exchanging the names i and j negates both factors, so the product does not depend on the order in which the subset is written. If $i < j$, then $i - j < 0$, so $\varepsilon_\rho(\{i, j\}) = -1$ exactly when $\rho(i) > \rho(j)$, that is, when (i, j) is an inversion of ρ. Hence, by Definition 6.3.2,

$$\operatorname{sgn}\rho = \prod_{P \in \mathcal{P}} \varepsilon_\rho(P). \tag{1}$$

Now let $\{i, j\} \in \mathcal{P}$. Since $\tau(i) \neq \tau(j)$, we have $(\tau(i) - \tau(j))^2 > 0$. Multiplying inside s by this positive integer does not change the value, so

$$\begin{aligned}\varepsilon_{\sigma\tau}(\{i, j\}) &= s\Big(\big(\sigma(\tau(i)) - \sigma(\tau(j))\big)\big(\tau(i) - \tau(j)\big) \cdot \big(\tau(i) - \tau(j)\big)(i - j)\Big) \\ &= \varepsilon_\sigma(\{\tau(i), \tau(j)\})\ \varepsilon_\tau(\{i, j\}).\end{aligned}$$

Let $\hat{\tau}\colon \mathcal{P} \to \mathcal{P}$, $\{i, j\} \mapsto \{\tau(i), \tau(j)\}$; the image has two elements because τ is injective. The same construction with τ^{-1} gives an inverse function, so $\hat{\tau}$ is a bijection (Theorem 0.4.7). Taking the product over all $P \in \mathcal{P}$ and using (1) three times,

$$\operatorname{sgn}(\sigma\tau) = \prod_{P \in \mathcal{P}} \varepsilon_\sigma(\hat{\tau}(P)) \cdot \prod_{P \in \mathcal{P}} \varepsilon_\tau(P) = \prod_{Q \in \mathcal{P}} \varepsilon_\sigma(Q) \cdot \operatorname{sgn}\tau = \operatorname{sgn}\sigma \cdot \operatorname{sgn}\tau,$$

where the second equality substitutes $Q = \hat{\tau}(P)$, which runs over $\mathcal{P}$ exactly once because $\hat{\tau}$ is a bijection, and reorders the finite product of integers. This proves the theorem.

■

By induction on the number of factors, $\operatorname{sgn}(\sigma_1\sigma_2\cdots\sigma_r) = \operatorname{sgn}\sigma_1\cdots\operatorname{sgn}\sigma_r$. In the language of Chapter 0, the set $\{1,-1\}$ is a group under multiplication (it contains 1, and it is closed under products and inverses, since $(-1)^{-1} = -1$), and the theorem says exactly that

$$\operatorname{sgn}\colon S_n \to \{1,-1\}$$

is a group homomorphism (Definition 0.10.3).

6.3.4 Transpositions and parity

Now we can compute the sign of the building blocks.

Corollary 6.3.2 — Sign of a Transposition

Every transposition is odd: $\operatorname{sgn}(i\ j) = -1$ for all $i \neq j$ in $\{1,\dots,n\}$.

Proof. Since $(i\ j) = (j\ i)$, we may assume $i < j$. Let $\tau = (i\ j)$ and let $p < q$ be positions. We decide when $\tau(p) > \tau(q)$.

- If neither p nor q lies in $\{i,j\}$, then $\tau(p) = p < q = \tau(q)$: no inversion.
- If $(p,q) = (i,j)$, then $\tau(i) = j > i = \tau(j)$: one inversion.
- If $p = i$ and $q \neq j$, then $\tau(p) = j$ and $\tau(q) = q$, an inversion exactly when $i < q < j$. This gives $j - i - 1$ inversions.
- If $q = j$ and $p \neq i$, then $\tau(p) = p$ and $\tau(q) = i$, an inversion exactly when $i < p < j$. This gives $j - i - 1$ inversions.
- If $p = j$ (so $q > j$), then $\tau(p) = i < q = \tau(q)$; if $q = i$ (so $p < i$), then $\tau(p) = p < j = \tau(q)$: no inversion.

These cases cover every pair, so $\operatorname{inv}(\tau) = 1 + 2(j - i - 1)$, an odd number. Hence $\operatorname{sgn}\tau = -1$.

■

The Quick check above is the case $(i,j) = (1,4)$: $1+2\cdot 2 = 5$ inversions. Combining the corollary with multiplicativity gives the fact that Chapter 0 left open.

Corollary 6.3.3 — Parity Is Well Defined

Let $n \geq 2$ and $\sigma \in S_n$. If $\sigma = \tau_1\cdots\tau_r$ is a product of r transpositions, then $\operatorname{sgn}\sigma = (-1)^r$. Consequently, if also $\sigma = \tau'_1\cdots\tau'_s$ with transpositions τ'_m, then r and s are both even or both odd.

Proof. By Theorem 6.3.1, extended to r factors, and Corollary 6.3.2, $\operatorname{sgn}\sigma = \operatorname{sgn}\tau_1\cdots\operatorname{sgn}\tau_r = (-1)^r$. In the same way $\operatorname{sgn}\sigma = (-1)^s$. Hence $(-1)^r = (-1)^s$, so $r - s$ is even.

■

So a permutation is even exactly when it is a product of an even number of transpositions, and the "number of swaps" has a well-defined parity even though the number itself is not defined.

Proposition 6.3.4 — Sign of a Cycle

A k-cycle has sign $(-1)^{k-1}$. In particular, cycles of even length are odd and cycles of odd length are even.

Proof. For $k = 1$ the cycle is id, with sign $1 = (-1)^0$. Let $k \geq 2$ and let $\gamma = (i_1\ i_2\ \cdots\ i_k)$. We claim

$$\gamma = (i_1\ i_k)(i_1\ i_{k-1}) \cdots (i_1\ i_3)(i_1\ i_2).$$

Apply the factors from right to left. The element i_1 is sent to i_2 by $(i_1\ i_2)$, and no later factor involves i_2. For $2 \leq m \leq k-1$, the element i_m is fixed by the factors before $(i_1\ i_m)$, sent to i_1 by it, then to i_{m+1} by $(i_1\ i_{m+1})$, and no later factor involves i_{m+1}. The element i_k is fixed until the last factor $(i_1\ i_k)$ sends it to i_1. Elements outside the cycle are fixed by every factor. This agrees with γ everywhere, proving the claim. The product has $k-1$ transpositions, so $\operatorname{sgn}\gamma = (-1)^{k-1}$ by Corollary 6.3.3.

■

Warning. **Only the parity of the number of transpositions is determined, and it is not the parity of the cycle length.** The identity in S_3 equals $(1\ 2)(1\ 2)$ and also $(1\ 2)(1\ 3)(1\ 2)(1\ 3)(1\ 2)(1\ 3)$, since $((1\ 2)(1\ 3))^3 = (1\ 3\ 2)^3 = \mathrm{id}$; the numbers 2 and 6 differ, only their parity agrees. And a 3-cycle, "of length 3", is **even**: $(1\ 2\ 3) = (1\ 3)(1\ 2)$. One more trap concerns order: $(1\ 3)(1\ 2) = (1\ 2\ 3)$ but $(1\ 2)(1\ 3) = (1\ 3\ 2)$. Multiplying in the wrong order gives the wrong permutation and the wrong bottom row, even though, by Theorem 6.3.1, it happens to give the right sign.

6.3.5 The alternating group

Since sgn is a homomorphism, its kernel is a subgroup of S_n (Theorem 0.10.3).

Definition 6.3.3 — Alternating Group

The **alternating group** A_n is the kernel of $\operatorname{sgn}\colon S_n \to \{1, -1\}$, that is, the subgroup of **even** permutations in S_n.

For example, $A_3 = \{\mathrm{id}, (1\ 2\ 3), (1\ 3\ 2)\}$ by the table above, and $A_2 = \{\mathrm{id}\}$. For $n \geq 2$, exactly half of the permutations are even (Exercise C1). The odd permutations do **not** form a subgroup: they do not contain id. The name is no coincidence: as we see below and in the next section, rearranging the arguments of an alternating form by an even permutation leaves its value unchanged.

6.3.6 Back to alternating forms

Here is why this section exists. Let f be an alternating 3-linear form and compare $f(\mathbf{v}_3, \mathbf{v}_1, \mathbf{v}_2)$ with $f(\mathbf{v}_1, \mathbf{v}_2, \mathbf{v}_3)$. Swapping the first two arguments of $(\mathbf{v}_3, \mathbf{v}_1, \mathbf{v}_2)$ gives $(\mathbf{v}_1, \mathbf{v}_3, \mathbf{v}_2)$, and swapping the last two then gives $(\mathbf{v}_1, \mathbf{v}_2, \mathbf{v}_3)$. By Theorem 6.2.1 (a) each swap costs a factor -1, so $f(\mathbf{v}_3, \mathbf{v}_1, \mathbf{v}_2) = (-1)^2 f(\mathbf{v}_1, \mathbf{v}_2, \mathbf{v}_3) = f(\mathbf{v}_1, \mathbf{v}_2, \mathbf{v}_3)$. The list $(\mathbf{v}_3, \mathbf{v}_1, \mathbf{v}_2)$ is $(\mathbf{v}_{\sigma(1)}, \mathbf{v}_{\sigma(2)}, \mathbf{v}_{\sigma(3)})$ for $\sigma = (1\ 3\ 2)$, with bottom row $3, 1, 2$, and the factor 1 we found is $\operatorname{sgn}\sigma$.

A different sequence of swaps could have been used, possibly a longer one. By Corollary 6.3.3, every such sequence has an even number of swaps, so every route gives the same factor. In general, the next section proves that $f(\mathbf{v}_{\sigma(1)}, \dots, \mathbf{v}_{\sigma(k)}) = \operatorname{sgn}\sigma \cdot f(\mathbf{v}_1, \dots, \mathbf{v}_k)$ for every alternating k-linear form, and uses it to turn each of the $n!$ surviving terms of the expansion sketched in the first section of this chapter into $\pm D(\mathbf{e}_1, \dots, \mathbf{e}_n)$. Without the corollary, the factor computed swap by swap could depend on the route, and could not be identified with $\operatorname{sgn}\sigma$.

6.3.7 Computing signs in practice

There are now two independent ways to find a sign: count inversions, or factor into cycles and use Proposition 6.3.4 with multiplicativity. Doing both is a good check.

Example. (A Sign Computed Two Ways)

Find the sign of the permutation $\sigma \in S_6$ with two-line notation $\begin{pmatrix} 1 & 2 & 3 & 4 & 5 & 6 \\ 4 & 5 & 3 & 6 & 2 & 1 \end{pmatrix}$, first by counting inversions and then from its cycles.

Solution. Inversions. Go through the bottom row $4, 5, 3, 6, 2, 1$ from left to right, and for each entry count the **later** entries that are smaller:

position i	1	2	3	4	5	6
$\sigma(i)$	4	5	3	6	2	1
later and smaller	3, 2, 1	3, 2, 1	2, 1	2, 1	1	none
count	3	3	2	2	1	0

So $\operatorname{inv}(\sigma) = 3 + 3 + 2 + 2 + 1 + 0 = 11$, which is odd, and $\operatorname{sgn}\sigma = -1$.

Cycles. Following elements as in Example (Computing with cycles): $1 \mapsto 4 \mapsto 6 \mapsto 1$, then $2 \mapsto 5 \mapsto 2$, and $3 \mapsto 3$. So $\sigma = (1\ 4\ 6)(2\ 5)$. By Proposition 6.3.4, the 3-cycle has sign 1 and the transposition has sign -1, so by Theorem 6.3.1, $\operatorname{sgn}\sigma = 1 \cdot (-1) = -1$. The two methods agree.

The following cell checks the example, and also tests Theorem 6.3.1 and Proposition 6.3.4 on all of S_5 by brute force. Permutations are stored as tuples of values $(\sigma(1), \dots, \sigma(n))$, shifted to start at 0.

```
from itertools import permutations, combinations

def inv(s):
    return sum(1 for i, j in combinations(range(len(s)), 2) if s[i] > s[j])
```

```
def sgn(s):
    return (-1) ** inv(s)

def compose(s, t):          # (s t)(i) = s(t(i)): first t, then s
    return tuple(s[t[i]] for i in range(len(t)))

def cycle(entries, n):      # the cycle (entries[0] entries[1] ...), 0-based
    s = list(range(n))
    for a, b in zip(entries, entries[1:] + entries[:1]):
        s[a] = b
    return tuple(s)

sigma = (4, 5, 3, 6, 2, 1)
sigma0 = tuple(x - 1 for x in sigma)
print("inversions:", inv(sigma0), " sign:", sgn(sigma0))
print("(1 4 6)(2 5) equals sigma:", compose(cycle([0, 3, 5], 6), cycle([1, 4], 6))
    == sigma0)

S5 = list(permutations(range(5)))
print("multiplicative on S_5:", all(sgn(compose(s, t)) == sgn(s) * sgn(t) for s in
    S5 for t in S5))
print("k-cycles have sign (-1)^(k-1):", all(sgn(cycle(list(range(k)), 5)) == (-1) **
     (k - 1) for k in range(1, 6)))
```

6.3.8 Exercises

6.3.8.1 A. Check your understanding

Exercise A1.

(a) Define an inversion of $\sigma \in S_n$ and the sign $\operatorname{sgn}\sigma$.

(b) True or false: every 3-cycle is odd. Justify your answer.

(c) True or false: some permutation is a product of 5 transpositions and also a product of 8 transpositions. Justify your answer.

(d) What is the kernel of $\operatorname{sgn}\colon S_n \to \{1, -1\}$? Is the set of odd permutations a subgroup?

(e) True or false: $\operatorname{sgn}(\sigma\tau) = \operatorname{sgn}(\tau\sigma)$ for all $\sigma, \tau \in S_n$, even when $\sigma\tau \neq \tau\sigma$. Justify your answer.

(f) Let f be an alternating 3-linear form. Express $f(\mathbf{v}_2, \mathbf{v}_3, \mathbf{v}_1)$ in terms of $f(\mathbf{v}_1, \mathbf{v}_2, \mathbf{v}_3)$.

Solution.

(a) An inversion of σ is a pair (i, j) with $1 \le i < j \le n$ and $\sigma(i) > \sigma(j)$ (Definition 6.3.1); $\operatorname{sgn}\sigma = (-1)^{\operatorname{inv}(\sigma)}$ (Definition 6.3.2).

(b) False. By Proposition 6.3.4 a 3-cycle has sign $(-1)^2 = 1$, so it is even; for instance $(1\ 2\ 3) = (1\ 3)(1\ 2)$.

(c) False. By Corollary 6.3.3 the numbers of transpositions in two such products have the same parity, and 5 and 8 do not.

(d) The kernel is the alternating group A_n of even permutations (Definition 6.3.3).

The odd permutations do not form a subgroup: id is even, so it is not among them.

(e) True. By Theorem 6.3.1 both sides equal $\operatorname{sgn}\sigma\cdot\operatorname{sgn}\tau$, and multiplication of integers is commutative. For example $(1\ 3)(1\ 2) \neq (1\ 2)(1\ 3)$, but both are 3-cycles, with sign 1.

(f) Swapping the first two arguments of $(\mathbf{v}_2, \mathbf{v}_3, \mathbf{v}_1)$ gives $(\mathbf{v}_3, \mathbf{v}_2, \mathbf{v}_1)$, and swapping the first and third then gives $(\mathbf{v}_1, \mathbf{v}_2, \mathbf{v}_3)$. Each swap costs a factor -1 by Theorem 6.2.1 (a), so $f(\mathbf{v}_2, \mathbf{v}_3, \mathbf{v}_1) = f(\mathbf{v}_1, \mathbf{v}_2, \mathbf{v}_3)$. This matches the sign of the rearrangement σ with bottom row $2, 3, 1$, namely $\sigma = (1\ 2\ 3)$, which is even.

6.3.8.2 B. Practice

Exercise B1: Computing Signs.

Find the sign of each permutation, both by counting inversions and by using cycles.

(a) $\sigma \in S_4$ with two-line notation $\begin{pmatrix} 1 & 2 & 3 & 4 \\ 2 & 4 & 1 & 3 \end{pmatrix}$.

(b) $(1\ 2)(3\ 4\ 5) \in S_5$.

(c) $(1\ 2\ 3)(2\ 3\ 4) \in S_4$.

Solution.

(a) *Inversions.* In the bottom row $2, 4, 1, 3$, the entry 2 is followed by the smaller entry 1, the entry 4 by 1 and 3, and the entry 1 by nothing smaller. So $\operatorname{inv}(\sigma) = 1 + 2 + 0 = 3$ and $\operatorname{sgn}\sigma = -1$. *Cycles.* $1 \mapsto 2 \mapsto 4 \mapsto 3 \mapsto 1$, so $\sigma = (1\ 2\ 4\ 3)$, a 4-cycle, with sign $(-1)^3 = -1$ by Proposition 6.3.4.

(b) *Cycles.* By Proposition 6.3.4 and Theorem 6.3.1, the sign is $(-1)\cdot(-1)^2 = -1$. *Inversions.* The permutation sends $1 \mapsto 2$, $2 \mapsto 1$, $3 \mapsto 4$, $4 \mapsto 5$, $5 \mapsto 3$, so the bottom row is $2, 1, 4, 5, 3$. The inversions are $(1, 2)$, $(3, 5)$ and $(4, 5)$, so there are 3, and the sign is -1.

(c) *Cycles.* Both factors are 3-cycles, so the sign is $1 \cdot 1 = 1$. *Inversions.* Apply $(2\ 3\ 4)$ first: $1 \mapsto 1 \mapsto 2$, $2 \mapsto 3 \mapsto 1$, $3 \mapsto 4 \mapsto 4$, $4 \mapsto 2 \mapsto 3$. The bottom row is $2, 1, 4, 3$, with inversions $(1, 2)$ and $(3, 4)$. So the sign is $(-1)^2 = 1$, and in fact the product is $(1\ 2)(3\ 4)$.

Exercise B2: Sign of the Inverse.

Prove that $\operatorname{sgn}(\sigma^{-1}) = \operatorname{sgn}\sigma$ for every $\sigma \in S_n$.

Solution. Let $\sigma \in S_n$. By Theorem 6.3.1, $\operatorname{sgn}\sigma \cdot \operatorname{sgn}(\sigma^{-1}) = \operatorname{sgn}(\sigma\sigma^{-1}) = \operatorname{sgn}(\mathrm{id}) = 1$, since id has no inversions. Since $\operatorname{sgn}\sigma \in \{1, -1\}$ and $(\pm 1)^{-1} = \pm 1$, multiplying both sides by $\operatorname{sgn}\sigma$ gives $\operatorname{sgn}(\sigma^{-1}) = \operatorname{sgn}\sigma$.

Exercise B3: The Reversal Permutation.

Let $\rho \in S_n$ be the reversal, $\rho(i) = n+1-i$. Show that $\mathrm{inv}(\rho) = n(n-1)/2$. Hence find the n for which ρ is even, and decide the sign of ρ for $n = 6$ and $n = 9$.

Solution. For $1 \le i < j \le n$, $\rho(i) = n+1-i > n+1-j = \rho(j)$. So **every** pair $i < j$ is an inversion, and $\mathrm{inv}(\rho)$ is the number of 2-element subsets of $\{1, \dots, n\}$, which is $n(n-1)/2$. Hence $\operatorname{sgn}\rho = (-1)^{n(n-1)/2}$.

Write $n = 4q + t$ with $t \in \{0, 1, 2, 3\}$. Then $n(n-1)/2$ is $2q(4q-1)$ for $t = 0$, $2q(4q+1)$ for $t = 1$, $(4q+1)(2q+1)$ for $t = 2$, and $(2q+1)(4q+3)$ for $t = 3$. The first two are even and the last two are odd. So ρ is even exactly when n leaves remainder 0 or 1 on division by 4. For $n = 6$, $\mathrm{inv}(\rho) = 15$ and ρ is odd; for $n = 9$, $\mathrm{inv}(\rho) = 36$ and ρ is even.

6.3.8.3 C. Going deeper

Exercise C1: Half the Permutations Are Even.

Let $n \ge 2$. Prove that exactly $n!/2$ permutations in S_n are even.

Hint: consider $\sigma \mapsto (1\ 2)\sigma$.

Solution. Let E and O be the sets of even and odd permutations; they are disjoint and $E \cup O = S_n$, so $|E| + |O| = n!$. Let $\tau = (1\ 2)$, which exists since $n \ge 2$, and define $L\colon S_n \to S_n$, $L(\sigma) = \tau\sigma$. By Theorem 6.3.1 and Corollary 6.3.2, $\operatorname{sgn} L(\sigma) = -\operatorname{sgn}\sigma$, so L maps E into O and O into E. Since $\tau\tau = \mathrm{id}$, $L(L(\sigma)) = \sigma$, so L restricted to E is a bijection $E \to O$ with inverse L restricted to O (Theorem 0.4.7). Hence $|E| = |O| = n!/2$.

Exercise C2: Sign from the Number of Cycles.

Suppose $\sigma \in S_n$ is written as a product $\sigma = \gamma_1\gamma_2\cdots\gamma_c$ of **disjoint** cycles (no element appears in two of them) whose lengths $k_1, \dots, k_c$ add up to n, where fixed points are included as cycles of length 1. (Such a product always exists: follow each element around its loop, as in Example (Computing with cycles).)

(a) Prove that $\operatorname{sgn}\sigma = (-1)^{n-c}$.

(b) Use (a) to find the sign of $\sigma = (1\ 4\ 6)(2\ 5) \in S_6$, and compare with Example (A Sign Computed Two Ways).

(c) Deduce that an n-cycle in S_n and the identity in S_n have the same sign exactly when n is odd.

Solution.

(a) By Theorem 6.3.1 and Proposition 6.3.4,

$$\operatorname{sgn}\sigma = \prod_{m=1}^{c} \operatorname{sgn}\gamma_m = \prod_{m=1}^{c} (-1)^{k_m - 1} = (-1)^{(k_1+\cdots+k_c)-c} = (-1)^{n-c}.$$

(b) Including the fixed point 3 as the cycle (3), $\sigma = (1\ 4\ 6)(2\ 5)(3)$, with lengths $3 + 2 + 1 = 6$ and $c = 3$. So $\operatorname{sgn}\sigma = (-1)^{6-3} = -1$, as in Example (A Sign Computed Two Ways).

(c) An n-cycle has $c = 1$ and sign $(-1)^{n-1}$; the identity consists of n cycles of length

1, so $c = n$ and its sign is $(-1)^0 = 1$. These agree exactly when $n-1$ is even, that is, when n is odd.

6.4 Existence and Uniqueness of the Determinant

In the first section of this chapter, signed area obeyed three rules: it is linear in each side, it vanishes when two sides are equal, and the unit square has area 1. In the second section we named functions obeying the first two rules, alternating multilinear forms, and in the third we built the sign of a permutation. This section puts the pieces together. We prove that on F^n there is **exactly one** alternating n-linear form that takes the value 1 on the standard basis, and we find a formula for it. That form is the determinant.

6.4.1 The goal and the plan

Here is the statement we are after.

> There is exactly one function $D\colon F^n \times \cdots \times F^n \to F$ (with n factors) that is n-linear (Definition 6.2.1), alternating (Definition 6.2.2), and satisfies $D(\mathbf{e}_1, \ldots, \mathbf{e}_n) = 1$.

It has two halves of a very different nature. **Uniqueness** says: if such a D exists, its values are forced. **Existence** says: some function really has all three properties. We prove uniqueness first, because its proof is how we *find* the formula. Suppose D exists, expand everything using the rules, and see what is left. The formula that comes out is then the only candidate, and existence reduces to checking that the candidate obeys the rules.

Throughout, a list of n columns $\mathbf{a}_1, \ldots, \mathbf{a}_n \in F^n$ and the matrix $\mathbf{A} = \begin{pmatrix} \mathbf{a}_1 & \cdots & \mathbf{a}_n \end{pmatrix} \in M_n(F)$ carry the same information, and we pass between them freely. We write a_{ij} for the i-th entry of $\mathbf{a}_j$, so that

$$\mathbf{a}_j = a_{1j}\mathbf{e}_1 + a_{2j}\mathbf{e}_2 + \cdots + a_{nj}\mathbf{e}_n = \sum_{i=1}^{n} a_{ij}\mathbf{e}_i.$$

6.4.2 Rearranging the arguments

Expanding a form on basis vectors will produce values like $f(\mathbf{e}_3, \mathbf{e}_1, \mathbf{e}_2)$: the standard basis in a scrambled order. Alternating forms handle scrambling by a sign, and the sign is exactly the one built from inversions.

Lemma 6.4.1 — Permuting the arguments of an alternating form

Let f be an alternating n-linear form on a vector space V over F, let $\mathbf{v}_1, \ldots, \mathbf{v}_n \in V$,

and let $\sigma \in S_n$. Then

$$f(\mathbf{v}_{\sigma(1)}, \mathbf{v}_{\sigma(2)}, \dots, \mathbf{v}_{\sigma(n)}) = \operatorname{sgn}(\sigma)\, f(\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_n).$$

Idea. A transposition swaps two arguments, and each swap costs a factor -1 by Theorem 6.2.1. Every permutation is a product of transpositions, so the value picks up $(-1)^k$ for a product of k of them. Multiplicativity of the sign says that $(-1)^k$ is $\operatorname{sgn}(\sigma)$, whichever product we chose.

Proof. If $n = 1$, then $S_1 = \{\mathrm{id}\}$ and $\operatorname{sgn}(\mathrm{id}) = 1$, since the identity has no inversions (Definition 6.3.2); there is nothing to prove. Let $n \geq 2$. For $\pi \in S_n$, write $f_\pi = f(\mathbf{v}_{\pi(1)}, \dots, \mathbf{v}_{\pi(n)})$.

First let $\pi \in S_n$ and let $\tau = (p\ q)$ be a transposition. The j-th argument of $f_{\pi\tau}$ is $\mathbf{v}_{\pi(\tau(j))}$. For $j \neq p, q$ this is $\mathbf{v}_{\pi(j)}$; for $j = p$ it is $\mathbf{v}_{\pi(q)}$; for $j = q$ it is $\mathbf{v}_{\pi(p)}$. So the arguments of $f_{\pi\tau}$ are those of f_π with positions p and q exchanged. By Theorem 6.2.1, swapping two arguments changes the sign, so

$$f_{\pi\tau} = -f_\pi. \tag{$*$}$$

Now let $\sigma \in S_n$. By Theorem 0.10.4, $\sigma = \tau_1\tau_2\cdots\tau_k$ for some transpositions $\tau_1, \dots, \tau_k$ with $k \geq 1$. Put $\pi_0 = \mathrm{id}$ and $\pi_m = \tau_1 \cdots \tau_m$, so that $\pi_m = \pi_{m-1}\tau_m$. Applying $(*)$ k times,

$$f_\sigma = f_{\pi_k} = -f_{\pi_{k-1}} = \cdots = (-1)^k f_{\pi_0} = (-1)^k f(\mathbf{v}_1, \dots, \mathbf{v}_n).$$

On the other hand, by Theorem 6.3.1 and Corollary 6.3.2, $\operatorname{sgn}(\sigma) = \operatorname{sgn}(\tau_1)\cdots\operatorname{sgn}(\tau_k) = (-1)^k$. This proves the lemma.

■

The proof chose a factorization of σ into transpositions, and different choices can have different lengths. The answer does not depend on the choice, because only the parity of k enters, and Corollary 6.3.3 says the parity is determined by σ. In the proof this is absorbed into the equation $(-1)^k = \operatorname{sgn}(\sigma)$.

6.4.3 Uniqueness

We now expand an alternating form completely. It helps to see the case $n = 2$ first.

Theorem 6.4.2 — Uniqueness of Alternating Forms

Let f be an alternating n-linear form on F^n, and let $\mathbf{a}_1, \dots, \mathbf{a}_n \in F^n$ have entries a_{ij} as above. Then

$$f(\mathbf{a}_1, \dots, \mathbf{a}_n) = f(\mathbf{e}_1, \dots, \mathbf{e}_n) \sum_{\sigma \in S_n} \operatorname{sgn}(\sigma)\, a_{\sigma(1)1}\, a_{\sigma(2)2} \cdots a_{\sigma(n)n}.$$

In particular, an alternating n-linear form on F^n is determined by the single value $f(\mathbf{e}_1, \dots, \mathbf{e}_n)$.

Idea. For $n = 2$, write $\mathbf{a}_1 = a_{11}\mathbf{e}_1 + a_{21}\mathbf{e}_2$ and $\mathbf{a}_2 = a_{12}\mathbf{e}_1 + a_{22}\mathbf{e}_2$. Linearity in the first argument, then in the second, gives four terms:

$$\begin{aligned} f(\mathbf{a}_1, \mathbf{a}_2) &= a_{11}\, f(\mathbf{e}_1, \mathbf{a}_2) + a_{21}\, f(\mathbf{e}_2, \mathbf{a}_2) \\ &= a_{11}a_{12}\, f(\mathbf{e}_1, \mathbf{e}_1) + a_{11}a_{22}\, f(\mathbf{e}_1, \mathbf{e}_2) \\ &\quad + a_{21}a_{12}\, f(\mathbf{e}_2, \mathbf{e}_1) + a_{21}a_{22}\, f(\mathbf{e}_2, \mathbf{e}_2). \end{aligned}$$

The first and last terms vanish because two arguments are equal, and $f(\mathbf{e}_2, \mathbf{e}_1) = -f(\mathbf{e}_1, \mathbf{e}_2)$. What is left is $(a_{11}a_{22} - a_{21}a_{12})\, f(\mathbf{e}_1, \mathbf{e}_2)$, the formula for $n = 2$.

In general the four terms become one term for each way of choosing, for every argument j, which basis vector $\mathbf{e}_{\varphi(j)}$ to take from $\mathbf{a}_j$. A choice is a function $\varphi\colon \{1, \dots, n\} \to \{1, \dots, n\}$, and there are n^n of them. The ones that pick some basis vector twice die. The survivors pick every basis vector once, so they are permutations, and Lemma 6.4.1 converts each into a sign.

Proof. Write $[k] = \{1, \dots, k\}$ for $k \geq 1$. We first expand the arguments one at a time.

Claim. For each $k \in \{0, 1, \dots, n\}$,

$$f(\mathbf{a}_1, \dots, \mathbf{a}_n) = \sum_{\varphi\colon [k] \to [n]} a_{\varphi(1)1} \cdots a_{\varphi(k)k}\, f(\mathbf{e}_{\varphi(1)}, \dots, \mathbf{e}_{\varphi(k)}, \mathbf{a}_{k+1}, \dots, \mathbf{a}_n),$$

where the sum runs over **all** functions $\varphi\colon [k] \to [n]$. For $k = 0$ we read the right side as the single term $f(\mathbf{a}_1, \dots, \mathbf{a}_n)$.

Proof. We use induction on k. For $k = 0$ both sides are $f(\mathbf{a}_1, \dots, \mathbf{a}_n)$. Suppose the claim holds for some $k < n$. In each term, the argument in position $k + 1$ is $\mathbf{a}_{k+1} = \sum_{i=1}^{n} a_{i,k+1}\mathbf{e}_i$. Since f is linear in argument $k + 1$,

$$f(\mathbf{e}_{\varphi(1)}, \dots, \mathbf{e}_{\varphi(k)}, \mathbf{a}_{k+1}, \dots, \mathbf{a}_n) = \sum_{i=1}^{n} a_{i,k+1}\, f(\mathbf{e}_{\varphi(1)}, \dots, \mathbf{e}_{\varphi(k)}, \mathbf{e}_i, \mathbf{a}_{k+2}, \dots, \mathbf{a}_n).$$

Substituting this into the induction hypothesis gives a sum over all pairs (φ, i) with $\varphi\colon [k] \to [n]$ and $i \in [n]$. Such a pair is the same thing as a function $\psi\colon [k+1] \to [n]$, namely $\psi(j) = \varphi(j)$ for $j \leq k$ and $\psi(k+1) = i$; and each ψ arises from exactly one pair. The term for the pair (φ, i) is $a_{\psi(1)1} \cdots a_{\psi(k+1),k+1}\, f(\mathbf{e}_{\psi(1)}, \dots, \mathbf{e}_{\psi(k+1)}, \mathbf{a}_{k+2}, \dots, \mathbf{a}_n)$. This is the claim for $k + 1$.

■

Taking $k = n$ in the claim,

$$f(\mathbf{a}_1, \dots, \mathbf{a}_n) = \sum_{\varphi\colon [n] \to [n]} a_{\varphi(1)1} \cdots a_{\varphi(n)n}\, f(\mathbf{e}_{\varphi(1)}, \dots, \mathbf{e}_{\varphi(n)}). \qquad (**)$$

We sort the functions φ into two kinds.

Case 1: φ is not injective. Then $\varphi(p) = \varphi(q)$ for some $p \neq q$, so the arguments in positions p and q of $f(\mathbf{e}_{\varphi(1)}, \dots, \mathbf{e}_{\varphi(n)})$ are equal. Since f is alternating, this value is 0, and the whole term is 0.

Case 2: φ is injective. Since $[n]$ is finite, φ is bijective by Theorem 0.4.9, so $\varphi = \sigma$ for some $\sigma \in S_n$. By Lemma 6.4.1 with $\mathbf{v}_i = \mathbf{e}_i$,

$$f(\mathbf{e}_{\sigma(1)}, \dots, \mathbf{e}_{\sigma(n)}) = \operatorname{sgn}(\sigma)\, f(\mathbf{e}_1, \dots, \mathbf{e}_n).$$

Hence only the terms of Case 2 survive in $(**)$, there is exactly one for each $\sigma \in S_n$, and

$$f(\mathbf{a}_1, \dots, \mathbf{a}_n) = \sum_{\sigma \in S_n} a_{\sigma(1)1} \cdots a_{\sigma(n)n}\, \operatorname{sgn}(\sigma)\, f(\mathbf{e}_1, \dots, \mathbf{e}_n),$$

which is the stated formula after moving the scalar $f(\mathbf{e}_1, \dots, \mathbf{e}_n)$ to the front. This proves the theorem.

■

So the three rules leave no freedom at all. If a normalized alternating form exists, it **must** be

$$\mathbf{a}_1, \dots, \mathbf{a}_n \longmapsto \sum_{\sigma \in S_n} \operatorname{sgn}(\sigma)\, a_{\sigma(1)1} \cdots a_{\sigma(n)n}.$$

Out of n^n terms, the rules killed all but $n!$. For $n = 3$ that is 6 out of 27.

6.4.4 Existence

The candidate has been found. Now we check it against the rules, forgetting where it came from.

Theorem 6.4.3 — Existence: the Leibniz Formula

Define $D\colon F^n \times \cdots \times F^n \to F$ by

$$D(\mathbf{a}_1, \dots, \mathbf{a}_n) = \sum_{\sigma \in S_n} \operatorname{sgn}(\sigma)\, a_{\sigma(1)1}\, a_{\sigma(2)2} \cdots a_{\sigma(n)n},$$

where a_{ij} is the i-th entry of $\mathbf{a}_j$. Then D is an alternating n-linear form on F^n, and $D(\mathbf{e}_1, \dots, \mathbf{e}_n) = 1$.

Idea. Linearity is visible: each product takes exactly one entry from each column. For alternation, suppose columns p and q are equal. Pair each σ with $\sigma(p\ q)$. The two permutations have opposite signs. Their products use the same entries, except that the entries taken from columns p and q trade places, and those two columns are equal. So each pair contributes $x - x = 0$.

Why pair terms instead of arguing "swapping the equal columns changes D to $-D$, so $D = -D$ and $D = 0$"? Because $D = -D$ gives $2D = 0$, and over a field with $1 + 1 = 0$, such as $\mathbb{F}_2$, that says nothing. The pairing argument never divides by 2.

Proof. Multilinearity. Fix $k \in [n]$ and fix all columns except the k-th. For a fixed σ, the product $a_{\sigma(1)1} \cdots a_{\sigma(n)n}$ contains exactly one entry of $\mathbf{a}_k$, namely $a_{\sigma(k)k}$, the $\sigma(k)$-th coordinate of $\mathbf{a}_k$. So the term for σ equals $c_\sigma\, a_{\sigma(k)k}$, where $c_\sigma = \operatorname{sgn}(\sigma) \prod_{j \neq k} a_{\sigma(j)j}$ does not depend on $\mathbf{a}_k$. The map $\mathbf{a}_k \mapsto a_{\sigma(k)k}$ is linear, since coordinates of a sum are sums of coordinates and coordinates of $c\mathbf{a}_k$ are c times the coordinates. So each term is linear

in $\mathbf{a}_k$, and hence so is their sum D.

Alternation. Suppose $\mathbf{a}_p = \mathbf{a}_q$ with $p < q$, that is, $a_{ip} = a_{iq}$ for all i. Let $\tau = (p\ q)$, let $A_n = \{\sigma \in S_n : \operatorname{sgn}(\sigma) = 1\}$ be the even permutations (Definition 6.3.3), so that $S_n \setminus A_n = \{\sigma \in S_n : \operatorname{sgn}(\sigma) = -1\}$ consists of the odd ones. Since $\operatorname{sgn}(\sigma\tau) = \operatorname{sgn}(\sigma)\operatorname{sgn}(\tau) = -\operatorname{sgn}(\sigma)$ by Theorem 6.3.1 and Corollary 6.3.2, the map $\sigma \mapsto \sigma\tau$ sends A_n to $S_n \setminus A_n$. It is a bijection $A_n \to S_n \setminus A_n$, because $\rho \mapsto \rho\tau$ sends $S_n \setminus A_n$ back to A_n and $\sigma\tau\tau = \sigma$. Every $\sigma \in S_n$ has sign 1 or -1, so

$$D(\mathbf{a}_1, \dots, \mathbf{a}_n) = \sum_{\sigma \in A_n} \Big(\prod_{j=1}^{n} a_{\sigma(j)j} - \prod_{j=1}^{n} a_{\sigma\tau(j)\,j} \Big).$$

Fix $\sigma \in A_n$ and compare the two products factor by factor. For $j \neq p, q$, $\sigma\tau(j) = \sigma(j)$, so the factors agree. For $j = p$, the second product has $a_{\sigma(q)p} = a_{\sigma(q)q}$, which is the factor of the first product at $j = q$. For $j = q$, the second product has $a_{\sigma(p)q} = a_{\sigma(p)p}$, the factor of the first product at $j = p$. So the two products consist of the same n factors in a different order, and they are equal because multiplication in F is commutative. Every bracket is 0, and $D(\mathbf{a}_1, \dots, \mathbf{a}_n) = 0$.

Normalization. For $\mathbf{a}_j = \mathbf{e}_j$, a_{ij} is 1 if $i = j$ and 0 otherwise. The product $a_{\sigma(1)1} \cdots a_{\sigma(n)n}$ is therefore 1 if $\sigma(j) = j$ for all j, and 0 otherwise. Only $\sigma = \mathrm{id}$ contributes, and $\operatorname{sgn}(\mathrm{id}) = 1$. Hence $D(\mathbf{e}_1, \dots, \mathbf{e}_n) = 1$. This proves the theorem.

■

Uniqueness and existence together answer the question of the first section: the rules of signed area single out exactly one function.

6.4.5 The determinant

We now have a function of square matrices that is forced on us by three reasonable rules, and it deserves a name. It is the central notion of this chapter.

The determinant is the only way to attach a number to n vectors in F^n that is linear in each vector, vanishes when two vectors coincide, and gives 1 on the standard basis.

Definition 6.4.1 — Determinant

Let $n \geq 1$ and $\mathbf{A} = (a_{ij}) \in M_n(F)$. The **determinant** of $\mathbf{A}$ is

$$\det \mathbf{A} := \sum_{\sigma \in S_n} \operatorname{sgn}(\sigma)\, a_{\sigma(1)1}\, a_{\sigma(2)2} \cdots a_{\sigma(n)n} \ \in F.$$

For columns $\mathbf{a}_1, \dots, \mathbf{a}_n \in F^n$ we also write $\det(\mathbf{a}_1, \dots, \mathbf{a}_n)$ for the determinant of the matrix $\begin{pmatrix} \mathbf{a}_1 & \cdots & \mathbf{a}_n \end{pmatrix}$.

In words: run over **all** $n!$ permutations σ. For each, pick from column j the entry in row $\sigma(j)$; this picks one entry in every column and, because σ is a bijection, one entry in every row. Multiply the n picked entries, attach the sign of σ, and add up. The determinant is defined **only for square matrices**, and its value lies in the field F of the entries.

Well-definedness. The formula is a finite sum, so it always gives a number. What the name "**the** determinant" really claims is that nothing else satisfies the three rules, and that is Theorem 6.4.2; Theorem 6.4.3 shows det does satisfy them. The sign $\operatorname{sgn}(\sigma)$ is fixed by counting inversions (Definition 6.3.2), and by Corollary 6.3.3 any factorization of σ into transpositions gives the same sign, so either method may be used to evaluate the formula.

Examples.

- $n = 1$. $S_1 = \{\mathrm{id}\}$, so $\det(a) = a$. A degenerate case, but it is the base of every induction on size.
- $n = 2$. $S_2 = \{\mathrm{id}, (1\ 2)\}$, with signs 1 and -1. The identity picks $a_{11}a_{22}$, and $(1\ 2)$ picks $a_{21}a_{12}$. So
$$\det \begin{pmatrix} a & b \\ c & d \end{pmatrix} = ad - cb,$$
the value derived from the rules in Example ($ad - bc$ from the Rules), and the number whose non-vanishing decides invertibility in Theorem 0.9.8.
- $n = 3$. The six permutations of S_3 and their signs (a 3-cycle has sign 1, a transposition -1) give
$$\begin{aligned} \det \mathbf{A} = {} & a_{11}a_{22}a_{33} - a_{21}a_{12}a_{33} - a_{31}a_{22}a_{13} - a_{11}a_{32}a_{23} \\ & + a_{21}a_{32}a_{13} + a_{31}a_{12}a_{23}, \end{aligned}$$
the terms coming from $\mathrm{id}, (1\ 2), (1\ 3), (2\ 3), (1\ 2\ 3), (1\ 3\ 2)$ in this order. For instance $\sigma = (1\ 2\ 3)$ has $\sigma(1) = 2$, $\sigma(2) = 3$, $\sigma(3) = 1$, and picks $a_{21}a_{32}a_{13}$.
- **A numerical** 3×3. For $\mathbf{A} = \begin{pmatrix} 2 & 1 & 3 \\ 0 & 4 & 1 \\ 5 & 2 & 1 \end{pmatrix}$, the six terms in the same order are 8, -0, -60, -4, 0 and 5, so $\det \mathbf{A} = 8 - 60 - 4 + 5 = -51$.
- **Identity and zero.** $\det \mathbf{I}_n = 1$ by the normalization in Theorem 6.4.3, and $\det 0 = 0$, since every product contains a zero factor.

Non-example by minimal change. Delete the sign. The **permanent** $\operatorname{per} \mathbf{A} = \sum_\sigma a_{\sigma(1)1} \cdots a_{\sigma(n)n}$ is still n-linear in the columns, by the same argument as in Theorem 6.4.3, and still gives 1 at $\mathbf{I}_n$. But it is not alternating: $\operatorname{per} \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix} = 1 + 1 = 2$, which is non-zero over $\mathbb{R}$ although the two columns are equal. The sign is exactly what makes the pairing argument cancel.

Why this definition. Each rule has a job. Without normalization, the uniqueness theorem only pins the form down up to the scalar $f(\mathbf{e}_1, \ldots, \mathbf{e}_n)$. Without alternation, the permanent and many other functions qualify. Multilinearity is what let us expand at all. The choice of **columns** rather than rows is a convention: we show below that the transpose has the same determinant, so rows would give the same function. We have avoided "Sarrus's rule" on purpose. It is a picture of the six-term formula for $n = 3$ and nothing more, and for $n = 4$ its diagonal pattern would produce 8 products while the Leibniz formula has 24.

> *Warning.* **The determinant is not linear.** It is linear in **each column separately**, not in the matrix. For $n = 2$, $\det \mathbf{I}_2 = 1$ but $\det(\mathbf{I}_2 + \mathbf{I}_2) = \det(2\mathbf{I}_2) = 4 \neq 1 + 1$. In general each product in the Leibniz formula has n factors, and scaling $\mathbf{A}$ scales every factor, so
>
> $$\det(c\mathbf{A}) = c^n \det \mathbf{A}, \qquad \text{in particular} \qquad \det(-\mathbf{A}) = (-1)^n \det \mathbf{A}.$$
>
> So $\det(-\mathbf{A}) = \det \mathbf{A}$ for 2×2 matrices, not $-\det \mathbf{A}$.

Quick check. Which permutations give a non-zero term in the determinant of $\begin{pmatrix} 0 & 0 & 1 \\ 0 & 2 & 0 \\ 3 & 0 & 0 \end{pmatrix}$, and what is the determinant?

Solution. Column 1 has its only non-zero entry in row 3, column 2 in row 2, and column 3 in row 1. A non-zero term needs $a_{\sigma(j)j} \neq 0$ for every j, so $\sigma(1) = 3$, $\sigma(2) = 2$, $\sigma(3) = 1$, that is, $\sigma = (1\ 3)$, of sign -1. The determinant is $-3 \cdot 2 \cdot 1 = -6$.

The payoff for the forms of the second section is immediate. There we saw that the alternating n-linear forms on F^n form a vector space (Theorem 6.2.3) and promised its dimension.

Corollary 6.4.4 — Alternating n-Forms on F^n Form a Line

The vector space of alternating n-linear forms on F^n has dimension 1, with basis (det). Explicitly, every alternating n-linear form f on F^n satisfies

$$f(\mathbf{a}_1, \dots, \mathbf{a}_n) = f(\mathbf{e}_1, \dots, \mathbf{e}_n)\ \det(\mathbf{a}_1, \dots, \mathbf{a}_n).$$

Proof. By Theorem 6.4.3, det is an element of this space, and it is not the zero form since $\det(\mathbf{e}_1, \dots, \mathbf{e}_n) = 1$. So the list (det) is linearly independent. By Theorem 6.4.2 and Definition 6.4.1, every f in the space satisfies the displayed formula, so $f = f(\mathbf{e}_1, \dots, \mathbf{e}_n) \det$ lies in the span of det. Hence (det) is a basis, and the dimension is 1. ∎

This corollary is the most useful form of uniqueness. To prove that some function g of n columns is a multiple of the determinant, check that g is multilinear and alternating, and compute $g(\mathbf{e}_1, \dots, \mathbf{e}_n)$. The multiplicativity of the determinant in the next section is proved exactly this way.

6.4.6 Transposes and triangular matrices

The definition read the matrix column by column. Reading it row by row gives nothing new.

Theorem 6.4.5 — Determinant of the Transpose

For every $\mathbf{A} \in M_n(F)$, $\det \mathbf{A}^\top = \det \mathbf{A}$. Consequently, $\det \mathbf{A}$ is also an alternating n-linear function of the **rows** of $\mathbf{A}$, with value 1 at $\mathbf{I}_n$.

Idea. A term of $\det \mathbf{A}^\top$ picks the entries $a_{j\sigma(j)}$, one in each row. The same n positions are also "one in each column": position $(j, \sigma(j))$ is $(\sigma^{-1}(i), i)$ with $i = \sigma(j)$. So the term is the term of $\det \mathbf{A}$ for σ^{-1}, and σ^{-1} has the same sign as σ.

Proof. The (i,j)-entry of $\mathbf{A}^\top$ is a_{ji} (Definition 0.9.10), so by Definition 6.4.1

$$\det \mathbf{A}^\top = \sum_{\sigma \in S_n} \operatorname{sgn}(\sigma)\, a_{1\sigma(1)}\, a_{2\sigma(2)} \cdots a_{n\sigma(n)}.$$

Fix σ. As j runs through $[n]$, $i = \sigma(j)$ runs through $[n]$ exactly once, and $j = \sigma^{-1}(i)$. Since multiplication in F is commutative, we may reorder the factors by i:

$$\prod_{j=1}^{n} a_{j\sigma(j)} = \prod_{i=1}^{n} a_{\sigma^{-1}(i)\,i}.$$

Next, $\operatorname{sgn}(\sigma)\operatorname{sgn}(\sigma^{-1}) = \operatorname{sgn}(\sigma\sigma^{-1}) = \operatorname{sgn}(\mathrm{id}) = 1$ by Theorem 6.3.1, and both signs lie in $\{1, -1\}$, so $\operatorname{sgn}(\sigma^{-1}) = \operatorname{sgn}(\sigma)$. Therefore

$$\det \mathbf{A}^{\top} = \sum_{\sigma \in S_n} \operatorname{sgn}(\sigma^{-1}) \prod_{i=1}^{n} a_{\sigma^{-1}(i)\,i} = \sum_{\rho \in S_n} \operatorname{sgn}(\rho) \prod_{i=1}^{n} a_{\rho(i)\,i} = \det \mathbf{A},$$

where the second equality substitutes $\rho = \sigma^{-1}$; this is allowed because $\sigma \mapsto \sigma^{-1}$ is a bijection of S_n onto itself, being its own inverse.

For the second statement, let $\mathbf{r}_1, \dots, \mathbf{r}_n$ be the rows of $\mathbf{A}$. The columns of $\mathbf{A}^{\top}$ are $\mathbf{r}_1^{\top}, \dots, \mathbf{r}_n^{\top}$, so $\det \mathbf{A} = \det \mathbf{A}^{\top} = \det(\mathbf{r}_1^{\top}, \dots, \mathbf{r}_n^{\top})$. The map $\mathbf{r} \mapsto \mathbf{r}^{\top}$ is linear (Theorem 0.9.5), so by Theorem 6.4.3 the function $(\mathbf{r}_1, \dots, \mathbf{r}_n) \mapsto \det(\mathbf{r}_1^{\top}, \dots, \mathbf{r}_n^{\top})$ is linear in each $\mathbf{r}_i$. If $\mathbf{r}_p = \mathbf{r}_q$ for some $p \neq q$, then $\mathbf{r}_p^{\top} = \mathbf{r}_q^{\top}$, and the value is 0. Finally $\mathbf{I}_n^{\top} = \mathbf{I}_n$. This proves the theorem.

■

So every statement about columns has a twin about rows. In particular Theorem 6.2.1 applies to rows: swapping two rows changes the sign of det, and adding a multiple of one row to another does not change it. The next section turns this into a method of computation.

Before that, one class of matrices whose determinant can be read off directly. Recall that $\mathbf{A}$ is upper triangular if $a_{ij} = 0$ whenever $i > j$ (Definition 0.9.5).

Theorem 6.4.6 — Determinant of a Triangular Matrix

If $\mathbf{A} \in M_n(F)$ is upper triangular or lower triangular, then

$$\det \mathbf{A} = a_{11}\, a_{22} \cdots a_{nn}.$$

Idea. Which permutations can pick only entries on or above the diagonal? Picking $a_{\sigma(j)j}$ with $\sigma(j) \leq j$ for every j forces $\sigma = \mathrm{id}$: the numbers $\sigma(1), \dots, \sigma(n)$ are $1, \dots, n$ in some order, so they have the same sum, and none of them is allowed to exceed its partner.

Proof. Suppose $\mathbf{A}$ is upper triangular, and let $\sigma \in S_n$ with $\sigma \neq \mathrm{id}$. We claim $\sigma(j) > j$ for some j. Otherwise $\sigma(j) \leq j$ for all j. Since σ is a bijection of $[n]$, $\sum_{j=1}^{n} \sigma(j) = \sum_{j=1}^{n} j$, so $\sum_{j=1}^{n} \big(j - \sigma(j)\big) = 0$ is a sum of non-negative integers equal to 0. Hence $\sigma(j) = j$ for every j, contradicting $\sigma \neq \mathrm{id}$. For such j, $a_{\sigma(j)j} = 0$ by upper triangularity, so the term of σ is 0. Only the identity remains, and $\det \mathbf{A} = \operatorname{sgn}(\mathrm{id})\, a_{11} \cdots a_{nn} = a_{11} \cdots a_{nn}$.

If $\mathbf{A}$ is lower triangular, then $\mathbf{A}^{\top}$ is upper triangular with the same diagonal, and $\det \mathbf{A} = \det \mathbf{A}^{\top} = a_{11} \cdots a_{nn}$ by Theorem 6.4.5. This proves the theorem.

■

For example, $\det \begin{pmatrix} 2 & 7 & -1 \\ 0 & 3 & 5 \\ 0 & 0 & -4 \end{pmatrix} = 2 \cdot 3 \cdot (-4) = -24$: six terms, five of which vanish. Diagonal matrices are a special case, $\det \operatorname{diag}(d_1, \dots, d_n) = d_1 \cdots d_n$. Together with Chapter 2's result that an upper triangular matrix is invertible exactly when its diagonal entries are non-zero (Lemma 2.6.2), this already shows that for upper triangular matrices, $\mathbf{A}$ is invertible if and only if $\det \mathbf{A} \neq 0$. The next section proves this for all square matrices.

6.4.7 Determinants over a commutative ring

The characteristic polynomial at the end of this chapter is the determinant of a matrix whose entries are **polynomials**, such as $\begin{pmatrix} x-1 & -2 \\ -3 & x-4 \end{pmatrix}$. Polynomials form no field, since x has no inverse in $F[x]$. So we record exactly what this section used.

> *Remark.* **Commutative rings.** A **commutative ring** is a set R with an addition and a multiplication satisfying all the axioms of a field (Definition 0.7.1) except, possibly, the existence of multiplicative inverses (F8). The integers $\mathbb{Z}$ and the polynomials $F[x]$ are examples (Theorem 0.8.1). For $\mathbf{A} \in M_n(R)$, the Leibniz formula of Definition 6.4.1 still defines $\det \mathbf{A} \in R$, reading $\operatorname{sgn}(\sigma)\, r$ as r or $-r$.
>
> **Every proof in this section uses only addition, subtraction and multiplication**, together with commutativity, and never a multiplicative inverse. So the following hold verbatim over any commutative ring R, with "linear in each argument" meaning additive and compatible with multiplication by elements of R: Lemma 6.4.1, Theorem 6.4.2, Theorem 6.4.3, Theorem 6.4.5 and Theorem 6.4.6. The only outside input is the swap rule of Theorem 6.2.1, and it too is division-free: expanding $0 = f(\dots, \mathbf{u}+\mathbf{v}, \dots, \mathbf{u}+\mathbf{v}, \dots)$ by additivity leaves $f(\dots, \mathbf{u}, \dots, \mathbf{v}, \dots) + f(\dots, \mathbf{v}, \dots, \mathbf{u}, \dots) = 0$. The parts of Theorem 6.2.1 about dependent arguments are not used; they involve solving for one vector in terms of others, which needs division.

In the characteristic-polynomial section we will apply these results with $R = F[x]$. The next two sections flag, in the same way, which of their proofs survive the passage to a ring.

6.4.8 Exercises

6.4.8.1 A. Check your understanding

Exercise A1.

(a) State the three properties that characterize $\det\colon M_n(F) \to F$, and write down the Leibniz formula.

(b) How many terms does the Leibniz formula have for $n = 4$? How many of the corresponding permutations have sign 1?

(c) True or false: $\det(\mathbf{A}+\mathbf{B}) = \det \mathbf{A} + \det \mathbf{B}$ for all $\mathbf{A}, \mathbf{B} \in M_2(\mathbb{R})$. Justify your answer.

(d) True or false: $\det(-\mathbf{A}) = -\det \mathbf{A}$ for all $\mathbf{A} \in M_3(\mathbb{R})$. Justify your answer.

(e) In the proof of Theorem 6.4.2, why does a term with a non-injective φ vanish?

(f) Explain why the existence proof pairs σ with $\sigma(p\ q)$ instead of arguing "$D = -D$, so $D = 0$".

Solution.

(a) det is n-linear in the columns, alternating (zero whenever two columns are equal), and $\det \mathbf{I}_n = 1$. By Theorem 6.4.2 and Theorem 6.4.3 it is the only such function, and $\det \mathbf{A} = \sum_{\sigma \in S_n} \operatorname{sgn}(\sigma)\, a_{\sigma(1)1} \cdots a_{\sigma(n)n}$.

(b) One term per permutation: $4! = 24$. In the proof of Theorem 6.4.3, $\sigma \mapsto \sigma(1\ 2)$ is a bijection from the permutations of sign 1 to those of sign -1, so each set has 12 elements.

(c) False. For $\mathbf{A} = \mathbf{B} = \mathbf{I}_2$, $\det(\mathbf{A} + \mathbf{B}) = \det(2\mathbf{I}_2) = 4$ but $\det \mathbf{A} + \det \mathbf{B} = 2$.

(d) True. Each Leibniz product has 3 factors, each multiplied by -1, so $\det(-\mathbf{A}) = (-1)^3 \det \mathbf{A} = -\det \mathbf{A}$. (For $n = 2$ it is false.)

(e) If $\varphi(p) = \varphi(q)$ with $p \neq q$, the form is evaluated with the equal arguments $\mathbf{e}_{\varphi(p)}$ in positions p and q, and an alternating form vanishes there.

(f) $D = -D$ only gives $2D = 0$. Over a field in which $2 = 0$, such as $\mathbb{F}_2$, this does not imply $D = 0$. The pairing shows that the terms cancel in pairs, which works over every field.

6.4.8.2 B. Practice

Exercise B1: Six-term determinants.

Using the Leibniz formula, listing all six terms, compute the determinants of

$$\mathbf{A} = \begin{pmatrix} 3 & 1 & 2 \\ 1 & 0 & 4 \\ 2 & 5 & 1 \end{pmatrix}, \qquad \mathbf{B} = \begin{pmatrix} 1 & -1 & 2 \\ 0 & 3 & 1 \\ 4 & 2 & -2 \end{pmatrix} \in M_3(\mathbb{R}).$$

Then compute $\det \mathbf{A}^\top$ in the same way, and hence verify Theorem 6.4.5 for this $\mathbf{A}$.

Solution. We use the order $\mathrm{id}, (1\ 2), (1\ 3), (2\ 3), (1\ 2\ 3), (1\ 3\ 2)$ and the six-term formula from the examples after Definition 6.4.1:

$$a_{11}a_{22}a_{33},\ -a_{21}a_{12}a_{33},\ -a_{31}a_{22}a_{13},\ -a_{11}a_{32}a_{23},\ a_{21}a_{32}a_{13},\ a_{31}a_{12}a_{23}.$$

For $\mathbf{A}$: $3\cdot 0\cdot 1 = 0$; $-1\cdot 1\cdot 1 = -1$; $-2\cdot 0\cdot 2 = 0$; $-3\cdot 5\cdot 4 = -60$; $1\cdot 5\cdot 2 = 10$; $2\cdot 1\cdot 4 = 8$. Hence $\det \mathbf{A} = 0 - 1 + 0 - 60 + 10 + 8 = -43$.

For $\mathbf{B}$: $1\cdot 3\cdot(-2) = -6$; $-0\cdot(-1)\cdot(-2) = 0$; $-4\cdot 3\cdot 2 = -24$; $-1\cdot 2\cdot 1 = -2$; $0\cdot 2\cdot 2 = 0$; $4\cdot(-1)\cdot 1 = -4$. Hence $\det \mathbf{B} = -6 + 0 - 24 - 2 + 0 - 4 = -36$.

For $\mathbf{A}^\top = \begin{pmatrix} 3 & 1 & 2 \\ 1 & 0 & 5 \\ 2 & 4 & 1 \end{pmatrix}$: $3\cdot 0\cdot 1 = 0$; $-1\cdot 1\cdot 1 = -1$; $-2\cdot 0\cdot 2 = 0$; $-3\cdot 4\cdot 5 = -60$; $1\cdot 4\cdot 2 = 8$; $2\cdot 1\cdot 5 = 10$. The sum is $-43 = \det \mathbf{A}$, as Theorem 6.4.5 predicts; the six terms are the same numbers, with the two 3-cycles exchanged, because $(1\ 2\ 3)^{-1} = (1\ 3\ 2)$.

Exercise B2: The determinant of $\mathbf{P}_\sigma$.

Let $\sigma \in S_n$ and let $\mathbf{P}_\sigma = \begin{pmatrix} \mathbf{e}_{\sigma(1)} & \cdots & \mathbf{e}_{\sigma(n)} \end{pmatrix}$ be its permutation matrix (Definition 2.6.2).

(a) Prove that $\det \mathbf{P}_\sigma = \operatorname{sgn}(\sigma)$.

(b) Hence compute $\det \begin{pmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix}$ and $\det \begin{pmatrix} 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{pmatrix}$.

Solution.

(a) By Theorem 6.4.3, det is an alternating n-linear form on F^n. By Lemma 6.4.1 with $\mathbf{v}_i = \mathbf{e}_i$,

$$\det \mathbf{P}_\sigma = \det(\mathbf{e}_{\sigma(1)}, \ldots, \mathbf{e}_{\sigma(n)}) = \operatorname{sgn}(\sigma) \det(\mathbf{e}_1, \ldots, \mathbf{e}_n) = \operatorname{sgn}(\sigma) \det \mathbf{I}_n = \operatorname{sgn}(\sigma).$$

(b) The first matrix has columns $\mathbf{e}_2, \mathbf{e}_3, \mathbf{e}_1$, so it is $\mathbf{P}_\sigma$ with $\sigma(1) = 2$, $\sigma(2) = 3$, $\sigma(3) = 1$, that is, $\sigma = (1\ 2\ 3)$. A 3-cycle is $(1\ 3)(1\ 2)$ (Example (Computing with cycles)), a product of two transpositions, so its sign is 1 and the determinant is 1. The second matrix has columns $\mathbf{e}_2, \mathbf{e}_1, \mathbf{e}_4, \mathbf{e}_3$, so it is $\mathbf{P}_\sigma$ with $\sigma = (1\ 2)(3\ 4)$, of sign $(-1)^2 = 1$ by Theorem 6.3.1 and Corollary 6.3.2. Its determinant is 1.

Exercise B3: A zero row.

Let $\mathbf{A} \in M_n(F)$ have a zero row. Prove directly from Definition 6.4.1, without using Theorem 6.4.5, that $\det \mathbf{A} = 0$. Then prove the same for a zero column.

Solution. Suppose row i of $\mathbf{A}$ is zero, and let $\sigma \in S_n$. Since σ is surjective, there is j with $\sigma(j) = i$. The factor $a_{\sigma(j)j} = a_{ij}$ of the term for σ is 0, so the term is 0. This holds for every σ, so $\det \mathbf{A} = 0$.

Suppose column j is zero. For every σ, the term for σ contains the factor $a_{\sigma(j)j} = 0$, so again every term vanishes and $\det \mathbf{A} = 0$.

6.4.8.3 C. Going deeper

Exercise C1: Too many zeros.

Let $\mathbf{A} \in M_n(F)$.

(a) Prove that if more than $n^2 - n$ entries of $\mathbf{A}$ are zero, then $\det \mathbf{A} = 0$.

(b) Show that the bound is sharp: give, for each n, a matrix with exactly $n^2 - n$ zero entries and non-zero determinant.

Solution.

(a) If more than $n^2 - n$ entries are zero, then fewer than n entries are non-zero. For $\sigma \in S_n$, the term for σ is a product of the n entries in positions $(\sigma(1), 1), \ldots, (\sigma(n), n)$. These positions are distinct, since their column indices are distinct. They cannot

all hold non-zero entries, because there are fewer than n such entries. So at least one factor is 0, and the term is 0. Hence $\det \mathbf{A} = 0$.

(b) $\mathbf{I}_n$ has exactly $n^2 - n$ zero entries, and $\det \mathbf{I}_n = 1 \neq 0$.

Exercise C2: Counting the cost.

A computer performs about 10^9 multiplications per second.

(a) Show that evaluating the Leibniz formula term by term for an $n \times n$ matrix takes $n!\,(n-1)$ multiplications. Estimate the time this takes for $n = 20$.

(b) Gaussian elimination (Chapter 2) brings $\mathbf{A}$ to upper triangular form. Suppose no row swaps are needed. At step k (for $k = 1, \dots, n-1$), each of the $n-k$ rows below the pivot requires one division to find its multiplier and $n-k$ multiplications to update its entries in columns $k+1, \dots, n$. Show that the total number of multiplications and divisions is $\frac{(n-1)n(n+1)}{3}$, and evaluate it for $n = 20$.

In the next section we will see that the determinant can be read off from this triangular form with $n-1$ further multiplications.

Solution.

(a) There is one term for each $\sigma \in S_n$, that is, $n!$ terms, and each is a product of n entries, which takes $n-1$ multiplications. For $n = 20$, $20! \cdot 19 = 46\,225\,138\,155\,356\,160\,000 \approx 4.6 \times 10^{19}$. At 10^9 per second this takes about 4.6×10^{10} seconds, roughly 1 460 years.

(b) Step k costs $(n-k)(1+(n-k))$ operations. With $m = n-k$ running from 1 to $n-1$, the total is

$$\begin{aligned} \sum_{m=1}^{n-1} m(m+1) &= \sum_{m=1}^{n-1} m^2 + \sum_{m=1}^{n-1} m \\ &= \frac{(n-1)n(2n-1)}{6} + \frac{(n-1)n}{2} \\ &= \frac{(n-1)n\big((2n-1)+3\big)}{6} = \frac{(n-1)n(n+1)}{3}. \end{aligned}$$

For $n = 20$ this is $\frac{19 \cdot 20 \cdot 21}{3} = 2\,660$, a few microseconds. The Leibniz formula is a definition and a proof tool, not an algorithm.

Exercise C3: The permanent, and a change of field.

For $\mathbf{A} \in M_n(F)$ define $\operatorname{per} \mathbf{A} = \sum_{\sigma \in S_n} a_{\sigma(1)1} \cdots a_{\sigma(n)n}$.

(a) Prove that per is n-linear in the columns and $\operatorname{per} \mathbf{I}_n = 1$.

(b) Let $n \geq 2$. Prove that over $\mathbb{R}$, per is **not** alternating.

(c) Prove that over $\mathbb{F}_2$, $\operatorname{per} \mathbf{A} = \det \mathbf{A}$ for every $\mathbf{A} \in M_n(\mathbb{F}_2)$. Explain why this does not contradict (b) and Theorem 6.4.2.

Solution.

(a) The proof of multilinearity in Theorem 6.4.3 never used the signs: for fixed k, the term for σ is a constant times $a_{\sigma(k)k}$, which is linear in the k-th column. The normalization argument there also applies: only $\sigma = \mathrm{id}$ contributes at $\mathbf{I}_n$, with product 1.

(b) Let $\mathbf{J} \in M_n(\mathbb{R})$ have every entry equal to 1. Its first two columns are equal, but every term of $\operatorname{per}\mathbf{J}$ is 1, so $\operatorname{per}\mathbf{J} = n! \neq 0$ in $\mathbb{R}$.

(c) In $\mathbb{F}_2$, $-1 = 1$, so $\operatorname{sgn}(\sigma) \cdot r = r$ for every r, and the two formulas agree term by term. There is no contradiction: (b) is a statement over $\mathbb{R}$, where $n! \neq 0$. Over $\mathbb{F}_2$, $\operatorname{per}\mathbf{J} = n! \cdot 1 = 0$ for $n \geq 2$, and per = det is alternating, as Theorem 6.4.3 guarantees. Uniqueness is about a fixed field, and over each field there is exactly one normalized alternating form.

6.5 Row Operations and Multiplicativity

The previous section defined the determinant by the Leibniz formula and proved it is the only normalized alternating form. The formula settles every theoretical question in principle, but with $n!$ terms it is useless for computing, and it hides the two facts that make determinants worth having. The first is that $\det\mathbf{A} \neq 0$ exactly when $\mathbf{A}$ is invertible. The second is that $\det(\mathbf{AB}) = \det\mathbf{A}\det\mathbf{B}$. This section proves both. Along the way we get a fast algorithm, and we extend the determinant from matrices to operators.

6.5.1 Row operations

Row reduction is the workhorse of Chapter 2, and the three rules of a determinant say precisely how it reacts to each elementary row operation. Everything follows from Theorem 6.4.5, which lets us treat det as a function of the rows.

Theorem 6.5.1 — Row Operations and the Determinant

Let $\mathbf{A} \in M_n(F)$ and let $\mathbf{B}$ be obtained from $\mathbf{A}$ by one operation.

(a) **(Swap)** If $\mathbf{B}$ is obtained by $R_i \leftrightarrow R_j$ with $i \neq j$, then $\det\mathbf{B} = -\det\mathbf{A}$.

(b) **(Scale)** If $\mathbf{B}$ is obtained by $R_i \to cR_i$ with $c \in F$, then $\det\mathbf{B} = c\det\mathbf{A}$.

(c) **(Replace)** If $\mathbf{B}$ is obtained by $R_i \to R_i + cR_j$ with $i \neq j$ and $c \in F$, then $\det\mathbf{B} = \det\mathbf{A}$.

(d) The same three statements hold for the corresponding operations on **columns**.

(e) For the elementary matrices of Definition 2.4.1,

$$\det\mathbf{P}_{ij} = -1, \qquad \det\mathbf{D}_i(c) = c, \qquad \det(\mathbf{I}_n + c\mathbf{E}_{ij}) = 1 \quad (i \neq j),$$

and $\det(\mathbf{EA}) = \det\mathbf{E}\det\mathbf{A}$ for every elementary matrix $\mathbf{E} \in M_n(F)$.

Proof. By Theorem 6.4.5, det is an alternating n-linear function of the rows $\mathbf{r}_1, \dots, \mathbf{r}_n$ of $\mathbf{A}$. We write $\det(\mathbf{r}_1, \dots, \mathbf{r}_n)$ for it in this proof.

(b) This is linearity in row i.

(c) By linearity in row i,

$$\begin{aligned}\det \mathbf{B} &= \det(\dots, \mathbf{r}_i + c\mathbf{r}_j, \dots, \mathbf{r}_j, \dots) \\ &= \det(\dots, \mathbf{r}_i, \dots, \mathbf{r}_j, \dots) + c \det(\dots, \mathbf{r}_j, \dots, \mathbf{r}_j, \dots),\end{aligned}$$

where the displayed arguments sit in positions i and j. The last determinant has two equal rows, so it is 0. Hence $\det \mathbf{B} = \det \mathbf{A}$.

(d) This is the swap rule of Theorem 6.2.1, applied to the rows.

(e) By Theorem 6.4.3, det is an alternating n-linear function of the columns, and the arguments for (a), (b), (c) apply word for word.

(f) The matrices $\mathbf{P}_{ij}$, $\mathbf{D}_i(c)$ and $\mathbf{I}_n + c\mathbf{E}_{ij}$ are obtained from $\mathbf{I}_n$ by a swap, a scaling and a replacement respectively. By (a), (b), (c) and $\det \mathbf{I}_n = 1$, their determinants are -1, c and 1. Now let $\mathbf{E} = \rho(\mathbf{I}_n)$ be elementary. By Theorem 2.4.1, $\mathbf{EA} = \rho(\mathbf{A})$. By (a), (b) or (c), $\det \rho(\mathbf{A})$ is $\det \mathbf{A}$ times -1, c or 1 respectively, and this factor is $\det \mathbf{E}$. Hence $\det(\mathbf{EA}) = \det \mathbf{E} \det \mathbf{A}$. This proves the theorem.

■

Read part (e) as a bookkeeping rule. A swap flips the sign, a scaling by c multiplies by c, and a replacement changes nothing. Replacement, the operation used most in elimination, is free.

Warning. **A combined move is not a replacement.** The move $R_2 \to 3R_2 - R_1$ looks harmless but multiplies the determinant by 3: it is the scaling $R_2 \to 3R_2$ followed by the replacement $R_2 \to R_2 - R_1$. For $\mathbf{A} = \begin{pmatrix} 1 & 2 \\ 1 & 3 \end{pmatrix}$, with $\det \mathbf{A} = 1$, it produces $\begin{pmatrix} 1 & 2 \\ 2 & 7 \end{pmatrix}$, whose determinant is 3. Keep replacements in the form "row i plus a multiple of another row", with coefficient 1 on row i.

Since elimination brings any square matrix to an upper triangular one, and triangular determinants are products of diagonal entries (Theorem 6.4.6), we have an algorithm.

Example. ($\mathbf{A}$ 4×4 Determinant by Elimination)

Compute $\det \mathbf{A}$ for

$$\mathbf{A} = \begin{pmatrix} 0 & 2 & 4 & 2 \\ 1 & 1 & 0 & 3 \\ 2 & 3 & 1 & 5 \\ -1 & 2 & 3 & 1 \end{pmatrix} \in M_4(\mathbb{R}).$$

Solution. We record each operation and its effect, using Theorem 6.5.1.

Step 1. The $(1,1)$-entry is 0, so swap: $R_1 \leftrightarrow R_2$. This multiplies the determinant by

-1:

$$\det \mathbf{A} = -\det \begin{pmatrix} 1 & 1 & 0 & 3 \\ 0 & 2 & 4 & 2 \\ 2 & 3 & 1 & 5 \\ -1 & 2 & 3 & 1 \end{pmatrix}.$$

Step 2. Clear column 1 with the replacements $R_3 \to R_3 - 2R_1$ and $R_4 \to R_4 + R_1$, which change nothing. Row 2 has a common factor 2; pulling it out is linearity in row 2:

$$\det \mathbf{A} = -\det \begin{pmatrix} 1 & 1 & 0 & 3 \\ 0 & 2 & 4 & 2 \\ 0 & 1 & 1 & -1 \\ 0 & 3 & 3 & 4 \end{pmatrix} = -2 \det \begin{pmatrix} 1 & 1 & 0 & 3 \\ 0 & 1 & 2 & 1 \\ 0 & 1 & 1 & -1 \\ 0 & 3 & 3 & 4 \end{pmatrix}.$$

Step 3. Clear column 2: $R_3 \to R_3 - R_2$ and $R_4 \to R_4 - 3R_2$. Then clear column 3: $R_4 \to R_4 - 3R_3$. None of these changes the determinant:

$$\det \mathbf{A} = -2 \det \begin{pmatrix} 1 & 1 & 0 & 3 \\ 0 & 1 & 2 & 1 \\ 0 & 0 & -1 & -2 \\ 0 & 0 & -3 & 1 \end{pmatrix} = -2 \det \begin{pmatrix} 1 & 1 & 0 & 3 \\ 0 & 1 & 2 & 1 \\ 0 & 0 & -1 & -2 \\ 0 & 0 & 0 & 7 \end{pmatrix}.$$

Step 4. The last matrix is upper triangular, so by Theorem 6.4.6 its determinant is $1 \cdot 1 \cdot (-1) \cdot 7 = -7$. Hence $\det \mathbf{A} = -2 \cdot (-7) = 14$.

Elimination costs roughly $n^3/3$ arithmetic operations, and reading off the triangular determinant takes only $n - 1$ more multiplications, against $n!\,(n-1)$ multiplications for the Leibniz formula (Exercise (C2: Counting the cost)). For $n = 20$ that is a few thousand operations against about 4.6×10^{19}. Every practical determinant computation is some form of elimination.

6.5.2 Determinant and invertibility

The same bookkeeping answers the invertibility question. Row reduction multiplies the determinant by non-zero factors only, so it cannot turn a non-zero determinant into zero or back. And the end of the reduction is either $\mathbf{I}_n$ or a matrix with a zero row.

Theorem 6.5.2 — Invertible if and only if Non-Zero Determinant

A matrix $\mathbf{A} \in M_n(F)$ is invertible if and only if $\det \mathbf{A} \neq 0$.

Proof. Let $\mathbf{R}$ be the reduced row echelon form of $\mathbf{A}$ (Theorem 2.2.3, Theorem 2.3.4). By Definition 2.2.2 and Theorem 2.4.1, there are elementary matrices $\mathbf{E}_1, \ldots, \mathbf{E}_k$ (possibly $k = 0$) with $\mathbf{R} = \mathbf{E}_k \cdots \mathbf{E}_1 \mathbf{A}$. Applying Theorem 6.5.1 (e) k times,

$$\det \mathbf{R} = \det \mathbf{E}_k \cdots \det \mathbf{E}_1 \det \mathbf{A}.$$

Each $\det \mathbf{E}_m$ is -1, 1, or some $c \neq 0$, since a scaling operation requires $c \neq 0$. A product of non-zero elements of a field is non-zero (Theorem 0.7.1), so $\det \mathbf{R} = 0$ if and only if $\det \mathbf{A} = 0$.

By Lemma 2.4.3, either $\mathbf{R} = \mathbf{I}_n$, and then $\det \mathbf{R} = 1 \neq 0$; or the last row of $\mathbf{R}$ is zero. In the second case, scaling that row by 0 leaves $\mathbf{R}$ unchanged, so $\det \mathbf{R} = 0 \cdot \det \mathbf{R} = 0$ by Theorem 6.5.1 (b). Hence $\det \mathbf{A} \neq 0$ if and only if $\mathbf{R} = \mathbf{I}_n$, which by Theorem 2.4.4 holds if and only if $\mathbf{A}$ is invertible.

■

This is the promised addition to the list of equivalent conditions. We collect it with the conditions from Chapter 3 about the map $T_{\mathbf{A}} \colon \mathbf{x} \mapsto \mathbf{A}\mathbf{x}$, and with two conditions about rows that the determinant makes easy.

Theorem 6.5.3 — Invertible Matrix Theorem, with Determinants

Let $\mathbf{A} \in M_n(F)$ and $T_{\mathbf{A}} \colon F^n \to F^n$, $\mathbf{x} \mapsto \mathbf{A}\mathbf{x}$. The following are equivalent, and each is equivalent to each of the eight conditions of Theorem 2.4.4.

(a) $\mathbf{A}$ is invertible.
(b) $T_{\mathbf{A}}$ is injective.
(c) $T_{\mathbf{A}}$ is surjective.
(d) $\operatorname{rank} \mathbf{A} = n$.
(e) $\mathbf{A}^\top$ is invertible.
(f) The rows of $\mathbf{A}$ are linearly independent.
(g) $\det \mathbf{A} \neq 0$.

Proof. Item (a) is item (a) of Theorem 2.4.4, so it suffices to connect each new item with that theorem.

(a) ⇔ (g). This is Theorem 6.5.2.

(a) ⇔ (b). By Theorem 3.5.7 ((b) ⇔ (c)) with $V = F^n$, $T_{\mathbf{A}}$ is injective if and only if $\ker T_{\mathbf{A}} = \{\mathbf{x} : \mathbf{A}\mathbf{x} = \mathbf{0}\}$ is $\{\mathbf{0}\}$. That is item (b) of Theorem 2.4.4.

(b) ⇔ (c). This is Theorem 3.5.7 ((b) ⇔ (d)), since F^n is finite-dimensional.

(c) ⇔ (d). By Theorem 0.9.3, $\operatorname{im} T_{\mathbf{A}}$ is the set of combinations of the columns of $\mathbf{A}$, that is, $\operatorname{col}(\mathbf{A})$. So $T_{\mathbf{A}}$ is surjective if and only if $\operatorname{col}(\mathbf{A}) = F^n$. Since $\operatorname{col}(\mathbf{A})$ is a subspace of F^n, this holds if and only if $\operatorname{rank} \mathbf{A} = \dim \operatorname{col}(\mathbf{A}) = n$ (Definition 2.5.4, Theorem 1.6.8).

(a) ⇔ (e). By Theorem 6.4.5, $\det \mathbf{A}^\top = \det \mathbf{A}$. Applying (a) ⇔ (g) to $\mathbf{A}$ and to $\mathbf{A}^\top$, both "$\mathbf{A}$ invertible" and "$\mathbf{A}^\top$ invertible" are equivalent to $\det \mathbf{A} \neq 0$.

(e) ⇔ (f). Let $\mathbf{r}_1, \dots, \mathbf{r}_n$ be the rows of $\mathbf{A}$. The columns of $\mathbf{A}^\top$ are $\mathbf{r}_1^\top, \dots, \mathbf{r}_n^\top$. By Theorem 0.9.5, $c_1\mathbf{r}_1 + \cdots + c_n\mathbf{r}_n = \mathbf{0}$ if and only if $c_1\mathbf{r}_1^\top + \cdots + c_n\mathbf{r}_n^\top = \mathbf{0}$, so the rows of $\mathbf{A}$ are independent exactly when the columns of $\mathbf{A}^\top$ are. By Theorem 2.4.4 ((a) ⇔ (f)) applied to $\mathbf{A}^\top$, this holds exactly when $\mathbf{A}^\top$ is invertible. This proves the theorem.

■

The determinant is now one more item on the menu, and for the right problems it is the best one. For a concrete matrix with a parameter, one polynomial in the parameter decides invertibility at once. For an abstract matrix, such as $\mathbf{A} + \mathbf{I}$ when $\mathbf{A}^k = 0$, the determinant is usually hopeless,

and the kernel is the item to try first.

Quick check. For which $t \in \mathbb{R}$ is $\begin{pmatrix} 1 & t \\ t & 4 \end{pmatrix}$ invertible? Over $\mathbb{F}_3$, for which t?

Solution. The determinant is $4 - t^2 = (2 - t)(2 + t)$. Over $\mathbb{R}$ the matrix is invertible exactly for $t \neq \pm 2$. Over $\mathbb{F}_3$, $4 = 1$, so the determinant is $1 - t^2$, which is 1 for $t = 0$ and 0 for $t = 1, 2$; the matrix is invertible only for $t = 0$.

6.5.3 Multiplicativity

Now the second fact. A natural first attempt is to multiply out the Leibniz formula for $\mathbf{AB}$, whose entries are sums, and regroup. That is legitimate, but the bookkeeping is horrible. The uniqueness theorem does the work instead: we exhibit $\mathbf{B} \mapsto \det(\mathbf{AB})$ as an alternating form in the columns of $\mathbf{B}$, and then it has no choice.

Theorem 6.5.4 — Multiplicativity of the Determinant

For all $\mathbf{A}, \mathbf{B} \in M_n(F)$,

$$\det(\mathbf{AB}) = \det \mathbf{A} \det \mathbf{B}.$$

Idea. Fix $\mathbf{A}$. The j-th column of $\mathbf{AB}$ is $\mathbf{Ab}_j$, so $g(\mathbf{b}_1, \dots, \mathbf{b}_n) = \det(\mathbf{Ab}_1, \dots, \mathbf{Ab}_n)$ is $\det(\mathbf{AB})$ viewed as a function of the columns of $\mathbf{B}$. It inherits linearity in each $\mathbf{b}_j$ from det and from matrix multiplication, and equal columns $\mathbf{b}_p = \mathbf{b}_q$ give equal columns $\mathbf{Ab}_p = \mathbf{Ab}_q$. So g is an alternating form, hence a multiple of det, and the multiple is $g(\mathbf{e}_1, \dots, \mathbf{e}_n) = \det \mathbf{A}$.

Proof. Fix $\mathbf{A} \in M_n(F)$, and define $g \colon F^n \times \cdots \times F^n \to F$ by

$$g(\mathbf{b}_1, \dots, \mathbf{b}_n) = \det(\mathbf{Ab}_1, \dots, \mathbf{Ab}_n).$$

By Theorem 0.9.2 (columns), if $\mathbf{B}$ has columns $\mathbf{b}_1, \dots, \mathbf{b}_n$, then $\mathbf{AB}$ has columns $\mathbf{Ab}_1, \dots, \mathbf{Ab}_n$, so $g(\mathbf{b}_1, \dots, \mathbf{b}_n) = \det(\mathbf{AB})$.

g is n-linear. Fix k and all $\mathbf{b}_j$ with $j \neq k$. The map $\mathbf{b}_k \mapsto \mathbf{Ab}_k$ is linear by Theorem 0.9.4, and det is linear in its k-th argument by Theorem 6.4.3. A composite of linear maps is linear, so g is linear in $\mathbf{b}_k$.

g is alternating. If $\mathbf{b}_p = \mathbf{b}_q$ with $p \neq q$, then $\mathbf{Ab}_p = \mathbf{Ab}_q$, so $g(\mathbf{b}_1, \dots, \mathbf{b}_n) = 0$ since det is alternating.

By Corollary 6.4.4, $g(\mathbf{b}_1, \dots, \mathbf{b}_n) = g(\mathbf{e}_1, \dots, \mathbf{e}_n) \det(\mathbf{b}_1, \dots, \mathbf{b}_n)$. Finally $\mathbf{Ae}_j$ is the j-th column of $\mathbf{A}$ (Theorem 0.9.3), so $g(\mathbf{e}_1, \dots, \mathbf{e}_n) = \det \mathbf{A}$. Hence $\det(\mathbf{AB}) = \det \mathbf{A} \det \mathbf{B}$.

■

Remark. **Over a commutative ring.** This proof uses only Corollary 6.4.4 (in the explicit form of Theorem 6.4.2), linearity of matrix multiplication, and the Leibniz for-

mula. None of these divides. So $\det(\mathbf{AB}) = \det\mathbf{A}\det\mathbf{B}$ holds for $\mathbf{A},\mathbf{B} \in M_n(R)$ over any commutative ring R, such as $F[x]$.

Alternatively, the building blocks of Chapter 2 give a proof. If $\mathbf{A}$ is invertible, then $\mathbf{A} = \mathbf{E}_1 \cdots \mathbf{E}_k$ with elementary $\mathbf{E}_m$ (Theorem 2.4.4 (d)), and peeling off one factor at a time with Theorem 6.5.1 (e) gives $\det(\mathbf{AB}) = \det\mathbf{E}_1 \cdots \det\mathbf{E}_k \det\mathbf{B}$; the case $\mathbf{B} = \mathbf{I}_n$ of the same computation shows $\det\mathbf{A} = \det\mathbf{E}_1 \cdots \det\mathbf{E}_k$. If $\mathbf{A}$ is not invertible, neither is $\mathbf{AB}$: otherwise $(\mathbf{AB})\mathbf{C} = \mathbf{I}_n$ for some $\mathbf{C}$, so $\mathbf{A}(\mathbf{BC}) = \mathbf{I}_n$ and $\mathbf{A}$ would be invertible by Theorem 2.4.5. Then both sides are 0 by Theorem 6.5.2. This route leans on row reduction, which divides, so unlike the first proof it needs a field.

For reference, here are the two identities used most often, now both proved.

Theorem 6.5.5 — Properties of Determinants

Let $\mathbf{A},\mathbf{B} \in M_n(F)$. Then:

1. $\det(\mathbf{AB}) = \det\mathbf{A}\det\mathbf{B}$;
2. $\det\mathbf{A}^{\top} = \det\mathbf{A}$.

Proof. Part 1 is Theorem 6.5.4 and part 2 is Theorem 6.4.5. ∎

The first consequences are immediate.

Corollary 6.5.6 — Determinant of the Inverse

If $\mathbf{A} \in M_n(F)$ is invertible, then $\det\mathbf{A} \neq 0$ and $\det(\mathbf{A}^{-1}) = (\det\mathbf{A})^{-1}$.

Proof. By Theorem 6.5.4, $\det\mathbf{A}\det(\mathbf{A}^{-1}) = \det(\mathbf{A}\mathbf{A}^{-1}) = \det\mathbf{I}_n = 1$. Hence $\det\mathbf{A} \neq 0$, and $\det(\mathbf{A}^{-1})$ is the inverse of $\det\mathbf{A}$ in F. ∎

Warning. **Multiplicativity does not make** det **additive, and it does not make products commute.** For $\mathbf{A} = \begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix}$ and $\mathbf{B} = \begin{pmatrix} 0 & 1 \\ 1 & 5 \end{pmatrix}$, $\mathbf{AB} = \begin{pmatrix} 2 & 11 \\ 4 & 23 \end{pmatrix} \neq \begin{pmatrix} 3 & 4 \\ 16 & 22 \end{pmatrix} = \mathbf{BA}$, yet $\det(\mathbf{AB}) = \det(\mathbf{BA}) = 2$, since both equal $\det\mathbf{A}\det\mathbf{B} = (-2)(-1)$. On the other hand, $\det(\mathbf{A}+\mathbf{B})$ is not determined by $\det\mathbf{A}$ and $\det\mathbf{B}$ at all: $\mathbf{I}_2$ and $\mathbf{I}_2$ have determinants $1, 1$ and $\det(\mathbf{I}_2+\mathbf{I}_2) = 4$, while $\mathbf{I}_2$ and $\mathbf{C} = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}$ also have determinants $1, 1$ but $\det(\mathbf{I}_2+\mathbf{C}) = \det\begin{pmatrix} 1 & 1 \\ -1 & 1 \end{pmatrix} = 2$.

Quick check. Let $\mathbf{A} = \begin{pmatrix} 2 & 1 \\ 7 & 4 \end{pmatrix}$. Without multiplying any matrices, find $\det(\mathbf{A}^5)$, $\det(\mathbf{A}^{-1})$ and $\det(\mathbf{A}^{\top}\mathbf{A})$.

Solution. $\det \mathbf{A} = 8 - 7 = 1$. By Theorem 6.5.4, $\det(\mathbf{A}^5) = (\det \mathbf{A})^5 = 1$. By Corollary 6.5.6, $\det(\mathbf{A}^{-1}) = 1^{-1} = 1$. By Theorem 6.5.5, $\det(\mathbf{A}^\top \mathbf{A}) = \det \mathbf{A}^\top \det \mathbf{A} = (\det \mathbf{A})^2 = 1$.

6.5.4 The determinant of an operator

In Chapter 3 the trace passed from matrices to operators because similar matrices have the same trace (Definition 3.10.2). Multiplicativity gives the same for determinants.

Corollary 6.5.7 — Determinant Is a Similarity Invariant

If $\mathbf{A}, \mathbf{B} \in M_n(F)$ are similar, then $\det \mathbf{A} = \det \mathbf{B}$.

Proof. Let $\mathbf{B} = \mathbf{P}^{-1}\mathbf{A}\mathbf{P}$ with $\mathbf{P}$ invertible. By Theorem 6.5.4 and Corollary 6.5.6,

$$\det \mathbf{B} = \det(\mathbf{P}^{-1}) \det \mathbf{A} \det \mathbf{P} = (\det \mathbf{P})^{-1} \det \mathbf{P} \det \mathbf{A} = \det \mathbf{A},$$

where the middle step uses commutativity of multiplication in F.

■

The converse fails: $\mathbf{I}_2$ and $\begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$ both have determinant 1, but the only matrix similar to $\mathbf{I}_2$ is $\mathbf{P}^{-1}\mathbf{I}_2\mathbf{P} = \mathbf{I}_2$ itself.

By Theorem 3.7.4, all matrices of one operator in the various bases are similar to each other. So the corollary lets us define:

Definition 6.5.1 — Determinant of an operator

Let V be a finite-dimensional vector space over F with $\dim V \geq 1$, and let $T \in \mathcal{L}(V)$. The **determinant** of T is

$$\det T := \det[T]_{\mathcal{B}},$$

where $\mathcal{B}$ is **any** basis of V. For $V = \{\mathbf{0}\}$ we set $\det T = 1$.

Well-definedness. If $\mathcal{B}$ and $\mathcal{C}$ are bases of V, then $[T]_{\mathcal{C}} = \mathbf{P}^{-1}[T]_{\mathcal{B}}\mathbf{P}$ with $\mathbf{P} = [\mathrm{id}]_{\mathcal{C}}^{\mathcal{B}}$ invertible, by Theorem 3.7.3 and Theorem 3.7.4 (a). By Corollary 6.5.7 the two determinants agree. The convention for $V = \{\mathbf{0}\}$ is the empty product, and it keeps the next theorem true in that case.

Examples.

- **Scalars.** For $c \in F$ and $\dim V = n \geq 1$, $[c\,\mathrm{id}_V]_{\mathcal{B}} = c\mathbf{I}_n$ in every basis, so $\det(c\,\mathrm{id}_V) = c^n$ by Theorem 6.4.6.
- **A reflection.** $R(x, y) = (y, x)$ on $\mathbb{R}^2$ has standard matrix $\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$, of determinant -1. In the basis $((1, 1), (1, -1))$ its matrix is $\mathrm{diag}(1, -1)$ (Example (The reflection in a mirror-adapted basis)), again of determinant -1, as it must be.
- **Differentiation.** On $\mathbb{R}[x]_{\leq 3}$ with basis $(1, x, x^2, x^3)$, the matrix of $\mathbf{D}$ is upper triangular

with zero diagonal (Example (Differentiation on Cubic Polynomials)), so $\det \mathbf{D} = 0$.

The determinant of a map $T\colon V \to W$ between **different** spaces is not defined, even when $\dim V = \dim W$. A matrix $[T]_{\mathcal{B}}^{\mathcal{C}}$ exists, but changing $\mathcal{C}$ alone multiplies it on the left by an arbitrary invertible matrix, which can change its determinant to any non-zero value. For $\mathrm{id}\colon \mathbb{R}^2 \to \mathbb{R}^2$ with input basis $\mathcal{E}$ and output basis $((2,0),(0,1))$, the matrix is $\mathrm{diag}(\frac{1}{2}, 1)$, of determinant $\frac{1}{2}$, not 1.

Theorem 6.5.8 — Properties of the Determinant of an Operator

Let V be a finite-dimensional vector space over F and $S, T \in \mathcal{L}(V)$. Then

$$\det(ST) = \det S \det T, \qquad \det \mathrm{id}_V = 1,$$

and T is invertible if and only if $\det T \neq 0$.

Proof. If $V = \{\mathbf{0}\}$, all determinants are 1 and the only operator is id_V, which is invertible. Otherwise fix a basis $\mathcal{B}$ of V. By Theorem 3.6.2, $[ST]_{\mathcal{B}} = [S]_{\mathcal{B}}[T]_{\mathcal{B}}$, so $\det(ST) = \det S \det T$ by Theorem 6.5.4. Next $[\mathrm{id}_V]_{\mathcal{B}} = \mathbf{I}_n$, of determinant 1. Finally, by Theorem 3.6.5 (b), T is invertible if and only if $[T]_{\mathcal{B}}$ is, which by Theorem 6.5.2 holds if and only if $\det T = \det [T]_{\mathcal{B}} \neq 0$.

■

So the determinant is a property of the operator, not of the coordinates. Differentiation on $\mathbb{R}[x]_{\leq 3}$ is not invertible because its determinant is 0, whichever basis we compute in. In the section on orientation and volume we will see what the number $\det T$ measures geometrically.

6.5.5 The determinant as a homomorphism

In Chapter 0 we met groups and homomorphisms, and promised that the determinant would be one. The general linear group $\mathrm{GL}_n(F)$ is the group of invertible matrices in $M_n(F)$ under multiplication, and $F \setminus \{0\}$ is a group under multiplication (Example (Groups)).

Theorem 6.5.9 — The Determinant Is a Group Homomorphism

Let $n \geq 1$. The determinant restricts to a **surjective** group homomorphism

$$\det\colon \mathrm{GL}_n(F) \to F \setminus \{0\}.$$

Its kernel is the **special linear group** $\mathrm{SL}_n(F) := \{\mathbf{A} \in M_n(F) : \det \mathbf{A} = 1\}$, which is therefore a subgroup of $\mathrm{GL}_n(F)$.

Proof. By Theorem 6.5.2, $\det \mathbf{A} \neq 0$ for $\mathbf{A} \in \mathrm{GL}_n(F)$, so det maps $\mathrm{GL}_n(F)$ into $F \setminus \{0\}$, and Theorem 6.5.4 says it is a homomorphism (Definition 0.10.3). For $c \neq 0$, the matrix $\mathrm{diag}(c, 1, \ldots, 1)$ has determinant c by Theorem 6.4.6, which is non-zero, so it lies in $\mathrm{GL}_n(F)$; hence det is surjective. A matrix with determinant 1 is invertible by Theorem 6.5.2, so the kernel $\{\mathbf{A} \in \mathrm{GL}_n(F) : \det \mathbf{A} = 1\}$ is $\mathrm{SL}_n(F)$. It is a subgroup by Theorem 0.10.3.

■

For example, $\begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$ and the elementary matrices $\mathbf{I}_n + c\mathbf{E}_{ij}$ lie in $\mathrm{SL}_n(F)$, while $\mathbf{P}_{12}$, of determinant -1, does not. Over $\mathbb{R}$, the rotation matrices $\begin{pmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{pmatrix}$ have determinant $\cos^2\theta + \sin^2\theta = 1$ and lie in $\mathrm{SL}_2(\mathbb{R})$. The sign $\operatorname{sgn}\colon S_n \to \{1, -1\}$ of the third section is the other homomorphism promised in Chapter 0, and the two are linked: $\det \mathbf{P}_\sigma = \operatorname{sgn}(\sigma)$ (Exercise (B2: The determinant of $\mathbf{P}_\sigma$)), and $\mathbf{P}_\sigma\mathbf{P}_\tau = \mathbf{P}_{\sigma\tau}$ (Lemma 2.6.6).

6.5.6 Which proofs survive over a ring

Remark. **Commutative rings.** Over a commutative ring R (as in the remark at the end of the previous section), the following proofs of this section use no division and remain valid for matrices in $M_n(R)$: Theorem 6.5.1, with $c \in R$ arbitrary in (b) and (c); Theorem 6.5.4, by its first proof; and Theorem 6.5.5. The proofs of Corollary 6.5.6 and Corollary 6.5.7 also survive for matrices that have an inverse in $M_n(R)$ (then $\det \mathbf{A} \det(\mathbf{A}^{-1}) = 1$, so $\det \mathbf{A}$ has an inverse in R), for instance an invertible $\mathbf{P} \in M_n(F)$ regarded inside $M_n(F[x])$; this is the case needed for characteristic polynomials. What fails over a ring is the converse direction: a matrix whose determinant is non-zero need not be invertible, since det may be a non-zero element with no inverse, such as $2 \in \mathbb{Z}$ or $x \in F[x]$. By contrast, Theorem 6.5.2, Theorem 6.5.3 and the "Alternatively" proof of multiplicativity run through row reduction, which divides by pivots, and they are proved here only over a field.

6.5.7 Exercises

6.5.7.1 A. Check your understanding

Exercise A1.

(a) State how each of the three elementary row operations changes the determinant.

(b) True or false: the move $R_2 \to 3R_2 - R_1$ does not change the determinant. Justify your answer.

(c) True or false: if $\mathbf{A}, \mathbf{B} \in M_n(F)$ have $\det \mathbf{A} = \det \mathbf{B}$, then $\mathbf{A}$ and $\mathbf{B}$ are similar. Justify your answer.

(d) True or false: $\det(\mathbf{AB}) = \det(\mathbf{BA})$ for all $\mathbf{A}, \mathbf{B} \in M_n(F)$. Justify your answer.

(e) Explain why $\det T$ does not depend on the basis used to compute it.

(f) Is $\det\colon M_n(F) \to F$ a group homomorphism? Explain.

Solution.

(a) By Theorem 6.5.1: a swap multiplies it by -1, scaling a row by c multiplies it by c, and adding a multiple of one row to a different row leaves it unchanged.

(b) False. The move is $R_2 \to 3R_2$ followed by $R_2 \to R_2 - R_1$, so it multiplies the

determinant by 3. For $\mathbf{I}_2$ it gives $\begin{pmatrix} 1 & 0 \\ -1 & 3 \end{pmatrix}$, of determinant $3 \neq 1$.

(c) False. $\mathbf{I}_2$ and $\begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$ both have determinant 1, but $\mathbf{P}^{-1}\mathbf{I}_2\mathbf{P} = \mathbf{I}_2$ for every invertible $\mathbf{P}$, so $\mathbf{I}_2$ is similar only to itself.

(d) True. Both equal $\det \mathbf{A} \det \mathbf{B}$ by Theorem 6.5.4, since multiplication in F is commutative.

(e) Matrices of T in two bases are similar (Theorem 3.7.3), and similar matrices have equal determinants (Corollary 6.5.7).

(f) No: $M_n(F)$ is not a group under multiplication, since the zero matrix has no inverse. The restriction $\det\colon \mathrm{GL}_n(F) \to F\backslash\{0\}$ is a homomorphism (Theorem 6.5.9).

6.5.7.2 B. Practice

Exercise B1: Determinants by elimination.

Compute the determinants of the following real matrices by row reduction, recording the effect of each operation.

$$\mathbf{A} = \begin{pmatrix} 1 & 2 & 0 & 1 \\ 2 & 3 & 1 & 4 \\ 0 & 1 & 3 & 2 \\ -1 & 1 & 2 & 5 \end{pmatrix}, \qquad \mathbf{B} = \begin{pmatrix} 2 & -1 & 3 & 1 \\ 4 & -2 & 7 & 3 \\ -2 & 2 & -1 & 4 \\ 6 & -3 & 9 & 5 \end{pmatrix}.$$

Solution. For $\mathbf{A}$: the replacements $R_2 \to R_2 - 2R_1$ and $R_4 \to R_4 + R_1$ give rows $(1,2,0,1)$, $(0,-1,1,2)$, $(0,1,3,2)$, $(0,3,2,6)$. Then $R_3 \to R_3 + R_2$ and $R_4 \to R_4 + 3R_2$ give $(0,0,4,4)$ and $(0,0,5,12)$. Pulling the factor 4 out of row 3 leaves $(0,0,1,1)$, and $R_4 \to R_4 - 5R_3$ gives $(0,0,0,7)$. None of the replacements changes the determinant (Theorem 6.5.1), so

$$\det \mathbf{A} = 4 \det \begin{pmatrix} 1 & 2 & 0 & 1 \\ 0 & -1 & 1 & 2 \\ 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 7 \end{pmatrix} = 4 \cdot \big(1 \cdot (-1) \cdot 1 \cdot 7\big) = -28,$$

by Theorem 6.4.6.

For $\mathbf{B}$: $R_2 \to R_2 - 2R_1$, $R_3 \to R_3 + R_1$, $R_4 \to R_4 - 3R_1$ give rows $(2,-1,3,1)$, $(0,0,1,1)$, $(0,1,2,5)$, $(0,0,0,2)$, without changing the determinant. The $(2,2)$-entry is 0, so swap $R_2 \leftrightarrow R_3$, which multiplies the determinant by -1. The result is upper triangular with diagonal $2,1,1,2$, so

$$\det \mathbf{B} = -(2 \cdot 1 \cdot 1 \cdot 2) = -4.$$

Exercise B2: A parameter.

Let $t \in \mathbb{R}$ and $\mathbf{A}_t = \begin{pmatrix} t & 1 & 1 \\ 1 & t & 1 \\ 1 & 1 & t \end{pmatrix}$. Find $\det \mathbf{A}_t$ as a factored polynomial in t. Hence determine for which t the matrix $\mathbf{A}_t$ is invertible.

Solution. The replacements $R_1 \to R_1 + R_2$ and $R_1 \to R_1 + R_3$ do not change the determinant and make row 1 equal to $(t+2, t+2, t+2)$. By linearity in row 1 (this holds for every value of $t+2$, including 0),

$$\det \mathbf{A}_t = (t+2)\det \begin{pmatrix} 1 & 1 & 1 \\ 1 & t & 1 \\ 1 & 1 & t \end{pmatrix} = (t+2)\det \begin{pmatrix} 1 & 1 & 1 \\ 0 & t-1 & 0 \\ 0 & 0 & t-1 \end{pmatrix} = (t+2)(t-1)^2,$$

where the second step uses $R_2 \to R_2 - R_1$, $R_3 \to R_3 - R_1$, and the last uses Theorem 6.4.6. By Theorem 6.5.2, $\mathbf{A}_t$ is invertible if and only if $t \neq 1$ and $t \neq -2$.

Exercise B3: The shift operator.

Let $T\colon \mathbb{R}[x]_{\leq 3} \to \mathbb{R}[x]_{\leq 3}$, $T(p) = p(x+1)$. Find $\det T$. Hence show that T is invertible.

Solution. In the basis $\mathcal{B} = (1, x, x^2, x^3)$, $T(1) = 1$, $T(x) = 1 + x$, $T(x^2) = 1 + 2x + x^2$ and $T(x^3) = 1 + 3x + 3x^2 + x^3$. So

$$[T]_{\mathcal{B}} = \begin{pmatrix} 1 & 1 & 1 & 1 \\ 0 & 1 & 2 & 3 \\ 0 & 0 & 1 & 3 \\ 0 & 0 & 0 & 1 \end{pmatrix},$$

which is upper triangular with ones on the diagonal. By Definition 6.5.1 and Theorem 6.4.6, $\det T = 1$. Since $\det T \neq 0$, T is invertible by Theorem 6.5.8. (Its inverse is $p \mapsto p(x-1)$.)

6.5.7.3 C. Going deeper

Exercise C1: Orthogonal-type matrices.

(a) Let $\mathbf{A} \in M_n(\mathbb{R})$ satisfy $\mathbf{A}^\top \mathbf{A} = \mathbf{I}_n$. Prove that $\det \mathbf{A} = 1$ or $\det \mathbf{A} = -1$.

(b) Show that both values occur, for every $n \geq 1$.

(c) Over $\mathbb{F}_2$, what can $\det \mathbf{A}$ be if $\mathbf{A}^\top \mathbf{A} = \mathbf{I}_n$?

Solution.

(a) By Theorem 6.5.5, $1 = \det \mathbf{I}_n = \det(\mathbf{A}^\top \mathbf{A}) = \det \mathbf{A}^\top \det \mathbf{A} = (\det \mathbf{A})^2$. A real number with square 1 is 1 or -1.

(b) $\mathbf{I}_n^\top \mathbf{I}_n = \mathbf{I}_n$ and $\det \mathbf{I}_n = 1$. For $\mathbf{D} = \operatorname{diag}(-1, 1, \ldots, 1)$, $\mathbf{D}^\top \mathbf{D} = \mathbf{D}^2 = \mathbf{I}_n$ and $\det \mathbf{D} = -1$ by Theorem 6.4.6.

(c) The same computation gives $(\det \mathbf{A})^2 = 1$. In $\mathbb{F}_2$, $\det \mathbf{A} \in \{0, 1\}$ and $0^2 = 0$, so $\det \mathbf{A} = 1$. This agrees with (a), since $-1 = 1$ in $\mathbb{F}_2$.

Exercise C2: Left multiplication on matrices.

Let $\mathbf{A} \in M_n(F)$, and let $L_{\mathbf{A}} \colon M_n(F) \to M_n(F)$, $L_{\mathbf{A}}(\mathbf{X}) = \mathbf{AX}$. This is a linear operator on a space of dimension n^2. Prove that

$$\det L_{\mathbf{A}} = (\det \mathbf{A})^n.$$

(a) Order the matrix units column by column, $\mathcal{B} = (\mathbf{E}_{11}, \mathbf{E}_{21}, \dots, \mathbf{E}_{n1}, \mathbf{E}_{12}, \dots, \mathbf{E}_{n2}, \dots, \mathbf{E}_{1n}, \dots, \mathbf{E}_{nn})$. Show that $[L_{\mathbf{A}}]_{\mathcal{B}}$ consists of n copies of $\mathbf{A}$ placed along the diagonal, with zeros elsewhere.

(b) Show that $L_{\mathbf{AB}} = L_{\mathbf{A}} L_{\mathbf{B}}$, and prove the formula when $\mathbf{A}$ is an elementary matrix.

(c) Prove the formula for invertible $\mathbf{A}$, and then for non-invertible $\mathbf{A}$.

Hint: for a swap matrix, identify $[L_{\mathbf{P}_{ij}}]_{\mathcal{B}}$ as a permutation matrix and use Exercise (B2: The determinant of $\mathbf{P}_\sigma$).

Solution.

(a) By Theorem 0.9.2, the l-th column of $\mathbf{AE}_{kl}$ is $\mathbf{Ae}_k$, the k-th column of $\mathbf{A}$, and the other columns are zero. So $\mathbf{AE}_{kl} = \sum_i a_{ik}\mathbf{E}_{il}$. In $\mathcal{B}$, the coordinates of this vector are zero outside the l-th block of n positions, and inside that block they are the k-th column of $\mathbf{A}$. Hence the columns of $[L_{\mathbf{A}}]_{\mathcal{B}}$ belonging to the l-th block are those of $\mathbf{A}$, placed in the rows of the l-th block: $[L_{\mathbf{A}}]_{\mathcal{B}}$ has n copies of $\mathbf{A}$ along the diagonal.

(b) $L_{\mathbf{AB}}(\mathbf{X}) = \mathbf{ABX} = L_{\mathbf{A}}(L_{\mathbf{B}}(\mathbf{X}))$ by associativity. Now let $\mathbf{E}$ be elementary. If $\mathbf{E} = \mathbf{I}_n + c\mathbf{E}_{ij}$ with $i \neq j$, then by (a) $[L_{\mathbf{E}}]_{\mathcal{B}}$ is triangular (upper if $i < j$, lower if $i > j$) with all diagonal entries 1, so $\det L_{\mathbf{E}} = 1 = (\det \mathbf{E})^n$ by Theorem 6.4.6 and Theorem 6.5.1 (e). If $\mathbf{E} = \mathbf{D}_i(c)$, then $[L_{\mathbf{E}}]_{\mathcal{B}}$ is diagonal with c appearing n times and 1 elsewhere, so $\det L_{\mathbf{E}} = c^n = (\det \mathbf{E})^n$. If $\mathbf{E} = \mathbf{P}_{ij}$, then $[L_{\mathbf{E}}]_{\mathcal{B}}$ has exactly one 1 in each row and column, so it is a permutation matrix $\mathbf{P}_\sigma$ (Definition 2.6.2), and σ exchanges the positions of $\mathbf{E}_{il}$ and $\mathbf{E}_{jl}$ for each l: σ is a product of n disjoint transpositions. By Exercise (B2: The determinant of $\mathbf{P}_\sigma$), Theorem 6.3.1 and Corollary 6.3.2, $\det L_{\mathbf{E}} = \operatorname{sgn}(\sigma) = (-1)^n = (\det \mathbf{E})^n$.

(c) If $\mathbf{A}$ is invertible, then $\mathbf{A} = \mathbf{E}_1 \cdots \mathbf{E}_k$ with elementary $\mathbf{E}_m$ (Theorem 2.4.4 (d)). By (b) and Theorem 6.5.8, $\det L_{\mathbf{A}} = \det L_{\mathbf{E}_1} \cdots \det L_{\mathbf{E}_k} = (\det \mathbf{E}_1)^n \cdots (\det \mathbf{E}_k)^n = (\det \mathbf{E}_1 \cdots \det \mathbf{E}_k)^n = (\det \mathbf{A})^n$, where the last step is Theorem 6.5.4. If $\mathbf{A}$ is not invertible, there is $\mathbf{v} \neq \mathbf{0}$ with $\mathbf{Av} = \mathbf{0}$ (Theorem 2.4.4 (b)). The matrix $\mathbf{X} = \begin{pmatrix} \mathbf{v} & \mathbf{0} & \cdots & \mathbf{0} \end{pmatrix}$ is non-zero and $\mathbf{AX} = 0$, so $L_{\mathbf{A}}$ is not injective, hence not invertible, and $\det L_{\mathbf{A}} = 0$ by Theorem 6.5.8. Also $\det \mathbf{A} = 0$ by Theorem 6.5.2, so $(\det \mathbf{A})^n = 0$ as $n \geq 1$.

Exercise C3: Non-square factors.

(a) Give $\mathbf{A} \in M_{2\times 1}(\mathbb{R})$ and $\mathbf{B} \in M_{1\times 2}(\mathbb{R})$ with $\det(\mathbf{BA}) \neq \det(\mathbf{AB})$.

(b) Let $m > n$, $\mathbf{A} \in M_{m\times n}(F)$ and $\mathbf{B} \in M_{n\times m}(F)$. Prove that $\det(\mathbf{AB}) = 0$.

(c) Explain why (a) does not contradict Theorem 6.5.4.

Solution.

(a) Let $\mathbf{A} = \begin{pmatrix} 1 \\ 0 \end{pmatrix}$ and $\mathbf{B} = \begin{pmatrix} 1 & 0 \end{pmatrix}$. Then $\mathbf{BA} = (1)$, of determinant 1, and $\mathbf{AB} = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}$, of determinant 0.

(b) By Theorem 2.5.9, $\operatorname{rank}(\mathbf{AB}) \leq \operatorname{rank} \mathbf{A} \leq n$, since $\operatorname{col}(\mathbf{A})$ is spanned by n columns. So $\operatorname{rank}(\mathbf{AB}) < m$, and the $m \times m$ matrix $\mathbf{AB}$ is not invertible by Theorem 6.5.3 (d). Hence $\det(\mathbf{AB}) = 0$ by Theorem 6.5.2.

(c) Theorem 6.5.4 concerns two **square** matrices of the same size, and then $\det(\mathbf{AB}) = \det(\mathbf{BA})$. Here $\mathbf{A}$ and $\mathbf{B}$ are not square, $\det \mathbf{A}$ and $\det \mathbf{B}$ are not defined, and $\mathbf{AB}$, $\mathbf{BA}$ have different sizes.

6.6 Cofactor Expansion, the Adjugate and Cramer's Rule

We can now compute determinants by elimination and we know what they decide. This section adds a third view: a determinant of size n is a combination of determinants of size $n-1$. This recursive formula, the Laplace expansion, is rarely the fastest way to compute, but it has two important consequences. It gives an explicit formula for the inverse of a matrix, through the adjugate, and an explicit formula for the solution of a square linear system, Cramer's rule. Both rest on one identity built from the entries alone, with no division, and that identity holds for matrices of polynomials too, which is what later chapters need.

6.6.1 Minors and cofactors

Group the six terms of a 3×3 determinant (from the examples after Definition 6.4.1) by the entry they take from column 1:

$$\det \mathbf{A} = a_{11}\,(a_{22}a_{33} - a_{32}a_{23}) - a_{21}\,(a_{12}a_{33} - a_{32}a_{13}) + a_{31}\,(a_{12}a_{23} - a_{22}a_{13}).$$

Each bracket is a 2×2 determinant. The bracket beside a_{11} is the determinant of what remains of $\mathbf{A}$ after deleting row 1 and column 1; the bracket beside a_{21} is what remains after deleting row 2 and column 1; and similarly for a_{31}. The signs alternate. These smaller determinants recur constantly, so they get names.

A minor is the determinant of what is left after crossing out one row and one column; a cofactor is that minor with a checkerboard sign.

Definition 6.6.1 — Minor and cofactor

Let $n \geq 2$, $\mathbf{A} \in M_n(F)$ and $i, j \in \{1, \ldots, n\}$. The (i,j)**-minor** of $\mathbf{A}$ is

$$M_{ij} \coloneqq \det(\text{the } (n-1) \times (n-1) \text{ matrix obtained from } \mathbf{A} \text{ by deleting row } i \text{ and column } j).$$

The (i,j)**-cofactor** of $\mathbf{A}$ is $C_{ij} \coloneqq (-1)^{i+j} M_{ij}$.

The rows and columns that remain keep their original order. The sign $(-1)^{i+j}$ depends only on the position, and follows a checkerboard starting with $+$ in the top-left corner:

$$\begin{pmatrix} + & - & + & \cdots \\ - & + & - & \cdots \\ + & - & + & \cdots \\ \vdots & \vdots & \vdots & \ddots \end{pmatrix}.$$

When the matrix matters we write $M_{ij}(\mathbf{A})$ and $C_{ij}(\mathbf{A})$.

Examples. For $\mathbf{A} = \begin{pmatrix} a & b \\ c & d \end{pmatrix}$, the minors are 1×1 determinants: $M_{11} = d$, $M_{12} = c$, $M_{21} = b$, $M_{22} = a$, and the cofactors are $C_{11} = d$, $C_{12} = -c$, $C_{21} = -b$, $C_{22} = a$. For the matrix $\mathbf{A} = \begin{pmatrix} 2 & 1 & 3 \\ 0 & 4 & 1 \\ 5 & 2 & 1 \end{pmatrix}$ of the previous sections, the cofactors along column 1 are

$$C_{11} = +\det \begin{pmatrix} 4 & 1 \\ 2 & 1 \end{pmatrix} = 2,$$
$$C_{21} = -\det \begin{pmatrix} 1 & 3 \\ 2 & 1 \end{pmatrix} = 5,$$
$$C_{31} = +\det \begin{pmatrix} 1 & 3 \\ 4 & 1 \end{pmatrix} = -11,$$

and $a_{11}C_{11} + a_{21}C_{21} + a_{31}C_{31} = 4 + 0 - 55 = -51$, which is $\det \mathbf{A}$ as computed before. For the identity $\mathbf{I}_n$, $C_{ii} = \det \mathbf{I}_{n-1} = 1$, and $C_{ij} = 0$ for $i \neq j$, because deleting row i and a different column j leaves a matrix with a zero column.

Non-example by minimal change. A minor and a cofactor differ only by a sign, and forgetting the sign is the commonest slip. For the 2×2 matrix above, $M_{12} = c$ but $C_{12} = -c$; using minors throughout would turn $a_{11}C_{11} + a_{21}C_{21} = ad - cb$ into $ad + cb$, which is the permanent, not the determinant.

6.6.2 The Laplace expansion

The 3×3 grouping above is a special case of a general identity, valid along **every** row and **every** column.

Theorem 6.6.1 — Laplace Expansion

Let $n \geq 2$ and $\mathbf{A} \in M_n(F)$, with cofactors C_{ij}.

(a) **(Along column j)** For each $j \in \{1, \ldots, n\}$,

$$\det \mathbf{A} = a_{1j}C_{1j} + a_{2j}C_{2j} + \cdots + a_{nj}C_{nj} = \sum_{i=1}^{n} a_{ij}C_{ij}.$$

(b) **(Along row i)** For each $i \in \{1, \ldots, n\}$,

$$\det \mathbf{A} = a_{i1}C_{i1} + a_{i2}C_{i2} + \cdots + a_{in}C_{in} = \sum_{j=1}^{n} a_{ij}C_{ij}.$$

Idea. The plan for (a):

① Write column j as $\sum_i a_{ij}\mathbf{e}_i$ and use linearity in column j. This leaves n determinants, the i-th with column j replaced by $\mathbf{e}_i$.

② In such a determinant, move the lone 1 to the top-left corner. To keep the other rows and columns in their original order, use **adjacent** swaps: $j-1$ column swaps and $i-1$ row swaps, costing $(-1)^{(i-1)+(j-1)} = (-1)^{i+j}$.

③ A matrix whose first column is $\mathbf{e}_1$ has the same determinant as its lower-right $(n-1) \times (n-1)$ block: only permutations fixing 1 contribute to the Leibniz formula. After ②, that block is exactly the matrix defining M_{ij}.

Part (b) is part (a) for the transpose.

Proof.

(a) Fix j. For $i \in \{1, \ldots, n\}$, let $\mathbf{B}^{(i)}$ be the matrix obtained from $\mathbf{A}$ by replacing column j with $\mathbf{e}_i$.

Claim. $\det \mathbf{B}^{(i)} = C_{ij}$.

Proof. Write $\mathbf{B} = \mathbf{B}^{(i)}$, with columns $\mathbf{b}_1, \dots, \mathbf{b}_n$, so $\mathbf{b}_j = \mathbf{e}_i$ and $\mathbf{b}_k$ is the k-th column of $\mathbf{A}$ for $k \neq j$.
Moving the column. Swap columns $j-1$ and j, then columns $j-2$ and $j-1$, and so on, ending with columns 1 and 2. After these $j-1$ adjacent swaps the columns are $\mathbf{b}_j, \mathbf{b}_1, \dots, \mathbf{b}_{j-1}, \mathbf{b}_{j+1}, \dots, \mathbf{b}_n$: the column $\mathbf{b}_j$ is first and the others are in their original order. Call this matrix $\mathbf{B}_1$. By Theorem 6.5.1 (d), each swap multiplies the determinant by -1, so $\det \mathbf{B}_1 = (-1)^{j-1} \det \mathbf{B}$.
Moving the row. In the same way, move row i of $\mathbf{B}_1$ to the top by $i-1$ adjacent row swaps, keeping the other rows in their original order. Call the result $\mathbf{B}_2$. By Theorem 6.5.1 (a), $\det \mathbf{B}_2 = (-1)^{i-1} \det \mathbf{B}_1$.
The shape of $\mathbf{B}_2$. The first column of $\mathbf{B}_1$ is $\mathbf{e}_i$, and moving row i to the top turns it into $\mathbf{e}_1$. For $p, q \geq 2$, the (p, q)-entry of $\mathbf{B}_2$ comes from the rows of $\mathbf{A}$ other than i and the columns of $\mathbf{A}$ other than j, both in their original order. So the lower-right $(n-1) \times (n-1)$ block of $\mathbf{B}_2$ is the matrix $\mathbf{A}'$ obtained from $\mathbf{A}$ by deleting row i and column j. Writing b'_{pq} for the entries of $\mathbf{B}_2$, we have $b'_{11} = 1$, $b'_{p1} = 0$ for $p \geq 2$, and $b'_{pq} = a'_{p-1,q-1}$ for $p, q \geq 2$.
The block determinant. In the Leibniz formula for $\det \mathbf{B}_2$, the factor $b'_{\sigma(1)1}$ is 0 unless $\sigma(1) = 1$. Let $G = \{\sigma \in S_n : \sigma(1) = 1\}$. For $\sigma \in G$, define $\rho \in S_{n-1}$ by $\rho(k) = \sigma(k+1) - 1$; this is a bijection of $\{1, \dots, n-1\}$, because σ maps $\{2, \dots, n\}$ bijectively onto itself. The map $\sigma \mapsto \rho$ is a bijection $G \to S_{n-1}$, with inverse $\rho \mapsto \sigma$, $\sigma(1) = 1$, $\sigma(k+1) = \rho(k) + 1$. An inversion of σ (Definition 6.3.1) is a pair $p < q$ with $\sigma(p) > \sigma(q)$; it never has $p = 1$, since $\sigma(1) = 1$ is smallest, and for $p, q \geq 2$ it is exactly an inversion $(p-1, q-1)$ of ρ. So $\operatorname{sgn}(\sigma) = \operatorname{sgn}(\rho)$ by Definition 6.3.2. Therefore

$$\det \mathbf{B}_2 = \sum_{\sigma \in G} \operatorname{sgn}(\sigma) \cdot 1 \cdot \prod_{q=2}^{n} b'_{\sigma(q)q} = \sum_{\rho \in S_{n-1}} \operatorname{sgn}(\rho) \prod_{k=1}^{n-1} a'_{\rho(k)k} = \det \mathbf{A}' = M_{ij}.$$

Combining, $\det \mathbf{B} = (-1)^{j-1}(-1)^{i-1} \det \mathbf{B}_2 = (-1)^{i+j} M_{ij} = C_{ij}$. ∎

Now the j-th column of $\mathbf{A}$ is $\sum_{i=1}^{n} a_{ij} \mathbf{e}_i$, and the other columns of $\mathbf{A}$ and of each $\mathbf{B}^{(i)}$ agree. By linearity of det in column j (Theorem 6.4.3) and the claim,

$$\det \mathbf{A} = \sum_{i=1}^{n} a_{ij} \det \mathbf{B}^{(i)} = \sum_{i=1}^{n} a_{ij} C_{ij}.$$

(b) Fix i. The (k, i)-entry of $\mathbf{A}^\top$ is a_{ik}. Deleting row k and column i from $\mathbf{A}^\top$ gives the transpose of the matrix obtained from $\mathbf{A}$ by deleting row i and column k, so $M_{ki}(\mathbf{A}^\top) = M_{ik}(\mathbf{A})$ by Theorem 6.4.5, and hence $C_{ki}(\mathbf{A}^\top) = C_{ik}(\mathbf{A})$. Applying (a) to $\mathbf{A}^\top$ along column i, and Theorem 6.4.5 again,

$$\det \mathbf{A} = \det \mathbf{A}^\top = \sum_{k=1}^{n} a_{ik} \, C_{ki}(\mathbf{A}^\top) = \sum_{k=1}^{n} a_{ik} \, C_{ik}(\mathbf{A}).$$

This proves the theorem.

■

Quick check. In step ② of the Idea, why not move column j to the front with the single swap of columns 1 and j?

Solution. A single swap costs only one factor -1, but it puts the old first column in position j, so the lower-right block is no longer the matrix defining M_{ij}: its columns are out of order. For $j \geq 3$, putting that column back in place within the block takes $j-2$ further adjacent swaps, and the total sign is again $(-1)^{1+(j-2)} = (-1)^{j-1}$. Adjacent swaps keep the count honest from the start.

Remark. **Over a commutative ring.** The proof uses multilinearity and the swap rule for columns and rows, the Leibniz formula, and Theorem 6.4.5. All of these are division-free (see the remarks at the ends of the previous two sections). So the Laplace expansion holds for matrices with entries in any commutative ring R, for instance $F[x]$.

The expansion is most useful along a row or column with many zeros, since each zero entry kills its term without computing the minor.

Example. **($\mathbf{A}$ 4×4 Expansion)**

Compute $\det \mathbf{A}$ for

$$\mathbf{A} = \begin{pmatrix} 3 & 1 & 0 & 2 \\ 1 & 0 & 2 & 0 \\ 2 & 4 & 1 & 3 \\ 0 & 1 & 5 & 2 \end{pmatrix} \in M_4(\mathbb{R})$$

by expanding along a suitable row.

Solution. Row 2 has two zeros. Its signs in the checkerboard are $-, +, -, +$. By Theorem 6.6.1 (b) along row 2,

$$\det \mathbf{A} = 1 \cdot C_{21} + 0 \cdot C_{22} + 2 \cdot C_{23} + 0 \cdot C_{24} = -M_{21} - 2M_{23}.$$

Deleting row 2 and column 1, and then row 2 and column 3,

$$M_{21} = \det \begin{pmatrix} 1 & 0 & 2 \\ 4 & 1 & 3 \\ 1 & 5 & 2 \end{pmatrix}, \qquad M_{23} = \det \begin{pmatrix} 3 & 1 & 2 \\ 2 & 4 & 3 \\ 0 & 1 & 2 \end{pmatrix}.$$

Expand M_{21} along its first row, which has a zero:

$$M_{21} = 1 \cdot \det \begin{pmatrix} 1 & 3 \\ 5 & 2 \end{pmatrix} - 0 + 2 \cdot \det \begin{pmatrix} 4 & 1 \\ 1 & 5 \end{pmatrix} = (2 - 15) + 2(20 - 1) = 25.$$

Expand M_{23} along its third row $(0,1,2)$, with signs $+,-,+$:

$$M_{23} = -1 \cdot \det \begin{pmatrix} 3 & 2 \\ 2 & 3 \end{pmatrix} + 2 \cdot \det \begin{pmatrix} 3 & 1 \\ 2 & 4 \end{pmatrix} = -(9-4) + 2(12-2) = 15.$$

Hence $\det \mathbf{A} = -25 - 2 \cdot 15 = -55$.

Warning. **The sign belongs to the position, not to the place in the row.** Along row 2 the signs start with $-$. Using the first-row pattern $+,-,+,-$ in the example above would give $1 \cdot 25 + 2 \cdot 15 = 55$, the wrong sign. Always read the sign as $(-1)^{i+j}$.

Expansion alone is slow: expanding fully down to 1×1 determinants reproduces all $n!$ Leibniz terms. In practice one first creates zeros with replacements, which do not change the determinant, and then expands along the line of zeros.

6.6.3 The adjugate

In Chapter 0 we inverted a 2×2 matrix by multiplying it by $\begin{pmatrix} d & -b \\ -c & a \end{pmatrix}$ (Theorem 0.9.8). Compare with the cofactors listed after Definition 6.6.1: $C_{11} = d$, $C_{12} = -c$, $C_{21} = -b$, $C_{22} = a$. The matrix of Chapter 0 is the matrix of cofactors, **transposed**. That recurring matrix deserves a name in every size.

The adjugate is the transposed matrix of cofactors.

Definition 6.6.2 — Adjugate

Let $n \geq 2$ and $\mathbf{A} \in M_n(F)$. The **adjugate** of $\mathbf{A}$ is the matrix $\operatorname{adj} \mathbf{A} \in M_n(F)$ with entries

$$(\operatorname{adj} \mathbf{A})_{ij} := C_{ji},$$

that is, the **transpose** of the matrix (C_{ij}) of cofactors. For $n = 1$ we set $\operatorname{adj} \mathbf{A} := (1)$.

In words: the entry in row i, column j of $\operatorname{adj} \mathbf{A}$ is the cofactor from row j, column i of $\mathbf{A}$. The adjugate is defined for **every** square matrix, invertible or not.

Examples. For $n = 2$, $\operatorname{adj} \begin{pmatrix} a & b \\ c & d \end{pmatrix} = \begin{pmatrix} d & -b \\ -c & a \end{pmatrix}$. For $\mathbf{I}_n$, the cofactors computed above give $\operatorname{adj} \mathbf{I}_n = \mathbf{I}_n$. For

$$\mathbf{B} = \begin{pmatrix} 1 & 2 & 0 \\ 0 & 1 & 1 \\ 1 & 0 & 3 \end{pmatrix},$$

the nine cofactors, row by row, are $C_{11} = 3$, $C_{12} = 1$, $C_{13} = -1$; $C_{21} = -6$, $C_{22} = 3$, $C_{23} = 2$; $C_{31} = 2$, $C_{32} = -1$, $C_{33} = 1$. Transposing,

$$\operatorname{adj} \mathbf{B} = \begin{pmatrix} 3 & -6 & 2 \\ 1 & 3 & -1 \\ -1 & 2 & 1 \end{pmatrix}, \qquad \mathbf{B} \operatorname{adj} \mathbf{B} = \begin{pmatrix} 5 & 0 & 0 \\ 0 & 5 & 0 \\ 0 & 0 & 5 \end{pmatrix},$$

and $\det \mathbf{B} = 1 \cdot 3 + 2 \cdot 1 + 0 \cdot (-1) = 5$, by expansion along row 1.

Non-example by minimal change. Skip the transpose. The cofactor matrix $\begin{pmatrix} 3 & 1 & -1 \\ -6 & 3 & 2 \\ 2 & -1 & 1 \end{pmatrix}$ has the same entries in other places, and $\mathbf{B}$ times it is $\begin{pmatrix} -9 & 7 & 3 \\ -4 & 2 & 3 \\ 9 & -2 & 2 \end{pmatrix}$, which is not a multiple of $\mathbf{I}_3$. The transpose is what lines up row i of $\mathbf{B}$ with the cofactors **of row** i.

The product $\mathbf{B}\operatorname{adj}\mathbf{B} = (\det\mathbf{B})\mathbf{I}_3$ is no accident. Its diagonal entries are row expansions of $\det\mathbf{B}$. Its off-diagonal entries are expansions too, of a matrix that looks like $\mathbf{B}$ but has a repeated row.

Theorem 6.6.2 — The Adjugate Identity

For every $\mathbf{A} \in M_n(F)$,

$$\mathbf{A}\operatorname{adj}\mathbf{A} = \operatorname{adj}\mathbf{A}\,\mathbf{A} = (\det\mathbf{A})\,\mathbf{I}_n.$$

Idea. The (i,k)-entry of $\mathbf{A}\operatorname{adj}\mathbf{A}$ is $\sum_j a_{ij}C_{kj}$: the entries of row i against the cofactors of row k. If $i = k$, this is the expansion of $\det\mathbf{A}$ along row i. If $i \neq k$, build a look-alike matrix $\tilde{\mathbf{A}}$: copy $\mathbf{A}$, but overwrite row k with row i. The cofactors along row k never see row k, because computing them deletes it, so $\tilde{\mathbf{A}}$ has the same cofactors along row k as $\mathbf{A}$. Expanding $\det\tilde{\mathbf{A}}$ along row k gives exactly $\sum_j a_{ij}C_{kj}$, and $\det\tilde{\mathbf{A}} = 0$ because two rows are equal.

Proof. For $n = 1$, $\mathbf{A} = (a)$, $\operatorname{adj}\mathbf{A} = (1)$, and both products are $(a) = (\det\mathbf{A})\mathbf{I}_1$. Let $n \geq 2$.

The product $\mathbf{A}\operatorname{adj}\mathbf{A}$. By Theorem 0.9.2 and Definition 6.6.2, its (i,k)-entry is

$$\sum_{j=1}^{n} a_{ij}\,(\operatorname{adj}\mathbf{A})_{jk} = \sum_{j=1}^{n} a_{ij}\,C_{kj}.$$

If $i = k$, this is $\det\mathbf{A}$ by Theorem 6.6.1 (b) along row i. Suppose $i \neq k$, and let $\tilde{\mathbf{A}}$ be the matrix obtained from $\mathbf{A}$ by replacing row k with a copy of row i. Rows i and k of $\tilde{\mathbf{A}}$ are equal, so $\det\tilde{\mathbf{A}} = 0$ by Theorem 6.4.5. Expanding along row k by Theorem 6.6.1 (b),

$$0 = \det\tilde{\mathbf{A}} = \sum_{j=1}^{n} \tilde{a}_{kj}\,C_{kj}(\tilde{\mathbf{A}}).$$

Here $\tilde{a}_{kj} = a_{ij}$. The minor $M_{kj}(\tilde{\mathbf{A}})$ is computed from $\tilde{\mathbf{A}}$ with row k deleted, and outside row k the matrices $\tilde{\mathbf{A}}$ and $\mathbf{A}$ agree; so $C_{kj}(\tilde{\mathbf{A}}) = C_{kj}(\mathbf{A})$. Hence $\sum_j a_{ij}C_{kj} = 0$. Therefore $\mathbf{A}\operatorname{adj}\mathbf{A} = (\det\mathbf{A})\mathbf{I}_n$.

The product $\operatorname{adj}\mathbf{A}\,\mathbf{A}$. Its (i,k)-entry is $\sum_j C_{ji}\,a_{jk}$. If $i = k$, this is $\det\mathbf{A}$ by Theorem 6.6.1 (a) along column i. If $i \neq k$, let $\hat{\mathbf{A}}$ be $\mathbf{A}$ with column i replaced by a copy of column k. It has two equal columns, so $\det\hat{\mathbf{A}} = 0$ by Theorem 6.4.3. Expanding along column i, $0 = \sum_j \hat{a}_{ji}\,C_{ji}(\hat{\mathbf{A}}) = \sum_j a_{jk}\,C_{ji}(\mathbf{A})$, since deleting column i removes the only column where $\hat{\mathbf{A}}$ and $\mathbf{A}$ differ. Therefore $\operatorname{adj}\mathbf{A}\,\mathbf{A} = (\det\mathbf{A})\mathbf{I}_n$. This proves the theorem.

■

Remark. **Over a commutative ring.** This proof uses only Theorem 6.6.1 and the alternating property, so the adjugate identity holds for $\mathbf{A} \in M_n(R)$ over any commutative ring R. For $R = F[x]$, the matrix $\operatorname{adj}(x\mathbf{I} - \mathbf{A})$ has polynomial entries and $(x\mathbf{I} - \mathbf{A})\operatorname{adj}(x\mathbf{I} - \mathbf{A}) = \det(x\mathbf{I} - \mathbf{A})\,\mathbf{I}$. This identity reappears in Chapter 8. Over R the identity also shows that $\mathbf{A}$ has an inverse in $M_n(R)$ as soon as $\det \mathbf{A}$ has an inverse in R, namely $(\det \mathbf{A})^{-1} \operatorname{adj} \mathbf{A}$.

Dividing by the determinant, when we may, gives the inverse.

Corollary 6.6.3 — Inverse via the Adjugate

Let $\mathbf{A} \in M_n(F)$ with $\det \mathbf{A} \neq 0$. Then $\mathbf{A}$ is invertible and

$$\mathbf{A}^{-1} = \frac{1}{\det \mathbf{A}} \operatorname{adj} \mathbf{A}.$$

Proof. By Theorem 6.6.2, $\mathbf{A}\big((\det \mathbf{A})^{-1} \operatorname{adj} \mathbf{A}\big) = (\det \mathbf{A})^{-1}(\det \mathbf{A})\mathbf{I}_n = \mathbf{I}_n$, using that scalars commute with matrices (Theorem 0.9.4). By Theorem 2.4.5, $\mathbf{A}$ is invertible with inverse $(\det \mathbf{A})^{-1} \operatorname{adj} \mathbf{A}$.

■

For $n = 2$ this is Theorem 0.9.8 again. For the matrix $\mathbf{B}$ above, $\mathbf{B}^{-1} = \frac{1}{5}\begin{pmatrix} 3 & -6 & 2 \\ 1 & 3 & -1 \\ -1 & 2 & 1 \end{pmatrix}$.

Warning. **The adjugate exists for singular matrices too.** Nothing in Definition 6.6.2 needs $\det \mathbf{A} \neq 0$. For $S = \begin{pmatrix} 1 & 2 & 3 \\ 2 & 4 & 6 \\ 1 & 0 & 1 \end{pmatrix}$, with $\det S = 0$, one computes $\operatorname{adj} S = \begin{pmatrix} 4 & -2 & 0 \\ 4 & -2 & 0 \\ -4 & 2 & 0 \end{pmatrix} \neq 0$, and $S \operatorname{adj} S = 0$, as Theorem 6.6.2 predicts. So "adj $\mathbf{A}$ exists" says nothing about invertibility, and the formula $\mathbf{A}^{-1} = \operatorname{adj} \mathbf{A} / \det \mathbf{A}$ must never be used before checking $\det \mathbf{A} \neq 0$.

Quick check. What are $\operatorname{adj}(c\mathbf{I}_n)$ for $c \in F$ and $n \geq 2$, and $\operatorname{adj} 0$ for the zero matrix in $M_n(F)$, $n \geq 2$? What is $\operatorname{adj} 0$ for $n = 1$?

Solution. Deleting row i and column i from $c\mathbf{I}_n$ leaves $c\mathbf{I}_{n-1}$, of determinant c^{n-1}; deleting row i and a different column leaves a zero column, of determinant 0. So $\operatorname{adj}(c\mathbf{I}_n) = c^{n-1}\mathbf{I}_n$; in particular $\operatorname{adj} 0 = 0$ for $n \geq 2$, since $0^{n-1} = 0$. For $n = 1$, $\operatorname{adj}(0) = (1)$ by definition, and indeed $(0)(1) = (0) = (\det 0)\mathbf{I}_1$.

6.6.4 Cramer's rule

For an invertible $\mathbf{A}$, the system $\mathbf{A}\mathbf{x} = \mathbf{b}$ has exactly one solution. The adjugate expresses it in closed form, and the closed form has a direct proof by linearity that shows where it comes from.

For $k \in \{1, \dots, n\}$, write $\mathbf{A}_k(\mathbf{b})$ for the matrix obtained from $\mathbf{A}$ by replacing column k with $\mathbf{b}$.

Theorem 6.6.4 — Cramer's Rule

Let $\mathbf{A} \in M_n(F)$ be invertible and $\mathbf{b} \in F^n$. The unique solution $\mathbf{x}$ of $\mathbf{A}\mathbf{x} = \mathbf{b}$ is given by

$$x_k = \frac{\det \mathbf{A}_k(\mathbf{b})}{\det \mathbf{A}}, \qquad k = 1, \dots, n.$$

Idea. If $\mathbf{A}\mathbf{x} = \mathbf{b}$, then $\mathbf{b} = x_1\mathbf{a}_1 + \cdots + x_n\mathbf{a}_n$. Put this combination into column k and expand by linearity. Every term except the k-th has the column $\mathbf{a}_j$ twice, so it vanishes, and what remains is $x_k \det \mathbf{A}$.

Proof. By Theorem 0.9.7 (7), $\mathbf{A}\mathbf{x} = \mathbf{b}$ has exactly one solution $\mathbf{x}$. By Theorem 0.9.3, $\mathbf{b} = \sum_{j=1}^{n} x_j \mathbf{a}_j$, where $\mathbf{a}_j$ is the j-th column of $\mathbf{A}$. Since det is linear in column k (Theorem 6.4.3),

$$\det \mathbf{A}_k(\mathbf{b}) = \sum_{j=1}^{n} x_j \det \mathbf{A}_k(\mathbf{a}_j).$$

For $j \neq k$, the matrix $\mathbf{A}_k(\mathbf{a}_j)$ has the column $\mathbf{a}_j$ in positions j and k, so its determinant is 0. For $j = k$, $\mathbf{A}_k(\mathbf{a}_k) = \mathbf{A}$. Hence $\det \mathbf{A}_k(\mathbf{b}) = x_k \det \mathbf{A}$. Since $\mathbf{A}$ is invertible, $\det \mathbf{A} \neq 0$ by Theorem 6.5.2, and dividing gives the formula. ∎

Alternatively, $\mathbf{x} = \mathbf{A}^{-1}\mathbf{b} = (\det \mathbf{A})^{-1} \operatorname{adj} \mathbf{A}\, \mathbf{b}$ by Corollary 6.6.3, and the k-th entry of $\operatorname{adj} \mathbf{A}\, \mathbf{b}$ is $\sum_j C_{jk} b_j$, which is the expansion of $\det \mathbf{A}_k(\mathbf{b})$ along column k (Theorem 6.6.1 (a)); the cofactors along column k of $\mathbf{A}_k(\mathbf{b})$ and of $\mathbf{A}$ agree, because computing them deletes column k.

For example, the system $2x + y = 5$, $7x + 4y = 18$ has coefficient matrix of determinant $8 - 7 = 1$, so

$$x = \det \begin{pmatrix} 5 & 1 \\ 18 & 4 \end{pmatrix} = 2, \qquad y = \det \begin{pmatrix} 2 & 5 \\ 7 & 18 \end{pmatrix} = 1,$$

and indeed $2 \cdot 2 + 1 = 5$ and $7 \cdot 2 + 4 = 18$.

Warning. **Cramer's rule is a theoretical tool, not an algorithm.** It needs $n + 1$ determinants of size n. Evaluated by the Leibniz formula this is about $(n+1)!$ products; even with each determinant computed by elimination it costs about $n^4/3$ operations, while Gaussian elimination solves the system once in about $n^3/3$. For $n = 20$, term-by-term Leibniz evaluation at 10^9 multiplications per second would take tens of thousands of years. Use Cramer's rule to understand **how** the solution depends on $\mathbf{A}$ and $\mathbf{b}$, and elimination to find it.

6.6.5 Integer matrices

The adjugate formula shows that each entry of $\mathbf{A}^{-1}$ is a polynomial in the entries of $\mathbf{A}$ divided by the single polynomial $\det \mathbf{A}$. In particular, the entries of $\mathbf{A}^{-1}$ change continuously with those of $\mathbf{A}$ over $\mathbb{R}$, as long as $\det \mathbf{A} \neq 0$. Here is an arithmetic consequence. A matrix with integer entries lies in $M_n(\mathbb{Q})$, and we may ask when its inverse again has integer entries.

Corollary 6.6.5 — Integer Matrices with Integer Inverses

Let $\mathbf{A} \in M_n(\mathbb{Q})$ have all entries in $\mathbb{Z}$.

(a) $\det \mathbf{A} \in \mathbb{Z}$, and $\operatorname{adj} \mathbf{A}$ has all entries in $\mathbb{Z}$.

(b) $\mathbf{A}$ is invertible and $\mathbf{A}^{-1}$ has all entries in $\mathbb{Z}$ if and only if $\det \mathbf{A} = 1$ or $\det \mathbf{A} = -1$.

Proof.

(a) The Leibniz formula (Definition 6.4.1) is a sum of products of entries with signs ± 1, so the determinant of a matrix with integer entries is an integer. Each cofactor is $\pm$ such a determinant, so $\operatorname{adj} \mathbf{A}$ has integer entries (for $n = 1$, $\operatorname{adj} \mathbf{A} = (1)$).

(b) ($\Leftarrow$) If $\det \mathbf{A} = \pm 1$, then $\mathbf{A}$ is invertible and $\mathbf{A}^{-1} = \pm \operatorname{adj} \mathbf{A}$ by Corollary 6.6.3, which has integer entries by (a). ($\Rightarrow$) Suppose $\mathbf{A}^{-1}$ has integer entries. By Theorem 6.5.4, $\det \mathbf{A} \det(\mathbf{A}^{-1}) = \det \mathbf{I}_n = 1$, and both factors are integers by (a). The only integers whose product is 1 are $1 \cdot 1$ and $(-1)(-1)$, so $\det \mathbf{A} = \pm 1$.

■

For example, $\begin{pmatrix} 2 & 1 \\ 5 & 3 \end{pmatrix}$ has determinant 1 and inverse $\begin{pmatrix} 3 & -1 \\ -5 & 2 \end{pmatrix}$, while $\begin{pmatrix} 2 & 1 \\ 0 & 1 \end{pmatrix}$ has determinant 2 and inverse $\begin{pmatrix} 1/2 & -1/2 \\ 0 & 1 \end{pmatrix}$. In the language of the remark after Theorem 6.6.2, part (b) says that a matrix over the ring $\mathbb{Z}$ is invertible over $\mathbb{Z}$ exactly when its determinant is invertible in $\mathbb{Z}$.

6.6.6 Exercises

6.6.6.1 A. Check your understanding

Exercise A1.

(a) Define the (i, j)-minor, the (i, j)-cofactor and the adjugate of $\mathbf{A} \in M_n(F)$, $n \geq 2$.

(b) What are the signs $(-1)^{i+j}$ of the cofactors in positions $(2, 3)$ and $(4, 4)$?

(c) True or false: $\operatorname{adj} \mathbf{A}$ is defined only when $\mathbf{A}$ is invertible. Justify your answer.

(d) True or false: Cramer's rule (Theorem 6.6.4) gives the solutions of every square linear system $\mathbf{Ax} = \mathbf{b}$. Justify your answer.

(e) In the proof of Theorem 6.6.2, which matrix is expanded to show that $\sum_j a_{ij} C_{kj} = 0$ for $i \neq k$, and why is its determinant 0?

(f) True or false: if $\mathbf{A}$ has integer entries and $\det \mathbf{A} = 2$, then $\mathbf{A}^{-1}$ has integer entries. Justify your answer.

Solution.

(a) M_{ij} is the determinant of the $(n-1) \times (n-1)$ matrix obtained by deleting row i and column j; $C_{ij} = (-1)^{i+j} M_{ij}$; $\operatorname{adj} \mathbf{A}$ is the matrix with (i, j)-entry C_{ji} (Definition 6.6.1, Definition 6.6.2).

(b) $(-1)^5 = -1$ and $(-1)^8 = 1$.

(c) False. It is defined for every square matrix; for instance $\operatorname{adj}\begin{pmatrix}1&1\\1&1\end{pmatrix} = \begin{pmatrix}1&-1\\-1&1\end{pmatrix}$, although the matrix is singular.

(d) False. It requires $\det \mathbf{A} \neq 0$. For $\mathbf{A} = \begin{pmatrix}1&1\\1&1\end{pmatrix}$ and $\mathbf{b} = (1,1)$, the system has infinitely many solutions, and the formula would divide by 0.

(e) The matrix $\tilde{\mathbf{A}}$ obtained from $\mathbf{A}$ by replacing row k with row i, expanded along row k. It has two equal rows, i and k, so its determinant is 0.

(f) False. By Corollary 6.6.5, an integer inverse forces $\det \mathbf{A} = \pm 1$. For instance $\operatorname{diag}(2,1)$ has inverse $\operatorname{diag}(\frac{1}{2},1)$.

6.6.6.2 B. Practice

Exercise B1: Adjugate and inverse.

Let $\mathbf{A} = \begin{pmatrix}1&2&-1\\0&1&3\\2&1&1\end{pmatrix} \in M_3(\mathbb{R})$. Compute all nine cofactors, $\operatorname{adj}\mathbf{A}$ and $\det\mathbf{A}$. Verify that $\mathbf{A}\operatorname{adj}\mathbf{A} = (\det\mathbf{A})\mathbf{I}_3$, and hence write down $\mathbf{A}^{-1}$.

Solution. The cofactors are

$$\begin{aligned} C_{11} &= +(1\cdot 1 - 3\cdot 1) = -2, & C_{12} &= -(0\cdot 1 - 3\cdot 2) = 6,\\ C_{13} &= +(0\cdot 1 - 1\cdot 2) = -2, & C_{21} &= -(2\cdot 1 - (-1)\cdot 1) = -3,\\ C_{22} &= +(1\cdot 1 - (-1)\cdot 2) = 3, & C_{23} &= -(1\cdot 1 - 2\cdot 2) = 3,\\ C_{31} &= +(2\cdot 3 - (-1)\cdot 1) = 7, & C_{32} &= -(1\cdot 3 - (-1)\cdot 0) = -3,\\ C_{33} &= +(1\cdot 1 - 2\cdot 0) = 1. \end{aligned}$$

Transposing the cofactor matrix (Definition 6.6.2),

$$\operatorname{adj}\mathbf{A} = \begin{pmatrix}-2&-3&7\\6&3&-3\\-2&3&1\end{pmatrix}.$$

Expanding along row 1 (Theorem 6.6.1), $\det\mathbf{A} = 1\cdot(-2) + 2\cdot 6 + (-1)(-2) = 12$. Row 1 of $\mathbf{A}$ against the columns of $\operatorname{adj}\mathbf{A}$ gives $-2+12+2 = 12$, $-3+6-3 = 0$, $7-6-1 = 0$; row 2 gives $0+6-6 = 0$, $0+3+9 = 12$, $0-3+3 = 0$; row 3 gives $-4+6-2 = 0$, $-6+3+3 = 0$, $14-3+1 = 12$. So $\mathbf{A}\operatorname{adj}\mathbf{A} = 12\mathbf{I}_3$. By Corollary 6.6.3,

$$\mathbf{A}^{-1} = \frac{1}{12}\begin{pmatrix}-2&-3&7\\6&3&-3\\-2&3&1\end{pmatrix}.$$

Exercise B2: Cramer's rule.

Use Cramer's rule to solve

$$x_1 + 2x_2 - x_3 = -3, \qquad x_2 + 3x_3 = 5, \qquad 2x_1 + x_2 + x_3 = 3$$

over $\mathbb{R}$. Check your answer by substitution.

Solution. The coefficient matrix is the matrix $\mathbf{A}$ of Exercise (B1: Adjugate and inverse), with $\det \mathbf{A} = 12 \neq 0$, and $\mathbf{b} = (-3, 5, 3)$. Expanding each $\mathbf{A}_k(\mathbf{b})$ along its first row,

$$\begin{aligned}
\det \mathbf{A}_1(\mathbf{b}) &= \det \begin{pmatrix} -3 & 2 & -1 \\ 5 & 1 & 3 \\ 3 & 1 & 1 \end{pmatrix} \\
&= -3(1-3) - 2(5-9) - 1(5-3) = 6 + 8 - 2 = 12, \\
\det \mathbf{A}_2(\mathbf{b}) &= \det \begin{pmatrix} 1 & -3 & -1 \\ 0 & 5 & 3 \\ 2 & 3 & 1 \end{pmatrix} \\
&= 1(5-9) + 3(0-6) - 1(0-10) = -4 - 18 + 10 = -12, \\
\det \mathbf{A}_3(\mathbf{b}) &= \det \begin{pmatrix} 1 & 2 & -3 \\ 0 & 1 & 5 \\ 2 & 1 & 3 \end{pmatrix} \\
&= 1(3-5) - 2(0-10) - 3(0-2) = -2 + 20 + 6 = 24.
\end{aligned}$$

By Theorem 6.6.4, $x_1 = 12/12 = 1$, $x_2 = -12/12 = -1$, $x_3 = 24/12 = 2$. Check: $1 - 2 - 2 = -3$, $-1 + 6 = 5$, $2 - 1 + 2 = 3$.

Exercise B3: Choosing the best line.

Compute $\det \mathbf{N}$ for

$$\mathbf{N} = \begin{pmatrix} 2 & 0 & 0 & 3 \\ 1 & 4 & 0 & -1 \\ 0 & 5 & 0 & 2 \\ 3 & 1 & 2 & 0 \end{pmatrix} \in M_4(\mathbb{R}),$$

expanding along the row or column that needs the least work.

Solution. Column 3 has a single non-zero entry, $a_{43} = 2$, whose sign is $(-1)^{4+3} = -1$. By Theorem 6.6.1 (a) along column 3, $\det \mathbf{N} = -2M_{43}$, where

$$\begin{aligned}
M_{43} &= \det \begin{pmatrix} 2 & 0 & 3 \\ 1 & 4 & -1 \\ 0 & 5 & 2 \end{pmatrix} \\
&= 2\big(4 \cdot 2 - (-1) \cdot 5\big) - 0 + 3\big(1 \cdot 5 - 4 \cdot 0\big) = 26 + 15 = 41,
\end{aligned}$$

expanding along the first row. Hence $\det \mathbf{N} = -82$.

6.6.6.3 C. Going deeper

Exercise C1: The determinant of the adjugate.

Let $n \geq 2$ and $\mathbf{A} \in M_n(F)$. Prove that $\det(\operatorname{adj} \mathbf{A}) = (\det \mathbf{A})^{n-1}$.

Hint: treat $\det \mathbf{A} \neq 0$ *and* $\det \mathbf{A} = 0$ *separately; in the second case, ask whether* $\operatorname{adj} \mathbf{A}$ *can be invertible.*

Solution. Case 1: $\det \mathbf{A} \neq 0$. By Theorem 6.6.2 and Theorem 6.5.4, $\det \mathbf{A} \det(\operatorname{adj} \mathbf{A}) = \det\big((\det \mathbf{A})\mathbf{I}_n\big) = (\det \mathbf{A})^n$, where the last step is Theorem 6.4.6. Dividing by $\det \mathbf{A} \neq 0$ gives $\det(\operatorname{adj} \mathbf{A}) = (\det \mathbf{A})^{n-1}$.

Case 2: $\det \mathbf{A} = 0$. Then $\mathbf{A} \operatorname{adj} \mathbf{A} = 0$ by Theorem 6.6.2. Suppose, for a contradiction, that $\operatorname{adj} \mathbf{A}$ is invertible. Then $\mathbf{A} = (\mathbf{A} \operatorname{adj} \mathbf{A})(\operatorname{adj} \mathbf{A})^{-1} = 0$. But every minor of the zero matrix is the determinant of a zero matrix of size $n-1 \geq 1$, which is 0, so $\operatorname{adj} 0 = 0$, which is not invertible. This contradiction shows that $\operatorname{adj} \mathbf{A}$ is not invertible, so $\det(\operatorname{adj} \mathbf{A}) = 0 = (\det \mathbf{A})^{n-1}$ by Theorem 6.5.2, since $n - 1 \geq 1$.

Exercise C2: The rank of the adjugate.

Let $n \geq 2$ and $\mathbf{A} \in M_n(F)$. Prove that

$$\operatorname{rank}(\operatorname{adj} \mathbf{A}) = \begin{cases} n & \text{if } \operatorname{rank} \mathbf{A} = n, \\ 1 & \text{if } \operatorname{rank} \mathbf{A} = n-1, \\ 0 & \text{if } \operatorname{rank} \mathbf{A} \leq n-2. \end{cases}$$

(a) Prove the case $\operatorname{rank} \mathbf{A} = n$.

(b) Suppose $\operatorname{rank} \mathbf{A} \leq n - 2$. Prove that every minor M_{ij} is 0.

(c) Suppose $\operatorname{rank} \mathbf{A} = n - 1$. Prove that every column of $\operatorname{adj} \mathbf{A}$ lies in $\operatorname{nul}(\mathbf{A})$, and deduce $\operatorname{rank}(\operatorname{adj} \mathbf{A}) \leq 1$.

(d) Suppose $\operatorname{rank} \mathbf{A} = n - 1$. Prove that some minor M_{ij} is non-zero, and conclude.

Hint for (d): choose $n-1$ independent columns of $\mathbf{A}$, then $n-1$ independent rows of the resulting $n \times (n-1)$ matrix.

Solution.

(a) If $\operatorname{rank} \mathbf{A} = n$, then $\mathbf{A}$ is invertible by Theorem 6.5.3, so $\det \mathbf{A} \neq 0$ and $\operatorname{adj} \mathbf{A} = (\det \mathbf{A})\mathbf{A}^{-1}$ by Corollary 6.6.3. This is invertible, since $\mathbf{A}^{-1}$ is and $\det \mathbf{A} \neq 0$ (Theorem 0.9.7), so $\operatorname{rank}(\operatorname{adj} \mathbf{A}) = n$.

(b) Fix i, j, and let $\mathbf{A}'$ be $\mathbf{A}$ with row i and column j deleted. The $n-1$ columns of $\mathbf{A}$ other than column j lie in $\operatorname{col}(\mathbf{A})$, of dimension $\operatorname{rank} \mathbf{A} \leq n-2$, so they are linearly dependent by Theorem 1.6.3: $\sum_{k \neq j} c_k \mathbf{a}_k = \mathbf{0}$ with the c_k not all zero. Deleting the i-th entry of every vector preserves this relation, so the columns of $\mathbf{A}'$ are dependent. By Theorem 2.4.4, $\mathbf{A}'$ is not invertible, and $M_{ij} = \det \mathbf{A}' = 0$ by Theorem 6.5.2. Hence $\operatorname{adj} \mathbf{A} = 0$ and $\operatorname{rank}(\operatorname{adj} \mathbf{A}) = 0$.

(c) Since $\operatorname{rank} \mathbf{A} < n$, $\det \mathbf{A} = 0$ by Theorem 6.5.3, so $\mathbf{A} \operatorname{adj} \mathbf{A} = 0$ by Theorem 6.6.2. By Theorem 0.9.2, $\mathbf{A}$ kills each column of $\operatorname{adj} \mathbf{A}$, so $\operatorname{col}(\operatorname{adj} \mathbf{A}) \subseteq \operatorname{nul}(\mathbf{A})$. By Theorem 2.5.7, $\dim \operatorname{nul}(\mathbf{A}) = n - (n-1) = 1$. Hence $\operatorname{rank}(\operatorname{adj} \mathbf{A}) \leq 1$.

(d) By Theorem 2.5.2, the pivot columns of $\mathbf{A}$ form a basis of $\operatorname{col}(\mathbf{A})$; there are $n-1$ of them, so exactly one column index j is not a pivot column. Let $\mathbf{A}_0 \in M_{n \times (n-1)}(F)$ consist of the other $n-1$ columns. They are independent, so $\operatorname{rank} \mathbf{A}_0 = n - 1$, and $\dim \operatorname{row}(\mathbf{A}_0) = n - 1$ by Theorem 2.5.5. The n rows of $\mathbf{A}_0$ span $\operatorname{row}(\mathbf{A}_0)$, so by Theorem 1.5.4 some $n-1$ of them are independent; since $n-1$ independent vectors in a space of dimension $n-1$ form a basis, sifting leaves out exactly one row, say row i. Deleting row i from $\mathbf{A}_0$ gives an $(n-1) \times (n-1)$ matrix $\mathbf{A}'$ with independent rows, so $\det \mathbf{A}' \neq 0$ by Theorem 6.5.3. But $\mathbf{A}'$ is $\mathbf{A}$ with row

i and column j deleted, so $M_{ij} \neq 0$, hence $C_{ij} \neq 0$ and $\operatorname{adj}\mathbf{A} \neq 0$. With (c), $\operatorname{rank}(\operatorname{adj}\mathbf{A}) = 1$.

Exercise C3: An adjugate over $F[x]$.

Work in $M_2(\mathbb{R}[x])$, using the remarks after Theorem 6.6.1 and Theorem 6.6.2.

(a) For $\mathbf{A} = \begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix}$, compute $\det(x\mathbf{I} - \mathbf{A})$ and $\operatorname{adj}(x\mathbf{I} - \mathbf{A})$, and verify $(x\mathbf{I} - \mathbf{A})\operatorname{adj}(x\mathbf{I} - \mathbf{A}) = \det(x\mathbf{I} - \mathbf{A})\,\mathbf{I}$ by multiplying out.

(b) For a general $\mathbf{A} = \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in M_2(\mathbb{R})$, show that $\operatorname{adj}(x\mathbf{I} - \mathbf{A}) = x\mathbf{I} - \operatorname{adj}\mathbf{A}$ and $\mathbf{A} + \operatorname{adj}\mathbf{A} = (\operatorname{tr}\mathbf{A})\mathbf{I}$.

(c) Deduce from (b), without using Theorem 6.6.2 over $\mathbb{R}[x]$, that $(x\mathbf{I} - \mathbf{A})\operatorname{adj}(x\mathbf{I} - \mathbf{A}) = \big(x^2 - (\operatorname{tr}\mathbf{A})x + \det\mathbf{A}\big)\mathbf{I}$, and check that $x^2 - (\operatorname{tr}\mathbf{A})x + \det\mathbf{A} = \det(x\mathbf{I} - \mathbf{A})$.

Solution.

(a) $x\mathbf{I} - \mathbf{A} = \begin{pmatrix} x-1 & -2 \\ -3 & x-4 \end{pmatrix}$, so $\det(x\mathbf{I} - \mathbf{A}) = (x-1)(x-4) - 6 = x^2 - 5x - 2$, and by Definition 6.6.2, $\operatorname{adj}(x\mathbf{I} - \mathbf{A}) = \begin{pmatrix} x-4 & 2 \\ 3 & x-1 \end{pmatrix}$. The product has entries $(x-1)(x-4) - 6 = x^2 - 5x - 2$, $2(x-1) - 2(x-1) = 0$, $-3(x-4) + 3(x-4) = 0$ and $-6 + (x-4)(x-1) = x^2 - 5x - 2$, so it is $(x^2 - 5x - 2)\mathbf{I}$.

(b) $x\mathbf{I} - \mathbf{A} = \begin{pmatrix} x-a & -b \\ -c & x-d \end{pmatrix}$, so $\operatorname{adj}(x\mathbf{I} - \mathbf{A}) = \begin{pmatrix} x-d & b \\ c & x-a \end{pmatrix} = x\mathbf{I} - \begin{pmatrix} d & -b \\ -c & a \end{pmatrix} = x\mathbf{I} - \operatorname{adj}\mathbf{A}$. Also $\mathbf{A} + \operatorname{adj}\mathbf{A} = \begin{pmatrix} a+d & 0 \\ 0 & a+d \end{pmatrix} = (\operatorname{tr}\mathbf{A})\mathbf{I}$.

(c) Since $x\mathbf{I}$ commutes with every matrix, expanding with (b) gives

$$\begin{aligned}(x\mathbf{I} - \mathbf{A})(x\mathbf{I} - \operatorname{adj}\mathbf{A}) &= x^2\mathbf{I} - x(\mathbf{A} + \operatorname{adj}\mathbf{A}) + \mathbf{A}\operatorname{adj}\mathbf{A} \\ &= x^2\mathbf{I} - (\operatorname{tr}\mathbf{A})x\mathbf{I} + (ad - bc)\mathbf{I},\end{aligned}$$

where $\mathbf{A}\operatorname{adj}\mathbf{A} = (ad-bc)\mathbf{I}$ is the computation of Theorem 0.9.8 over $\mathbb{R}$. Finally $\det(x\mathbf{I} - \mathbf{A}) = (x-a)(x-d) - bc = x^2 - (a+d)x + (ad-bc)$, which is $x^2 - (\operatorname{tr}\mathbf{A})x + \det\mathbf{A}$.

6.7 Minors, Rank and Cauchy–Binet

The determinant of a square matrix answers a yes-or-no question: is the matrix invertible? A rectangular matrix has no determinant, and a singular square matrix has determinant 0, which says nothing about *how* singular it is. Yet every matrix is full of square pieces, and each piece has a determinant. This section shows that these small determinants measure the rank exactly. It then answers a second question left open by multiplicativity: if $\mathbf{A}$ is $m \times n$ and $\mathbf{B}$ is $n \times m$, the product $\mathbf{AB}$ is square, so what is $\det(\mathbf{AB})$? The answer, the Cauchy–Binet formula, is proved by the same multilinear expansion that gave uniqueness of the determinant in Theorem 6.4.2.

6.7.1 Submatrices and minors

In Definition 6.6.1 we deleted one row and one column of a square matrix and took the determinant of what was left. That is a special case of a more flexible operation: keep **any** k rows and **any** k columns. The recurring object is the square block sitting at the crossings of the chosen rows and columns, and it deserves a name.

A minor is the determinant of a square block cut out of a matrix by choosing some rows and the same number of columns.

For a positive integer m, write $[m] = \{1, 2, \dots, m\}$.

Definition 6.7.1 — Submatrix and Minor

Let $\mathbf{A} = (a_{ij}) \in M_{m\times n}(F)$, and let $1 \le k \le \min(m, n)$. Let $I = \{i_1 < i_2 < \cdots < i_k\} \subseteq [m]$ and $J = \{j_1 < j_2 < \cdots < j_k\} \subseteq [n]$ be sets with **exactly** k elements each, listed in **increasing** order. The **submatrix** of $\mathbf{A}$ on rows I and columns J is

$$\mathbf{A}_{I,J} := \left(a_{i_p j_q}\right)_{p,q=1}^{k} \in M_k(F),$$

the $k \times k$ matrix whose (p, q)-entry is $a_{i_p j_q}$. Its determinant $\det \mathbf{A}_{I,J}$ is a $k \times k$ **minor** of $\mathbf{A}$.

In words: cross out every row not in I and every column not in J, and push the surviving entries together **without changing their order**. The chosen rows need not be adjacent, and neither need the columns. The sets I and J have the **same** size, so the block is square and has a determinant.

A 1×1 minor is a single entry, $\det \mathbf{A}_{\{i\},\{j\}} = a_{ij}$. For a square $\mathbf{A} \in M_n(F)$ with $n \ge 2$, the minor M_{ij} of Definition 6.6.1 is the $(n-1) \times (n-1)$ minor with $I = [n] \setminus \{i\}$ and $J = [n] \setminus \{j\}$. The only $n \times n$ minor of a square matrix is $\det \mathbf{A}$ itself. An $m \times n$ matrix has $\binom{m}{k}\binom{n}{k}$ minors of size k, one for each choice of I and J.

Example. Let

$$\mathbf{A} = \begin{pmatrix} 1 & 2 & 0 \\ 0 & 1 & 3 \end{pmatrix} \in M_{2\times 3}(\mathbb{Q}).$$

Its 2×2 minors all use $I = \{1, 2\}$, and there are three choices of J:

$$\det \mathbf{A}_{I,\{1,2\}} = \det \begin{pmatrix} 1 & 2 \\ 0 & 1 \end{pmatrix} = 1,$$

$$\det \mathbf{A}_{I,\{1,3\}} = \det \begin{pmatrix} 1 & 0 \\ 0 & 3 \end{pmatrix} = 3,$$

$$\det \mathbf{A}_{I,\{2,3\}} = \det \begin{pmatrix} 2 & 0 \\ 1 & 3 \end{pmatrix} = 6.$$

Its six 1×1 minors are its entries. It has no 3×3 minors, since it has only two rows.

A degenerate example. Every minor of the zero matrix $0_{m\times n}$ is 0: each block is a zero matrix, whose determinant is 0 by Theorem 6.4.6. This case matters because it is exactly the matrix of rank 0, and the theorem below has to treat it separately.

Non-example by minimal change. Take the same rows and columns but list the columns of

$\mathbf{A}$ above in the order $3, 1$: the block $\begin{pmatrix} 0 & 1 \\ 3 & 0 \end{pmatrix}$ has determinant -3, not 3. Every entry is still an entry of $\mathbf{A}$ from rows $\{1, 2\}$ and columns $\{1, 3\}$; what fails is the clause **listed in increasing order**. Reordering columns changes the determinant by a sign (Theorem 6.2.1), so the order convention is what makes "the" minor on (I, J) a single well-defined number.

Why this definition. Insisting on increasing order costs nothing and removes all sign ambiguity. Insisting on $|I| = |J|$ is forced: only square blocks have determinants.

> *Warning.* **Rank is not read off principal minors.** A **principal** minor uses the same index set for rows and columns ($I = J$). It is tempting to test rank using only these, but they can all vanish for a non-zero matrix. For $\mathbf{N} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$, the principal minors are 0, 0 and $\det \mathbf{N} = 0$, yet $\operatorname{rank} \mathbf{N} = 1$. The non-zero minor is the off-diagonal entry $\det \mathbf{N}_{\{1\},\{2\}} = 1$. The theorem below uses **all** minors.

> *Quick check.* How many 2×2 minors does a 3×4 matrix have? How many 3×3 minors?

> *Solution.* A 2×2 minor needs 2 of the 3 rows and 2 of the 4 columns: $\binom{3}{2}\binom{4}{2} = 3 \cdot 6 = 18$. A 3×3 minor uses all three rows and 3 of the 4 columns: $\binom{3}{3}\binom{4}{3} = 4$.

6.7.2 Rank via minors

A non-zero determinant of a square block means the block is invertible, so its columns are independent. Independent columns inside a block come from independent columns of the whole matrix. So a large non-zero minor forces large rank. The converse, that large rank produces a large non-zero minor, needs us to find the right rows as well as the right columns. Both directions together give a description of rank using only determinants:

Theorem 6.7.1 — Rank via Minors

Let $\mathbf{A} \in M_{m \times n}(F)$ be **non-zero**.

(a) $\operatorname{rank} \mathbf{A}$ is the **largest** integer k such that $\mathbf{A}$ has a **non-zero** $k \times k$ minor.

(b) Equivalently, for each $1 \le k \le \min(m, n)$: $\operatorname{rank} \mathbf{A} \ge k$ if and only if some $k \times k$ minor of $\mathbf{A}$ is non-zero; and $\operatorname{rank} \mathbf{A} < k$ if and only if **every** $k \times k$ minor of $\mathbf{A}$ is zero.

> *Idea.* Two inequalities. ① A non-zero $k \times k$ minor on rows I and columns J makes $\mathbf{A}_{I,J}$ invertible; a dependence among the columns of $\mathbf{A}$ indexed by J would restrict to a dependence among the columns of $\mathbf{A}_{I,J}$. So $\operatorname{rank} \mathbf{A} \ge k$. ② If $\operatorname{rank} \mathbf{A} = r$, choose r independent columns (pivot columns). The $m \times r$ matrix they form has rank r, so by row rank = column rank it has r independent rows. Those rows cut out an $r \times r$ block with independent rows, hence a non-zero determinant.

> *Proof.* **Step 1: a non-zero $k \times k$ minor forces $\operatorname{rank} \mathbf{A} \ge k$.** Let $I = \{i_1 < \cdots < i_k\}$ and $J = \{j_1 < \cdots < j_k\}$ with $\det \mathbf{A}_{I,J} \neq 0$. Write $\mathbf{a}_1, \dots, \mathbf{a}_n$ for the columns of $\mathbf{A}$. Suppose $c_1 \mathbf{a}_{j_1} + \cdots + c_k \mathbf{a}_{j_k} = \mathbf{0}$ with $c_1, \dots, c_k \in F$. Reading only the entries in rows $i_1, \dots, i_k$ of this vector equation gives $\sum_q c_q \, a_{i_p j_q} = 0$ for $p = 1, \dots, k$, that is, $\mathbf{A}_{I,J}\mathbf{c} = \mathbf{0}$

with $\mathbf{c} = (c_1, \dots, c_k)$. By Theorem 6.5.2, $\mathbf{A}_{I,J}$ is invertible, so $\mathbf{c} = \mathbf{0}$ by Theorem 2.4.4. Hence $(\mathbf{a}_{j_1}, \dots, \mathbf{a}_{j_k})$ is a linearly independent list in $\operatorname{col}(\mathbf{A})$, and by Theorem 1.6.3 (a), $k \leq \dim \operatorname{col}(\mathbf{A}) = \operatorname{rank} \mathbf{A}$.

Step 2: A has a non-zero $r \times r$ minor, where $r = \operatorname{rank} \mathbf{A}$. Since $\mathbf{A} \neq 0$, some column is non-zero, so $r \geq 1$. By Theorem 2.5.2 (a), the pivot columns $\mathbf{a}_{j_1}, \dots, \mathbf{a}_{j_r}$ $(j_1 < \cdots < j_r)$ are linearly independent. Let $J = \{j_1, \dots, j_r\}$ and let $\mathbf{A}' = \mathbf{A}_{[m],J} \in M_{m \times r}(F)$ be the matrix with these columns. By Theorem 2.5.10 (a), $\operatorname{rank} \mathbf{A}' = r$, so by Theorem 2.5.5 the row space of $\mathbf{A}'$ has dimension r. The m rows of $\mathbf{A}'$ span its row space, so by Theorem 1.5.4 some r of them, in rows $i_1 < \cdots < i_r$, form a basis of it; in particular they are linearly independent. These are exactly the rows of $\mathbf{B} = \mathbf{A}_{I,J} \in M_r(F)$, where $I = \{i_1, \dots, i_r\}$. Transposition is a linear bijection from $1 \times r$ rows to columns in F^r, so the columns of $\mathbf{B}^\top$ are linearly independent. By Theorem 2.4.4, $\mathbf{B}^\top$ is invertible, so $\det \mathbf{B}^\top \neq 0$ by Theorem 6.5.2, and $\det \mathbf{B} = \det \mathbf{B}^\top \neq 0$ by Theorem 6.4.5.

Conclusion. By Step 2 there is a non-zero minor of size r, and by Step 1 there is none of size larger than r. This proves (a). For (b): if $\operatorname{rank} \mathbf{A} \geq k$, then Step 2 gives a non-zero $r \times r$ minor with $r \geq k$, and we still need one of size exactly k. Expanding that $r \times r$ determinant along any row (Theorem 6.6.1) writes it as a combination of $(r-1) \times (r-1)$ minors of the block, each of which is also an $(r-1) \times (r-1)$ minor of $\mathbf{A}$; since the determinant is non-zero, one of these minors is non-zero. Repeating $r - k$ times gives a non-zero $k \times k$ minor. Conversely, a non-zero $k \times k$ minor gives $\operatorname{rank} \mathbf{A} \geq k$ by Step 1. The second equivalence in (b) is the negation of the first.

■

The theorem turns "rank at most $k-1$" into a finite list of polynomial equations in the entries: all $k \times k$ minors vanish. That is why rank can only **drop** when the entries satisfy special equations, as the next example shows.

Example. (Rank of a Family of Matrices)

For $t \in \mathbb{Q}$, let

$$\mathbf{A}(t) = \begin{pmatrix} 1 & 2 & 1 \\ 2 & t & 3 \\ 3 & 6 & t \end{pmatrix}.$$

Find $\operatorname{rank} \mathbf{A}(t)$ for every t.

Solution. The only 3×3 minor is $\det \mathbf{A}(t)$. By cofactor expansion along the first row (Theorem 6.6.1),

$$\begin{aligned} \det \mathbf{A}(t) &= 1 \cdot (t^2 - 18) - 2 \cdot (2t - 9) + 1 \cdot (12 - 3t) \\ &= t^2 - 7t + 12 = (t-3)(t-4). \end{aligned}$$

So for $t \neq 3, 4$, $\mathbf{A}(t)$ has a non-zero 3×3 minor and $\operatorname{rank} \mathbf{A}(t) = 3$ by Theorem 6.7.1.

For $t \in \{3, 4\}$ every 3×3 minor is zero, so $\operatorname{rank} \mathbf{A}(t) \leq 2$. Look for a 2×2 minor that does not involve t: rows $\{1, 2\}$ and columns $\{1, 3\}$ give

$$\det \begin{pmatrix} 1 & 1 \\ 2 & 3 \end{pmatrix} = 1 \neq 0.$$

Hence $\operatorname{rank}\mathbf{A}(3) = \operatorname{rank}\mathbf{A}(4) = 2$. The same minor shows $\operatorname{rank}\mathbf{A}(t) \geq 2$ for every t, so rank 1 never occurs.

Remark. To **compute** the rank of one given matrix, elimination is far cheaper: a 10×10 matrix has $\binom{10}{5}^2 = 63504$ minors of size 5. Minors earn their keep in theory. They show that rank is unchanged by transposing (the minors of $\mathbf{A}^\top$ are the minors of $\mathbf{A}$, by Theorem 6.4.5) and by enlarging the field (Exercise (C2: Rank does not depend on the field)), and they describe the matrices of rank below k by polynomial equations.

6.7.3 The Cauchy–Binet formula

Multiplicativity, Theorem 6.5.4, handles $\det(\mathbf{AB})$ when both factors are square. Now let $\mathbf{A} \in M_{m\times n}(F)$ and $\mathbf{B} \in M_{n\times m}(F)$. The product $\mathbf{AB}$ is $m \times m$, so it has a determinant, but $\det\mathbf{A}$ and $\det\mathbf{B}$ do not exist. The natural candidates to replace them are the largest minors: the $m \times m$ minors of $\mathbf{A}$, which keep all rows and choose m columns S, and the $m \times m$ minors of $\mathbf{B}$, which keep all columns and choose the **same** m rows S.

Theorem 6.7.2 — Cauchy–Binet Formula

Let $\mathbf{A} \in M_{m\times n}(F)$ and $\mathbf{B} \in M_{n\times m}(F)$. Then

$$\det(\mathbf{AB}) = \sum_{\substack{S\subseteq[n]\\|S|=m}} \det\mathbf{A}_{[m],S}\,\det\mathbf{B}_{S,[m]},$$

the sum running over all m-element subsets S of $[n]$. In particular:

(a) if $m > n$, the sum is empty and $\det(\mathbf{AB}) = 0$;
(b) if $m = n$, the only subset is $S = [n]$ and the formula is $\det(\mathbf{AB}) = \det\mathbf{A}\det\mathbf{B}$.

Idea. Treat det as a function of the m columns of $\mathbf{AB}$. Column k of $\mathbf{AB}$ is $\mathbf{Ab}_k = \sum_j b_{jk}\mathbf{a}_j$, a combination of the columns of $\mathbf{A}$. Expand by multilinearity in all m columns at once, exactly as in the uniqueness proof: one term for each way of picking a column $\mathbf{a}_{\varphi(k)}$ of $\mathbf{A}$ in slot k. ① Terms that pick the same column twice vanish, because the determinant is alternating. ② The surviving picks use m **distinct** columns, forming a set S, in some order; putting them in increasing order costs the sign of the reordering (Lemma 6.4.1). ③ Collecting all orders of the same S produces a Leibniz sum, which is $\det\mathbf{B}_{S,[m]}$.

Proof. Write $\mathbf{a}_1,\dots,\mathbf{a}_n \in F^m$ for the columns of $\mathbf{A}$ and b_{jk} for the entries of $\mathbf{B}$. For $\mathbf{x}_1,\dots,\mathbf{x}_m \in F^m$, the function $D(\mathbf{x}_1,\dots,\mathbf{x}_m) = \det(\mathbf{x}_1,\dots,\mathbf{x}_m)$ is an alternating m-linear form by Theorem 6.4.3.

By Theorem 0.9.2, column k of $\mathbf{AB}$ is $\mathbf{Ab}_k = \sum_{j=1}^{n} b_{jk}\mathbf{a}_j$. Expanding D by linearity in each of its m arguments in turn,

$$\det(\mathbf{AB}) = D\Big(\sum_{j=1}^{n} b_{j1}\mathbf{a}_j,\dots,\sum_{j=1}^{n} b_{jm}\mathbf{a}_j\Big) = \sum_{\varphi}\Big(\prod_{k=1}^{m} b_{\varphi(k)k}\Big)\,D(\mathbf{a}_{\varphi(1)},\dots,\mathbf{a}_{\varphi(m)}),$$

where φ runs over **all** functions $[m] \to [n]$. If φ is not injective, two arguments of D are equal and the term is 0 because D is alternating (Definition 6.2.2). So only injective φ contribute. In particular, if $m > n$ there is no injective φ, and $\det(\mathbf{AB}) = 0$, which proves (a).

An injective φ has an image $S = \{s_1 < \cdots < s_m\} \subseteq [n]$ with m elements, and then $\varphi(k) = s_{\pi(k)}$ for exactly one $\pi \in S_m$. Conversely each pair (S, π) gives an injective φ. By Lemma 6.4.1 with $\mathbf{v}_p = \mathbf{a}_{s_p}$,

$$D(\mathbf{a}_{\varphi(1)}, \dots, \mathbf{a}_{\varphi(m)}) = \operatorname{sgn}(\pi)\, D(\mathbf{a}_{s_1}, \dots, \mathbf{a}_{s_m}) = \operatorname{sgn}(\pi)\, \det \mathbf{A}_{[m],S},$$

since $\mathbf{A}_{[m],S}$ has columns $\mathbf{a}_{s_1}, \dots, \mathbf{a}_{s_m}$. Hence

$$\det(\mathbf{AB}) = \sum_{|S|=m} \det \mathbf{A}_{[m],S} \sum_{\pi \in S_m} \operatorname{sgn}(\pi) \prod_{k=1}^{m} b_{s_{\pi(k)}k}.$$

The matrix $\mathbf{B}_{S,[m]}$ has (p,k)-entry $b_{s_p k}$, so its $(\pi(k),k)$-entry is $b_{s_{\pi(k)}k}$, and the inner sum is $\det \mathbf{B}_{S,[m]}$ by Definition 6.4.1. This proves the formula. For $m = n$, the only S is $[n]$, with $\mathbf{A}_{[n],[n]} = \mathbf{A}$ and $\mathbf{B}_{[n],[n]} = \mathbf{B}$, which gives (b).

■

Part (b) is a second proof of multiplicativity, and part (a) matches what rank predicts: if $m > n$, then $\operatorname{rank}(\mathbf{AB}) \le \operatorname{rank} \mathbf{A} \le n < m$ by Theorem 2.5.9, so $\mathbf{AB}$ is not invertible. The formula also passes a sanity check at $m = 1$: a $1 \times n$ row times an $n \times 1$ column is the 1×1 matrix $\sum_j a_{1j} b_{j1}$, and the 1×1 minors are single entries.

Remark. The proof uses only sums, differences and products of entries, together with Lemma 6.4.1, which is division-free by the remark in §4. So, like the results flagged in §4–§6, the Cauchy–Binet formula holds for matrices with entries in any commutative ring.

Example. (Cauchy–Binet for a 2×3 times 3×2 Product)

Let

$$\mathbf{A} = \begin{pmatrix} 1 & 2 & 0 \\ 0 & 1 & 3 \end{pmatrix}, \qquad \mathbf{B} = \begin{pmatrix} 1 & 0 \\ 1 & 1 \\ 2 & -1 \end{pmatrix}$$

over $\mathbb{Q}$. Compute $\det(\mathbf{AB})$ directly and by the Cauchy–Binet formula. Then compute $\det(\mathbf{BA})$.

Solution. Directly. $\mathbf{AB} = \begin{pmatrix} 1+2+0 & 0+2+0 \\ 0+1+6 & 0+1-3 \end{pmatrix} = \begin{pmatrix} 3 & 2 \\ 7 & -2 \end{pmatrix}$, so $\det(\mathbf{AB}) = -6-14 = -20$.

By Cauchy–Binet. Here $m = 2$, $n = 3$, and there are three subsets S. The minors of $\mathbf{A}$ were computed after Definition 6.7.1. The minors of $\mathbf{B}$ keep both columns and rows S:

S	$\det \mathbf{A}_{[2],S}$	$\det \mathbf{B}_{S,[2]}$	product
$\{1,2\}$	1	$\det \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix} = 1$	1

$\{1,3\}$	3	$\det\begin{pmatrix}1 & 0\\ 2 & -1\end{pmatrix} = -1$	-3
$\{2,3\}$	6	$\det\begin{pmatrix}1 & 1\\ 2 & -1\end{pmatrix} = -3$	-18

The sum is $1 - 3 - 18 = -20$, in agreement.

The other product. $\mathbf{BA}$ is 3×3, and here the roles are $m = 3 > n = 2$, so $\det(\mathbf{BA}) = 0$ by Theorem 6.7.2 (a). Indeed $\mathbf{BA} = \begin{pmatrix}1 & 2 & 0\\ 1 & 3 & 3\\ 2 & 3 & -3\end{pmatrix}$, whose third row is 3 times the first minus the second, so $\det(\mathbf{BA}) = 0$.

Warning. **For non-square factors, $\det(\mathbf{AB})$ and $\det(\mathbf{BA})$ differ.** For square matrices $\det(\mathbf{AB}) = \det\mathbf{A}\det\mathbf{B} = \det(\mathbf{BA})$. In the example above, $\det(\mathbf{AB}) = -20$ while $\det(\mathbf{BA}) = 0$. An even smaller case: $\mathbf{A} = \begin{pmatrix}1 & 1\end{pmatrix}$ and $\mathbf{B} = \begin{pmatrix}1\\ 1\end{pmatrix}$ give $\mathbf{AB} = (2)$ and $\mathbf{BA} = \begin{pmatrix}1 & 1\\ 1 & 1\end{pmatrix}$, with determinants 2 and 0. Also, do not write "$\det\mathbf{A}\det\mathbf{B}$" for non-square $\mathbf{A}$, $\mathbf{B}$: those symbols are undefined, and the sum over S is what replaces them.

Quick check. Let $\mathbf{u}, \mathbf{v} \in F^n$ with $n \geq 2$. Without computing, what is $\det(\mathbf{uv}^\top)$?

Solution. $\mathbf{uv}^\top$ is the product of the $n \times 1$ matrix $\mathbf{u}$ and the $1 \times n$ matrix $\mathbf{v}^\top$. Here the product is $n \times n$ and the middle size is $1 < n$, so $\det(\mathbf{uv}^\top) = 0$ by Theorem 6.7.2 (a).

6.7.4 Sums of squares over the reals

Over $\mathbb{R}$, take $\mathbf{B} = \mathbf{A}^\top$. The minors of $\mathbf{A}^\top$ are the minors of $\mathbf{A}$ with rows and columns exchanged, so Cauchy–Binet writes $\det(\mathbf{AA}^\top)$ as a sum of squares.

Corollary 6.7.3 — Gram Determinants Are Non-negative

Let $\mathbf{A} \in M_{m\times n}(\mathbb{R})$. Then

$$\det(\mathbf{AA}^\top) = \sum_{\substack{S\subseteq[n]\\ |S|=m}} \left(\det\mathbf{A}_{[m],S}\right)^2 \;\geq\; 0,$$

with equality if and only if $\operatorname{rank}\mathbf{A} < m$.

Proof. By Definition 0.9.10, the (p,k)-entry of $(\mathbf{A}^\top)_{S,[m]}$ is the (k,s_p)-entry of $\mathbf{A}$, so $(\mathbf{A}^\top)_{S,[m]} = (\mathbf{A}_{[m],S})^\top$. By Theorem 6.4.5, $\det(\mathbf{A}^\top)_{S,[m]} = \det\mathbf{A}_{[m],S}$. Substituting into Theorem 6.7.2 with $\mathbf{B} = \mathbf{A}^\top$ gives the formula. A sum of squares of real numbers is ≥ 0, and it is 0 if and only if every term is 0. Every $m \times m$ minor of $\mathbf{A}$ has the form $\det\mathbf{A}_{[m],S}$, since an $m \times m$ minor must use all m rows. If $m > n$, the sum is empty and $\operatorname{rank}\mathbf{A} \leq n < m$. Otherwise, by Theorem 6.7.1 (b) (or directly if $\mathbf{A} = 0$), all these

minors vanish if and only if $\operatorname{rank}\mathbf{A} < m$.

■

The matrix $\mathbf{A}\mathbf{A}^{\top}$ collects the dot products of the rows of $\mathbf{A}$ with each other. Such matrices of pairwise inner products are **Gram matrices**; Chapters 10 and 12 study them, and there this corollary becomes the statement that a Gram matrix is positive semidefinite. For $m = 2$ the corollary is a classical identity about two vectors, Exercise (B3: The Lagrange identity). Over $\mathbb{C}$ or $\mathbb{F}_p$ the conclusion "≥ 0" has no meaning, and the equality case can fail: over $\mathbb{C}$, $\mathbf{A} = \begin{pmatrix} 1 & i \end{pmatrix}$ has rank 1 but $\mathbf{A}\mathbf{A}^{\top} = (1 + i^2) = (0)$.

6.7.5 Exercises

6.7.5.1 A. Check your understanding

Exercise A1.

(a) Define the $k \times k$ minor of $\mathbf{A} \in M_{m\times n}(F)$ on rows I and columns J.

(b) True or false: if every principal minor of a square matrix is zero, the matrix is zero. Justify your answer.

(c) True or false: if $\mathbf{A} \in M_{4\times 5}(F)$ has a non-zero 3×3 minor, then $\operatorname{rank}\mathbf{A} \geq 3$. Justify your answer.

(d) True or false: if $\mathbf{A} \in M_3(F)$ has a zero 2×2 minor, then $\operatorname{rank}\mathbf{A} \leq 1$. Justify your answer.

(e) State the Cauchy–Binet formula, and say what it gives when $m > n$.

(f) Let $\mathbf{A} \in M_{2\times 3}(\mathbb{R})$. Why is $\det(\mathbf{A}^{\top}\mathbf{A}) = 0$?

Solution.

(a) For $I = \{i_1 < \cdots < i_k\} \subseteq [m]$ and $J = \{j_1 < \cdots < j_k\} \subseteq [n]$, it is $\det \mathbf{A}_{I,J}$, where $\mathbf{A}_{I,J} \in M_k(F)$ has (p, q)-entry $a_{i_p j_q}$ (Definition 6.7.1).

(b) False. $\mathbf{N} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$ has principal minors $0, 0, 0$ but $\mathbf{N} \neq 0$.

(c) True, by Step 1 of the proof of Theorem 6.7.1, or by part (b) of that theorem.

(d) False. The rank is decided by whether **some** minor is non-zero, not by one zero minor. $\mathbf{I}_3$ has the zero 2×2 minor on rows $\{1, 2\}$ and columns $\{2, 3\}$, namely $\det \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix} = 0$, but $\operatorname{rank}\mathbf{I}_3 = 3$.

(e) For $\mathbf{A} \in M_{m\times n}(F)$ and $\mathbf{B} \in M_{n\times m}(F)$, $\det(\mathbf{AB}) = \sum_{|S|=m} \det \mathbf{A}_{[m],S} \det \mathbf{B}_{S,[m]}$, summed over m-subsets $S \subseteq [n]$. If $m > n$ there are no such subsets and $\det(\mathbf{AB}) = 0$.

(f) $\mathbf{A}^{\top}\mathbf{A}$ is 3×3, the product of a 3×2 and a 2×3 matrix. By Theorem 6.7.2 (a) with $m = 3 > n = 2$, $\det(\mathbf{A}^{\top}\mathbf{A}) = 0$.

6.7.5.2 B. Practice

Exercise B1: Rank with a parameter.

For $s \in \mathbb{Q}$, let $\mathbf{A}(s) = \begin{pmatrix} 1 & s & 1 \\ s & 1 & 1 \\ 1 & 1 & s \end{pmatrix}$. Use minors to find $\operatorname{rank} \mathbf{A}(s)$ for every s.

Solution. By cofactor expansion along the first row (Theorem 6.6.1),

$$\begin{aligned} \det \mathbf{A}(s) &= 1 \cdot (s-1) - s\,(s^2-1) + 1 \cdot (s-1) \\ &= -s^3 + 3s - 2 = -(s-1)^2(s+2). \end{aligned}$$

If $s \neq 1, -2$, this 3×3 minor is non-zero, so $\operatorname{rank} \mathbf{A}(s) = 3$ by Theorem 6.7.1.

If $s = -2$, then $\det \mathbf{A}(-2) = 0$, so $\operatorname{rank} \mathbf{A}(-2) \leq 2$. The minor on rows $\{1,2\}$ and columns $\{1,2\}$ is $\det \begin{pmatrix} 1 & -2 \\ -2 & 1 \end{pmatrix} = 1 - 4 = -3 \neq 0$. Hence $\operatorname{rank} \mathbf{A}(-2) = 2$.

If $s = 1$, every entry is 1. Every 2×2 minor is $\det \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix} = 0$, and the 1×1 minors are non-zero. Hence $\operatorname{rank} \mathbf{A}(1) = 1$.

Exercise B2: Checking Cauchy–Binet.

Let $\mathbf{A} = \begin{pmatrix} 1 & 0 & 2 \\ -1 & 1 & 1 \end{pmatrix}$ and $\mathbf{B} = \begin{pmatrix} 2 & 1 \\ 0 & 1 \\ 1 & -1 \end{pmatrix}$ over $\mathbb{Q}$.

(a) Compute $\det(\mathbf{AB})$ directly.
(b) Compute $\det(\mathbf{AB})$ by the Cauchy–Binet formula.
(c) Hence, without multiplying, find $\det(\mathbf{BA})$.

Solution.

(a) $\mathbf{AB} = \begin{pmatrix} 2+0+2 & 1+0-2 \\ -2+0+1 & -1+1-1 \end{pmatrix} = \begin{pmatrix} 4 & -1 \\ -1 & -1 \end{pmatrix}$, so $\det(\mathbf{AB}) = -4 - 1 = -5$.

(b) The three subsets of $[3]$ of size 2 give

$$\begin{aligned} S = \{1,2\}: &\ \det \begin{pmatrix} 1 & 0 \\ -1 & 1 \end{pmatrix} \det \begin{pmatrix} 2 & 1 \\ 0 & 1 \end{pmatrix} = 1 \cdot 2 = 2, \\ S = \{1,3\}: &\ \det \begin{pmatrix} 1 & 2 \\ -1 & 1 \end{pmatrix} \det \begin{pmatrix} 2 & 1 \\ 1 & -1 \end{pmatrix} = 3 \cdot (-3) = -9, \\ S = \{2,3\}: &\ \det \begin{pmatrix} 0 & 2 \\ 1 & 1 \end{pmatrix} \det \begin{pmatrix} 0 & 1 \\ 1 & -1 \end{pmatrix} = (-2)(-1) = 2. \end{aligned}$$

The sum is $2 - 9 + 2 = -5$, agreeing with (a).

(c) $\mathbf{BA} \in M_3(\mathbb{Q})$ is a product through F^2, so $\det(\mathbf{BA}) = 0$ by Theorem 6.7.2 (a).

Exercise B3: The Lagrange identity.

Let $\mathbf{a} = (a_1, \dots, a_n)$ and $\mathbf{b} = (b_1, \dots, b_n)$ be vectors in $\mathbb{R}^n$, $n \geq 2$, and write $\mathbf{a} \cdot \mathbf{b} = \sum_i a_i b_i$.

(a) Let $\mathbf{M} \in M_{2\times n}(\mathbb{R})$ have rows $\mathbf{a}^\top$ and $\mathbf{b}^\top$. Compute $\mathbf{M}\mathbf{M}^\top$.

(b) Hence prove the **Lagrange identity**

$$(\mathbf{a}\cdot\mathbf{a})(\mathbf{b}\cdot\mathbf{b}) - (\mathbf{a}\cdot\mathbf{b})^2 = \sum_{1\leq i<j\leq n} (a_i b_j - a_j b_i)^2.$$

(c) Check it for $\mathbf{a} = (1,2,3)$ and $\mathbf{b} = (4,5,6)$, and deduce $(\mathbf{a}\cdot\mathbf{b})^2 \leq (\mathbf{a}\cdot\mathbf{a})(\mathbf{b}\cdot\mathbf{b})$ for all $\mathbf{a}, \mathbf{b} \in \mathbb{R}^n$.

Solution.

(a) By Theorem 0.9.2, the (p,q)-entry of $\mathbf{M}\mathbf{M}^\top$ is row p of $\mathbf{M}$ times column q of $\mathbf{M}^\top$, which is row q of $\mathbf{M}$ transposed. Hence

$$\mathbf{M}\mathbf{M}^\top = \begin{pmatrix} \mathbf{a}\cdot\mathbf{a} & \mathbf{a}\cdot\mathbf{b} \\ \mathbf{b}\cdot\mathbf{a} & \mathbf{b}\cdot\mathbf{b} \end{pmatrix}, \qquad \mathbf{b}\cdot\mathbf{a} = \mathbf{a}\cdot\mathbf{b}.$$

(b) The left side of the identity is $\det(\mathbf{M}\mathbf{M}^\top)$. By Corollary 6.7.3 with $m = 2$, it equals the sum over $S = \{i < j\}$ of $(\det \mathbf{M}_{[2],S})^2$, and $\mathbf{M}_{[2],\{i,j\}} = \begin{pmatrix} a_i & a_j \\ b_i & b_j \end{pmatrix}$ has determinant $a_i b_j - a_j b_i$. This proves the identity.

(c) Left side: $\mathbf{a}\cdot\mathbf{a} = 14$, $\mathbf{b}\cdot\mathbf{b} = 77$, $\mathbf{a}\cdot\mathbf{b} = 32$, so $14\cdot 77 - 32^2 = 1078 - 1024 = 54$. Right side: the pairs $(1,2), (1,3), (2,3)$ give $5-8=-3$, $6-12=-6$, $12-15=-3$, and $9+36+9 = 54$. In general the right side is a sum of squares of reals, hence ≥ 0, so $(\mathbf{a}\cdot\mathbf{b})^2 \leq (\mathbf{a}\cdot\mathbf{a})(\mathbf{b}\cdot\mathbf{b})$.

6.7.5.3 C. Going deeper

Exercise C1: Counting spanning trees.

Consider the network with vertices $1, 2, 3, 4$ and five edges, oriented as $e_1 = 1 \to 2$, $e_2 = 2 \to 3$, $e_3 = 3 \to 4$, $e_4 = 4 \to 1$, $e_5 = 1 \to 3$. A **spanning tree** is a set of 3 edges that connects all four vertices (ignoring orientation). Let $\mathbf{N} \in M_{4\times 5}(\mathbb{R})$ be its incidence matrix (Definition 2.7.1), let $Ł = \mathbf{N}\mathbf{N}^\top$, and let $\mathbf{N}_0$ and $Ł_0$ be $\mathbf{N}$ and $Ł$ with the row (and, for $Ł$, the column) of vertex 4 deleted.

(a) Compute $Ł$ and $\det Ł_0$.

(b) List the spanning trees and count them.

(c) Show that $Ł_0 = \mathbf{N}_0\mathbf{N}_0^\top$, and use Corollary 6.7.3 to write $\det Ł_0$ as a sum over 3-element sets of edges.

(d) Compute the minor of $\mathbf{N}_0$ for the tree $\{e_1, e_2, e_3\}$ and for the non-tree $\{e_1, e_2, e_5\}$. Explain, for these two sets, why the answers are ± 1 and 0.

The **matrix-tree theorem** says that for every connected network, $\det Ł_0$ equals the number of spanning trees; parts (c) and (d) are the heart of its proof, which Chapter 23 completes.

Hint: for (d), a set of edges containing a cycle gives dependent columns.

Solution.

(a) Column e of $\mathbf{N}$ has 1 at the tail and -1 at the head:

$$\mathbf{N} = \begin{pmatrix} 1 & 0 & 0 & -1 & 1 \\ -1 & 1 & 0 & 0 & 0 \\ 0 & -1 & 1 & 0 & -1 \\ 0 & 0 & -1 & 1 & 0 \end{pmatrix}, \qquad Ł = \mathbf{N}\mathbf{N}^\top = \begin{pmatrix} 3 & -1 & -1 & -1 \\ -1 & 2 & -1 & 0 \\ -1 & -1 & 3 & -1 \\ -1 & 0 & -1 & 2 \end{pmatrix}.$$

(Diagonal entries count the edges at a vertex; off-diagonal entries are -1 for each edge joining two vertices.) Expanding along the first row,

$$\begin{aligned} \det Ł_0 &= \det \begin{pmatrix} 3 & -1 & -1 \\ -1 & 2 & -1 \\ -1 & -1 & 3 \end{pmatrix} \\ &= 3(6-1) + 1\cdot(-3-1) - 1\cdot(1+2) = 15 - 4 - 3 = 8. \end{aligned}$$

(b) There are $\binom{5}{3} = 10$ sets of three edges. Three edges on four vertices connect everything exactly when they contain no cycle, and the only 3-edge cycles are the triangles $\{e_1, e_2, e_5\}$ (vertices $1, 2, 3$) and $\{e_3, e_4, e_5\}$ (vertices $1, 3, 4$). So there are $10 - 2 = 8$ spanning trees, matching $\det Ł_0$.

(c) Deleting row 4 of $\mathbf{N}$ deletes row 4 of $\mathbf{N}\mathbf{N}^\top$ (row view) and column 4 of $\mathbf{N}\mathbf{N}^\top$ (column view of $\mathbf{N}^\top$), by Theorem 0.9.2. So $Ł_0 = \mathbf{N}_0\mathbf{N}_0^\top$, with $\mathbf{N}_0 \in M_{3\times 5}(\mathbb{R})$, and Corollary 6.7.3 gives $\det Ł_0 = \sum_{|S|=3} (\det(\mathbf{N}_0)_{[3],S})^2$, one term for each set S of three edges.

(d) For $S = \{e_1, e_2, e_3\}$, $(\mathbf{N}_0)_{[3],S} = \begin{pmatrix} 1 & 0 & 0 \\ -1 & 1 & 0 \\ 0 & -1 & 1 \end{pmatrix}$, which is lower triangular with determinant 1 (Theorem 6.4.6). For $S = \{e_1, e_2, e_5\}$, the columns are $(1, -1, 0)$, $(0, 1, -1)$, $(1, 0, -1)$, and the third is the sum of the first two: going around the cycle $1 \to 2 \to 3$ equals going directly $1 \to 3$. So the columns are dependent and the minor is 0 by Theorem 6.2.1. Thus the non-tree contributes 0^2 and the tree contributes 1^2.

Exercise C2: Rank does not depend on the field.

Let K be a subfield of a field L (Definition 1.9.1), and let $\mathbf{A} \in M_{m\times n}(K)$. We may also regard $\mathbf{A}$ as a matrix in $M_{m\times n}(L)$.

(a) Explain why each minor $\det \mathbf{A}_{I,J}$ is the same element whether computed in K or in L.

(b) Prove that the rank of $\mathbf{A}$ over K equals its rank over L.

(c) Deduce: if a system $\mathbf{A}\mathbf{x} = \mathbf{0}$ with rational coefficients has a non-zero complex solution, it has a non-zero rational solution.

Solution.

(a) By Definition 6.4.1, $\det \mathbf{A}_{I,J}$ is a finite sum of $\pm$ products of entries of $\mathbf{A}$. The

entries lie in K, and K has the same addition and multiplication as L, so the sum is the same element of $K \subseteq L$.

(b) If $\mathbf{A} = 0$, both ranks are 0. Otherwise, by Theorem 6.7.1 (a) applied over K and over L, each rank is the largest k for which some $k \times k$ minor is non-zero. By (a) the list of minors, and which of them are non-zero, is the same in both cases. Hence the two ranks agree.

(c) Take $K = \mathbb{Q}$, $L = \mathbb{C}$. A non-zero complex solution means nullity $\mathbf{A} \geq 1$ over $\mathbb{C}$, so $\operatorname{rank}_{\mathbb{C}} \mathbf{A} \leq n - 1$ by Theorem 2.5.7. By (b), $\operatorname{rank}_{\mathbb{Q}} \mathbf{A} \leq n - 1$, so nullity $\mathbf{A} \geq 1$ over $\mathbb{Q}$, and a non-zero rational solution exists.

6.8 Special Determinants

A determinant of size n has $n!$ terms, so a general formula for a large matrix is hopeless. Some matrices, though, have so much structure that their determinants collapse to a short product or a recurrence. This section computes the most useful of them: the Vandermonde determinant, which governs polynomial interpolation; tridiagonal determinants, which satisfy a three-term recurrence; block triangular determinants, which split into smaller ones; and the determinant of a rank-one update of the identity. The proofs share one idea: find the structure first (a polynomial with known roots, a row with two non-zero entries, a pattern of zeros) and let the defining properties of the determinant do the rest.

6.8.1 The Vandermonde determinant

Chapter 2 proved that there is exactly one polynomial of degree at most n through $n+1$ points with distinct first coordinates (Theorem 2.7.3). Behind it sat a square matrix of powers of the nodes. Its determinant turns out to be a product of all the differences of the nodes, and that product explains at a glance why distinct nodes are exactly what is needed.

For $x_1, \ldots, x_n \in F$, the **Vandermonde matrix** is

$$\mathbf{V}(x_1, \ldots, x_n) := \begin{pmatrix} 1 & x_1 & x_1^2 & \cdots & x_1^{n-1} \\ 1 & x_2 & x_2^2 & \cdots & x_2^{n-1} \\ \vdots & \vdots & \vdots & & \vdots \\ 1 & x_n & x_n^2 & \cdots & x_n^{n-1} \end{pmatrix} \in M_n(F),$$

whose (i, j)-entry is x_i^{j-1}. Row i lists the powers $1, x_i, \ldots, x_i^{n-1}$ of the i-th node. For $n = 1$ it is the 1×1 matrix (1), and for $n = 2$ its determinant is $x_2 - x_1$.

Theorem 6.8.1 — Vandermonde Determinant

Let $n \geq 1$ and $x_1, \ldots, x_n \in F$. Then

$$\det \mathbf{V}(x_1, \ldots, x_n) = \prod_{1 \leq i < j \leq n} (x_j - x_i),$$

where the empty product (for $n = 1$) is 1.

Idea. Induction on n. Replace the last node x_n by a variable t. Expanding along the last row shows the determinant is a polynomial $f(t)$ of degree at most $n-1$, with leading coefficient the smaller Vandermonde determinant. Setting $t = x_i$ for $i < n$ makes two rows equal, so $x_1, \dots, x_{n-1}$ are roots of f. A polynomial of degree at most $n-1$ with these $n-1$ roots is its leading coefficient times $\prod_{i<n}(t - x_i)$. Now put $t = x_n$ back. The roots argument needs the x_i distinct; if they are not, both sides are 0 anyway.

Proof. We use induction on n (Theorem 0.2.7). For $n = 1$, $\det(1) = 1$, the empty product.

Let $n \geq 2$, assume the formula for $n-1$ nodes, and write $\mathbf{V} = \mathbf{V}(x_1, \dots, x_n)$. Let $C_{n1}, \dots, C_{nn}$ be the cofactors of $\mathbf{V}$ along row n (Definition 6.6.1). Each C_{nj} is computed after deleting row n, so it does not involve x_n. Define

$$f(t) \coloneqq \sum_{j=1}^{n} C_{nj}\, t^{j-1} \in F[t].$$

For $c \in F$, let $\mathbf{V}_c$ be $\mathbf{V}$ with row n replaced by $(1, c, \dots, c^{n-1})$. Then $\mathbf{V}_c$ has the same cofactors along row n as $\mathbf{V}$, so by Theorem 6.6.1 along row n,

$$\det \mathbf{V}_c = \sum_{j=1}^{n} c^{j-1} C_{nj} = f(c). \qquad (*)$$

In particular $\det \mathbf{V} = f(x_n)$. The coefficient of t^{n-1} in f is $C_{nn} = (-1)^{2n} \det \mathbf{V}(x_1, \dots, x_{n-1})$, since deleting row n and column n of $\mathbf{V}$ leaves the Vandermonde matrix of the first $n-1$ nodes.

Case 1: two of $x_1, \dots, x_{n-1}$ are equal, say $x_p = x_q$ with $p < q < n$. Then rows p and q of $\mathbf{V}$ are equal. By Theorem 6.4.5, $\det \mathbf{V} = \det \mathbf{V}^\top$, and $\mathbf{V}^\top$ has two equal columns, so $\det \mathbf{V} = 0$ because the determinant is alternating (Definition 6.2.2). The product also vanishes, since it contains the factor $x_q - x_p = 0$.

Case 2: $x_1, \dots, x_{n-1}$ are distinct. For $i < n$, the matrix $\mathbf{V}_{x_i}$ has rows i and n equal, so $f(x_i) = \det \mathbf{V}_{x_i} = 0$ by $(*)$ and the argument of Case 1. Hence $x_1, \dots, x_{n-1}$ are $n-1$ distinct roots of f, and by Corollary 5.1.4,

$$g(t) \coloneqq (t - x_1)(t - x_2) \cdots (t - x_{n-1}) \quad \text{divides} \quad f.$$

Write $f = hg$ with $h \in F[t]$. If $h \neq 0$, then $\deg h = \deg f - (n-1) \leq 0$ by Theorem 0.8.3, since $\deg f \leq n-1$; so in every case h is a constant $h \in F$. As g is monic of degree $n-1$, the coefficient of t^{n-1} in hg is h, so $h = C_{nn} = \det \mathbf{V}(x_1, \dots, x_{n-1})$. Evaluating at x_n (Theorem 0.8.5) and using the induction hypothesis,

$$\begin{aligned} \det \mathbf{V} = f(x_n) &= \det \mathbf{V}(x_1, \dots, x_{n-1}) \prod_{i=1}^{n-1} (x_n - x_i) \\ &= \prod_{1 \leq i < j \leq n-1} (x_j - x_i) \prod_{i=1}^{n-1} (x_n - x_i). \end{aligned}$$

The two products together run over all pairs $i < j \leq n$, the second one collecting exactly the pairs with $j = n$. This proves the formula for n, and the theorem follows by induction.

■

Example. (A 3×3 Vandermonde Determinant)

Compute $\det \mathbf{V}(1, 2, 4)$ from the formula and by cofactor expansion.

Solution. The formula gives $(2-1)(4-1)(4-2) = 1 \cdot 3 \cdot 2 = 6$. Directly, expanding

$$\mathbf{V}(1,2,4) = \begin{pmatrix} 1 & 1 & 1 \\ 1 & 2 & 4 \\ 1 & 4 & 16 \end{pmatrix}$$

along the first row gives $1 \cdot (32-16) - 1 \cdot (16-4) + 1 \cdot (4-2) = 16 - 12 + 2 = 6$.

The product vanishes exactly when a factor does, because a field has no zero divisors. So:

Corollary 6.8.2 — Distinct Nodes Give an Invertible Vandermonde Matrix

$\mathbf{V}(x_1, \ldots, x_n)$ is invertible if and only if $x_1, \ldots, x_n$ are **distinct**.

Proof. In a field, a product is non-zero if and only if every factor is non-zero (Theorem 0.7.1 (f), applied repeatedly). So by Theorem 6.8.1, $\det \mathbf{V}(x_1, \ldots, x_n) \neq 0$ if and only if $x_j \neq x_i$ for all $i < j$. By Theorem 6.5.2, this is equivalent to invertibility.

■

Now the promised two-line proof of Theorem 2.7.3. Given distinct $x_0, \ldots, x_n$ and values $y_0, \ldots, y_n$, a polynomial $p = c_0 + c_1 x + \cdots + c_n x^n$ satisfies $p(x_i) = y_i$ for all i if and only if $\mathbf{V}(x_0, \ldots, x_n)\,\mathbf{c} = \mathbf{y}$, since row i of this system reads $c_0 + c_1 x_i + \cdots + c_n x_i^n = y_i$. By Corollary 6.8.2 the matrix is invertible, so the system has exactly one solution $\mathbf{c} = \mathbf{V}(x_0, \ldots, x_n)^{-1}\mathbf{y}$ (Theorem 2.4.4), and the interpolating polynomial exists and is unique.

Remark. This is not a proof from nothing. The root bound of Chapter 5 did the real work inside Theorem 6.8.1, exactly as the root bound did in Chapter 2. What the determinant adds is an explicit number: it says how close to singular the interpolation problem is, since nodes that nearly coincide make the product small.

Warning. **Watch the shape and the order.** The formula is for rows $(1, x_i, \ldots, x_i^{n-1})$ starting at the power 0, and for the factors $x_j - x_i$ with $i < j$, "later node minus earlier node". Dropping the column of ones changes the answer: $\det \begin{pmatrix} x_1 & x_1^2 \\ x_2 & x_2^2 \end{pmatrix} = x_1 x_2 (x_2 - x_1)$, not $x_2 - x_1$. Writing the factors as $x_i - x_j$ instead flips the sign of each of the $\binom{n}{2}$ factors, so it multiplies the answer by $(-1)^{\binom{n}{2}}$: already for $n = 2$ and $n = 3$ this is -1, a wrong sign.

Quick check. Without expanding, find $\det \mathbf{V}(1, 2, 3, 5)$.

Solution. The pairs $i<j$ give $(2-1)(3-1)(5-1)(3-2)(5-2)(5-3)=1\cdot2\cdot4\cdot1\cdot3\cdot2=48$.

6.8.2 Tridiagonal determinants

Many matrices in applications have non-zero entries only on the diagonal and next to it: discretized differential equations, chains of springs, the recurrences of orthogonal polynomials. Such a matrix is **tridiagonal**. Its determinant is not a closed formula in general, but it obeys a recurrence in the size, because the last row has only two non-zero entries.

Let $\mathbf{T}_n \in M_n(F)$ have diagonal entries $a_1,\dots,a_n$, entries $b_1,\dots,b_{n-1}$ just above the diagonal ($(i,i+1)$-entry b_i), entries $c_1,\dots,c_{n-1}$ just below it ($(i+1,i)$-entry c_i), and zeros elsewhere:

$$\mathbf{T}_n=\begin{pmatrix} a_1 & b_1 & & & \\ c_1 & a_2 & b_2 & & \\ & c_2 & \ddots & \ddots & \\ & & \ddots & a_{n-1} & b_{n-1} \\ & & & c_{n-1} & a_n \end{pmatrix}.$$

For $1\le k\le n$, the top-left $k\times k$ block of $\mathbf{T}_n$ is the tridiagonal matrix $\mathbf{T}_k$ built from $a_1,\dots,a_k$, $b_1,\dots,b_{k-1}$, $c_1,\dots,c_{k-1}$. Write $D_k=\det\mathbf{T}_k$, and set $D_0=1$.

Theorem 6.8.3 — Tridiagonal Recurrence

With this notation, $D_1=a_1$, and for $2\le k\le n$,

$$D_k=a_k\,D_{k-1}-b_{k-1}c_{k-1}\,D_{k-2}.$$

Proof. $D_1=\det(a_1)=a_1$. For $k=2$, $D_2=a_1a_2-b_1c_1=a_2D_1-b_1c_1D_0$. Let $k\ge3$. Row k of $\mathbf{T}_k$ has only two possibly non-zero entries, c_{k-1} in column $k-1$ and a_k in column k. By Theorem 6.6.1 along row k,

$$D_k=c_{k-1}(-1)^{2k-1}M_{k,k-1}+a_k(-1)^{2k}M_{kk}=a_kM_{kk}-c_{k-1}M_{k,k-1},$$

where $M_{kk}=\det\mathbf{T}_{k-1}=D_{k-1}$. The minor $M_{k,k-1}$ is the determinant of the $(k-1)\times(k-1)$ matrix obtained by deleting row k and column $k-1$. Its last column consists of rows $1,\dots,k-1$ of column k of $\mathbf{T}_k$, which is b_{k-1} in the last position and 0 elsewhere. Expanding along this last column (Theorem 6.6.1), with sign $(-1)^{(k-1)+(k-1)}=1$, gives $M_{k,k-1}=b_{k-1}\det\mathbf{T}_{k-2}=b_{k-1}D_{k-2}$, because deleting the last row and column leaves rows and columns $1,\dots,k-2$ of $\mathbf{T}_k$. Substituting proves the recurrence. ∎

Example. (Fibonacci Numbers as Determinants)

Let $\mathbf{T}_n$ have 1 on the diagonal, 1 above it and -1 below it. Find $D_n=\det\mathbf{T}_n$.

Solution. Here $a_k=1$ and $b_{k-1}c_{k-1}=1\cdot(-1)=-1$, so Theorem 6.8.3 gives $D_k=$

$D_{k-1} + D_{k-2}$ for $k \geq 2$, with $D_0 = 1$ and $D_1 = 1$. Hence

$$D_1, D_2, D_3, \cdots = 1, 2, 3, 5, 8, 13, 21, 34, \ldots,$$

the Fibonacci numbers: $D_n = F_{n+1}$, where $F_1 = F_2 = 1$ and $F_k = F_{k-1} + F_{k-2}$. For instance

$$D_3 = \det \begin{pmatrix} 1 & 1 & 0 \\ -1 & 1 & 1 \\ 0 & -1 & 1 \end{pmatrix} = 1 \cdot (1+1) - 1 \cdot (-1-0) + 0 = 3.$$

Only the products $b_{k-1}c_{k-1}$ enter the recurrence, never b_{k-1} and c_{k-1} separately. For example, for a real number t, putting $2t$ on the diagonal and 1 on both neighboring lines gives $D_k = 2t\,D_{k-1} - D_{k-2}$, so $D_1 = 2t$, $D_2 = 4t^2 - 1$, $D_3 = 8t^3 - 4t$. These are the Chebyshev polynomials of the second kind.

6.8.3 Block triangular matrices

A matrix can be cut into blocks by a horizontal and a vertical line. When the block in the lower left is zero, the determinant should see only the two square blocks on the diagonal, just as a triangular determinant sees only diagonal entries. This result is used constantly, for instance in Chapter 7 for Schur complements.

Theorem 6.8.4 — Block Triangular Determinant

Let $\mathbf{A} \in M_k(F)$, $\mathbf{D} \in M_l(F)$ and $\mathbf{B} \in M_{k\times l}(F)$, with $k, l \geq 1$. Then

$$\det \begin{pmatrix} \mathbf{A} & \mathbf{B} \\ 0 & \mathbf{D} \end{pmatrix} = \det \mathbf{A} \cdot \det \mathbf{D},$$

where 0 is the $l \times k$ zero matrix. The same holds for $\begin{pmatrix} \mathbf{A} & 0 \\ \mathbf{C} & \mathbf{D} \end{pmatrix}$ with $\mathbf{C} \in M_{l\times k}(F)$.

Idea. In the Leibniz formula for the whole matrix, a term picks one entry from each column. The first k columns have zeros below row k, so a non-zero term must pick rows $1, \ldots, k$ for the first k columns, and is then forced to pick rows $k+1, \ldots, n$ for the last l columns. Such a permutation is a permutation of each block, its inversions are the inversions inside the blocks, and the Leibniz sum factors into two Leibniz sums.

Proof. Let $n = k + l$ and $\mathbf{M} = \begin{pmatrix} \mathbf{A} & \mathbf{B} \\ 0 & \mathbf{D} \end{pmatrix} = (m_{ij})$. By Definition 6.4.1, $\det \mathbf{M} = \sum_{\sigma \in S_n} \operatorname{sgn}(\sigma) \prod_{j=1}^{n} m_{\sigma(j)j}$. Since $m_{ij} = 0$ for $i > k \geq j$, the term of σ is 0 unless $\sigma(j) \leq k$ for every $j \leq k$. For such σ, the injective map σ sends $\{1, \ldots, k\}$ into itself, hence onto itself (a finite set), and so it sends $\{k+1, \ldots, n\}$ onto itself. Therefore σ determines $\alpha \in S_k$ and $\beta \in S_l$ by

$$\alpha(j) = \sigma(j) \quad (j \leq k), \qquad \beta(q) = \sigma(k+q) - k \quad (q \leq l),$$

and every pair (α, β) arises from exactly one such σ.

We compare signs through inversions (Definition 6.3.1). A pair $i < j$ with $i, j \leq k$ is

an inversion of σ exactly when it is one of α; a pair $k+p<k+q$ is an inversion of σ exactly when $p<q$ is one of β; and a pair $i\le k<j$ is never an inversion, since $\sigma(i)\le k<\sigma(j)$. By Definition 6.3.2, $\operatorname{sgn}(\sigma)=\operatorname{sgn}(\alpha)\operatorname{sgn}(\beta)$. Also $m_{\sigma(j)j}=a_{\alpha(j)j}$ for $j\le k$ and $m_{\sigma(k+q),k+q}=d_{\beta(q)q}$. Hence

$$\det\mathbf{M}=\sum_{\alpha\in S_k}\sum_{\beta\in S_l}\operatorname{sgn}(\alpha)\operatorname{sgn}(\beta)\prod_{j=1}^{k}a_{\alpha(j)j}\prod_{q=1}^{l}d_{\beta(q)q}=\det\mathbf{A}\cdot\det\mathbf{D},$$

using Definition 6.4.1 twice. For the lower block triangular case, the transpose of $\begin{pmatrix}\mathbf{A}&0\\ \mathbf{C}&\mathbf{D}\end{pmatrix}$ is $\begin{pmatrix}\mathbf{A}^{\top}&\mathbf{C}^{\top}\\ 0&\mathbf{D}^{\top}\end{pmatrix}$, so by Theorem 6.4.5 and the first case its determinant is $\det\mathbf{A}^{\top}\det\mathbf{D}^{\top}=\det\mathbf{A}\det\mathbf{D}$.

■

The proof uses only sums and products of entries, so, like the results flagged in §4–§6, it holds for matrices over any commutative ring; §10 uses this over $F[x]$. By induction on the number of blocks, a matrix with square blocks $\mathbf{A}_1,\dots,\mathbf{A}_r$ on the diagonal and zeros below them has determinant $\det\mathbf{A}_1\cdots\det\mathbf{A}_r$; Theorem 6.4.6 is the case where every block is 1×1.

For example,

$$\det\begin{pmatrix}2&1&5&-3\\1&1&0&7\\0&0&3&1\\0&0&4&2\end{pmatrix}=\det\begin{pmatrix}2&1\\1&1\end{pmatrix}\det\begin{pmatrix}3&1\\4&2\end{pmatrix}=1\cdot2=2,$$

and the entries $5,-3,0,7$ of the upper right block play no role.

Warning. **There is no "block $ad-bc$" rule.** For a general block matrix, $\det\begin{pmatrix}\mathbf{A}&\mathbf{B}\\ \mathbf{C}&\mathbf{D}\end{pmatrix}\neq\det\mathbf{A}\det\mathbf{D}-\det\mathbf{B}\det\mathbf{C}$. Take $\mathbf{A}=\mathbf{D}=0$ and $\mathbf{B}=\mathbf{C}=\mathbf{I}_2$: the 4×4 matrix $\begin{pmatrix}0&\mathbf{I}_2\\ \mathbf{I}_2&0\end{pmatrix}$ is the permutation matrix of $(1\ 3)(2\ 4)$, a product of two transpositions, so its determinant is $+1$; the rule would give $0\cdot0-1\cdot1=-1$. The zero block in the corner is what the theorem needs. The correct formulas for general blocks use Schur complements, in Chapter 7.

Quick check. Is $\det\begin{pmatrix}\mathbf{A}&\mathbf{B}\\ 0&\mathbf{D}\end{pmatrix}=\det\mathbf{A}\det\mathbf{D}$ meaningful when $\mathbf{A}$ is 2×3 and $\mathbf{D}$ is 3×2 (so the whole matrix is 5×5)?

Solution. No. The theorem requires $\mathbf{A}$ and $\mathbf{D}$ square; here $\det\mathbf{A}$ and $\det\mathbf{D}$ are undefined. In fact the whole determinant is 0 whatever the entries: the first 3 columns have their non-zero entries only in the first 2 rows, so they are linearly dependent in a 2-dimensional space, and a determinant with dependent columns is 0 (Theorem 6.2.1).

6.8.4 Rank-one updates

Changing a matrix by a rank-one matrix $\mathbf{u}\mathbf{v}^{\top}$ is the smallest possible change in the sense of rank, and it happens often: updating one observation in statistics, modifying one row of a system, or

adding the same number to every entry. The determinant of the updated identity turns out to be a single dot product.

Theorem 6.8.5 — Matrix Determinant Lemma

Let $\mathbf{u}, \mathbf{v} \in F^n$. Then

$$\det(\mathbf{I}_n + \mathbf{u}\mathbf{v}^\top) = 1 + \mathbf{v}^\top \mathbf{u}.$$

Idea. Border $\mathbf{I}_n + \mathbf{u}\mathbf{v}^\top$ by an extra column $\mathbf{u}$ and an extra row $(\mathbf{0}^\top, 1)$, giving a block triangular matrix $\mathbf{M}$ with the same determinant. Then clear the update by elimination with blocks. Rows: add $\mathbf{v}^\top$ times the top n rows to the new bottom row (multiply by Ł on the left). Columns: subtract the last column times $\mathbf{v}^\top$ from the first n columns (multiply by Ł′ on the right). The factors Ł, Ł′ have determinant 1, and the result is block triangular with $\mathbf{I}_n$ and the 1×1 block $1 + \mathbf{v}^\top \mathbf{u}$ on the diagonal.

Proof. Consider the $(n+1) \times (n+1)$ block matrices

$$Ł = \begin{pmatrix} \mathbf{I}_n & \mathbf{0} \\ \mathbf{v}^\top & 1 \end{pmatrix}, \qquad \mathbf{M} = \begin{pmatrix} \mathbf{I}_n + \mathbf{u}\mathbf{v}^\top & \mathbf{u} \\ \mathbf{0}^\top & 1 \end{pmatrix}, \qquad Ł' = \begin{pmatrix} \mathbf{I}_n & \mathbf{0} \\ -\mathbf{v}^\top & 1 \end{pmatrix}.$$

Splitting the sum $\sum_j$ in Theorem 0.9.2 (1) into the indices $j \le n$ and $j = n+1$ shows that matrices partitioned in this way multiply block by block, like 2×2 matrices whose entries are blocks. Hence

$$Ł\mathbf{M} = \begin{pmatrix} \mathbf{I}_n + \mathbf{u}\mathbf{v}^\top & \mathbf{u} \\ \mathbf{v}^\top + (\mathbf{v}^\top \mathbf{u})\mathbf{v}^\top & \mathbf{v}^\top \mathbf{u} + 1 \end{pmatrix},$$

where we used $\mathbf{v}^\top(\mathbf{u}\mathbf{v}^\top) = (\mathbf{v}^\top \mathbf{u})\mathbf{v}^\top$ by associativity, $\mathbf{v}^\top \mathbf{u}$ being a 1×1 matrix, that is, a scalar. Multiplying on the right by Ł′,

$$Ł\mathbf{M}Ł' = \begin{pmatrix} \mathbf{I}_n + \mathbf{u}\mathbf{v}^\top - \mathbf{u}\mathbf{v}^\top & \mathbf{u} \\ \mathbf{v}^\top + (\mathbf{v}^\top \mathbf{u})\mathbf{v}^\top - (1 + \mathbf{v}^\top \mathbf{u})\mathbf{v}^\top & 1 + \mathbf{v}^\top \mathbf{u} \end{pmatrix} = \begin{pmatrix} \mathbf{I}_n & \mathbf{u} \\ \mathbf{0}^\top & 1 + \mathbf{v}^\top \mathbf{u} \end{pmatrix}.$$

By Theorem 6.8.4, $\det Ł = \det \mathbf{I}_n \cdot 1 = 1$, $\det Ł' = 1$, $\det \mathbf{M} = \det(\mathbf{I}_n + \mathbf{u}\mathbf{v}^\top) \cdot 1$, and $\det(Ł\mathbf{M}Ł') = \det \mathbf{I}_n \, (1 + \mathbf{v}^\top \mathbf{u}) = 1 + \mathbf{v}^\top \mathbf{u}$. By Theorem 6.5.4, $\det(Ł\mathbf{M}Ł') = \det Ł \det \mathbf{M} \det Ł' = \det(\mathbf{I}_n + \mathbf{u}\mathbf{v}^\top)$. This proves the lemma. ∎

Example. (a on the Diagonal, 1 Elsewhere)

Let $a \in \mathbb{R}$ and $n \ge 1$, and let $\mathbf{A}_n \in M_n(\mathbb{R})$ have every diagonal entry a and every other entry 1. Find $\det \mathbf{A}_n$.

Solution. Let $\mathbf{1} = (1, \dots, 1) \in \mathbb{R}^n$. Every entry of $\mathbf{1}\mathbf{1}^\top$ is 1, so $\mathbf{A}_n = (a-1)\mathbf{I}_n + \mathbf{1}\mathbf{1}^\top$.

Case $a \neq 1$. Then $\mathbf{A}_n = (a-1)\big(\mathbf{I}_n + \mathbf{u}\mathbf{1}^\top\big)$ with $\mathbf{u} = \frac{1}{a-1}\mathbf{1}$. Scaling an $n \times n$ matrix by c multiplies its determinant by c^n (multilinearity in each of the n columns), so by Theorem 6.8.5

$$\det \mathbf{A}_n = (a-1)^n \Big(1 + \frac{n}{a-1}\Big) = (a-1)^{n-1}(a - 1 + n),$$

since $\mathbf{1}^\top \mathbf{u} = \frac{n}{a-1}$.

Case $a = 1$. For $n \geq 2$, all columns are equal, so $\det \mathbf{A}_n = 0$, which the formula also gives. For $n = 1$, $\det \mathbf{A}_1 = 1$, and the formula gives $(a-1)^0 \cdot 1 = 1$.

So $\det \mathbf{A}_n = (a-1)^{n-1}(a+n-1)$ for every a. For $n = 3$ this is $(a-1)^2(a+2)$; with $a = 3$ it gives $4 \cdot 5 = 20$.

Warning. **The lemma is about $\mathbf{I}_n + \mathbf{u}\mathbf{v}^\top$, not $\mathbf{u}\mathbf{v}^\top$ or $\mathbf{u}^\top\mathbf{v}$.** The rank-one matrix $\mathbf{u}\mathbf{v}^\top$ is $n \times n$ and, for $n \geq 2$, has determinant 0; the scalar $\mathbf{v}^\top\mathbf{u}$ is its trace. Do not confuse $\det(\mathbf{I}_n + \mathbf{u}\mathbf{v}^\top) = 1 + \mathbf{v}^\top\mathbf{u}$ with $\det(\mathbf{I}_n) + \det(\mathbf{u}\mathbf{v}^\top) = 1$ (for $n \geq 2$), which is false whenever $\mathbf{v}^\top\mathbf{u} \neq 0$: for $\mathbf{u} = \mathbf{v} = \mathbf{e}_1$, $\mathbf{I}_n + \mathbf{e}_1\mathbf{e}_1^\top = \operatorname{diag}(2, 1, \ldots, 1)$ has determinant 2.

6.8.5 Exercises

6.8.5.1 A. Check your understanding

Exercise A1.

(a) State the Vandermonde determinant formula, including the order of the factors.

(b) True or false: $\mathbf{V}(x_1, \ldots, x_n)$ is invertible whenever $x_1, \ldots, x_n$ are non-zero. Justify your answer.

(c) Write down the recurrence for the determinant of a tridiagonal matrix, and say which row the proof expands along.

(d) True or false: $\det \begin{pmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{C} & \mathbf{D} \end{pmatrix} = \det \mathbf{A} \det \mathbf{D}$ whenever $\mathbf{A}$ and $\mathbf{D}$ are square and $\mathbf{B} = 0$. Justify your answer.

(e) True or false: $\det(\mathbf{I}_n + \mathbf{u}\mathbf{v}^\top) = \det(\mathbf{I}_n + \mathbf{v}\mathbf{u}^\top)$ for all $\mathbf{u}, \mathbf{v} \in F^n$. Justify your answer.

Solution.

(a) $\det \mathbf{V}(x_1, \ldots, x_n) = \prod_{1 \leq i < j \leq n}(x_j - x_i)$, where $\mathbf{V}$ has (i, j)-entry x_i^{j-1} (Theorem 6.8.1).

(b) False. $\mathbf{V}(1, 1) = \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix}$ has non-zero nodes and determinant 0. The condition is that the nodes are **distinct** (Corollary 6.8.2); 0 is allowed as a node.

(c) $D_k = a_k D_{k-1} - b_{k-1}c_{k-1}D_{k-2}$, with $D_0 = 1$, $D_1 = a_1$ (Theorem 6.8.3). The proof expands along the last row, which has only two non-zero entries.

(d) True. With $\mathbf{B} = 0$ the matrix is lower block triangular, and Theorem 6.8.4 applies.

(e) True. Both equal $1 + \mathbf{v}^\top\mathbf{u} = 1 + \mathbf{u}^\top\mathbf{v}$ by Theorem 6.8.5, since $\mathbf{v}^\top\mathbf{u} = \sum_i v_i u_i = \mathbf{u}^\top\mathbf{v}$.

6.8.5.2 B. Practice

Exercise B1: A 4×4 Vandermonde determinant.

Compute $\det\begin{pmatrix}1 & -1 & 1 & -1\\ 1 & 0 & 0 & 0\\ 1 & 1 & 1 & 1\\ 1 & 2 & 4 & 8\end{pmatrix}$. Hence decide whether there is exactly one polynomial $p \in \mathbb{R}[x]_{\le 3}$ with $p(-1) = 3$, $p(0) = 1$, $p(1) = 0$, $p(2) = 5$.

Solution. Row i is $(1, x_i, x_i^2, x_i^3)$ with nodes $-1, 0, 1, 2$, so this is $\mathbf{V}(-1, 0, 1, 2)$. By Theorem 6.8.1 its determinant is

$$(0-(-1))(1-(-1))(2-(-1))(1-0)(2-0)(2-1) = 1\cdot 2\cdot 3\cdot 1\cdot 2\cdot 1 = 12.$$

(Check by expanding along row 2, which is $(1,0,0,0)$: the determinant is $(-1)^{2+1}\det\begin{pmatrix}-1 & 1 & -1\\ 1 & 1 & 1\\ 2 & 4 & 8\end{pmatrix} = -\big(-1(8-4) - 1(8-2) - 1(4-2)\big) = -(-4-6-2) = 12$.) Hence the coefficient matrix of the interpolation system is invertible, and there is exactly one $p \in \mathbb{R}[x]_{\le 3}$ with the given values.

Exercise B2: The second-difference matrix.

Let $\mathbf{K}_n \in M_n(\mathbb{R})$ have 2 on the diagonal, -1 directly above and below it, and 0 elsewhere. Prove that $\det \mathbf{K}_n = n + 1$. Hence show that $\mathbf{K}_n$ is invertible for every n.

Solution. Here $a_k = 2$ and $b_{k-1}c_{k-1} = (-1)(-1) = 1$. By Theorem 6.8.3, $D_k = 2D_{k-1} - D_{k-2}$ for $k \ge 2$, with $D_0 = 1$, $D_1 = 2$. We show $D_k = k+1$ by strong induction on k (Theorem 0.2.10). It holds for $k = 0, 1$. If it holds for $k-1$ and $k-2$, then $D_k = 2k - (k-1) = k+1$. Hence $\det \mathbf{K}_n = D_n = n+1 \neq 0$, and $\mathbf{K}_n$ is invertible by Theorem 6.5.2.

Exercise B3: A rank-one update.

Let $\mathbf{u} = (1, 2, 3)$ and $\mathbf{v} = (1, -1, 2)$ in $\mathbb{Q}^3$.

(a) Use Theorem 6.8.5 to find $\det(\mathbf{I}_3 + \mathbf{u}\mathbf{v}^{\top})$.

(b) Write out $\mathbf{I}_3 + \mathbf{u}\mathbf{v}^{\top}$ and check your answer by elimination.

(c) Find all $t \in \mathbb{Q}$ for which $\mathbf{I}_3 + t\,\mathbf{u}\mathbf{v}^{\top}$ is **not** invertible.

Solution.

(a) $\mathbf{v}^{\top}\mathbf{u} = 1 - 2 + 6 = 5$, so $\det(\mathbf{I}_3 + \mathbf{u}\mathbf{v}^{\top}) = 6$.

(b) $\mathbf{u}\mathbf{v}^{\top} = \begin{pmatrix}1 & -1 & 2\\ 2 & -2 & 4\\ 3 & -3 & 6\end{pmatrix}$, so $\mathbf{I}_3 + \mathbf{u}\mathbf{v}^{\top} = \begin{pmatrix}2 & -1 & 2\\ 2 & -1 & 4\\ 3 & -3 & 7\end{pmatrix}$. Subtract row 1 from row 2, which does not change the determinant (Theorem 6.5.1), to get row 2 equal to $(0, 0, 2)$. Expanding along that row,

$$\det = 2\cdot(-1)^{2+3}\det\begin{pmatrix}2 & -1\\ 3 & -3\end{pmatrix} = -2(-6+3) = 6.$$

(c) $\mathbf{I}_3 + t\,\mathbf{u}\mathbf{v}^{\top} = \mathbf{I}_3 + (t\mathbf{u})\mathbf{v}^{\top}$, whose determinant is $1 + t\,\mathbf{v}^{\top}\mathbf{u} = 1 + 5t$. It is zero

exactly for $t = -\frac{1}{5}$, and by Theorem 6.5.2 that is the only t for which the matrix is not invertible.

6.8.5.3 C. Going deeper

Exercise C1: The Cauchy determinant.

Let $x_1, \ldots, x_n, y_1, \ldots, y_n \in F$ with $x_i + y_j \neq 0$ for all i, j, and let $\mathbf{Q}_n \in M_n(F)$ have (i,j)-entry $\dfrac{1}{x_i + y_j}$. The goal is

$$\det \mathbf{Q}_n = \frac{\prod_{1 \leq i < j \leq n} (x_j - x_i)(y_j - y_i)}{\prod_{i=1}^{n} \prod_{j=1}^{n} (x_i + y_j)}.$$

(a) For $i < n$, subtract row n from row i. Show that the new (i,j)-entry is $\dfrac{x_n - x_i}{(x_i + y_j)(x_n + y_j)}$, and deduce that $\det \mathbf{Q}_n = \dfrac{\prod_{i<n}(x_n - x_i)}{\prod_j (x_n + y_j)} \det \mathbf{Q}'$, where $\mathbf{Q}'$ agrees with $\mathbf{Q}_n$ in rows $1, \ldots, n-1$ and has last row $(1, \ldots, 1)$.

(b) In $\mathbf{Q}'$, for $j < n$, subtract column n from column j. Deduce that $\det \mathbf{Q}' = \dfrac{\prod_{j<n}(y_n - y_j)}{\prod_{i<n}(x_i + y_n)} \det \mathbf{Q}_{n-1}$, where $\mathbf{Q}_{n-1}$ is built from $x_1, \ldots, x_{n-1}$ and $y_1, \ldots, y_{n-1}$.

(c) Prove the formula by induction on n.

(d) The **Hilbert matrix** $\mathbf{H}_n$ has (i,j)-entry $\frac{1}{i+j-1}$. Show that it is a Cauchy matrix, and use (c) to compute $\det \mathbf{H}_3$.

Hint: in (a) and (b), factor scalars out of whole rows and columns using multilinearity.

Solution.

(a) For $i < n$, $\frac{1}{x_i+y_j} - \frac{1}{x_n+y_j} = \frac{(x_n+y_j)-(x_i+y_j)}{(x_i+y_j)(x_n+y_j)} = \frac{x_n-x_i}{(x_i+y_j)(x_n+y_j)}$. These row operations do not change the determinant (Theorem 6.5.1). In the new matrix, row $i < n$ has the factor $x_n - x_i$ in every entry, and column j has the factor $\frac{1}{x_n+y_j}$ in every entry (in row n, $\frac{1}{x_n+y_j} = \frac{1}{x_n+y_j} \cdot 1$). Pulling these scalars out of each row and column by multilinearity (Theorem 6.5.1, in its row and column forms) leaves the matrix $\mathbf{Q}'$ with entries $\frac{1}{x_i+y_j}$ in rows $i < n$ and 1 in row n. This gives the stated formula.

(b) For $j < n$, subtracting column n from column j leaves the determinant unchanged, makes the last row $(0, \ldots, 0, 1)$, and for $i < n$ gives $\frac{1}{x_i+y_j} - \frac{1}{x_i+y_n} = \frac{y_n-y_j}{(x_i+y_j)(x_i+y_n)}$. Pull $y_n - y_j$ out of column j ($j < n$) and $\frac{1}{x_i+y_n}$ out of row i ($i < n$); the last row $(0, \ldots, 0, 1)$ is unaffected by the column factors because its first $n-1$ entries are 0, and row factors do not touch row n. What remains has $\frac{1}{x_i+y_j}$ in positions $i, j < n$, entries $(x_i + y_n) \cdot \frac{1}{x_i+y_n} = 1$ in column n above the corner, and last row $(0, \ldots, 0, 1)$. Expanding along the last row (Theorem 6.6.1) gives $\det \mathbf{Q}_{n-1}$, with sign $(-1)^{2n} = 1$.

(c) For $n = 1$, $\det \mathbf{Q}_1 = \frac{1}{x_1+y_1}$, which is the formula with empty products upstairs. For $n \geq 2$, combining (a) and (b),

$$\det \mathbf{Q}_n = \frac{\prod_{i<n}(x_n - x_i)(y_n - y_i)}{\prod_{j \leq n}(x_n + y_j) \prod_{i<n}(x_i + y_n)} \det \mathbf{Q}_{n-1}.$$

The numerator supplies exactly the factors of $\prod_{i<j}(x_j - x_i)(y_j - y_i)$ with $j = n$, and the denominator supplies exactly the factors $x_i + y_j$ with $\max(i, j) = n$, each once. By the induction hypothesis, $\det \mathbf{Q}_{n-1}$ supplies all the remaining factors. This proves the formula.

(d) With $x_i = i$ and $y_j = j - 1$, $x_i + y_j = i + j - 1 \geq 1$, so $\mathbf{H}_n$ is a Cauchy matrix over $\mathbb{Q}$. For $n = 3$, the numerator is $\big((2-1)(3-1)(3-2)\big)^2 = 4$, since $y_j - y_i = j - i = x_j - x_i$. The denominator is the product of all $i + j - 1$: the rows give $1\cdot2\cdot3 = 6$, $2\cdot3\cdot4 = 24$, $3\cdot4\cdot5 = 60$, in total 8640. Hence $\det \mathbf{H}_3 = \frac{4}{8640} = \frac{1}{2160}$. (In general $\det \mathbf{H}_n = c_n^4/c_{2n}$ with $c_n = \prod_{k=1}^{n-1} k!$; we state this without proof. These determinants shrink extremely fast, which is why Hilbert matrices are a standard test of numerical methods.)

Exercise C2: A circulant determinant over $\mathbb{C}$.

Let $a, b, c \in \mathbb{C}$, let $\omega = e^{2\pi i/3}$, and let

$$\mathbf{Z} = \begin{pmatrix} a & b & c \\ c & a & b \\ b & c & a \end{pmatrix}.$$

(a) For $k = 0, 1, 2$, let $\mathbf{w}_k = (1, \omega^k, \omega^{2k})$ and $\lambda_k = a + b\omega^k + c\omega^{2k}$. Show that $\mathbf{Z}\mathbf{w}_k = \lambda_k \mathbf{w}_k$.

(b) Let $\mathbf{W}$ be the matrix with columns $\mathbf{w}_0, \mathbf{w}_1, \mathbf{w}_2$. Show that $\mathbf{Z}\mathbf{W} = \mathbf{W}\,\mathrm{diag}(\lambda_0, \lambda_1, \lambda_2)$ and that $\det \mathbf{W} \neq 0$. Deduce $\det \mathbf{Z} = \lambda_0\lambda_1\lambda_2$.

(c) Using $\omega^3 = 1$ and $1 + \omega + \omega^2 = 0$, deduce $\det \mathbf{Z} = a^3 + b^3 + c^3 - 3abc$, and check this against the Leibniz formula.

Circulant matrices of every size are treated in Chapter 11.

Solution.

(a) By Example (Roots of Unity), $\omega^3 = 1$, so $\omega^{-k} = \omega^{2k}$ and $\omega^{-2k} = \omega^k$. Row 1 of $\mathbf{Z}\mathbf{w}_k$ is $a + b\omega^k + c\omega^{2k} = \lambda_k$. Row 2 is $c + a\omega^k + b\omega^{2k} = \omega^k(c\omega^{-k} + a + b\omega^k) = \omega^k(a + b\omega^k + c\omega^{2k}) = \omega^k\lambda_k$. Row 3 is $b + c\omega^k + a\omega^{2k} = \omega^{2k}(b\omega^{-2k} + c\omega^{-k} + a) = \omega^{2k}\lambda_k$. Hence $\mathbf{Z}\mathbf{w}_k = \lambda_k\mathbf{w}_k$.

(b) By Theorem 0.9.2, column k of $\mathbf{Z}\mathbf{W}$ is $\mathbf{Z}\mathbf{w}_k = \lambda_k\mathbf{w}_k$, which is column k of $\mathbf{W}\,\mathrm{diag}(\lambda_0, \lambda_1, \lambda_2)$. The (i, k)-entry of $\mathbf{W}$ is $(\omega^k)^{i-1}$, so $\mathbf{W} = \mathbf{V}(1, \omega, \omega^2)^\top$. The nodes $1, \omega, \omega^2$ are distinct (they are $e^{2\pi ik/3}$ for $k = 0, 1, 2$), so $\det \mathbf{W} = \det \mathbf{V}(1, \omega, \omega^2) \neq 0$ by Theorem 6.4.5 and Corollary 6.8.2. By Theorem 6.5.4 and Theorem 6.4.6, $\det \mathbf{Z} \det \mathbf{W} = \det \mathbf{W}\, \lambda_0\lambda_1\lambda_2$, and canceling $\det \mathbf{W} \neq 0$ gives $\det \mathbf{Z} = \lambda_0\lambda_1\lambda_2$.

(c) Multiply out $\lambda_1\lambda_2 = (a + b\omega + c\omega^2)(a + b\omega^2 + c\omega)$. The nine terms are a^2, $ab\omega^2 + ab\omega$, $ac\omega + ac\omega^2$, $b^2\omega^3$, $bc\omega^2$, $bc\omega^4 = bc\omega$, $c^2\omega^3$. Using $\omega^3 = 1$ and $\omega + \omega^2 = -1$,

$$\lambda_1\lambda_2 = a^2 + b^2 + c^2 - ab - ac - bc.$$

Then $\det \mathbf{Z} = (a + b + c)(a^2 + b^2 + c^2 - ab - ac - bc) = a^3 + b^3 + c^3 - 3abc$, expanding and canceling. The Leibniz formula for $\mathbf{Z}$ gives the three even terms $a \cdot a \cdot a$, $c \cdot c \cdot c$ (from $\sigma = (1\ 2\ 3)$) and $b \cdot b \cdot b$, and the three odd terms, each equal to abc with sign $-$: the same answer.

Exercise C3: Rank-one updates of an invertible matrix.

Let $\mathbf{A} \in M_n(F)$ be invertible and $\mathbf{u}, \mathbf{v} \in F^n$.

(a) Prove that $\det(\mathbf{A} + \mathbf{u}\mathbf{v}^\top) = \det \mathbf{A}\,\big(1 + \mathbf{v}^\top \mathbf{A}^{-1}\mathbf{u}\big)$.

(b) Deduce that $\mathbf{A} + \mathbf{u}\mathbf{v}^\top$ is invertible if and only if $\mathbf{v}^\top \mathbf{A}^{-1}\mathbf{u} \neq -1$.

(c) Give an example over $\mathbb{Q}$ with $n = 2$ where $\mathbf{A}$ is invertible, $\mathbf{u}\mathbf{v}^\top \neq 0$, and $\mathbf{A} + \mathbf{u}\mathbf{v}^\top$ is **not** invertible.

Solution.

(a) Since $\mathbf{A}$ is invertible, $\mathbf{A} + \mathbf{u}\mathbf{v}^\top = \mathbf{A}(\mathbf{I}_n + \mathbf{A}^{-1}\mathbf{u}\mathbf{v}^\top) = \mathbf{A}\big(\mathbf{I}_n + (\mathbf{A}^{-1}\mathbf{u})\mathbf{v}^\top\big)$ by Theorem 0.9.4. By Theorem 6.5.4 and Theorem 6.8.5 applied to the vectors $\mathbf{A}^{-1}\mathbf{u}$ and $\mathbf{v}$, $\det(\mathbf{A} + \mathbf{u}\mathbf{v}^\top) = \det \mathbf{A}\,(1 + \mathbf{v}^\top \mathbf{A}^{-1}\mathbf{u})$.

(b) $\det \mathbf{A} \neq 0$ by Theorem 6.5.2, so $\det(\mathbf{A} + \mathbf{u}\mathbf{v}^\top) \neq 0$ exactly when $1 + \mathbf{v}^\top \mathbf{A}^{-1}\mathbf{u} \neq 0$. Apply Theorem 6.5.2 again.

(c) Take $\mathbf{A} = \mathbf{I}_2$, $\mathbf{u} = (-1, 0)$, $\mathbf{v} = (1, 0)$. Then $\mathbf{v}^\top \mathbf{u} = -1$, and indeed $\mathbf{A} + \mathbf{u}\mathbf{v}^\top = \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix}$ is not invertible.

6.9 Orientation and Volume

The chapter began in §1 with a picture: the area of a parallelogram, with a sign attached, obeys a few simple rules, and those rules pinned down $ad - bc$. We have since built the determinant in every size from the same rules. It is time to return to geometry and say precisely what the determinant measures. There are two halves to the answer. Its absolute value measures volume, and its sign measures orientation, the difference between a left hand and a right hand. Both halves need care. "Volume" in $\mathbb{R}^7$ has no meaning until someone defines it, and "orientation" has no meaning at all over $\mathbb{C}$.

Throughout this section the field is $\mathbb{R}$.

6.9.1 What should the volume of a parallelepiped be?

For vectors $\mathbf{a}_1, \dots, \mathbf{a}_n \in \mathbb{R}^n$, the **parallelepiped** they span is the set

$$P(\mathbf{a}_1, \dots, \mathbf{a}_n) := \{t_1\mathbf{a}_1 + \cdots + t_n\mathbf{a}_n : 0 \le t_i \le 1 \text{ for every } i\}.$$

For $n = 2$ it is the parallelogram with sides $\mathbf{a}_1, \mathbf{a}_2$ at the origin, and for $n = 3$ a slanted box. For $n = 1$ it is the segment from 0 to $\mathbf{a}_1$.

We would like to say "its volume is $|\det(\mathbf{a}_1 \ \cdots \ \mathbf{a}_n)|$". But a theorem needs two sides, and one side is missing: we have no definition of the volume of a subset of $\mathbb{R}^n$. School geometry supplies one for $n = 2$ and $n = 3$ through "base times height", and the proper general notion, Lebesgue measure, belongs to a course in measure theory. So we proceed honestly in three steps. We **define** the volume of a parallelepiped by the determinant. We **prove** that this is the only

function obeying the rules that any reasonable notion of volume must obey. And we **state**, without proof, that it agrees with Lebesgue measure.

The volume of a parallelepiped is the size of the determinant of its edge vectors.

Definition 6.9.1 — Volume of a Parallelepiped

Let $n \geq 1$ and $\mathbf{a}_1, \dots, \mathbf{a}_n \in \mathbb{R}^n$. The ($n$-dimensional) **volume** of the parallelepiped spanned by $\mathbf{a}_1, \dots, \mathbf{a}_n$ is

$$\operatorname{vol}(\mathbf{a}_1, \dots, \mathbf{a}_n) \coloneqq \left| \det \begin{pmatrix} \mathbf{a}_1 & \mathbf{a}_2 & \cdots & \mathbf{a}_n \end{pmatrix} \right| \geq 0.$$

In words: stack the n edge vectors as the columns of a square matrix, take its determinant, and forget the sign. There must be **exactly** n vectors in $\mathbb{R}^n$, so that the matrix is square.

Examples.

- The unit cube $P(\mathbf{e}_1, \dots, \mathbf{e}_n)$ has volume $|\det \mathbf{I}_n| = 1$.
- A box with edges $d_1\mathbf{e}_1, \dots, d_n\mathbf{e}_n$ has volume $|\det \operatorname{diag}(d_1, \dots, d_n)| = |d_1 \cdots d_n|$ by Theorem 6.4.6: the product of its side lengths, as it should be.
- The parallelepiped spanned by $(1, 2, 0)$, $(0, 1, 1)$, $(1, 0, 3)$ in $\mathbb{R}^3$ has volume

$$\left| \det \begin{pmatrix} 1 & 0 & 1 \\ 2 & 1 & 0 \\ 0 & 1 & 3 \end{pmatrix} \right| = |1 \cdot (3 - 0) - 0 + 1 \cdot (2 - 0)| = 5,$$

  expanding along the first row.
- **Degenerate case.** If $\mathbf{a}_1, \dots, \mathbf{a}_n$ are linearly dependent, the parallelepiped is flattened into a proper subspace, and its volume is 0 by Theorem 6.2.1. For $n = 2$, $P((1, 2), (2, 4))$ is the segment from $(0, 0)$ to $(3, 6)$, with area $|4 - 4| = 0$. This case matters: "volume zero" is the geometric face of "not invertible".

Non-example by minimal change. Drop one vector: $(1, 2, 0)$ and $(0, 1, 1)$ span a genuine parallelogram in $\mathbb{R}^3$, but the matrix $\begin{pmatrix} 1 & 0 \\ 2 & 1 \\ 0 & 1 \end{pmatrix}$ is 3×2 and has no determinant. The clause that fails is **exactly n vectors in $\mathbb{R}^n$**. The 3-dimensional volume of that flat parallelogram would be 0, and its area needs a different formula (Exercise (C1: Area of a triangle in space)).

Why this definition. Reordering the vectors multiplies the determinant by a sign (Theorem 6.2.1), which the absolute value removes, so the volume does not depend on the order in which the edges are listed. The absolute value is also what makes volume non-negative. The sign we threw away is not garbage: it is the orientation, the subject of the second half of this section.

> *Warning.* **Volume is not linear.** Scaling **one** edge by 2 doubles the volume, but scaling the whole parallelepiped by 2 multiplies it by 2^n: $\operatorname{vol}(2\mathbf{a}_1, \dots, 2\mathbf{a}_n) = |\det(2\mathbf{A})| = 2^n \operatorname{vol}(\mathbf{a}_1, \dots, \mathbf{a}_n)$, where $\mathbf{A}$ has columns $\mathbf{a}_1, \dots, \mathbf{a}_n$. A cube of side 2 in $\mathbb{R}^3$ has volume 8, not 2; this failure persists even with the sign kept, since det is linear in each edge separately, not in all edges at once. The absolute value also destroys additivity in a single edge: $\operatorname{vol}(\mathbf{a}_1 + \mathbf{b}_1, \mathbf{a}_2, \dots)$ is in general not $\operatorname{vol}(\mathbf{a}_1, \mathbf{a}_2, \dots) + \operatorname{vol}(\mathbf{b}_1, \mathbf{a}_2, \dots)$: with $\mathbf{a}_1 = \mathbf{e}_1$, $\mathbf{b}_1 = -\mathbf{e}_1$ in $\mathbb{R}^2$ and $\mathbf{a}_2 = \mathbf{e}_2$, the left side is 0 and the right side is 2.

6.9.2 Volume is forced by its rules

Why should anyone accept Definition 6.9.1? Because of what any notion of volume of parallelepipeds must satisfy. The pictures in §1 showed three facts about area, and they have obvious n-dimensional versions: stretching one edge by a factor c multiplies the volume by $|c|$; sliding one edge parallel to another (a shear) does not change the volume; and the unit cube has volume 1. The next theorem says that these three rules alone determine the volume completely. So any definition that obeys them, whether from school geometry or from measure theory, must agree with ours.

Theorem 6.9.1 — Volume Is Determined by Its Rules

Let $n \geq 1$, and let g be a function assigning a real number $g(\mathbf{a}_1, \dots, \mathbf{a}_n)$ to every list of n vectors in $\mathbb{R}^n$. Suppose that for every list, every $i \neq j$ and every $c \in \mathbb{R}$:

(V1) $g(\mathbf{a}_1, \dots, c\mathbf{a}_i, \dots, \mathbf{a}_n) = |c|\, g(\mathbf{a}_1, \dots, \mathbf{a}_i, \dots, \mathbf{a}_n)$ (only slot i changes);
(V2) $g(\mathbf{a}_1, \dots, \mathbf{a}_i + c\mathbf{a}_j, \dots, \mathbf{a}_n) = g(\mathbf{a}_1, \dots, \mathbf{a}_i, \dots, \mathbf{a}_n)$ (only slot i changes);
(V3) $g(\mathbf{e}_1, \dots, \mathbf{e}_n) = 1$.

Then $g(\mathbf{a}_1, \dots, \mathbf{a}_n) = \mathrm{vol}(\mathbf{a}_1, \dots, \mathbf{a}_n)$ for every list. Moreover, vol itself satisfies (V1)–(V3).

Idea. Think of g as a function of the matrix $\mathbf{M}$ with columns $\mathbf{a}_1, \dots, \mathbf{a}_n$. ① If the columns are dependent, shear one column to $\mathbf{0}$ and scale by 0: $g = 0$. ② Each elementary column operation changes g by the factor $|\det \mathbf{E}|$. Scaling and shearing are (V1) and (V2); a swap is not among the rules, but three shears and a sign change perform it. ③ An invertible $\mathbf{M}$ is a product of elementary matrices, so peel them off one at a time until only $\mathbf{I}$ is left.

Proof. For $\mathbf{M} \in M_n(\mathbb{R})$ with columns $\mathbf{a}_1, \dots, \mathbf{a}_n$, write $h(\mathbf{M}) = g(\mathbf{a}_1, \dots, \mathbf{a}_n)$.

Step 1: dependent columns give $h(\mathbf{M}) = 0$. Suppose the columns are linearly dependent. By Theorem 1.4.1, some $\mathbf{a}_i = c_1\mathbf{a}_1 + \cdots + c_{i-1}\mathbf{a}_{i-1}$ (for $i = 1$, $\mathbf{a}_1 = \mathbf{0}$). Applying (V2) to slot i with the scalars $-c_1, \dots, -c_{i-1}$, one at a time, does not change g, and it replaces $\mathbf{a}_i$ by $\mathbf{0}$ while the other slots stay fixed. Then (V1) with $c = 0$ gives $g(\dots, \mathbf{0}, \dots) = g(\dots, 0 \cdot \mathbf{0}, \dots) = 0 \cdot g(\dots, \mathbf{0}, \dots) = 0$. Hence $h(\mathbf{M}) = 0$.

Step 2: $h(\mathbf{ME}) = |\det \mathbf{E}|\, h(\mathbf{M})$ for every elementary matrix $\mathbf{E}$. By Theorem 2.4.1 and Theorem 0.9.5, $\mathbf{ME} = (\mathbf{E}^\top \mathbf{M}^\top)^\top$, and $\mathbf{E}^\top$ is the elementary matrix $\mathbf{P}_{ij}$, $\mathbf{D}_i(c)$ or $\mathbf{I} + c\mathbf{E}_{ji}$ when $\mathbf{E}$ is $\mathbf{P}_{ij}$, $\mathbf{D}_i(c)$ or $\mathbf{I} + c\mathbf{E}_{ij}$. So right multiplication by $\mathbf{E}$ performs a column operation: swap columns i and j; multiply column i by $c \neq 0$; or add c times column i to column j. The determinants are $\det \mathbf{P}_{ij} = -1$, $\det \mathbf{D}_i(c) = c$ and $\det(\mathbf{I} + c\mathbf{E}_{ij}) = 1$ by Theorem 6.5.1.

- For $\mathbf{E} = \mathbf{I} + c\mathbf{E}_{ij}$, (V2) gives $h(\mathbf{ME}) = h(\mathbf{M}) = |1|\, h(\mathbf{M})$.
- For $\mathbf{E} = \mathbf{D}_i(c)$, (V1) gives $h(\mathbf{ME}) = |c|\, h(\mathbf{M})$.
- For $\mathbf{E} = \mathbf{P}_{ij}$, watch only slots i and j, holding $\mathbf{x}$ and $\mathbf{y}$. By (V2) three times, $(\mathbf{x}, \mathbf{y}) \to (\mathbf{x} + \mathbf{y}, \mathbf{y}) \to (\mathbf{x} + \mathbf{y}, -\mathbf{x}) \to (\mathbf{y}, -\mathbf{x})$ leaves g unchanged, where the second step subtracts slot i from slot j and the third adds slot j to slot i. By (V1) with $c = -1$ on slot j, g at $(\mathbf{y}, \mathbf{x})$ equals $|-1|$ times g at $(\mathbf{y}, -\mathbf{x})$. Hence $h(\mathbf{MP}_{ij}) = h(\mathbf{M}) = |-1|\, h(\mathbf{M})$.

Step 3: conclusion. If the columns of $\mathbf{M}$ are dependent, then $h(\mathbf{M}) = 0$ by Step 1 and $\det \mathbf{M} = 0$ by Theorem 6.2.1, so $h(\mathbf{M}) = |\det \mathbf{M}|$. Otherwise $\mathbf{M}$ is invertible by Theorem 2.4.4, hence $\mathbf{M} = \mathbf{E}_1\mathbf{E}_2 \cdots \mathbf{E}_k$ is a product of elementary matrices by the same theorem. Applying Step 2 k times, starting from $\mathbf{I}$, and then (V3),

$$h(\mathbf{M}) = h(\mathbf{I}\mathbf{E}_1 \cdots \mathbf{E}_k) = |\det \mathbf{E}_1| \cdots |\det \mathbf{E}_k|\, h(\mathbf{I}) = |\det(\mathbf{E}_1 \cdots \mathbf{E}_k)| = |\det \mathbf{M}|,$$

where the third equality uses Theorem 6.5.4 and $|xy| = |x||y|$. This proves $g = \mathrm{vol}$.

Finally, vol satisfies (V1) because the determinant is linear in each column (Theorem 6.4.3) and $|c\,d| = |c||d|$; (V2) by Theorem 6.2.1; and (V3) because $\det \mathbf{I}_n = 1$.

■

Agreement with area and volume from school. For $n = 2$, let $g(\mathbf{a}_1, \mathbf{a}_2)$ be the area of the parallelogram $P(\mathbf{a}_1, \mathbf{a}_2)$ in the sense of school geometry, base times height. The pictures of §1 are exactly (V1)–(V3) for this g: stretching a side by c stretches the base or the height by $|c|$; a shear $\mathbf{a}_1 \mapsto \mathbf{a}_1 + c\mathbf{a}_2$ slides the opposite side along a line parallel to the base $\mathbf{a}_2$, keeping base and height; and the unit square has area 1. Hence, by Theorem 6.9.1, school area equals $|\det \begin{pmatrix} \mathbf{a}_1 & \mathbf{a}_2 \end{pmatrix}|$. For $n = 3$ the same argument works with "area of base times height". What the theorem cannot supply is the geometric input itself: it takes the three rules as given.

Agreement with Lebesgue measure. In measure theory, every reasonable subset $S \subseteq \mathbb{R}^n$ has an n-dimensional volume, its Lebesgue measure. One can prove that the Lebesgue measure of $P(\mathbf{a}_1, \ldots, \mathbf{a}_n)$ satisfies (V1)–(V3), and hence equals $\mathrm{vol}(\mathbf{a}_1, \ldots, \mathbf{a}_n)$. We state this without proof; nothing in this book depends on it.

Quick check. Which of the rules (V1)–(V3) does the function $g(\mathbf{a}_1, \mathbf{a}_2) = |\det \begin{pmatrix} \mathbf{a}_1 & \mathbf{a}_2 \end{pmatrix}|^2$ on $\mathbb{R}^2$ break?

Solution. It satisfies (V2), since shears do not change the determinant, and (V3), since $1^2 = 1$. It breaks (V1): $g(2\mathbf{e}_1, \mathbf{e}_2) = 4$, while $|2|\, g(\mathbf{e}_1, \mathbf{e}_2) = 2$. So the theorem does not apply, and indeed $g \neq \mathrm{vol}$.

6.9.3 Linear maps scale volume

Applying a linear map to a parallelepiped gives another parallelepiped: by linearity, $T\big(\sum t_i \mathbf{a}_i\big) = \sum t_i T\mathbf{a}_i$, so $T(P(\mathbf{a}_1, \ldots, \mathbf{a}_n)) = P(T\mathbf{a}_1, \ldots, T\mathbf{a}_n)$. How does the volume change? Multiplicativity answers this in one line, and the answer does not depend on the parallelepiped.

Theorem 6.9.2 — Linear Maps Scale Volume by $|\det|$

Let $T \in \mathcal{L}(\mathbb{R}^n)$ and $\mathbf{a}_1, \ldots, \mathbf{a}_n \in \mathbb{R}^n$. Then

$$\mathrm{vol}(T\mathbf{a}_1, \ldots, T\mathbf{a}_n) = |\det T| \cdot \mathrm{vol}(\mathbf{a}_1, \ldots, \mathbf{a}_n).$$

In particular, the image of the unit cube under T has volume $|\det T|$.

Proof. Let $\mathbf{B}$ be the matrix of T in the standard basis, so $T\mathbf{x} = \mathbf{B}\mathbf{x}$ for all $\mathbf{x}$ (Theorem 3.6.1) and $\det T = \det \mathbf{B}$ (Definition 6.5.1). Let $\mathbf{A} = \begin{pmatrix} \mathbf{a}_1 & \cdots & \mathbf{a}_n \end{pmatrix}$. By Theo-

rem 0.9.2, $\mathbf{BA} = \begin{pmatrix} \mathbf{Ba}_1 & \cdots & \mathbf{Ba}_n \end{pmatrix}$. By Theorem 6.5.4,

$$\operatorname{vol}(T\mathbf{a}_1, \ldots, T\mathbf{a}_n) = |\det(\mathbf{BA})| = |\det \mathbf{B}|\,|\det \mathbf{A}| = |\det T|\,\operatorname{vol}(\mathbf{a}_1, \ldots, \mathbf{a}_n).$$

For the unit cube take $\mathbf{a}_i = \mathbf{e}_i$, with $\operatorname{vol}(\mathbf{e}_1, \ldots, \mathbf{e}_n) = 1$.

■

This is the meaning of the determinant of a real operator: **the factor by which it scales every volume**. An operator with $\det T = 0$ squashes $\mathbb{R}^n$ into a lower-dimensional subspace, where n-dimensional volume is 0. In multivariable calculus the same fact, applied to the linear approximation of a smooth map, becomes the Jacobian factor $|\det \mathbf{J}|$ in the change-of-variables formula for integrals.

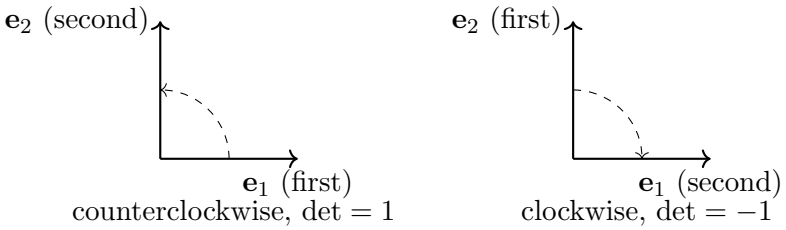
Example. (Area of an Image)

Let $T\colon \mathbb{R}^2 \to \mathbb{R}^2$ be $T(x, y) = (3x + y,\ x + 2y)$. Find the area of the image of the unit square, and of the image of the parallelogram $P((1, 1), (-1, 2))$.

Solution. The standard matrix is $\mathbf{B} = \begin{pmatrix} 3 & 1 \\ 1 & 2 \end{pmatrix}$, with $\det T = 6 - 1 = 5$. By Theorem 6.9.2 the image of the unit square, the parallelogram spanned by $(3, 1)$ and $(1, 2)$, has area 5. The parallelogram $P((1, 1), (-1, 2))$ has area $|2 + 1| = 3$, so its image has area $5 \cdot 3 = 15$. Check directly: $T(1, 1) = (4, 3)$ and $T(-1, 2) = (-1, 3)$, and $|\det \begin{pmatrix} 4 & -1 \\ 3 & 3 \end{pmatrix}| = |12 + 3| = 15$.

6.9.4 Orientation

Now the sign. In $\mathbb{R}^2$, the ordered basis $(\mathbf{e}_1, \mathbf{e}_2)$ turns **counterclockwise** from its first vector to its second, while $(\mathbf{e}_2, \mathbf{e}_1)$ turns clockwise. No rotation carries one arrangement to the other: a rotation of the plane keeps counterclockwise turns counterclockwise. The determinant sees the difference: $\det \begin{pmatrix} \mathbf{e}_1 & \mathbf{e}_2 \end{pmatrix} = 1 > 0$ and $\det \begin{pmatrix} \mathbf{e}_2 & \mathbf{e}_1 \end{pmatrix} = -1 < 0$.



To compare two bases of an arbitrary real space, we compare them with each other rather than with a fixed standard basis, using the change-of-coordinates matrix of Chapter 3.

Two bases have the same orientation when the matrix converting one into the other has positive determinant.

Definition 6.9.2 — Orientation

Let V be a vector space **over** $\mathbb{R}$ with $\dim V = n \geq 1$, and let $\mathcal{B}$ and $\mathcal{C}$ be **ordered** bases of V. We say $\mathcal{B}$ and $\mathcal{C}$ have the **same orientation** if

$$\det[\mathrm{id}]_{\mathcal{B}}^{\mathcal{C}} > 0,$$

and **opposite orientations** if $\det[\mathrm{id}]_{\mathcal{B}}^{\mathcal{C}} < 0$.

In words: write each vector of $\mathcal{B}$ in coordinates with respect to $\mathcal{C}$, put the coordinate columns side by side (Definition 3.7.1), and look at the **sign** of the determinant. Exactly one of the two cases occurs, because $[\mathrm{id}]_{\mathcal{B}}^{\mathcal{C}}$ is invertible (Theorem 3.7.1 (c)), so its determinant is non-zero (Theorem 6.5.2), and a non-zero real number is either positive or negative. The bases must be **ordered**: reordering a basis can change the answer.

For $V = \mathbb{R}^n$ there is a shortcut. If $\mathbf{B}$ and $\mathbf{C}$ are the matrices whose columns are the vectors of $\mathcal{B}$ and $\mathcal{C}$, then $[\mathrm{id}]_{\mathcal{B}}^{\mathcal{E}} = \mathbf{B}$ and $[\mathrm{id}]_{\mathcal{C}}^{\mathcal{E}} = \mathbf{C}$ for the standard basis $\mathcal{E}$. By Theorem 3.7.1 (b) and (c), $[\mathrm{id}]_{\mathcal{B}}^{\mathcal{C}} = \mathbf{C}^{-1}\mathbf{B}$. Since $\det \mathbf{C} \det \mathbf{C}^{-1} = \det \mathbf{I} = 1$ (Theorem 6.5.4), $\det[\mathrm{id}]_{\mathcal{B}}^{\mathcal{C}} = \det \mathbf{B} / \det \mathbf{C}$. So **$\mathcal{B}$ and $\mathcal{C}$ have the same orientation if and only if $\det \mathbf{B}$ and $\det \mathbf{C}$ have the same sign.**

Examples.

- In $\mathbb{R}^2$, $(\mathbf{e}_1, \mathbf{e}_2)$ and $(\mathbf{e}_2, \mathbf{e}_1)$ have opposite orientations: $\det \mathbf{I}_2 = 1$ and $\det \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} = -1$.
- In $\mathbb{R}^3$, $(\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3)$ and $(\mathbf{e}_2, \mathbf{e}_3, \mathbf{e}_1)$ have the **same** orientation. The second matrix is the permutation matrix of a 3-cycle, whose sign is $(-1)^{3-1} = 1$. A cyclic shift of three vectors is two swaps.
- In $V = \mathbb{R}[x]_{\leq 1}$, the bases $\mathcal{B} = (1, x)$ and $\mathcal{C} = (x, 1 + x)$ have $1 = -x + (1 + x)$ and $x = x + 0 \cdot (1 + x)$, so $[\mathrm{id}]_{\mathcal{B}}^{\mathcal{C}} = \begin{pmatrix} -1 & 1 \\ 1 & 0 \end{pmatrix}$, with determinant -1. They have opposite orientations. Orientation makes sense in any real space, with no picture at all.
- **Degenerate case, $n = 1$.** Bases of $\mathbb{R}$ are single non-zero numbers (a), and $[\mathrm{id}]_{(a)}^{(b)} = (a/b)$. So (a) and (b) have the same orientation exactly when a and b have the same sign. The two orientations of a line are its two directions.

Non-example by minimal change. In $\mathbb{R}^2$, $(-\mathbf{e}_1, -\mathbf{e}_2)$ has the same orientation as $(\mathbf{e}_1, \mathbf{e}_2)$: $\det(-\mathbf{I}_2) = 1$, and indeed it is the rotation of $(\mathbf{e}_1, \mathbf{e}_2)$ by a half-turn. Change only **one** sign, to $(\mathbf{e}_1, -\mathbf{e}_2)$: the determinant becomes -1, and the orientation flips. What changed is the sign of the determinant, which is the whole content of the definition. In $\mathbb{R}^3$, by contrast, $-\mathbf{I}_3$ has determinant -1: negating all three vectors reverses orientation.

Why this definition. Using the change-of-coordinates matrix, rather than the matrices $\mathbf{B}$ and $\mathbf{C}$ above, makes the definition work in every real space, including spaces like $\mathbb{R}[x]_{\leq 1}$ that have no standard picture. Requiring $\det > 0$ rather than $\det = 1$ is what gives a coarse, two-valued answer: rescaling a basis vector by a positive number should not change its handedness.

The payoff is that "same orientation" really sorts all bases into two families, as the pictures suggest.

Theorem 6.9.3 — There Are Exactly Two Orientations

Let V be a vector space over $\mathbb{R}$ with $\dim V = n \geq 1$.

(a) "Having the same orientation" is an equivalence relation on the set of ordered bases of V.

(b) It has **exactly two** equivalence classes. If $\mathcal{B} = (\mathbf{v}_1, \ldots, \mathbf{v}_n)$, then $\mathcal{B}^- = (-\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_n)$ lies in the class not containing $\mathcal{B}$.

Idea. The three axioms are three facts about change-of-coordinates matrices: $[\mathrm{id}]_{\mathcal{B}}^{\mathcal{B}} = \mathbf{I}$; the matrix back is the inverse; and matrices compose along a chain $\mathcal{B} \to \mathcal{C} \to \mathcal{D}$. Determinants turn these into $1 > 0$, $1/\text{positive} > 0$ and $\text{positive} \cdot \text{positive} > 0$. For "exactly two", flipping one vector gives a second class, and "negative times negative is positive" shows there is no third.

Proof. Write $d(\mathcal{B}, \mathcal{C}) = \det[\mathrm{id}]_{\mathcal{B}}^{\mathcal{C}}$. By Theorem 3.7.1 (b) and Theorem 6.5.4, for bases $\mathcal{B}, \mathcal{C}, \mathcal{D}$,

$$d(\mathcal{B}, \mathcal{D}) = d(\mathcal{C}, \mathcal{D})\, d(\mathcal{B}, \mathcal{C}). \qquad (*)$$

(a) *Reflexive:* $[\mathrm{id}]_{\mathcal{B}}^{\mathcal{B}} = \mathbf{I}_n$, so $d(\mathcal{B}, \mathcal{B}) = 1 > 0$. *Symmetric:* by $(*)$ with $\mathcal{D} = \mathcal{B}$, $d(\mathcal{C}, \mathcal{B})\, d(\mathcal{B}, \mathcal{C}) = d(\mathcal{B}, \mathcal{B}) = 1$, so $d(\mathcal{C}, \mathcal{B}) = 1/d(\mathcal{B}, \mathcal{C})$, which is positive when $d(\mathcal{B}, \mathcal{C})$ is. *Transitive:* if $d(\mathcal{B}, \mathcal{C}) > 0$ and $d(\mathcal{C}, \mathcal{D}) > 0$, then $d(\mathcal{B}, \mathcal{D}) > 0$ by $(*)$, since a product of positive reals is positive. By Definition 0.5.2, this is an equivalence relation.

(b) *At least two classes.* $\mathcal{B}^-$ is a basis, and $[\mathrm{id}]_{\mathcal{B}^-}^{\mathcal{B}} = \mathrm{diag}(-1, 1, \ldots, 1)$, because $-\mathbf{v}_1 = (-1)\mathbf{v}_1$ and $\mathbf{v}_j = 1 \cdot \mathbf{v}_j$. Its determinant is -1 by Theorem 6.4.6. So $d(\mathcal{B}^-, \mathcal{B}) < 0$, and $\mathcal{B}^-$ and $\mathcal{B}$ lie in different classes.

At most two classes. Let $\mathcal{C}$ and $\mathcal{D}$ be bases, neither of which has the same orientation as $\mathcal{B}$. Then $d(\mathcal{C}, \mathcal{B}) < 0$ and $d(\mathcal{D}, \mathcal{B}) < 0$, and by symmetry $d(\mathcal{B}, \mathcal{D}) < 0$ as well. By $(*)$, $d(\mathcal{C}, \mathcal{D}) = d(\mathcal{B}, \mathcal{D})\, d(\mathcal{C}, \mathcal{B})$ is a product of two negative reals, hence positive. So all bases outside the class of $\mathcal{B}$ lie in one class, and there are exactly two classes.

■

Choosing one of the two classes is called **orienting** V; its bases are then called **positively oriented**, and the others **negatively oriented**. On $\mathbb{R}^n$ the standard choice is the class of $(\mathbf{e}_1, \ldots, \mathbf{e}_n)$. By the shortcut above, $(\mathbf{a}_1, \ldots, \mathbf{a}_n)$ is positively oriented if and only if $\det \begin{pmatrix} \mathbf{a}_1 & \cdots & \mathbf{a}_n \end{pmatrix} > 0$. So the determinant of a real square matrix carries two independent pieces of information: its absolute value is a volume, and its sign is an orientation.

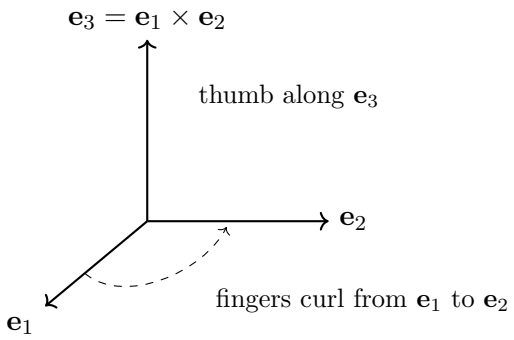
Warning. **Orientation needs $\mathbb{R}$.** The proof used two facts about the reals: every non-zero number is positive or negative, and products and inverses of positive numbers are positive. Over $\mathbb{C}$ there is no such splitting. Suppose we tried "$\mathcal{B}$ and $\mathcal{C}$ have the same orientation if $d(\mathcal{B}, \mathcal{C})$ has positive real part". In $\mathbb{C}^1$, with $z = e^{i\pi/3}$, the bases $(\mathbf{e}_1)$, $(z\mathbf{e}_1)$, $(z^2\mathbf{e}_1)$ give $d((\mathbf{e}_1), (z\mathbf{e}_1)) = z^{-1}$ and $d((z\mathbf{e}_1), (z^2\mathbf{e}_1)) = z^{-1}$, both with real part $\frac{1}{2} > 0$, but $d((\mathbf{e}_1), (z^2\mathbf{e}_1)) = z^{-2}$ has real part $-\frac{1}{2}$: transitivity fails. Over $\mathbb{F}_2$, $-1 = 1$, so the second basis $\mathcal{B}^-$ of the proof is $\mathcal{B}$ itself. The theorem holds verbatim over any field with a compatible order, such as $\mathbb{Q}$, but not over $\mathbb{C}$ or a finite field.

Quick check. Do $((1,2),(3,4))$ and $((3,4),(1,2))$ have the same orientation? Does $((1,2),(3,4))$ have the standard orientation of $\mathbb{R}^2$?

Solution. $\det \begin{pmatrix} 1 & 3 \\ 2 & 4 \end{pmatrix} = 4 - 6 = -2$ and $\det \begin{pmatrix} 3 & 1 \\ 4 & 2 \end{pmatrix} = 6 - 4 = 2$. The signs differ, so the two bases have opposite orientations. The first has negative determinant, so it is negatively oriented: it is **not** in the class of $(\mathbf{e}_1, \mathbf{e}_2)$.

6.9.5 The right-hand rule

In $\mathbb{R}^3$, the standard orientation is the one described by the right hand: curl the fingers of the right hand from the first basis vector toward the second, and the thumb points along the third. For $(\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3)$ with the usual picture of the axes, this is the familiar arrangement below.



The **cross product** of $\mathbf{a} = (a_1, a_2, a_3)$ and $\mathbf{b} = (b_1, b_2, b_3)$ in $\mathbb{R}^3$ is

$$\mathbf{a} \times \mathbf{b} \coloneqq (a_2 b_3 - a_3 b_2,\ a_3 b_1 - a_1 b_3,\ a_1 b_2 - a_2 b_1).$$

Physics defines it by the right-hand rule. Here is the linear-algebra reason the two descriptions match: $(\mathbf{a}, \mathbf{b}, \mathbf{a} \times \mathbf{b})$ is always positively oriented.

Expand $\det \begin{pmatrix} \mathbf{a} & \mathbf{b} & \mathbf{a} \times \mathbf{b} \end{pmatrix}$ along its third column (Theorem 6.6.1). The cofactors of that column are $C_{13} = a_2 b_3 - a_3 b_2$, $C_{23} = -(a_1 b_3 - a_3 b_1)$ and $C_{33} = a_1 b_2 - a_2 b_1$, which are exactly the three components of $\mathbf{a} \times \mathbf{b}$. Hence

$$\det \begin{pmatrix} \mathbf{a} & \mathbf{b} & \mathbf{a} \times \mathbf{b} \end{pmatrix} = (a_2 b_3 - a_3 b_2)^2 + (a_3 b_1 - a_1 b_3)^2 + (a_1 b_2 - a_2 b_1)^2 \ \geq\ 0.$$

If $\mathbf{a}$ and $\mathbf{b}$ are linearly independent, the 3×2 matrix $\begin{pmatrix} \mathbf{a} & \mathbf{b} \end{pmatrix}$ has rank 2, so one of its 2×2 minors, which are $\pm$ the components of $\mathbf{a} \times \mathbf{b}$, is non-zero (Theorem 6.7.1). Then the determinant is strictly positive, so $(\mathbf{a}, \mathbf{b}, \mathbf{a} \times \mathbf{b})$ is a basis (Theorem 6.5.2) with the standard orientation. For example, $\mathbf{e}_1 \times \mathbf{e}_2 = (0, 0, 1) = \mathbf{e}_3$, matching the picture.

6.9.6 Orientation-preserving maps

An invertible operator carries each basis to a basis. Does it keep the orientation? The answer is the same for every basis and depends only on the sign of $\det T$.

Proposition 6.9.4 — Determinant Sign and Orientation

Let V be a vector space over $\mathbb{R}$ with $\dim V = n \geq 1$, let $T \in \mathcal{L}(V)$ be invertible, and let

$\mathcal{B} = (\mathbf{v}_1, \dots, \mathbf{v}_n)$ be any basis of V. Then $T\mathcal{B} = (T\mathbf{v}_1, \dots, T\mathbf{v}_n)$ is a basis of V, and

$$[\mathrm{id}]_{T\mathcal{B}}^{\mathcal{B}} = [T]_{\mathcal{B}}.$$

Hence $\mathcal{B}$ and $T\mathcal{B}$ have the same orientation if and only if $\det T > 0$, and this does not depend on $\mathcal{B}$.

Proof. Since T is invertible, it is an isomorphism, so $T\mathcal{B}$ is a basis by Theorem 3.5.2. By Definition 3.7.1, column j of $[\mathrm{id}]_{T\mathcal{B}}^{\mathcal{B}}$ is $[T\mathbf{v}_j]_{\mathcal{B}}$, which is column j of $[T]_{\mathcal{B}}$ by Definition 3.6.1. Hence the two matrices are equal, and by Definition 6.5.1, $\det[\mathrm{id}]_{T\mathcal{B}}^{\mathcal{B}} = \det T$. By Definition 6.9.2 and the symmetry in Theorem 6.9.3 (a), $\mathcal{B}$ and $T\mathcal{B}$ have the same orientation exactly when $\det T > 0$. ∎

An invertible operator with $\det T > 0$ is **orientation-preserving**, and one with $\det T < 0$ is **orientation-reversing**. Rotations of the plane preserve orientation and reflections reverse it (Exercise (C2: Rotations and reflections)). In $\mathbb{R}^3$, the map $\mathbf{x} \mapsto -\mathbf{x}$ reverses orientation, since $\det(-\mathbf{I}_3) = -1$: a right hand, pushed through the origin, becomes a left hand.

6.9.7 Exercises

6.9.7.1 A. Check your understanding

Exercise A1.

(a) State the definition of the volume of the parallelepiped spanned by $\mathbf{a}_1, \dots, \mathbf{a}_n \in \mathbb{R}^n$, and say what it is when the vectors are dependent.

(b) True or false: $\mathrm{vol}(\mathbf{a}_1 + \mathbf{b}, \mathbf{a}_2, \dots, \mathbf{a}_n) = \mathrm{vol}(\mathbf{a}_1, \dots, \mathbf{a}_n) + \mathrm{vol}(\mathbf{b}, \mathbf{a}_2, \dots, \mathbf{a}_n)$. Justify your answer.

(c) Which three rules characterize volume in Theorem 6.9.1?

(d) True or false: if $\det T = -2$, then T doubles every volume. Justify your answer.

(e) Define "same orientation" for two ordered bases of a real vector space.

(f) True or false: for every $n \geq 1$, the map $\mathbf{x} \mapsto -\mathbf{x}$ on $\mathbb{R}^n$ reverses orientation. Justify your answer.

Solution.

(a) $\mathrm{vol}(\mathbf{a}_1, \dots, \mathbf{a}_n) = |\det \begin{pmatrix} \mathbf{a}_1 & \cdots & \mathbf{a}_n \end{pmatrix}|$ (Definition 6.9.1). For dependent vectors it is 0, by Theorem 6.2.1.

(b) False. With $n = 2$, $\mathbf{a}_1 = \mathbf{e}_1$, $\mathbf{b} = -\mathbf{e}_1$, $\mathbf{a}_2 = \mathbf{e}_2$: the left side is $\mathrm{vol}(\mathbf{0}, \mathbf{e}_2) = 0$, the right side is $1 + 1 = 2$. The absolute value destroys additivity.

(c) (V1) scaling one vector by c scales the volume by $|c|$; (V2) adding a multiple of one vector to another does not change it; (V3) the unit cube has volume 1.

(d) True. By Theorem 6.9.2, $\mathrm{vol}(T\mathbf{a}_1, \dots, T\mathbf{a}_n) = |-2|\,\mathrm{vol}(\mathbf{a}_1, \dots, \mathbf{a}_n)$. The sign only affects orientation.

(e) $\mathcal{B}$ and $\mathcal{C}$ have the same orientation if $\det[\mathrm{id}]_{\mathcal{B}}^{\mathcal{C}} > 0$ (Definition 6.9.2).

(f) False. $\det(-\mathbf{I}_n) = (-1)^n$, so by Proposition 6.9.4 the map reverses orientation for odd n and preserves it for even n. In $\mathbb{R}^2$ it is the rotation by a half-turn.

6.9.7.2 B. Practice

Exercise B1: Volume of a parallelepiped.

Find the volume of the parallelepiped in $\mathbb{R}^3$ spanned by $(2,1,0)$, $(1,3,1)$ and $(0,1,1)$. Hence find the volume of its image under the map $T(x,y,z) = (x+y,\ y+z,\ 2z)$.

Solution. Expanding along the first row,

$$\det \begin{pmatrix} 2 & 1 & 0 \\ 1 & 3 & 1 \\ 0 & 1 & 1 \end{pmatrix} = 2(3-1) - 1\cdot(1-0) + 0 = 3,$$

so the volume is 3. The standard matrix of T is $\begin{pmatrix} 1 & 1 & 0 \\ 0 & 1 & 1 \\ 0 & 0 & 2 \end{pmatrix}$, upper triangular with determinant 2 (Theorem 6.4.6). By Theorem 6.9.2 the image has volume $2 \cdot 3 = 6$.

Exercise B2: Comparing orientations.

In $\mathbb{R}^3$, let $\mathcal{B} = ((1,1,0),(0,1,1),(1,0,1))$, $\mathcal{C} = ((0,1,0),(1,0,0),(1,1,1))$ and $\mathcal{D} = ((1,0,1),(1,1,0),(0,1,1))$. Determine which pairs have the same orientation, and which are positively oriented. Justify your answer.

Solution. By the shortcut after Definition 6.9.2, compare signs of the determinants of the matrices with these columns. Expanding along the first row:

$$\det \begin{pmatrix} 1 & 0 & 1 \\ 1 & 1 & 0 \\ 0 & 1 & 1 \end{pmatrix} = 1\cdot(1-0) - 0 + 1\cdot(1-0) = 2, \qquad \det \begin{pmatrix} 0 & 1 & 1 \\ 1 & 0 & 1 \\ 0 & 0 & 1 \end{pmatrix} = -1,$$

the second by expanding along the last row: $1 \cdot \det \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} = -1$. The list $\mathcal{D}$ is $\mathcal{B}$ shifted cyclically, $(\mathbf{b}_3, \mathbf{b}_1, \mathbf{b}_2)$; moving the last column to the front takes two column swaps, so by Theorem 6.2.1 its determinant is $(-1)^2 \cdot 2 = 2$. Hence $\mathcal{B}$ and $\mathcal{D}$ are positively oriented and have the same orientation; $\mathcal{C}$ is negatively oriented, opposite to both.

Exercise B3: Areas of images.

Let $T(x,y) = (2x+y,\ -x+3y)$ on $\mathbb{R}^2$.

(a) Find the area of the image of the unit square under T.

(b) Find the area of the image of the parallelogram $P((1,0),(1,2))$, first by Theorem 6.9.2 and then directly.

(c) Is T orientation-preserving?

Solution.

(a) The standard matrix $\begin{pmatrix} 2 & 1 \\ -1 & 3 \end{pmatrix}$ has determinant $6 + 1 = 7$, so the image of the unit square has area 7.

(b) $\text{vol}((1,0),(1,2)) = |\det \begin{pmatrix} 1 & 1 \\ 0 & 2 \end{pmatrix}| = 2$, so the image has area $7 \cdot 2 = 14$. Directly, $T(1,0) = (2,-1)$ and $T(1,2) = (4,5)$, and $|\det \begin{pmatrix} 2 & 4 \\ -1 & 5 \end{pmatrix}| = |10 + 4| = 14$.

(c) Yes: $\det T = 7 > 0$, so by Proposition 6.9.4 T preserves orientation.

6.9.7.3 C. Going deeper

Exercise C1: Area of a triangle in space.

For $\mathbf{u}, \mathbf{v} \in \mathbb{R}^3$, let $\mathbf{A} = \begin{pmatrix} \mathbf{u} & \mathbf{v} \end{pmatrix} \in M_{3\times 2}(\mathbb{R})$. We **define** the area of the parallelogram $P(\mathbf{u}, \mathbf{v}) \subseteq \mathbb{R}^3$ to be $\sqrt{\det(\mathbf{A}^\top \mathbf{A})}$; Chapter 12 justifies this with inner products, where $\det(\mathbf{A}^\top \mathbf{A})$ is recognized as a Gram determinant.

(a) Show that $\det(\mathbf{A}^\top \mathbf{A}) \geq 0$, so the square root exists, and that $\det(\mathbf{A}^\top \mathbf{A}) = (u_2v_3 - u_3v_2)^2 + (u_3v_1 - u_1v_3)^2 + (u_1v_2 - u_2v_1)^2$.

(b) Show that if $\mathbf{u}$ and $\mathbf{v}$ lie in the plane $z = 0$, this area equals the area $\text{vol}((u_1,u_2),(v_1,v_2))$ of Definition 6.9.1 in $\mathbb{R}^2$.

(c) Find the area of the triangle with vertices $(1,0,0)$, $(0,2,0)$, $(0,0,3)$.

Hint: apply Corollary 6.7.3 to $\mathbf{A}^\top$.

Solution.

(a) $\mathbf{A}^\top \in M_{2\times 3}(\mathbb{R})$ and $(\mathbf{A}^\top)^\top = \mathbf{A}$, so by Corollary 6.7.3 applied to $\mathbf{A}^\top$, $\det(\mathbf{A}^\top \mathbf{A}) = \sum_{|S|=2} (\det(\mathbf{A}^\top)_{[2],S})^2 \geq 0$. The 2×2 minors of $\mathbf{A}^\top = \begin{pmatrix} u_1 & u_2 & u_3 \\ v_1 & v_2 & v_3 \end{pmatrix}$ are $u_1v_2 - u_2v_1$, $u_1v_3 - u_3v_1$, $u_2v_3 - u_3v_2$ for $S = \{1,2\},\{1,3\},\{2,3\}$; squaring removes the signs, giving the stated sum.

(b) If $u_3 = v_3 = 0$, two of the three squares vanish, and $\det(\mathbf{A}^\top \mathbf{A}) = (u_1v_2 - u_2v_1)^2$. Hence $\sqrt{\det(\mathbf{A}^\top \mathbf{A})} = |u_1v_2 - u_2v_1| = |\det \begin{pmatrix} u_1 & v_1 \\ u_2 & v_2 \end{pmatrix}|$, which is $\text{vol}((u_1,u_2),(v_1,v_2))$.

(c) The triangle is half of the parallelogram spanned by $\mathbf{u} = (0,2,0) - (1,0,0) = (-1,2,0)$ and $\mathbf{v} = (0,0,3) - (1,0,0) = (-1,0,3)$. By (a), $\det(\mathbf{A}^\top \mathbf{A}) = (6-0)^2 + (0+3)^2 + (0+2)^2 = 36+9+4 = 49$. As a check, $\mathbf{A}^\top \mathbf{A} = \begin{pmatrix} 5 & 1 \\ 1 & 10 \end{pmatrix}$ has determinant $50 - 1 = 49$. So the parallelogram has area 7, and the triangle has area $\frac{7}{2}$.

Exercise C2: Rotations and reflections.

For $\theta \in \mathbb{R}$, let $\mathbf{R}_\theta = \begin{pmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{pmatrix}$ (rotation by θ) and $\mathbf{S}_\theta = \begin{pmatrix} \cos 2\theta & \sin 2\theta \\ \sin 2\theta & -\cos 2\theta \end{pmatrix}$ (reflection in the line through 0 at angle θ).

(a) Show that every rotation preserves orientation and area, and every reflection reverses orientation and preserves area.

(b) Show that $\mathbf{S}_\theta \mathbf{S}_\varphi$ is orientation-preserving for all θ, φ. (It is in fact a rotation, but you need not show this.)

(c) Prove that no $\mathbf{M} \in M_2(\mathbb{R})$ satisfies $\mathbf{M}^2 = \mathbf{S}_0 = \operatorname{diag}(1, -1)$. Does the same argument rule out $\mathbf{M}^2 = -\mathbf{I}_2$?

Solution.

(a) $\det \mathbf{R}_\theta = \cos^2\theta + \sin^2\theta = 1 > 0$ and $\det \mathbf{S}_\theta = -\cos^2 2\theta - \sin^2 2\theta = -1 < 0$. By Proposition 6.9.4, rotations preserve and reflections reverse orientation. Both have $|\det| = 1$, so both preserve area by Theorem 6.9.2.

(b) By Theorem 6.5.4, $\det(\mathbf{S}_\theta \mathbf{S}_\varphi) = (-1)(-1) = 1 > 0$.

(c) If $\mathbf{M}^2 = \mathbf{S}_0$, then $(\det \mathbf{M})^2 = \det \mathbf{S}_0 = -1$ by Theorem 6.5.4, impossible for a real number $\det \mathbf{M}$. The argument says nothing about $-\mathbf{I}_2$, since $\det(-\mathbf{I}_2) = 1$; and indeed $\mathbf{R}_{\pi/2}^2 = \mathbf{R}_{\pi/2}\mathbf{R}_{\pi/2} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}^2 = -\mathbf{I}_2$. An orientation-reversing map can never be the square of a real map, since the square of anything preserves orientation.

6.10 The Characteristic Polynomial

For a square matrix $\mathbf{A}$ over F and a scalar $c \in F$, when is $c\mathbf{I} - \mathbf{A}$ invertible? The question matters: $c\mathbf{I} - \mathbf{A}$ fails to be invertible exactly when $\mathbf{A}\mathbf{v} = c\mathbf{v}$ for some non-zero vector $\mathbf{v}$, the situation Chapter 8 is built around. The determinant answers the question for each single c. This section lets c vary. Replacing the number c by a variable x turns $\det(c\mathbf{I} - \mathbf{A})$ into a polynomial, the characteristic polynomial, and the scalars we are looking for become its roots. The price is that $x\mathbf{I} - \mathbf{A}$ is a matrix of **polynomials**, not of field elements, so we must check which determinant facts survive there. The remarks at the ends of §4, §5 and §6 did exactly that bookkeeping, and here we cash them in.

6.10.1 From a number to a variable

Take $\mathbf{A} = \begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix} \in M_2(\mathbb{Q})$. For each $c \in \mathbb{Q}$,

$$\det(c\mathbf{I} - \mathbf{A}) = \det \begin{pmatrix} c-1 & -2 \\ -3 & c-4 \end{pmatrix} = (c-1)(c-4) - 6 = c^2 - 5c - 2.$$

The same expression $c^2 - 5c - 2$ appears whatever c is. It is the value at c of one polynomial, and that polynomial deserves a name. To define it directly, without first choosing c, we put the variable x into the matrix and take the determinant of

$$x\mathbf{I} - \mathbf{A} = \begin{pmatrix} x-1 & -2 \\ -3 & x-4 \end{pmatrix},$$

a matrix whose entries lie in $F[x]$.

Is that allowed? $F[x]$ is not a field, but it is a **commutative ring** in the sense of the remark in §4: all the field axioms hold except the existence of inverses (Theorem 0.8.1). The Leibniz formula of Definition 6.4.1 uses only sums, differences and products of entries, so it defines $\det \mathbf{M} \in F[x]$ for every $\mathbf{M} \in M_n(F[x])$.

The characteristic polynomial of $\mathbf{A}$ *is the determinant of* $x\mathbf{I} - \mathbf{A}$*, computed with polynomial entries.*

Definition 6.10.1 — Characteristic Polynomial

Let $n \geq 1$ and $\mathbf{A} = (a_{ij}) \in M_n(F)$. The **characteristic polynomial** of $\mathbf{A}$ is

$$p_{\mathbf{A}}(x) := \det(x\mathbf{I}_n - \mathbf{A}) = \sum_{\sigma \in S_n} \operatorname{sgn}(\sigma) \prod_{j=1}^{n} \left(x\,\delta_{\sigma(j)j} - a_{\sigma(j)j} \right) \in F[x],$$

where $\delta_{ij} = 1$ if $i = j$ and 0 otherwise, so that $x\delta_{ij} - a_{ij}$ is the (i,j)-entry of $x\mathbf{I}_n - \mathbf{A}$. The determinant is the Leibniz sum of Definition 6.4.1, computed in the commutative ring $F[x]$.

In words: subtract $\mathbf{A}$ from x times the identity, so that x appears only on the diagonal; then take the determinant exactly as for a matrix of numbers, multiplying and adding polynomials instead of scalars. The result is **one** polynomial, not a number.

Well-definedness. Each term of the Leibniz sum is a product of n polynomials, and the sum is finite, so $p_{\mathbf{A}}$ is a polynomial. It depends only on $\mathbf{A}$.

How to compute it. By the remarks in §4, §5 and §6, the following results were proved without dividing, and so hold for matrices over $F[x]$: Theorem 6.4.5 and Theorem 6.4.6 (§4), Theorem 6.5.4 by its first proof (§5), Theorem 6.6.1 (§6), and Theorem 6.8.4 (§8). So we may expand $\det(x\mathbf{I} - \mathbf{A})$ along any row or column, and read it off from triangular or block triangular shape. What we may **not** do is row reduce $x\mathbf{I} - \mathbf{A}$ by dividing by a polynomial entry, as the warning below explains.

Examples.

- 1×1. For $\mathbf{A} = (a)$, $p_{\mathbf{A}}(x) = x - a$.
- 2×2. For $\mathbf{A} = \begin{pmatrix} a & b \\ c & d \end{pmatrix}$,

$$\begin{aligned} p_{\mathbf{A}}(x) &= (x-a)(x-d) - bc = x^2 - (a+d)x + (ad - bc) \\ &= x^2 - (\operatorname{tr} \mathbf{A})\, x + \det \mathbf{A}. \end{aligned}$$

  For $\mathbf{A} = \begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix}$ this is $x^2 - 5x - 2$, as above.
- **Triangular.** If $\mathbf{A}$ is upper or lower triangular, so is $x\mathbf{I} - \mathbf{A}$, with diagonal entries $x - a_{ii}$. By Theorem 6.4.6 over $F[x]$, $p_{\mathbf{A}}(x) = (x - a_{11})(x - a_{22}) \cdots (x - a_{nn})$.
- **Degenerate cases.** The zero matrix has $p_0(x) = x^n$, and the identity has $p_{\mathbf{I}_n}(x) = (x-1)^n$; both are triangular. These two polynomials are different, although both matrices are as simple as possible, which already shows that $p_{\mathbf{A}}$ records something about $\mathbf{A}$.

Example. (A 3×3 Characteristic Polynomial)

Find $p_{\mathbf{A}}$ for $\mathbf{A} = \begin{pmatrix} 2 & 0 & 1 \\ 1 & 3 & 1 \\ 1 & 0 & 2 \end{pmatrix} \in M_3(\mathbb{Q})$.

Solution. We have

$$x\mathbf{I} - \mathbf{A} = \begin{pmatrix} x-2 & 0 & -1 \\ -1 & x-3 & -1 \\ -1 & 0 & x-2 \end{pmatrix}.$$

Column 2 has a single non-zero entry, $x - 3$ in position $(2, 2)$. Expanding along it (Theorem 6.6.1 over $F[x]$),

$$\begin{aligned} p_{\mathbf{A}}(x) &= (x-3)\,(-1)^{2+2} \det \begin{pmatrix} x-2 & -1 \\ -1 & x-2 \end{pmatrix} \\ &= (x-3)\big((x-2)^2 - 1\big) = (x-1)(x-3)^2. \end{aligned}$$

Multiplied out, $p_{\mathbf{A}}(x) = x^3 - 7x^2 + 15x - 9$. Compare with $\operatorname{tr} \mathbf{A} = 2 + 3 + 2 = 7$ and $\det \mathbf{A} = 9$ (expand $\mathbf{A}$ along column 2: $3(4 - 1) = 9$).

A companion-type example. Let $\mathbf{A} = \begin{pmatrix} 0 & 0 & 6 \\ 1 & 0 & -11 \\ 0 & 1 & 6 \end{pmatrix}$, with ones just below the diagonal, a last column $(6, -11, 6)$, and zeros elsewhere. Expanding $x\mathbf{I} - \mathbf{A} = \begin{pmatrix} x & 0 & -6 \\ -1 & x & 11 \\ 0 & -1 & x-6 \end{pmatrix}$ along the first row (Theorem 6.6.1 over $F[x]$),

$$\begin{aligned} p_{\mathbf{A}}(x) &= x \det \begin{pmatrix} x & 11 \\ -1 & x-6 \end{pmatrix} + (-6) \det \begin{pmatrix} -1 & x \\ 0 & -1 \end{pmatrix} \\ &= x(x^2 - 6x + 11) - 6 = x^3 - 6x^2 + 11x - 6, \end{aligned}$$

which factors as $(x - 1)(x - 2)(x - 3)$. The last column of $\mathbf{A}$ lists the coefficients $-6, 11, -6$ of $1, x, x^2$ in $p_{\mathbf{A}}$, with their signs changed. This is no accident: Exercise (C1: Companion matrices) shows that the same pattern works in every size.

Non-example by minimal change. Swap the order of subtraction: $\det(\mathbf{A} - x\mathbf{I})$. Each of the n columns of $\mathbf{A} - x\mathbf{I}$ is -1 times the corresponding column of $x\mathbf{I} - \mathbf{A}$, so by multilinearity $\det(\mathbf{A} - x\mathbf{I}) = (-1)^n p_{\mathbf{A}}(x)$. For $\mathbf{A} = (a)$ this is $a - x$, whose leading coefficient is -1. What still works: the roots are the same. What fails: the result is **not monic** when n is odd.

Why this definition. Some books use $\det(\mathbf{A} - x\mathbf{I})$. We use $x\mathbf{I} - \mathbf{A}$ so that the characteristic polynomial is always **monic** (Theorem 6.10.2 below), which makes statements like "$p_{\mathbf{A}} = (x - 1)(x - 3)^2$" true without sign bookkeeping. The name comes from the fact that the roots of this polynomial are the "characteristic values" of $\mathbf{A}$, which Chapter 8 calls eigenvalues.

Warning. **Do not row reduce $x\mathbf{I} - \mathbf{A}$ by dividing by polynomials.** Over a field, a matrix with non-zero determinant is invertible (Theorem 6.5.2), but that proof runs through elimination, which divides by pivots, and it fails over $F[x]$. For $\mathbf{A} = (0) \in M_1(F)$, the matrix $x\mathbf{I} - \mathbf{A} = (x)$ has determinant $x \neq 0$, yet it has no inverse in $M_1(F[x])$: if $x\,q(x) = 1$ for a polynomial q, then $q \neq 0$, and $1 + \deg q = \deg 1 = 0$ by Theorem 0.8.3, which is impossible since $\deg q \geq 0$. Likewise, "divide row 1 of $x\mathbf{I} - \mathbf{A}$

by $x - 1$" produces entries that are not polynomials and that make no sense at $x = 1$. Compute $p_{\mathbf{A}}$ by expansion, by triangular or block shape, or by the Leibniz formula.

Before looking at the coefficients, we record the fact that makes $p_{\mathbf{A}}$ useful: evaluating it at a scalar c gives the same result as putting c in place of x before taking the determinant.

Lemma 6.10.1 — Evaluating the Characteristic Polynomial

Let $\mathbf{A} \in M_n(F)$ and $c \in F$. Then $p_{\mathbf{A}}(c) = \det(c\mathbf{I}_n - \mathbf{A})$.

Proof. By Theorem 0.8.5, evaluation at c turns sums of polynomials into sums and products into products, and sends a constant a to a. Applying it to the Leibniz sum in Definition 6.10.1 term by term,

$$p_{\mathbf{A}}(c) = \sum_{\sigma \in S_n} \operatorname{sgn}(\sigma) \prod_{j=1}^{n} \left(c\,\delta_{\sigma(j)j} - a_{\sigma(j)j}\right),$$

and $c\,\delta_{ij} - a_{ij}$ is the (i,j)-entry of $c\mathbf{I}_n - \mathbf{A}$. By Definition 6.4.1, the right side is $\det(c\mathbf{I}_n - \mathbf{A})$.

■

6.10.2 The shape of the characteristic polynomial

The 2×2 example suggests a pattern: the leading coefficient is 1, the next coefficient is minus the trace, and the constant term is the determinant up to sign. The same holds in every size.

Theorem 6.10.2 — Coefficients of the Characteristic Polynomial

Let $n \geq 1$ and $\mathbf{A} \in M_n(F)$. Then $p_{\mathbf{A}}$ is **monic of degree** n, and

$$p_{\mathbf{A}}(x) = x^n - (\operatorname{tr} \mathbf{A})\, x^{n-1} + \cdots + (-1)^n \det \mathbf{A},$$

that is, the coefficient of x^{n-1} is $-\operatorname{tr} \mathbf{A}$ and the constant term is $(-1)^n \det \mathbf{A}$. (For $n = 1$ these two statements concern the same coefficient, and both say it is $-a_{11}$.)

Idea. Look at the Leibniz sum term by term and count powers of x. A factor $x\delta_{\sigma(j)j} - a_{\sigma(j)j}$ contains x only if $\sigma(j) = j$. A permutation other than the identity moves at least **two** indices, so its term has degree at most $n - 2$ and cannot affect the top two coefficients. The identity contributes $\prod_j (x - a_{jj})$, whose top two coefficients are 1 and $-\sum_j a_{jj}$. For the constant term, set $x = 0$.

Proof. Write $m_{ij} = x\delta_{ij} - a_{ij}$ for the entries of $x\mathbf{I} - \mathbf{A}$. By Definition 6.10.1, $p_{\mathbf{A}} = \sum_\sigma t_\sigma$ with $t_\sigma = \operatorname{sgn}(\sigma) \prod_j m_{\sigma(j)j}$.

Terms with $\sigma \neq \mathrm{id}$. If $\sigma(j) \neq j$ for some j, then $\sigma(\sigma(j)) \neq \sigma(j)$, because σ is injective. So σ moves at least two indices, and at most $n - 2$ indices are fixed. For a moved index j, $m_{\sigma(j)j} = -a_{\sigma(j)j}$ has degree at most 0; for a fixed index it has degree at most 1. By

Theorem 0.8.3, $\deg t_\sigma \le n-2$.

The term $\sigma = \mathrm{id}$. We show by induction on $k \ge 1$ that $\prod_{j=1}^{k}(x-a_{jj}) = x^k - s_k x^{k-1} + r_k$ with $s_k = a_{11}+\cdots+a_{kk}$ and $\deg r_k \le k-2$. For $k=1$, take $r_1 = 0$. If it holds for k, then with $a = a_{k+1,k+1}$,

$$(x^k - s_k x^{k-1} + r_k)(x-a) = x^{k+1} - (s_k + a)x^k + \big(s_k a x^{k-1} + r_k x - a r_k\big),$$

and the bracket has degree at most $k-1$ by Theorem 0.8.2 and Theorem 0.8.3. This completes the induction. Since $\mathrm{sgn}(\mathrm{id}) = 1$, $t_{\mathrm{id}} = x^n - (\operatorname{tr}\mathbf{A})\,x^{n-1} + r_n$ with $\deg r_n \le n-2$.

Adding, $p_{\mathbf{A}} = x^n - (\operatorname{tr}\mathbf{A})\,x^{n-1} + \big(r_n + \sum_{\sigma\neq\mathrm{id}} t_\sigma\big)$, and the bracket has degree at most $n-2$ by Theorem 0.8.2. Hence $p_{\mathbf{A}}$ is monic of degree n, with coefficient $-\operatorname{tr}\mathbf{A}$ at x^{n-1} (Definition 0.9.12).

Constant term. The constant term of a polynomial is its value at 0 (Definition 0.8.6). By Lemma 6.10.1 with $c = 0$, $p_{\mathbf{A}}(0) = \det(-\mathbf{A})$. The matrix $-\mathbf{A}$ is obtained from $\mathbf{A}$ by multiplying each of its n columns by -1, so $\det(-\mathbf{A}) = (-1)^n \det\mathbf{A}$ by Theorem 6.5.1 (d). This proves the theorem.

■

So the characteristic polynomial packages two invariants we already know, the trace and the determinant, and adds $n-2$ more coefficients in between. For $n = 2$ nothing is in between, which is why $p_{\mathbf{A}}(x) = x^2 - (\operatorname{tr}\mathbf{A})x + \det\mathbf{A}$ for every 2×2 matrix.

Quick check. Without expanding any determinant, find the coefficient of x^2 and the constant term of $p_{\mathbf{A}}$ for $\mathbf{A} = \begin{pmatrix} 0 & 1 & 1 \\ 1 & 0 & 1 \\ 1 & 1 & 0 \end{pmatrix}$, given that $\det\mathbf{A} = 2$.

Solution. By Theorem 6.10.2, the coefficient of x^2 is $-\operatorname{tr}\mathbf{A} = 0$, and the constant term is $(-1)^3\det\mathbf{A} = -2$. (In full, $p_{\mathbf{A}}(x) = x^3 - 3x - 2 = (x-2)(x+1)^2$.)

6.10.3 Similar matrices, same polynomial

Similar matrices describe the same operator in different bases (Theorem 3.7.4), so everything intrinsic to the operator should agree for them. The trace and determinant do (Theorem 3.7.5, Corollary 6.5.7). The characteristic polynomial, which contains both, does too, and the proof is the proof for the determinant, run over $F[x]$.

Theorem 6.10.3 — Similar Matrices Have the Same Characteristic Polynomial

If $\mathbf{A}, \mathbf{B} \in M_n(F)$ are similar, then $p_{\mathbf{A}} = p_{\mathbf{B}}$.

Proof. Let $\mathbf{B} = \mathbf{P}^{-1}\mathbf{A}\mathbf{P}$ with $\mathbf{P} \in M_n(F)$ invertible. Regard $\mathbf{P}$, $\mathbf{P}^{-1}$, $\mathbf{A}$ and $\mathbf{I}$ as matrices over $F[x]$ whose entries happen to be constants. The laws of matrix arithmetic in Theorem 0.9.4 are proved from the ring axioms alone, so they hold in $M_n(F[x])$.

Hence

$$\mathbf{P}^{-1}(x\mathbf{I}-\mathbf{A})\mathbf{P} = x\,\mathbf{P}^{-1}\mathbf{P} - \mathbf{P}^{-1}\mathbf{A}\mathbf{P} = x\mathbf{I}-\mathbf{B}.$$

By Theorem 6.5.4, valid over $F[x]$ by the remark in §5,

$$\begin{aligned} p_{\mathbf{B}} &= \det\left(\mathbf{P}^{-1}(x\mathbf{I}-\mathbf{A})\mathbf{P}\right) = \det(\mathbf{P}^{-1})\,\det(x\mathbf{I}-\mathbf{A})\,\det\mathbf{P} \\ &= \det(\mathbf{P}^{-1})\det(\mathbf{P})\,p_{\mathbf{A}}, \end{aligned}$$

using commutativity of $F[x]$ in the last step. Finally $\det(\mathbf{P}^{-1})\det\mathbf{P} = \det(\mathbf{P}^{-1}\mathbf{P}) = \det\mathbf{I} = 1$ by Theorem 6.5.4 over F. Hence $p_{\mathbf{B}} = p_{\mathbf{A}}$.

■

This is exactly the case singled out in the remark in §5: the proof of Corollary 6.5.7 survives over $F[x]$ because $\mathbf{P}$ is invertible already over F. The theorem lets us attach a characteristic polynomial to an operator.

Definition 6.10.2 — Characteristic Polynomial of an Operator

Let V be a vector space over F with $\dim V = n \geq 1$, and let $T \in \mathcal{L}(V)$. The **characteristic polynomial** of T is

$$p_T(x) := p_{[T]_{\mathcal{B}}}(x) = \det\left(x\mathbf{I}_n - [T]_{\mathcal{B}}\right),$$

where $\mathcal{B}$ is **any** basis of V.

This does not depend on $\mathcal{B}$: for bases $\mathcal{B}$ and $\mathcal{C}$, the matrices $[T]_{\mathcal{B}}$ and $[T]_{\mathcal{C}}$ are similar by Theorem 3.7.4 (a), so they have the same characteristic polynomial by Theorem 6.10.3. By Theorem 6.10.2, p_T is monic of degree $\dim V$, with coefficient $-\operatorname{tr} T$ at x^{n-1} and constant term $(-1)^n \det T$ (Definition 3.10.2, Definition 6.5.1).

Example. (Characteristic Polynomials of Two Operators)

On $V = \mathbb{R}[x]_{\leq 2}$, find the characteristic polynomials of differentiation $D(q) = q'$ and of the shift $S(q)(x) = q(x+1)$.

Solution. Use the basis $\mathcal{B} = (1, x, x^2)$. Since $D(1) = 0$, $D(x) = 1$, $D(x^2) = 2x$, and $S(1) = 1$, $S(x) = 1 + x$, $S(x^2) = 1 + 2x + x^2$,

$$[D]_{\mathcal{B}} = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 2 \\ 0 & 0 & 0 \end{pmatrix}, \qquad [S]_{\mathcal{B}} = \begin{pmatrix} 1 & 1 & 1 \\ 0 & 1 & 2 \\ 0 & 0 & 1 \end{pmatrix}.$$

Both are upper triangular, so $p_D(t) = t^3$ and $p_S(t) = (t-1)^3$. (We name the variable t here, since x is already the variable of the polynomials in V.) As a check, $\operatorname{tr} S = 3$ and $\det S = 1$, matching the coefficient -3 of t^2 and the constant term $(-1)^3 \cdot 1$.

Warning. **Equal characteristic polynomials do not make matrices similar.** The converse of Theorem 6.10.3 is false. Recall the pair from the warning in Chapter 3, §7: $\mathbf{I}_2$ and $\mathbf{J} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$ both have characteristic polynomial $(x-1)^2$, since both are

triangular with diagonal $1, 1$. But $\mathbf{I}_2$ is similar only to itself, so $\mathbf{J} \not\sim \mathbf{I}_2$. In particular the characteristic polynomial does not determine the matrix, not even up to similarity. Deciding similarity needs finer invariants; Chapter 9 finds a complete set.

6.10.4 Roots and singular matrices

We can now answer the opening question. The determinant tests invertibility of $c\mathbf{I} - \mathbf{A}$ for one c at a time; the characteristic polynomial tests all c at once, and the answer is a finite set.

Theorem 6.10.4 — Roots of the Characteristic Polynomial

Let $\mathbf{A} \in M_n(F)$ with $n \geq 1$, and let $c \in F$.

(a) The following are equivalent: (i) $p_{\mathbf{A}}(c) = 0$; (ii) $c\mathbf{I} - \mathbf{A}$ is **not** invertible; (iii) there is a **non-zero** $\mathbf{v} \in F^n$ with $\mathbf{A}\mathbf{v} = c\mathbf{v}$.

(b) There are **at most** n scalars $c \in F$ with these properties.

Proof.

(a) By Lemma 6.10.1, $p_{\mathbf{A}}(c) = \det(c\mathbf{I} - \mathbf{A})$, which is a determinant of a matrix over the **field** F. By Theorem 6.5.2, it is zero if and only if $c\mathbf{I} - \mathbf{A}$ is not invertible; this is (i) $\Leftrightarrow$ (ii). By Theorem 2.4.4, $c\mathbf{I} - \mathbf{A}$ is not invertible if and only if $(c\mathbf{I} - \mathbf{A})\mathbf{v} = \mathbf{0}$ for some $\mathbf{v} \neq \mathbf{0}$, and $(c\mathbf{I} - \mathbf{A})\mathbf{v} = c\mathbf{v} - \mathbf{A}\mathbf{v}$ by Theorem 0.9.4; this is (ii) $\Leftrightarrow$ (iii).

(b) By Theorem 6.10.2, $p_{\mathbf{A}}$ is monic of degree n, in particular non-zero. By Corollary 5.1.4, it has at most n distinct roots in F, and by (a) these are exactly the scalars in question.

■

Notice where the evaluation happens: **first** substitute c, getting a matrix over the field F, **then** use the invertibility test, which is valid over fields. That order is what the warning about $F[x]$ above requires.

The same holds for an operator T on V with $\dim V = n \geq 1$: $p_T(c) = 0$ if and only if $c\,\mathrm{id}_V - T$ is not invertible, by (a) applied to $[T]_{\mathcal{B}}$ together with Theorem 3.6.5 (b), since $[c\,\mathrm{id}_V - T]_{\mathcal{B}} = c\mathbf{I} - [T]_{\mathcal{B}}$.

The scalars c of this theorem are the **eigenvalues** of $\mathbf{A}$, and the vectors $\mathbf{v}$ in (iii) its eigenvectors. They are the subject of Chapter 8, which starts from this theorem.

Examples.

- For $\mathbf{A}$ in Example (A 3×3 Characteristic Polynomial), $p_{\mathbf{A}} = (x-1)(x-3)^2$, so $c\mathbf{I} - \mathbf{A}$ is singular exactly for $c = 1$ and $c = 3$. For instance $3\mathbf{I} - \mathbf{A} = \begin{pmatrix} 1 & 0 & -1 \\ -1 & 0 & -1 \\ -1 & 0 & 1 \end{pmatrix}$ has a zero column, and $\mathbf{v} = \mathbf{e}_2$ satisfies $\mathbf{A}\mathbf{e}_2 = 3\mathbf{e}_2$.
- The rotation $\mathbf{R} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$ has $p_{\mathbf{R}} = x^2 + 1$. Over $\mathbb{R}$ this has no root, so $c\mathbf{I} - \mathbf{R}$ is invertible for **every** real c: no non-zero real vector is merely stretched by a quarter-turn.

Over $\mathbb{C}$, the roots $\pm i$ appear, and for example $\mathbf{R}(1,-i) = (i,1) = i\,(1,-i)$. The field matters.

Quick check. For which $c \in \mathbb{Q}$ is $c\mathbf{I} - \mathbf{A}$ invertible, where $\mathbf{A} = \begin{pmatrix} 5 & -2 \\ 3 & 0 \end{pmatrix}$?

Solution. $p_{\mathbf{A}}(x) = x^2 - (\operatorname{tr}\mathbf{A})x + \det\mathbf{A} = x^2 - 5x + 6 = (x-2)(x-3)$. By Theorem 6.10.4, $c\mathbf{I} - \mathbf{A}$ is invertible exactly for $c \neq 2, 3$.

6.10.5 A tempting false proof

Here is a statement that is true, and important: **every square matrix satisfies its own characteristic polynomial**, $p_{\mathbf{A}}(\mathbf{A}) = 0$. This is the Cayley–Hamilton Theorem, proved in Chapter 8. Here $p_{\mathbf{A}}(\mathbf{A})$ means substituting the matrix $\mathbf{A}$ into the polynomial $p_{\mathbf{A}}$, replacing each x^k by $\mathbf{A}^k$ and the constant term a_0 by $a_0\mathbf{I}$ (Definition 0.9.14). For a 2×2 matrix it says $\mathbf{A}^2 - (\operatorname{tr}\mathbf{A})\mathbf{A} + (\det\mathbf{A})\mathbf{I} = 0$, which you can check by multiplying out.

A one-line "proof" suggests itself, and it is wrong.

Warning. **The fake proof of Cayley–Hamilton.** "Since $p_{\mathbf{A}}(x) = \det(x\mathbf{I} - \mathbf{A})$, put $x = \mathbf{A}$: $p_{\mathbf{A}}(\mathbf{A}) = \det(\mathbf{A}\mathbf{I} - \mathbf{A}) = \det(0) = 0$." This is invalid for two reasons. First, the two sides are different kinds of object: $p_{\mathbf{A}}(\mathbf{A})$ is an $n \times n$ **matrix**, while $\det(\cdots)$ is a **scalar**, so "$= 0$" compares a matrix with a number. Second, Lemma 6.10.1 lets us substitute only a **scalar** $c \in F$ into the entries of $x\mathbf{I} - \mathbf{A}$. Substituting a matrix for x inside the entries would produce a matrix whose entries are matrices, and "$\mathbf{A}\mathbf{I} - \mathbf{A}$" silently treats the x in the entry $x - a_{11}$ as if the entry became $\mathbf{A} - a_{11}$, which is not what substitution into a polynomial means.

The same "argument" proves false statements, which shows it is not a proof. Replace det by tr: let $q(x) = \operatorname{tr}(x\mathbf{I} - \mathbf{A}) = nx - \operatorname{tr}\mathbf{A}$. The fake reasoning gives "$q(\mathbf{A}) = \operatorname{tr}(\mathbf{A}\mathbf{I} - \mathbf{A}) = \operatorname{tr} 0 = 0$". But for $\mathbf{A} = \operatorname{diag}(1,0)$, $q(x) = 2x - 1$ and $q(\mathbf{A}) = 2\mathbf{A} - \mathbf{I} = \operatorname{diag}(1,-1) \neq 0$.

6.10.6 Exercises

6.10.6.1 A. Check your understanding

Exercise A1.

(a) Define the characteristic polynomial of $\mathbf{A} \in M_n(F)$, and say in which ring its determinant is computed.

(b) State the degree, leading coefficient, coefficient of x^{n-1} and constant term of $p_{\mathbf{A}}$.

(c) True or false: $\det(\mathbf{A} - x\mathbf{I}) = p_{\mathbf{A}}(x)$ for every $\mathbf{A} \in M_3(F)$. Justify your answer.

(d) True or false: if $p_{\mathbf{A}} = p_{\mathbf{B}}$, then $\mathbf{A} \sim \mathbf{B}$. Justify your answer.

(e) What does $p_{\mathbf{A}}(c) = 0$ say about the matrix $c\mathbf{I} - \mathbf{A}$? About vectors?

(f) Explain in one sentence why "$p_{\mathbf{A}}(\mathbf{A}) = \det(\mathbf{A}\mathbf{I} - \mathbf{A}) = 0$" is not a proof.

Solution.

(a) $p_{\mathbf{A}}(x) = \det(x\mathbf{I}_n - \mathbf{A})$, the Leibniz sum computed in the commutative ring $F[x]$ (Definition 6.10.1).

(b) Degree n, leading coefficient 1, coefficient $-\operatorname{tr}\mathbf{A}$ at x^{n-1}, constant term $(-1)^n \det\mathbf{A}$ (Theorem 6.10.2).

(c) False. $\det(\mathbf{A} - x\mathbf{I}) = (-1)^3 p_{\mathbf{A}}(x) = -p_{\mathbf{A}}(x)$, since each of the three columns changes sign. For $\mathbf{A} = 0$, $\det(-x\mathbf{I}_3) = -x^3 \neq x^3 = p_{\mathbf{A}}(x)$.

(d) False. $\mathbf{I}_2$ and $\begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$ both have $p = (x-1)^2$ but are not similar.

(e) $c\mathbf{I} - \mathbf{A}$ is not invertible; equivalently there is a non-zero $\mathbf{v}$ with $\mathbf{A}\mathbf{v} = c\mathbf{v}$ (Theorem 6.10.4).

(f) $p_{\mathbf{A}}(\mathbf{A})$ is a matrix obtained by substituting $\mathbf{A}$ into a polynomial, while $\det(\mathbf{A}\mathbf{I} - \mathbf{A})$ is a scalar, and substitution into the entries of $x\mathbf{I} - \mathbf{A}$ is only justified for scalars (Lemma 6.10.1).

6.10.6.2 B. Practice

Exercise B1: Computing characteristic polynomials.

Find the characteristic polynomial of each matrix over $\mathbb{Q}$, factor it as far as possible over $\mathbb{Q}$, and check the trace and determinant against Theorem 6.10.2.

$$\mathbf{A} = \begin{pmatrix} 1 & 1 & 0 \\ 0 & 1 & 1 \\ 1 & 0 & 1 \end{pmatrix}, \qquad \mathbf{B} = \begin{pmatrix} 2 & 1 & 0 & 0 \\ 0 & 2 & 0 & 0 \\ 0 & 0 & 1 & 3 \\ 0 & 0 & 1 & -1 \end{pmatrix}.$$

Hence list the $c \in \mathbb{Q}$ for which $c\mathbf{I} - \mathbf{A}$, respectively $c\mathbf{I} - \mathbf{B}$, is not invertible.

Solution. *For* $\mathbf{A}$. Expanding $x\mathbf{I} - \mathbf{A} = \begin{pmatrix} x-1 & -1 & 0 \\ 0 & x-1 & -1 \\ -1 & 0 & x-1 \end{pmatrix}$ along the first row (Theorem 6.6.1 over $F[x]$),

$$\begin{aligned} p_{\mathbf{A}}(x) &= (x-1)\big((x-1)^2 - 0\big) - (-1)\big(0 - 1\big) + 0 \\ &= (x-1)^3 - 1 = x^3 - 3x^2 + 3x - 2. \end{aligned}$$

Check: $-\operatorname{tr}\mathbf{A} = -3$; $\det\mathbf{A} = 1\cdot(1-0) - 1\cdot(0-1) + 0 = 2$, and $(-1)^3 \cdot 2 = -2$. Since $p_{\mathbf{A}}(2) = 1 - 1 = 0$, divide by $x - 2$: $p_{\mathbf{A}} = (x-2)(x^2 - x + 1)$. The quadratic has discriminant $1 - 4 = -3 < 0$, so no rational (indeed no real) root. By Theorem 6.10.4, $c\mathbf{I} - \mathbf{A}$ is singular only for $c = 2$.

For $\mathbf{B}$. $x\mathbf{I} - \mathbf{B}$ is block upper triangular with diagonal blocks $x\mathbf{I} - \begin{pmatrix} 2 & 1 \\ 0 & 2 \end{pmatrix}$ and $x\mathbf{I} - \begin{pmatrix} 1 & 3 \\ 1 & -1 \end{pmatrix}$. By Theorem 6.8.4 over $F[x]$ and the 2×2 formula,

$$p_{\mathbf{B}}(x) = (x-2)^2\left(x^2 - 0\cdot x + (-1-3)\right) = (x-2)^2(x^2 - 4) = (x-2)^3(x+2).$$

Multiplied out, $p_{\mathbf{B}} = x^4 - 4x^3 + 16x - 16$. Check: $-\operatorname{tr}\mathbf{B} = -(2+2+1-1) = -4$; $\det\mathbf{B} = 4\cdot(-4) = -16$ by Theorem 6.8.4, and $(-1)^4(-16) = -16$. So $c\mathbf{I}-\mathbf{B}$ is singular exactly for $c = 2$ and $c = -2$.

Exercise B2: Transpose.

Prove that $p_{\mathbf{A}^\top} = p_{\mathbf{A}}$ for every $\mathbf{A} \in M_n(F)$. Hence show that $c\mathbf{I}-\mathbf{A}$ is invertible if and only if $c\mathbf{I}-\mathbf{A}^\top$ is.

Solution. By Theorem 0.9.5, $(x\mathbf{I}-\mathbf{A})^\top = x\mathbf{I}^\top - \mathbf{A}^\top = x\mathbf{I}-\mathbf{A}^\top$; these rules are proved entrywise from the ring axioms, so they hold over $F[x]$. By Theorem 6.4.5, which holds over $F[x]$ by the remark in §4,

$$p_{\mathbf{A}^\top} = \det(x\mathbf{I}-\mathbf{A}^\top) = \det\left((x\mathbf{I}-\mathbf{A})^\top\right) = \det(x\mathbf{I}-\mathbf{A}) = p_{\mathbf{A}}.$$

By Theorem 6.10.4, $c\mathbf{I}-\mathbf{A}$ is not invertible exactly when $p_{\mathbf{A}}(c) = 0$, which is exactly when $p_{\mathbf{A}^\top}(c) = 0$, that is, when $c\mathbf{I}-\mathbf{A}^\top$ is not invertible.

Exercise B3: AB and BA.

Let $\mathbf{A}, \mathbf{B} \in M_n(F)$ with $\mathbf{A}$ invertible.

(a) Show that $\mathbf{BA} = \mathbf{A}^{-1}(\mathbf{AB})\mathbf{A}$, and deduce $p_{\mathbf{AB}} = p_{\mathbf{BA}}$.

(b) Deduce that $\operatorname{tr}(\mathbf{AB}) = \operatorname{tr}(\mathbf{BA})$ and $\det(\mathbf{AB}) = \det(\mathbf{BA})$ in this case.

(c) Check (a) for $\mathbf{A} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$, $\mathbf{B} = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix}$, and note that $\mathbf{AB} \neq \mathbf{BA}$.

(Chapter 8 removes the hypothesis that $\mathbf{A}$ is invertible.)

Solution.

(a) By associativity, $\mathbf{A}^{-1}(\mathbf{AB})\mathbf{A} = (\mathbf{A}^{-1}\mathbf{A})(\mathbf{BA}) = \mathbf{BA}$. So $\mathbf{BA} \sim \mathbf{AB}$ (Definition 3.7.2, with $\mathbf{P} = \mathbf{A}$), and $p_{\mathbf{AB}} = p_{\mathbf{BA}}$ by Theorem 6.10.3.

(b) By Theorem 6.10.2, the coefficient of x^{n-1} is $-\operatorname{tr}(\mathbf{AB})$ in $p_{\mathbf{AB}}$ and $-\operatorname{tr}(\mathbf{BA})$ in $p_{\mathbf{BA}}$; the constant terms are $(-1)^n\det(\mathbf{AB})$ and $(-1)^n\det(\mathbf{BA})$. Equal polynomials have equal coefficients.

(c) $\mathbf{AB} = \begin{pmatrix} 1 & 0 \\ 1 & 0 \end{pmatrix}$ and $\mathbf{BA} = \begin{pmatrix} 0 & 0 \\ 1 & 1 \end{pmatrix}$, so $\mathbf{AB} \neq \mathbf{BA}$. Both have trace 1 and determinant 0, so both characteristic polynomials are $x^2 - x = x(x-1)$.

6.10.6.3 C. Going deeper

Exercise C1: Companion matrices.

Let $n \geq 2$ and $p(x) = x^n + a_{n-1}x^{n-1} + \cdots + a_1x + a_0 \in F[x]$. The **companion matrix** of p is the matrix $\mathbf{C}(p) \in M_n(F)$ with 1 in each position $(i+1, i)$ just below the diagonal,

last column $(-a_0, -a_1, \ldots, -a_{n-1})$, and 0 elsewhere:

$$\mathbf{C}(p) = \begin{pmatrix} 0 & 0 & \cdots & 0 & -a_0 \\ 1 & 0 & \cdots & 0 & -a_1 \\ 0 & 1 & \cdots & 0 & -a_2 \\ \vdots & & \ddots & & \vdots \\ 0 & 0 & \cdots & 1 & -a_{n-1} \end{pmatrix}.$$

(The matrix $\mathbf{C}$ of Exercise (B2: An annihilating polynomial by elimination) is $\mathbf{C}(x^3 - 2x^2 + x - 2)$.)

(a) Let $\mathbf{M} = x\mathbf{I} - \mathbf{C}(p)$. For each i, show that deleting row i and column n of $\mathbf{M}$ leaves a block diagonal matrix whose blocks are an $(i-1)\times(i-1)$ lower triangular matrix with diagonal $x, \ldots, x$ and an $(n-i)\times(n-i)$ upper triangular matrix with diagonal $-1, \ldots, -1$ (either block may be absent when $i = 1$ or $i = n$). Deduce that the cofactor C_{in} of $\mathbf{M}$ equals x^{i-1}.

(b) Deduce, by expanding along the last column, that $p_{\mathbf{C}(p)} = p$.

(c) Verify (b) for $p = x^4 + x^3 - 2x + 3$ by writing $\mathbf{C}(p)$ and checking the coefficients predicted by Theorem 6.10.2.

(d) Deduce that every monic polynomial of degree $n \geq 1$ over F is the characteristic polynomial of some $n \times n$ matrix over F.

Solution.

(a) The entries of $\mathbf{M}$ are: x at (j, j) for $j < n$; -1 at $(j+1, j)$; a_{j-1} at (j, n) for $j < n$; $x + a_{n-1}$ at (n, n); 0 elsewhere. Delete row i and column n. In the remaining matrix, rows $1, \ldots, i-1$ have non-zero entries only in columns $j-1$ and j for row j, all at most $i-1$; and rows $i+1, \ldots, n$ have non-zero entries only in columns $j-1$ and $j \leq n-1$, all at least i. So the matrix is block diagonal with blocks on rows and columns $\{1, \ldots, i-1\}$ and on rows $\{i+1, \ldots, n\}$, columns $\{i, \ldots, n-1\}$. The first block has x on its diagonal and -1 just below it, so it is lower triangular. In the second block, row j of $\mathbf{M}$ (for $j > i$) has -1 in column $j-1$, which is the diagonal position of the block, and x in column j, one step to the right; so it is upper triangular with diagonal $-1, \ldots, -1$. By Theorem 6.8.4 and Theorem 6.4.6 over $F[x]$ (both division-free), the minor is $M_{in} = x^{i-1}(-1)^{n-i}$, where an absent block contributes the factor 1 (for $i = 1$ or $i = n$ the matrix is a single triangular block). Hence $C_{in} = (-1)^{i+n}(-1)^{n-i}x^{i-1} = (-1)^{2n}x^{i-1} = x^{i-1}$.

(b) By Theorem 6.6.1 along column n, valid over $F[x]$,

$$\begin{aligned} p_{\mathbf{C}(p)} = \det \mathbf{M} &= \sum_{i=1}^{n-1} a_{i-1}\, x^{i-1} + (x + a_{n-1})\, x^{n-1} \\ &= a_0 + a_1 x + \cdots + a_{n-1}x^{n-1} + x^n = p. \end{aligned}$$

(c) Here $a_3 = 1$, $a_2 = 0$, $a_1 = -2$, $a_0 = 3$, so

$$\mathbf{C}(p) = \begin{pmatrix} 0 & 0 & 0 & -3 \\ 1 & 0 & 0 & 2 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & -1 \end{pmatrix}.$$

Its trace is -1, so Theorem 6.10.2 predicts the coefficient $1 = a_3$ at x^3, as in p. Its determinant, expanding along the first row, whose only non-zero entry is -3 in position $(1,4)$, is $(-3)(-1)^{1+4} \det \mathbf{I}_3 = 3$, since deleting row 1 and column 4 leaves $\mathbf{I}_3$. So the predicted constant term is $(-1)^4 \cdot 3 = 3 = a_0$.

(d) For $n \geq 2$, take $\mathbf{C}(p)$ and use (b). For $n = 1$, $p = x + a_0$ is $p_{(-a_0)}$.

Exercise C2: Nilpotent 2×2 matrices.

Let $\mathbf{A} \in M_2(F)$ satisfy $\mathbf{A}^k = 0$ for some $k \geq 1$.

(a) Show that the constant term of $p_{\mathbf{A}}$ is 0.

(b) By multiplying out, verify that $\mathbf{A}^2 - (\operatorname{tr} \mathbf{A})\mathbf{A} + (\det \mathbf{A})\mathbf{I} = 0$ for every $\mathbf{A} \in M_2(F)$.

(c) Deduce that $\operatorname{tr} \mathbf{A} = 0$, and hence $p_{\mathbf{A}} = x^2$ and $\mathbf{A}^2 = 0$.

(d) Give an example showing that $\mathbf{A}^2 = 0$ does not force $\mathbf{A} = 0$.

Solution.

(a) By Theorem 6.5.4, $(\det \mathbf{A})^k = \det(\mathbf{A}^k) = \det 0 = 0$, so $\det \mathbf{A} = 0$ because a field has no zero divisors (Theorem 0.7.1). The constant term is $(-1)^2 \det \mathbf{A} = 0$ by Theorem 6.10.2.

(b) Let $\mathbf{A} = \begin{pmatrix} a & b \\ c & d \end{pmatrix}$. Then $\mathbf{A}^2 = \begin{pmatrix} a^2 + bc & ab + bd \\ ca + dc & bc + d^2 \end{pmatrix}$ and $(a+d)\mathbf{A} = \begin{pmatrix} a^2 + ad & ab + bd \\ ac + dc & ad + d^2 \end{pmatrix}$. The difference is $\begin{pmatrix} bc - ad & 0 \\ 0 & bc - ad \end{pmatrix} = -(\det \mathbf{A})\mathbf{I}$, as claimed.

(c) By (a) and (b), $\mathbf{A}^2 = (\operatorname{tr} \mathbf{A})\mathbf{A}$. By induction, $\mathbf{A}^m = (\operatorname{tr} \mathbf{A})^{m-1}\mathbf{A}$ for all $m \geq 1$: if it holds for m, then $\mathbf{A}^{m+1} = (\operatorname{tr} \mathbf{A})^{m-1}\mathbf{A}^2 = (\operatorname{tr} \mathbf{A})^m \mathbf{A}$. If $\mathbf{A} = 0$, then $\operatorname{tr} \mathbf{A} = 0$. If $\mathbf{A} \neq 0$, then $0 = \mathbf{A}^k = (\operatorname{tr} \mathbf{A})^{k-1}\mathbf{A}$ forces $(\operatorname{tr} \mathbf{A})^{k-1} = 0$, since a non-zero matrix times a scalar is zero only if the scalar is zero; here $k \geq 2$, because $k = 1$ would give $\mathbf{A} = 0$. Hence $\operatorname{tr} \mathbf{A} = 0$ by Theorem 0.7.1 (f), applied repeatedly. So $p_{\mathbf{A}} = x^2 - 0 \cdot x + 0 = x^2$, and $\mathbf{A}^2 = (\operatorname{tr} \mathbf{A})\mathbf{A} = 0$.

(d) $\mathbf{A} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$ has $\mathbf{A}^2 = 0$ and $\mathbf{A} \neq 0$.

Exercise C3: Odd size over the reals.

Let n be odd and $\mathbf{A} \in M_n(\mathbb{R})$.

(a) Prove that there is $c \in \mathbb{R}$ and a non-zero $\mathbf{v} \in \mathbb{R}^n$ with $\mathbf{A}\mathbf{v} = c\mathbf{v}$.

(b) Show by an example that (a) fails for $n = 2$.

(c) Show that (a) holds for every $\mathbf{A} \in M_n(\mathbb{C})$ and every $n \geq 1$.

Solution.

(a) By Theorem 6.10.2, $p_{\mathbf{A}} \in \mathbb{R}[x]$ has odd degree n. By Corollary 5.5.9, it has a real root c. By Theorem 6.10.4, there is a non-zero $\mathbf{v} \in \mathbb{R}^n$ with $\mathbf{A}\mathbf{v} = c\mathbf{v}$.

(b) The rotation $\mathbf{R} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$ has $p_{\mathbf{R}} = x^2 + 1$, with no real root; by Theorem 6.10.4

no real c and non-zero real $\mathbf{v}$ satisfy $\mathbf{R}\mathbf{v} = c\mathbf{v}$.

(c) $p_{\mathbf{A}} \in \mathbb{C}[x]$ has degree $n \geq 1$, so it has a root $c \in \mathbb{C}$ by Theorem 5.5.1. Apply Theorem 6.10.4 over $F = \mathbb{C}$.

Chapter 7

Block Matrices

A large matrix often has structure that its entries hide. Split it into blocks, smaller matrices arranged in a grid, and the structure shows. A direct sum of subspaces becomes a block-diagonal matrix. A subspace that an operator maps into itself becomes a block of zeros in the corner. A system of equations that splits into two groups becomes a two-by-two system whose "entries" are matrices.

This chapter makes block arithmetic rigorous and then puts it to work. Multiplying block by block, eliminating a whole block at once, and taking the Schur complement $\mathbf{D} - \mathbf{C}\mathbf{A}^{-1}\mathbf{B}$ turn statements about big matrices into statements about small ones: ranks, determinants and inverses. The Kronecker product rewrites matrix equations such as $\mathbf{A}\mathbf{X} + \mathbf{X}\mathbf{B} = \mathbf{C}$ as ordinary linear systems. The chapter ends with a question that looks like it needs heavy machinery but does not: which matrices can be written as a commutator $\mathbf{X}\mathbf{Y} - \mathbf{Y}\mathbf{X}$?

What you need. From Chapter 0, matrix multiplication (Definition 0.9.9) and polynomials without zero divisors (Corollary 0.8.4). From Chapter 2, rank (Definition 2.5.4). From Chapter 3, the matrix of a linear map and change of basis (Definition 3.6.1, Theorem 3.7.3), quotient spaces (Definition 3.9.3), the rank inequalities (Theorem 3.8.5) and the trace (Definition 3.10.2). From Chapter 6, determinants of block triangular matrices and the characteristic polynomial (Theorem 6.8.4, Theorem 6.10.2).

7.0.1 Roadmap

- **Partitions and block multiplication.** Multiplying matrices block by block, and what block-diagonal and block-triangular shapes say about a linear map.
- **Rank and block matrices.** Rank inequalities proved by clearing blocks, including Frobenius's inequality.
- **Schur complements.** The Schur complement, the determinant, rank and inverse of a block matrix, the Woodbury formula, and determinants with commuting blocks over any field.
- **The Kronecker product.** A product of matrices of different sizes, and matrix equations turned into linear systems.
- **Commutators and trace-zero matrices.** Every trace-zero matrix over a field of characteristic zero is a commutator.

7.0.2 Named moves

- **Partition to match the structure.** Choose the blocks so that the zeros you know about sit in whole blocks.
- **Eliminate a block.** Multiply by an invertible block triangular matrix to clear a block, just as a row operation clears an entry.
- **Pass to the Schur complement.** Reduce a question about $\begin{pmatrix}\mathbf{A} & \mathbf{B}\\ \mathbf{C} & \mathbf{D}\end{pmatrix}$ with $\mathbf{A}$ invertible to a question about $\mathbf{A}$ and $\mathbf{D}-\mathbf{C}\mathbf{A}^{-1}\mathbf{B}$.
- **Vectorize.** Turn a linear equation in an unknown matrix $\mathbf{X}$ into a linear system in the entries of $\mathbf{X}$.
- **Adjoin an indeterminate.** To remove an invertibility hypothesis, replace $\mathbf{D}$ by $\mathbf{D}+x\mathbf{I}$, work over $F[x]$, and set $x=0$ at the end.

7.1 Partitions and Block Multiplication

A large matrix often has structure that its individual entries hide: a corner of zeros, a copy of the identity, a smaller matrix repeated. Chapter 6 already met one such shape, the block triangular matrix, and computed its determinant from two smaller determinants. This section makes the idea systematic. We cut matrices into rectangular pieces, prove that products can be computed piece by piece, and use the pieces to read off structure: direct sums become block diagonal matrices, and a subspace that an operator maps into itself becomes a zero block in the corner.

7.1.1 Cutting a matrix into blocks

Take two 4×4 matrices over $\mathbb{Q}$ whose top-right 2×2 corners are zero:

$$\mathbf{M}=\left(\begin{array}{cc|cc} 1 & 2 & 0 & 0\\ 0 & 1 & 0 & 0\\ \hline 1 & 0 & 2 & 1\\ 2 & 1 & 1 & 1\end{array}\right),\qquad \mathbf{N}=\left(\begin{array}{cc|cc} 1 & -1 & 0 & 0\\ 1 & 0 & 0 & 0\\ \hline 0 & 1 & 1 & 0\\ 1 & 1 & 3 & 1\end{array}\right).$$

The lines cut each matrix into four 2×2 pieces. Name them: $\mathbf{M}=\begin{pmatrix}\mathbf{A} & 0\\ \mathbf{C} & \mathbf{D}\end{pmatrix}$ and $\mathbf{N}=\begin{pmatrix}\mathbf{E} & 0\\ \mathbf{G} & \mathbf{H}\end{pmatrix}$, with $\mathbf{A}=\begin{pmatrix}1 & 2\\ 0 & 1\end{pmatrix}$, $\mathbf{C}=\begin{pmatrix}1 & 0\\ 2 & 1\end{pmatrix}$, and so on. If we pretend that the pieces are numbers and multiply as for 2×2 matrices, keeping the order of every product, we get

$$\mathbf{M}\mathbf{N}\overset{?}{=}\begin{pmatrix}\mathbf{A}\mathbf{E}+0\mathbf{G} & \mathbf{A}0+0\mathbf{H}\\ \mathbf{C}\mathbf{E}+\mathbf{D}\mathbf{G} & \mathbf{C}0+\mathbf{D}\mathbf{H}\end{pmatrix}=\begin{pmatrix}\mathbf{A}\mathbf{E} & 0\\ \mathbf{C}\mathbf{E}+\mathbf{D}\mathbf{G} & \mathbf{D}\mathbf{H}\end{pmatrix}.$$

With $\mathbf{A}\mathbf{E}=\begin{pmatrix}3 & -1\\ 1 & 0\end{pmatrix}$, $\mathbf{C}\mathbf{E}+\mathbf{D}\mathbf{G}=\begin{pmatrix}2 & 2\\ 4 & 0\end{pmatrix}$ and $\mathbf{D}\mathbf{H}=\begin{pmatrix}5 & 1\\ 4 & 1\end{pmatrix}$, this predicts

$$\mathbf{M}\mathbf{N}=\begin{pmatrix}3 & -1 & 0 & 0\\ 1 & 0 & 0 & 0\\ 2 & 2 & 5 & 1\\ 4 & 0 & 4 & 1\end{pmatrix},$$

and multiplying out the sixteen entries directly gives exactly this matrix. Two things happened. The zero corner of the product came for free, with no arithmetic. And the product of two 4×4 matrices became four products of 2×2 matrices, **AE**, **CE**, **DG** and **DH**; the other four products in the block formula have a zero factor and cost nothing. To use this safely we need to say precisely what "cutting" means and prove that the pretend multiplication is always correct.

Draw horizontal lines between rows and vertical lines between columns; the pieces are the blocks.

Definition 7.1.1 — Block Partition

Let $\mathbf{A} = (a_{ij}) \in M_{m\times n}(F)$. A **row partition** of $\mathbf{A}$ is a list of **positive** integers $m_1, \dots, m_a$ with $m_1 + \cdots + m_a = m$, and a **column partition** is a list of positive integers $n_1, \dots, n_b$ with $n_1 + \cdots + n_b = n$. Put $\mu_r = m_1 + \cdots + m_r$ and $\nu_s = n_1 + \cdots + n_s$, with $\mu_0 = \nu_0 = 0$. For $1 \le r \le a$ and $1 \le s \le b$, the (r, s) **block** of $\mathbf{A}$ is the matrix $\mathbf{A}_{rs} \in M_{m_r \times n_s}(F)$ with entries

$$(\mathbf{A}_{rs})_{ij} = a_{\mu_{r-1}+i,\ \nu_{s-1}+j} \qquad (1 \le i \le m_r,\ 1 \le j \le n_s).$$

We then write $\mathbf{A} = (\mathbf{A}_{rs})$, displayed as an $a \times b$ array of blocks, and call $\mathbf{A}$ a **block matrix**.

Let $\mathbf{B} \in M_{n\times p}(F)$. Partitions of $\mathbf{A}$ and $\mathbf{B}$ are **conformable** if the column partition of $\mathbf{A}$ and the row partition of $\mathbf{B}$ are **the same list** $n_1, \dots, n_b$, in the same order.

In words: the row partition says where the horizontal lines go. Block row r consists of the rows with indices in $I_r = \{\mu_{r-1}+1, \dots, \mu_r\}$, a run of m_r consecutive rows, and similarly block column s consists of the columns in $J_s = \{\nu_{s-1} + 1, \dots, \nu_s\}$. The block $\mathbf{A}_{rs}$ is what survives when we keep only the rows in I_r and the columns in J_s, renumbered from 1. Conformability says that the vertical lines through $\mathbf{A}$ sit at the same places as the horizontal lines through $\mathbf{B}$. That is exactly what will make each product "block of $\mathbf{A}$ times block of $\mathbf{B}$" defined.

Well-definedness. The runs $I_1, \dots, I_a$ are disjoint and cover $\{1, \dots, m\}$, and the same holds for $J_1, \dots, J_b$. So every entry of $\mathbf{A}$ lies in exactly one block. Conversely, if we are given matrices $\mathbf{A}_{rs} \in M_{m_r \times n_s}(F)$, there is exactly one $\mathbf{A} \in M_{m\times n}(F)$ with these blocks. Block sizes must fit: all blocks in block row r have m_r rows, and all blocks in block column s have n_s columns. We allow only positive parts, so no block is empty.

Examples.

- **Every entry a block.** With $m_r = 1$ and $n_s = 1$ for all r, s, the block $\mathbf{A}_{rs}$ is the 1×1 matrix (a_{rs}). A matrix is its own finest block matrix.
- **One block.** With $a = b = 1$, the single block is $\mathbf{A}$ itself. This degenerate partition matters because a statement about block matrices then says something about ordinary matrices, and the statement must not break.
- **Columns as blocks.** Row partition m, column partition $1, 1, \dots, 1$. The blocks are the n columns of $\mathbf{A}$: $\mathbf{A} = \begin{pmatrix} \mathbf{a}_1 & \cdots & \mathbf{a}_n \end{pmatrix}$, as in Chapter 0.
- **The hook.** For $\mathbf{M}$ and $\mathbf{N}$ above, both partitions are $2, 2$, so the column partition of $\mathbf{M}$ equals the row partition of $\mathbf{N}$: they are conformable.

Non-example by minimal change. Keep $\mathbf{M}$ with column partition $2, 2$, but cut $\mathbf{N}$ with row partition $1, 3$. The product $\mathbf{MN}$ is still defined, and both partitions are legitimate. What fails is conformability: the first block column of $\mathbf{M}$ has 2 columns, while the first block row of $\mathbf{N}$ has 1 row, so the "product" $\mathbf{A} \cdot \mathbf{N}_{11}$ of a 2×2 matrix with a 1×2 matrix is undefined.

Quick check. Let $\mathbf{A} \in M_{3\times 5}(F)$ have row partition $1, 2$ and column partition $3, 2$, and let $\mathbf{B} \in M_{5\times 4}(F)$ have row partition $2, 3$. Are the partitions conformable? What are the sizes of the blocks $\mathbf{A}_{21}$ and $\mathbf{B}_{2t}$?

Solution. No. The column partition of $\mathbf{A}$ is $3, 2$ and the row partition of $\mathbf{B}$ is $2, 3$. Both lists sum to 5, but they differ in order, and conformability asks for the same list. The block $\mathbf{A}_{21}$ is 2×3 (block row 2 has 2 rows, block column 1 has 3 columns), and every $\mathbf{B}_{2t}$ has 3 rows.

7.1.2 Block multiplication

Here is the theorem that justifies the computation in the hook. The proof is nothing but the entry formula for a product, with the sum over the middle index cut into the runs $J_1, \dots, J_b$.

Theorem 7.1.1 — Block Multiplication

Let $\mathbf{A} \in M_{m\times n}(F)$ and $\mathbf{B} \in M_{n\times p}(F)$ be conformably partitioned: $\mathbf{A}$ with row partition $m_1, \dots, m_a$ and column partition $n_1, \dots, n_b$, and $\mathbf{B}$ with row partition $n_1, \dots, n_b$ and column partition $p_1, \dots, p_c$. Partition $\mathbf{AB} \in M_{m\times p}(F)$ with row partition $m_1, \dots, m_a$ and column partition $p_1, \dots, p_c$. Then for all $1 \le r \le a$ and $1 \le t \le c$,

$$(\mathbf{AB})_{rt} = \sum_{s=1}^{b} \mathbf{A}_{rs}\mathbf{B}_{st} = \mathbf{A}_{r1}\mathbf{B}_{1t} + \mathbf{A}_{r2}\mathbf{B}_{2t} + \cdots + \mathbf{A}_{rb}\mathbf{B}_{bt}.$$

Each product $\mathbf{A}_{rs}\mathbf{B}_{st}$ is defined and lies in $M_{m_r\times p_t}(F)$.

Idea. Look at one entry of $\mathbf{AB}$, in row i^* and column k^*. It is a sum over the middle index $j = 1, \dots, n$. Cut that sum into the runs $J_1, \dots, J_b$ given by the common partition. The part over J_s pairs row i^* of $\mathbf{A}$, restricted to the columns of block column s, with column k^* of $\mathbf{B}$, restricted to the rows of block row s. That is one entry of $\mathbf{A}_{rs}\mathbf{B}_{st}$. The only real work is translating indices between the big matrix and the blocks.

Proof. Let μ_r, ν_s, ρ_t be the partial sums of the three partitions, as in Definition 7.1.1, and $J_s = \{\nu_{s-1}+1, \dots, \nu_s\}$. The block $\mathbf{A}_{rs}$ is $m_r \times n_s$ and $\mathbf{B}_{st}$ is $n_s \times p_t$, so their product is defined and is $m_r \times p_t$, as is the block $(\mathbf{AB})_{rt}$.

Fix r, t, and let $1 \le i \le m_r$ and $1 \le k \le p_t$. Put $i^* = \mu_{r-1} + i$ and $k^* = \rho_{t-1} + k$. By Definition 7.1.1 and Definition 0.9.9,

$$\big((\mathbf{AB})_{rt}\big)_{ik} = (\mathbf{AB})_{i^*k^*} = \sum_{j=1}^{n} a_{i^*j}\, b_{jk^*}.$$

The sets $J_1, \dots, J_b$ are disjoint with union $\{1, \dots, n\}$, so the finite sum may be grouped according to them. In the group for J_s, substitute $j = \nu_{s-1} + l$; as l runs through

$1, \dots, n_s$, j runs through J_s exactly once. Hence

$$\begin{aligned}\big((\mathbf{AB})_{rt}\big)_{ik} &= \sum_{s=1}^{b} \sum_{j \in J_s} a_{i^* j}\, b_{j k^*} \\ &= \sum_{s=1}^{b} \sum_{l=1}^{n_s} a_{\mu_{r-1}+i,\ \nu_{s-1}+l}\ b_{\nu_{s-1}+l,\ \rho_{t-1}+k} \\ &= \sum_{s=1}^{b} \sum_{l=1}^{n_s} (\mathbf{A}_{rs})_{il}\, (\mathbf{B}_{st})_{lk},\end{aligned}$$

where the last step is the definition of the blocks $\mathbf{A}_{rs}$ and $\mathbf{B}_{st}$. By Definition 0.9.9 the inner sum is $(\mathbf{A}_{rs}\mathbf{B}_{st})_{ik}$, and by Definition 0.9.6 the outer sum is the (i,k)-entry of $\sum_s \mathbf{A}_{rs}\mathbf{B}_{st}$. Since i and k were arbitrary, $(\mathbf{AB})_{rt} = \sum_s \mathbf{A}_{rs}\mathbf{B}_{st}$. This proves the theorem.

■

So conformably partitioned matrices multiply like matrices whose entries are matrices. The commonest case is a 2×2 block matrix:

$$\begin{pmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{C} & \mathbf{D} \end{pmatrix} \begin{pmatrix} \mathbf{A}' & \mathbf{B}' \\ \mathbf{C}' & \mathbf{D}' \end{pmatrix} = \begin{pmatrix} \mathbf{AA}' + \mathbf{BC}' & \mathbf{AB}' + \mathbf{BD}' \\ \mathbf{CA}' + \mathbf{DC}' & \mathbf{CB}' + \mathbf{DD}' \end{pmatrix},$$

whenever the partitions are conformable. Sums and scalar multiples of matrices with the same partition are also computed blockwise, straight from Definition 0.9.6 and Definition 0.9.7, since each entry lies in exactly one block.

Over a commutative ring. The proof uses only sums and products of entries and the regrouping of a finite sum. So block multiplication holds verbatim for matrices with entries in any commutative ring R in the sense of Chapter 6 §4, for instance $R = F[x]$. Section 3 uses this.

Warning. **Keep the order inside every block product.** The top-left block of the product above is $\mathbf{AA}' + \mathbf{BC}'$, not $\mathbf{A}'\mathbf{A} + \mathbf{C}'\mathbf{B}$: blocks are matrices, and matrices do not commute. In the hook, $\mathbf{CE} + \mathbf{DG} = \begin{pmatrix} 2 & 2 \\ 4 & 0 \end{pmatrix}$, while $\mathbf{EC} + \mathbf{GD} = \begin{pmatrix} 0 & 0 \\ 4 & 2 \end{pmatrix}$. For the same reason, the formula $ad - bc$ for a 2×2 determinant does **not** survive with blocks: in general $\det \begin{pmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{C} & \mathbf{D} \end{pmatrix} \neq \det(\mathbf{AD} - \mathbf{BC})$. Take $\mathbf{A} = \mathbf{I}_2$, $\mathbf{B} = \mathbf{E}_{12}$, $\mathbf{C} = \mathbf{E}_{21}$, $\mathbf{D} = \mathbf{E}_{11}$ in $M_2(\mathbb{Q})$. Then $\mathbf{AD} - \mathbf{BC} = \mathbf{E}_{11} - \mathbf{E}_{12}\mathbf{E}_{21} = \mathbf{E}_{11} - \mathbf{E}_{11} = 0$, with determinant 0. But

$$\mathbf{M} = \begin{pmatrix} 1 & 0 & 0 & 1 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 1 & 0 & 0 & 0 \end{pmatrix},$$

and subtracting row 4 from row 1, which does not change the determinant (Theorem 6.5.1), gives the permutation matrix that swaps $\mathbf{e}_1$ and $\mathbf{e}_4$, whose determinant is -1. So $\det \mathbf{M} = -1 \neq 0$. Section 3 shows that the formula does hold when $\mathbf{C}$ and $\mathbf{D}$ commute; here $\mathbf{CD} = \mathbf{E}_{21} \neq 0 = \mathbf{DC}$.

Transposing a block matrix transposes each block and reflects the array of blocks.

Proposition 7.1.2 — Transpose of a Block Matrix

Let $\mathbf{A} \in M_{m\times n}(F)$ have row partition $m_1,\dots,m_a$, column partition $n_1,\dots,n_b$ and blocks $\mathbf{A}_{rs}$. Give $\mathbf{A}^\top$ the row partition $n_1,\dots,n_b$ and the column partition $m_1,\dots,m_a$. Then $(\mathbf{A}^\top)_{sr} = (\mathbf{A}_{rs})^\top$. In particular $\begin{pmatrix}\mathbf{A} & \mathbf{B}\\ \mathbf{C} & \mathbf{D}\end{pmatrix}^\top = \begin{pmatrix}\mathbf{A}^\top & \mathbf{C}^\top\\ \mathbf{B}^\top & \mathbf{D}^\top\end{pmatrix}$.

Proof. For $1 \le j \le n_s$ and $1 \le i \le m_r$, by Definition 7.1.1 and Definition 0.9.10, $\big((\mathbf{A}^\top)_{sr}\big)_{ji} = (\mathbf{A}^\top)_{\nu_{s-1}+j,\ \mu_{r-1}+i} = a_{\mu_{r-1}+i,\ \nu_{s-1}+j} = (\mathbf{A}_{rs})_{ij} = \big((\mathbf{A}_{rs})^\top\big)_{ji}$.

■

7.1.3 Rows, columns and outer products

The finest and coarsest partitions turn Theorem 7.1.1 into facts we already know, and one mixed choice gives something new.

Partition $\mathbf{A} \in M_{m\times n}(F)$ trivially (one block) and $\mathbf{B} \in M_{n\times p}(F)$ into columns (row partition n, column partition $1,\dots,1$). These are conformable, and the theorem says that the k-th block of $\mathbf{AB}$, its k-th column, is $\mathbf{A}\mathbf{b}_k$. That is the column view of Theorem 0.9.2. Partitioning $\mathbf{A}$ into rows and $\mathbf{B}$ trivially gives the row view in the same way.

Now cut $\mathbf{A}$ into columns and $\mathbf{B}$ into rows. Both middle partitions are $1,1,\dots,1$ (with n ones), so they are conformable, and the product has a single block.

Corollary 7.1.3 — Outer Product Expansion

Let $\mathbf{A} \in M_{m\times n}(F)$ have columns $\mathbf{a}_1,\dots,\mathbf{a}_n \in F^m$, and let $\mathbf{B} \in M_{n\times p}(F)$ have rows $\mathbf{r}_1,\dots,\mathbf{r}_n \in M_{1\times p}(F)$. Then

$$\mathbf{AB} = \mathbf{a}_1\mathbf{r}_1 + \mathbf{a}_2\mathbf{r}_2 + \cdots + \mathbf{a}_n\mathbf{r}_n = \sum_{k=1}^{n} \mathbf{a}_k\mathbf{r}_k,$$

where each $\mathbf{a}_k\mathbf{r}_k \in M_{m\times p}(F)$ is column k of $\mathbf{A}$ times row k of $\mathbf{B}$.

Proof. Give $\mathbf{A}$ the row partition m and the column partition $1,\dots,1$, so that its blocks are $\mathbf{A}_{1k} = \mathbf{a}_k$; give $\mathbf{B}$ the row partition $1,\dots,1$ and the column partition p, so that $\mathbf{B}_{k1} = \mathbf{r}_k$. The partitions are conformable, and by Theorem 7.1.1 the single block of $\mathbf{AB}$ is $\sum_k \mathbf{A}_{1k}\mathbf{B}_{k1} = \sum_k \mathbf{a}_k\mathbf{r}_k$.

■

Each term $\mathbf{a}_k\mathbf{r}_k$ is a column times a row, an **outer product**, and it has rank at most 1: its columns are the multiples $r_{kj}\mathbf{a}_k$ of the single vector $\mathbf{a}_k$. So the corollary writes every product of an $m\times n$ and an $n\times p$ matrix as a sum of n matrices of rank at most one, in the spirit of Exercise (B3: Rank-one pieces), which writes a matrix of rank r as a sum of r rank-one matrices. For

example,

$$\begin{aligned}
&\begin{pmatrix} 1 & 2 \\ 3 & 4 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 & 2 \\ -1 & 1 & 1 \end{pmatrix} \\
&\quad = \begin{pmatrix} 1 \\ 3 \\ 0 \end{pmatrix} \begin{pmatrix} 1 & 0 & 2 \end{pmatrix} + \begin{pmatrix} 2 \\ 4 \\ 1 \end{pmatrix} \begin{pmatrix} -1 & 1 & 1 \end{pmatrix} \\
&\quad = \begin{pmatrix} 1 & 0 & 2 \\ 3 & 0 & 6 \\ 0 & 0 & 0 \end{pmatrix} + \begin{pmatrix} -2 & 2 & 2 \\ -4 & 4 & 4 \\ -1 & 1 & 1 \end{pmatrix} \\
&\quad = \begin{pmatrix} -1 & 2 & 4 \\ -1 & 4 & 10 \\ -1 & 1 & 1 \end{pmatrix},
\end{aligned}$$

which is the product computed entry by entry.

7.1.4 Block diagonal matrices

Diagonal matrices are the easiest matrices to compute with: they multiply, power and invert entry by entry along the diagonal. Replace the diagonal entries by square blocks and all of this survives, one block at a time.

A block diagonal matrix is several square matrices placed corner to corner along the diagonal, with zeros everywhere else.

Definition 7.1.2 — Block Diagonal Matrix

Let $k_1, \dots, k_r$ be positive integers and $\mathbf{A}_i \in M_{k_i}(F)$ **square** for each i. Their **direct sum** $\mathbf{A}_1 \oplus \cdots \oplus \mathbf{A}_r$ is the matrix in $M_{k_1+\cdots+k_r}(F)$ which, with row partition and column partition both equal to $k_1, \dots, k_r$, has (i,i) block $\mathbf{A}_i$ and (i,j) block 0 for $i \neq j$. A square matrix is **block diagonal with respect to** the partition $k_1, \dots, k_r$ if it has this form. For two blocks,

$$\mathbf{A} \oplus \mathbf{B} = \begin{pmatrix} \mathbf{A} & 0 \\ 0 & \mathbf{B} \end{pmatrix}.$$

In words: the same partition is used for rows and columns, so the diagonal blocks are square; the blocks on the diagonal may be anything; every block off the diagonal is zero. Whether a matrix is block diagonal depends on the partition, which is part of the statement.

Examples.

- **Diagonal matrices.** $\operatorname{diag}(d_1, \dots, d_n) = (d_1) \oplus \cdots \oplus (d_n)$, with all $k_i = 1$.
- **The identity.** $\mathbf{I}_k \oplus \mathbf{I}_l = \mathbf{I}_{k+l}$, and more generally $\mathbf{I}_k \oplus 0_l$ is the matrix of a projection (Corollary 3.10.2).
- **A genuine block.** $\begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix} \oplus (2) = \begin{pmatrix} 1 & 1 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 2 \end{pmatrix}$, with partition $2, 1$.
- **One block.** With $r = 1$, $\mathbf{A}_1$ itself. Every square matrix is block diagonal with respect to the trivial partition, which is why the partition must always be named.

Non-example by minimal change. Change the $(1,3)$-entry of the third example from 0 to 1. The partition $2,1$ still has square diagonal blocks $\begin{pmatrix}1&1\\0&1\end{pmatrix}$ and (2), and the $(2,1)$ block $\begin{pmatrix}0&0\end{pmatrix}$ is still zero. What fails is the clause that the $(1,2)$ block is zero: it is now $\begin{pmatrix}1\\0\end{pmatrix}$. The matrix is block upper triangular, which is treated below, but not block diagonal for this partition.

Why the symbol $\oplus$. The matrix $\mathbf{A}\oplus\mathbf{B}$ acts on $F^{k+l}=\operatorname{span}(\mathbf{e}_1,\dots,\mathbf{e}_k)\oplus\operatorname{span}(\mathbf{e}_{k+1},\dots,\mathbf{e}_{k+l})$ by sending each of the two summands into itself, acting as $\mathbf{A}$ on the first and as $\mathbf{B}$ on the second. The theorem on adapted bases below makes this precise for any operator and any direct sum, and it is the reason the same symbol is used.

> *Warning.* **$\mathbf{A}\oplus\mathbf{B}$ is a matrix, not a subspace, and the order matters.** For subspaces, $U\oplus W$ and $W\oplus U$ are the same set. For matrices, $(1)\oplus(2)=\operatorname{diag}(1,2)$ and $(2)\oplus(1)=\operatorname{diag}(2,1)$ are different matrices. They are similar (swap the two basis vectors), but they are not equal.

Theorem 7.1.4 — Arithmetic of Block Diagonal Matrices

Let $\mathbf{A},\mathbf{A}'\in M_k(F)$, $\mathbf{B},\mathbf{B}'\in M_l(F)$ and $c\in F$. Then:

(a) $(\mathbf{A}\oplus\mathbf{B})+(\mathbf{A}'\oplus\mathbf{B}')=(\mathbf{A}+\mathbf{A}')\oplus(\mathbf{B}+\mathbf{B}')$, $c(\mathbf{A}\oplus\mathbf{B})=c\mathbf{A}\oplus c\mathbf{B}$, and $(\mathbf{A}\oplus\mathbf{B})(\mathbf{A}'\oplus\mathbf{B}')=\mathbf{A}\mathbf{A}'\oplus\mathbf{B}\mathbf{B}'$;

(b) $(\mathbf{A}\oplus\mathbf{B})^j=\mathbf{A}^j\oplus\mathbf{B}^j$ for every $j\in\mathbb{N}$, and $p(\mathbf{A}\oplus\mathbf{B})=p(\mathbf{A})\oplus p(\mathbf{B})$ for every $p\in F[x]$;

(c) $\mathbf{A}\oplus\mathbf{B}$ is invertible if and only if $\mathbf{A}$ and $\mathbf{B}$ are both invertible, and then $(\mathbf{A}\oplus\mathbf{B})^{-1}=\mathbf{A}^{-1}\oplus\mathbf{B}^{-1}$;

(d) $\det(\mathbf{A}\oplus\mathbf{B})=\det\mathbf{A}\det\mathbf{B}$ and $\operatorname{tr}(\mathbf{A}\oplus\mathbf{B})=\operatorname{tr}\mathbf{A}+\operatorname{tr}\mathbf{B}$.

Proof.

(a) Sums and scalar multiples are computed blockwise, and by Theorem 7.1.1 the product has blocks $\mathbf{A}\mathbf{A}'+0\cdot0=\mathbf{A}\mathbf{A}'$, $\mathbf{A}0+0\mathbf{B}'=0$, $0\mathbf{A}'+\mathbf{B}0=0$ and $0\cdot0+\mathbf{B}\mathbf{B}'=\mathbf{B}\mathbf{B}'$.

(b) By induction on j. For $j=0$, $(\mathbf{A}\oplus\mathbf{B})^0=\mathbf{I}_{k+l}=\mathbf{I}_k\oplus\mathbf{I}_l$ by Definition 0.9.14. If $(\mathbf{A}\oplus\mathbf{B})^j=\mathbf{A}^j\oplus\mathbf{B}^j$, then $(\mathbf{A}\oplus\mathbf{B})^{j+1}=(\mathbf{A}^j\oplus\mathbf{B}^j)(\mathbf{A}\oplus\mathbf{B})=\mathbf{A}^{j+1}\oplus\mathbf{B}^{j+1}$ by (a). For $p=\sum_j c_jx^j$, (a) gives $p(\mathbf{A}\oplus\mathbf{B})=\sum_j c_j(\mathbf{A}^j\oplus\mathbf{B}^j)=\big(\sum_j c_j\mathbf{A}^j\big)\oplus\big(\sum_j c_j\mathbf{B}^j\big)=p(\mathbf{A})\oplus p(\mathbf{B})$.

(c) The matrix $\mathbf{A}\oplus\mathbf{B}$ is block upper triangular with square diagonal blocks, so $\det(\mathbf{A}\oplus\mathbf{B})=\det\mathbf{A}\det\mathbf{B}$ by Theorem 6.8.4. Its diagonal entries are those of $\mathbf{A}$ followed by those of $\mathbf{B}$, so the traces add (Definition 0.9.12).

(d) ($\Leftarrow$) By (a), $(\mathbf{A}\oplus\mathbf{B})(\mathbf{A}^{-1}\oplus\mathbf{B}^{-1})=\mathbf{I}_k\oplus\mathbf{I}_l=\mathbf{I}_{k+l}$, so by Theorem 2.4.5 $\mathbf{A}\oplus\mathbf{B}$ is invertible with inverse $\mathbf{A}^{-1}\oplus\mathbf{B}^{-1}$. ($\Rightarrow$) If $\mathbf{A}\oplus\mathbf{B}$ is invertible, then $\det\mathbf{A}\det\mathbf{B}\neq0$ by (d) and Theorem 6.5.2. A product in a field is non-zero only if both factors are (Theorem 0.7.1 (d)), so $\det\mathbf{A}\neq0\neq\det\mathbf{B}$, and both are invertible by Theorem 6.5.2.

■

By induction on the number of blocks, the same rules hold for $\mathbf{A}_1 \oplus \cdots \oplus \mathbf{A}_r$: everything is done block by block. For instance $\left(\begin{pmatrix}1 & 1\\ 0 & 1\end{pmatrix} \oplus (2)\right)^5 = \begin{pmatrix}1 & 5\\ 0 & 1\end{pmatrix} \oplus (32)$, since $\begin{pmatrix}1 & 1\\ 0 & 1\end{pmatrix}^j = \begin{pmatrix}1 & j\\ 0 & 1\end{pmatrix}$ by induction.

7.1.5 Block triangular matrices

Allow one more non-zero block: $\mathbf{M} = \begin{pmatrix}\mathbf{A} & \mathbf{B}\\ 0 & \mathbf{D}\end{pmatrix}$ with $\mathbf{A} \in M_k(F)$, $\mathbf{D} \in M_l(F)$ square and $\mathbf{B} \in M_{k\times l}(F)$. Such a matrix is **block upper triangular**; with the zero block above the diagonal instead, **block lower triangular**. Chapter 6 computed $\det \mathbf{M} = \det \mathbf{A} \det \mathbf{D}$ (Theorem 6.8.4). Products and inverses keep the shape.

Theorem 7.1.5 — Block Triangular Products and Inverses

Let $k, l \geq 1$, and let $\mathbf{M} = \begin{pmatrix}\mathbf{A} & \mathbf{B}\\ 0 & \mathbf{D}\end{pmatrix}$ and $\mathbf{M}' = \begin{pmatrix}\mathbf{A}' & \mathbf{B}'\\ 0 & \mathbf{D}'\end{pmatrix}$, with $\mathbf{A}, \mathbf{A}' \in M_k(F)$, $\mathbf{D}, \mathbf{D}' \in M_l(F)$ and $\mathbf{B}, \mathbf{B}' \in M_{k\times l}(F)$.

(a) $\mathbf{MM}' = \begin{pmatrix}\mathbf{AA}' & \mathbf{AB}' + \mathbf{BD}'\\ 0 & \mathbf{DD}'\end{pmatrix}$; in particular it is block upper triangular.

(b) $\mathbf{M}$ is invertible if and only if $\mathbf{A}$ and $\mathbf{D}$ are both invertible.

(c) In that case

$$\mathbf{M}^{-1} = \begin{pmatrix}\mathbf{A}^{-1} & -\mathbf{A}^{-1}\mathbf{B}\mathbf{D}^{-1}\\ 0 & \mathbf{D}^{-1}\end{pmatrix}.$$

Idea. Where does the formula come from? Solve $\mathbf{M}\begin{pmatrix}\mathbf{x}\\ \mathbf{y}\end{pmatrix} = \begin{pmatrix}\mathbf{f}\\ \mathbf{g}\end{pmatrix}$ by back substitution with blocks. The second block row says $\mathbf{Dy} = \mathbf{g}$, so $\mathbf{y} = \mathbf{D}^{-1}\mathbf{g}$. The first says $\mathbf{Ax}+\mathbf{By} = \mathbf{f}$, so $\mathbf{x} = \mathbf{A}^{-1}\mathbf{f} - \mathbf{A}^{-1}\mathbf{B}\mathbf{D}^{-1}\mathbf{g}$. Reading off the coefficients of $\mathbf{f}$ and $\mathbf{g}$ gives the four blocks of $\mathbf{M}^{-1}$. The proof only has to check the answer.

Proof.

(a) By Theorem 7.1.1, the blocks of $\mathbf{MM}'$ are $\mathbf{AA}' + \mathbf{B}0 = \mathbf{AA}'$, $\mathbf{AB}' + \mathbf{BD}'$, $0\mathbf{A}' + \mathbf{D}0 = 0$ and $0\mathbf{B}' + \mathbf{DD}' = \mathbf{DD}'$.

(b) By Theorem 6.8.4, $\det \mathbf{M} = \det \mathbf{A} \det \mathbf{D}$. By Theorem 6.5.2, $\mathbf{M}$ is invertible if and only if $\det \mathbf{A} \det \mathbf{D} \neq 0$, which in a field happens exactly when $\det \mathbf{A} \neq 0$ and $\det \mathbf{D} \neq 0$ (Theorem 0.7.1 (f) and (d)), that is, when $\mathbf{A}$ and $\mathbf{D}$ are both invertible.

(c) Let $\mathbf{X}$ be the displayed matrix. By (a) with $\mathbf{A}' = \mathbf{A}^{-1}$, $\mathbf{B}' = -\mathbf{A}^{-1}\mathbf{B}\mathbf{D}^{-1}$ and $\mathbf{D}' = \mathbf{D}^{-1}$,

$$\mathbf{MX} = \begin{pmatrix}\mathbf{A}\mathbf{A}^{-1} & -\mathbf{A}\mathbf{A}^{-1}\mathbf{B}\mathbf{D}^{-1} + \mathbf{B}\mathbf{D}^{-1}\\ 0 & \mathbf{D}\mathbf{D}^{-1}\end{pmatrix} = \begin{pmatrix}\mathbf{I}_k & 0\\ 0 & \mathbf{I}_l\end{pmatrix} = \mathbf{I}_{k+l}.$$

By Theorem 2.4.5, $\mathbf{X} = \mathbf{M}^{-1}$.

■

Transposing with Proposition 7.1.2 turns this into the lower triangular version: if $\mathbf{A}$ and $\mathbf{D}$ are invertible, then $\begin{pmatrix} \mathbf{A} & 0 \\ \mathbf{C} & \mathbf{D} \end{pmatrix}^{-1} = \begin{pmatrix} \mathbf{A}^{-1} & 0 \\ -\mathbf{D}^{-1}\mathbf{C}\mathbf{A}^{-1} & \mathbf{D}^{-1} \end{pmatrix}$. A special case is used constantly: $\begin{pmatrix} \mathbf{I}_k & \mathbf{X} \\ 0 & \mathbf{I}_l \end{pmatrix}^{-1} = \begin{pmatrix} \mathbf{I}_k & -\mathbf{X} \\ 0 & \mathbf{I}_l \end{pmatrix}$ for every $\mathbf{X} \in M_{k\times l}(F)$. Adding $\mathbf{X}$ times the second block of coordinates to the first is undone by subtracting it.

Quick check. The matrix $\mathbf{M} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix}$, with row partition $2,1$ and column partition $1,2$, has a zero lower-left block and is invertible. Does this contradict Theorem 7.1.5?

Solution. No. The theorem needs the diagonal blocks square, which means equal row and column partitions. Here the top-left block $\begin{pmatrix} 1 \\ 0 \end{pmatrix}$ is 2×1 and the bottom-right block $\begin{pmatrix} 1 & 0 \end{pmatrix}$ is 1×2, so "$\mathbf{A}$ is invertible" does not even make sense. (The lower-left block is the 1×1 entry in position $(3,1)$, which is 0.)

7.1.6 Matrices of operators in adapted bases

Now the shapes pay off. For an operator $T \in \mathcal{L}(V)$ and a subspace $U \subseteq V$, we say that T **maps** U **into** U if $T\mathbf{u} \in U$ for every $\mathbf{u} \in U$. Then the **restriction** $T|_U \colon U \to U$, $\mathbf{u} \mapsto T\mathbf{u}$, is an operator on U, linear because its values are those of T. Such subspaces are the subject of Chapter 8; here we only ask what they do to the matrix of T.

When $V = U \oplus W$ and a basis of U is followed by a basis of W, the combined list is a basis of V (Theorem 1.7.5), which we call **adapted** to the decomposition. If T maps both pieces into themselves, the matrix splits.

Theorem 7.1.6 — Direct Sums Give Block Diagonal Matrices

Let $V = U \oplus W$ be finite-dimensional with $U \neq \{\mathbf{0}\} \neq W$, let $\mathcal{B}_U = (\mathbf{u}_1, \dots, \mathbf{u}_k)$ and $\mathcal{B}_W = (\mathbf{w}_1, \dots, \mathbf{w}_l)$ be bases of U and W, and let $\mathcal{B} = (\mathbf{u}_1, \dots, \mathbf{u}_k, \mathbf{w}_1, \dots, \mathbf{w}_l)$. For $T \in \mathcal{L}(V)$, the following are equivalent:

(a) T maps U into U and W into W;

(b) $[T]_{\mathcal{B}}$ is block diagonal with respect to the partition k, l.

In that case $[T]_{\mathcal{B}} = [T|_U]_{\mathcal{B}_U} \oplus [T|_W]_{\mathcal{B}_W}$.

Proof. By Theorem 1.7.5, $\mathcal{B}$ is a basis of V. By Definition 3.6.1, column $j \le k$ of $[T]_{\mathcal{B}}$ holds the coordinates of $T\mathbf{u}_j$, and column $k+q$ those of $T\mathbf{w}_q$.

(a) $\Rightarrow$ (b). Since $T\mathbf{u}_j \in U = \operatorname{span}(\mathcal{B}_U)$, write $T\mathbf{u}_j = \sum_i a_{ij}\mathbf{u}_i$. By uniqueness of coordinates (Theorem 1.5.1), the last l entries of column j are 0 and the first k are $a_{1j}, \dots, a_{kj}$, which is column j of $[T|_U]_{\mathcal{B}_U}$. In the same way $T\mathbf{w}_q = \sum_p d_{pq}\mathbf{w}_p$, so column $k+q$ is 0 in its first k entries and equals column q of $[T|_W]_{\mathcal{B}_W}$ in its last l. This shows $[T]_{\mathcal{B}} = [T|_U]_{\mathcal{B}_U} \oplus [T|_W]_{\mathcal{B}_W}$.

(b) $\Rightarrow$ (a). If the $(2,1)$ block is zero, then the coordinates of each $T\mathbf{u}_j$ vanish in the

last l places, so $T\mathbf{u}_j \in \operatorname{span}(\mathcal{B}_U) = U$. For $\mathbf{u} = \sum_j c_j\mathbf{u}_j \in U$, linearity gives $T\mathbf{u} = \sum_j c_j T\mathbf{u}_j \in U$, since U is a subspace. The $(1,2)$ block being zero gives $T\mathbf{w}_q \in W$ in the same way, and hence T maps W into W.

■

For example, let $T = \frac{d^2}{dx^2}$ on $\mathbb{R}[x]_{\le 3} = U \oplus W$ with $U = \operatorname{span}(1, x^2)$ (even polynomials) and $W = \operatorname{span}(x, x^3)$ (odd polynomials). Since $T(1) = 0$, $T(x^2) = 2$, $T(x) = 0$ and $T(x^3) = 6x$, T maps each piece into itself, and in the basis $\mathcal{B} = (1, x^2, x, x^3)$

$$[T]_{\mathcal{B}} = \begin{pmatrix} 0 & 2 \\ 0 & 0 \end{pmatrix} \oplus \begin{pmatrix} 0 & 6 \\ 0 & 0 \end{pmatrix}.$$

In the standard order $(1, x, x^2, x^3)$ the same operator has the matrix with 2 in position $(1,3)$ and 6 in position $(2,4)$, which is not block diagonal for the partition $2,2$. **Ordering the basis to match the decomposition is part of the method.**

If T maps only one subspace U into itself, we can still take a basis of U first, but the remaining basis vectors need not be sent anywhere special. What survives is a zero block in the lower left, and the lower-right block turns out to describe the operator that T induces on the quotient V/U. This was Exercise (C2: The operator induced on a quotient) in Chapter 3; we now record it as a theorem, with its converse.

Theorem 7.1.7 — Subspaces Mapped into Themselves Give Block Triangular Matrices

Let V be finite-dimensional, $T \in \mathcal{L}(V)$, and U a subspace with $\{\mathbf{0}\} \neq U \neq V$. Let $\mathcal{B}_U = (\mathbf{u}_1, \dots, \mathbf{u}_k)$ be a basis of U, extended to a basis $\mathcal{B} = (\mathbf{u}_1, \dots, \mathbf{u}_k, \mathbf{w}_1, \dots, \mathbf{w}_l)$ of V.

(a) T maps U into U if and only if the lower-left $l \times k$ block of $[T]_{\mathcal{B}}$ is zero.

(b) In that case the rule $\bar{T}(\mathbf{v} + U) = T\mathbf{v} + U$ defines an operator $\bar{T}$ on V/U, and

$$[T]_{\mathcal{B}} = \begin{pmatrix} [T|_U]_{\mathcal{B}_U} & \mathbf{B} \\ 0 & [\bar{T}]_{\bar{\mathcal{B}}} \end{pmatrix}$$

for some $\mathbf{B} \in M_{k\times l}(F)$, where $\bar{\mathcal{B}} = (\mathbf{w}_1 + U, \dots, \mathbf{w}_l + U)$ is a basis of V/U.

Idea. Read the matrix one column at a time. The first k columns describe $T\mathbf{u}_j$, which lie in U exactly when their $\mathbf{w}$-coordinates vanish. The last l columns describe $T\mathbf{w}_q$, which may have any $\mathbf{u}$-part; passing to V/U erases that part and leaves precisely the $\mathbf{w}$-coordinates, which are the lower-right block.

Proof.

(a) Column $j \le k$ of $[T]_{\mathcal{B}}$ is the coordinate vector of $T\mathbf{u}_j$ (Definition 3.6.1), and by Theorem 1.5.1 its last l entries vanish if and only if $T\mathbf{u}_j \in \operatorname{span}(\mathbf{u}_1, \dots, \mathbf{u}_k) = U$. If T maps U into U, this holds for every j. Conversely, if it holds for every j, then for $\mathbf{u} = \sum_j c_j\mathbf{u}_j \in U$ we get $T\mathbf{u} = \sum_j c_j T\mathbf{u}_j \in U$, because U is a subspace.

(b) Let $\pi\colon V \to V/U$ be the quotient map, linear with kernel U (Theorem 3.9.4). The composite πT is linear (Theorem 3.4.2), and for $\mathbf{u} \in U$, $\pi(T\mathbf{u}) = \mathbf{0}$ because

$T\mathbf{u} \in U$. So $U \subseteq \ker(\pi T)$, and by Theorem 3.9.10 (a) there is exactly one linear $\bar{T}\colon V/U \to V/U$ with $\bar{T}(\mathbf{v}+U) = T\mathbf{v}+U$. By Theorem 3.9.5, $\bar{\mathcal{B}}$ is a basis of V/U.

By (a), the lower-left block is zero, and as in the proof of Theorem 7.1.6, the upper-left block is $[T|_U]_{\mathcal{B}_U}$. For $1 \le q \le l$, write $T\mathbf{w}_q = \sum_{i=1}^{k} b_{iq}\mathbf{u}_i + \sum_{p=1}^{l} d_{pq}\mathbf{w}_p$, so that column $k+q$ of $[T]_{\mathcal{B}}$ is $(b_{1q}, \dots, b_{kq}, d_{1q}, \dots, d_{lq})$. Applying the linear map π, and using $\pi(\mathbf{u}_i) = \mathbf{0}$,

$$\bar{T}(\mathbf{w}_q + U) = \pi(T\mathbf{w}_q) = \sum_{p=1}^{l} d_{pq}\,(\mathbf{w}_p + U).$$

By Definition 3.6.1, column q of $[\bar{T}]_{\bar{\mathcal{B}}}$ is $(d_{1q}, \dots, d_{lq})$, which is the lower-right part of column $k+q$ of $[T]_{\mathcal{B}}$. This proves (b), with $\mathbf{B} = (b_{iq})$.

■

The upper-left block depends only on the basis $\mathcal{B}_U$, and the lower-right block only on the cosets $\mathbf{w}_1+U, \dots, \mathbf{w}_l+U$. So replacing each $\mathbf{w}_q$ by $\mathbf{w}_q+\mathbf{u}'_q$ with $\mathbf{u}'_q \in U$ can change the top-right block $\mathbf{B}$, but leaves both diagonal blocks unchanged. The theorem splits T into two smaller operators, and every quantity that sees only diagonal blocks splits with it. By Theorem 6.8.4, $\det T = \det(T|_U)\det\bar{T}$. Applied over $F[x]$ (Chapter 6 §8 notes that the block triangular determinant holds over any commutative ring), $x\mathbf{I} - [T]_{\mathcal{B}} = \begin{pmatrix} x\mathbf{I}_k - [T|_U]_{\mathcal{B}_U} & -\mathbf{B} \\ 0 & x\mathbf{I}_l - [\bar{T}]_{\bar{\mathcal{B}}} \end{pmatrix}$ gives $p_T = p_{T|_U}\,p_{\bar{T}}$. Chapter 8 builds on exactly this factorization.

Example. (A Plane Mapped into Itself)

Let $T\colon \mathbb{R}^3 \to \mathbb{R}^3$, $T(x,y,z) = (y,z,x)$, and $U = \{(x,y,z) : x+y+z = 0\}$. Show that T maps U into U, find $[T]_{\mathcal{B}}$ for the basis $\mathcal{B} = (\mathbf{u}_1, \mathbf{u}_2, \mathbf{e}_3)$ with $\mathbf{u}_1 = (1,-1,0)$, $\mathbf{u}_2 = (0,1,-1)$, and interpret the lower-right block.

Solution. If $x+y+z = 0$, then the entries of $T(x,y,z) = (y,z,x)$ also sum to 0, so T maps U into U. The vectors $\mathbf{u}_1, \mathbf{u}_2$ lie in U and are independent (look at the first entries, then the last), and $\dim U = 2$ since U is the kernel of the non-zero functional $(x,y,z) \mapsto x+y+z$ (Theorem 3.3.1). So $(\mathbf{u}_1, \mathbf{u}_2)$ is a basis of U (Theorem 1.6.4), and $\mathcal{B}$ is a basis of $\mathbb{R}^3$: in a relation $a\mathbf{u}_1 + b\mathbf{u}_2 + c\mathbf{e}_3 = \mathbf{0}$, the entries sum to $c = 0$, and then $a = b = 0$, so $\mathcal{B}$ is an independent list of 3 vectors (Theorem 1.6.4). Now

$$\begin{aligned} T\mathbf{u}_1 &= (-1,0,1) = -\mathbf{u}_1 - \mathbf{u}_2, \\ T\mathbf{u}_2 &= (1,-1,0) = \mathbf{u}_1, \\ T\mathbf{e}_3 &= (0,1,0) = \mathbf{u}_2 + \mathbf{e}_3, \end{aligned}$$

so

$$[T]_{\mathcal{B}} = \left(\begin{array}{cc|c} -1 & 1 & 0 \\ -1 & 0 & 1 \\ \hline 0 & 0 & 1 \end{array}\right).$$

The lower-left block is zero, as Theorem 7.1.7 predicts. The lower-right block (1) says $\bar{T}(\mathbf{e}_3+U) = \mathbf{e}_3+U$, so $\bar{T}$ is the identity on the line $\mathbb{R}^3/U$. Indeed $T\mathbf{v}-\mathbf{v} = (y-x, z-y, x-z)$ has entries summing to 0, so $T\mathbf{v}+U = \mathbf{v}+U$ for every $\mathbf{v}$: T moves vectors, but never changes the sum of their coordinates, and that sum is all that $\mathbb{R}^3/U$ remembers.

7.1.7 Exercises

7.1.7.1 A. Check your understanding

Exercise A1.

(a) Define what it means for partitions of $\mathbf{A} \in M_{m\times n}(F)$ and $\mathbf{B} \in M_{n\times p}(F)$ to be conformable.

(b) State the block multiplication formula for $\begin{pmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{C} & \mathbf{D} \end{pmatrix}\begin{pmatrix} \mathbf{A}' & \mathbf{B}' \\ \mathbf{C}' & \mathbf{D}' \end{pmatrix}$.

(c) True or false: the top-left block of that product is $\mathbf{A}'\mathbf{A}+\mathbf{C}'\mathbf{B}$. Justify your answer.

(d) True or false: if $\mathbf{A} \in M_k(F)$ and $\mathbf{B} \in M_l(F)$, then $\mathbf{A} \oplus \mathbf{B} = \mathbf{B} \oplus \mathbf{A}$. Justify your answer.

(e) True or false: if $\mathbf{M} = \begin{pmatrix} \mathbf{A} & \mathbf{B} \\ 0 & \mathbf{D} \end{pmatrix}$ with $\mathbf{A}$, $\mathbf{D}$ square is invertible, then $\mathbf{M}^{-1}$ is block upper triangular. Justify your answer.

(f) In a basis whose first k vectors form a basis of U, what does a zero lower-left block of $[T]_{\mathcal{B}}$ say about T?

Solution.

(a) The column partition of $\mathbf{A}$ and the row partition of $\mathbf{B}$ are the same list $n_1, \dots, n_b$, in the same order (Definition 7.1.1).

(b) It is $\begin{pmatrix} \mathbf{A}\mathbf{A}' + \mathbf{B}\mathbf{C}' & \mathbf{A}\mathbf{B}' + \mathbf{B}\mathbf{D}' \\ \mathbf{C}\mathbf{A}' + \mathbf{D}\mathbf{C}' & \mathbf{C}\mathbf{B}' + \mathbf{D}\mathbf{D}' \end{pmatrix}$, provided the partitions are conformable (Theorem 7.1.1).

(c) False in general. The block is $\mathbf{A}\mathbf{A}' + \mathbf{B}\mathbf{C}'$, with each block of the left factor on the left. For 4×4 matrices with partition $2, 2$, take $\mathbf{A} = \mathbf{E}_{12}$, $\mathbf{A}' = \mathbf{E}_{21}$ in $M_2(F)$ and all other blocks zero. Then the top-left block of the product is $\mathbf{A}\mathbf{A}' = \mathbf{E}_{11}$, while $\mathbf{A}'\mathbf{A} + \mathbf{C}'\mathbf{B} = \mathbf{E}_{22}$.

(d) False. For $k = l = 1$, $(1) \oplus (2) = \operatorname{diag}(1, 2) \neq \operatorname{diag}(2, 1) = (2) \oplus (1)$.

(e) True. By Theorem 7.1.5 (b), $\mathbf{A}$ and $\mathbf{D}$ are invertible, and (c) gives $\mathbf{M}^{-1}$ with lower-left block 0.

(f) That T maps U into U (Theorem 7.1.7 (a)).

7.1.7.2 B. Practice

Exercise B1: Multiplying block matrices.

Let

$$\mathbf{M} = \left(\begin{array}{cc|c} 1 & 2 & 1 \\ 0 & 1 & -1 \\ \hline 2 & 0 & 3 \end{array}\right), \qquad \mathbf{N} = \left(\begin{array}{cc|c} 1 & 0 & 0 \\ 1 & 1 & 2 \\ \hline 1 & -1 & 1 \end{array}\right) \in M_3(\mathbb{Q}),$$

both with row and column partition $2, 1$.

(a) Compute $\mathbf{MN}$ blockwise, and check one block against the entry formula.

(b) Explain why the partitions would **not** be conformable if $\mathbf{N}$ were given the row partition $1, 2$ instead.

Solution.

(a) Write $\mathbf{M} = \begin{pmatrix} \mathbf{A} & \mathbf{b} \\ \mathbf{c} & d \end{pmatrix}$ and $\mathbf{N} = \begin{pmatrix} \mathbf{E} & \mathbf{f} \\ \mathbf{g} & h \end{pmatrix}$ with $\mathbf{A} = \begin{pmatrix} 1 & 2 \\ 0 & 1 \end{pmatrix}$, $\mathbf{b} = \begin{pmatrix} 1 \\ -1 \end{pmatrix}$, $\mathbf{c} = \begin{pmatrix} 2 & 0 \end{pmatrix}$, $d = (3)$, $\mathbf{E} = \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix}$, $\mathbf{f} = \begin{pmatrix} 0 \\ 2 \end{pmatrix}$, $\mathbf{g} = \begin{pmatrix} 1 & -1 \end{pmatrix}$, $h = (1)$. The partitions are conformable (both middle partitions are $2, 1$), so by Theorem 7.1.1

$$\mathbf{AE} + \mathbf{bg} = \begin{pmatrix} 3 & 2 \\ 1 & 1 \end{pmatrix} + \begin{pmatrix} 1 & -1 \\ -1 & 1 \end{pmatrix} = \begin{pmatrix} 4 & 1 \\ 0 & 2 \end{pmatrix},$$

$$\mathbf{Af} + \mathbf{b}h = \begin{pmatrix} 4 \\ 2 \end{pmatrix} + \begin{pmatrix} 1 \\ -1 \end{pmatrix} = \begin{pmatrix} 5 \\ 1 \end{pmatrix},$$

$$\mathbf{cE} + d\mathbf{g} = \begin{pmatrix} 2 & 0 \end{pmatrix} + \begin{pmatrix} 3 & -3 \end{pmatrix} = \begin{pmatrix} 5 & -3 \end{pmatrix}, \qquad \mathbf{cf} + dh = (0) + (3) = (3).$$

Hence

$$\mathbf{MN} = \begin{pmatrix} 4 & 1 & 5 \\ 0 & 2 & 1 \\ 5 & -3 & 3 \end{pmatrix}.$$

Check the $(3, 3)$-entry directly: row 3 of $\mathbf{M}$ is $(2, 0, 3)$ and column 3 of $\mathbf{N}$ is $(0, 2, 1)$, giving $0 + 0 + 3 = 3$.

(b) The column partition of $\mathbf{M}$ is $2, 1$, and the row partition $1, 2$ is a different list. Concretely, the top-left block $\mathbf{A}$ of $\mathbf{M}$ is 2×2, while the top-left block of $\mathbf{N}$ would be 1×2, and a 2×2 matrix cannot multiply a 1×2 matrix.

Exercise B2: Inverting a block triangular matrix.

Use Theorem 7.1.5 to find the inverse of

$$\mathbf{M} = \begin{pmatrix} 2 & 1 & 1 & 0 \\ 1 & 1 & 2 & 1 \\ 0 & 0 & 1 & 2 \\ 0 & 0 & 0 & 1 \end{pmatrix} \in M_4(\mathbb{Q}),$$

and check one block of $\mathbf{MM}^{-1}$.

Solution. With the partition $2, 2$, $\mathbf{M} = \begin{pmatrix} \mathbf{A} & \mathbf{B} \\ 0 & \mathbf{D} \end{pmatrix}$ with $\mathbf{A} = \begin{pmatrix} 2 & 1 \\ 1 & 1 \end{pmatrix}$, $\mathbf{B} = \begin{pmatrix} 1 & 0 \\ 2 & 1 \end{pmatrix}$, $\mathbf{D} = \begin{pmatrix} 1 & 2 \\ 0 & 1 \end{pmatrix}$. Both $\det \mathbf{A} = 1$ and $\det \mathbf{D} = 1$ are non-zero, so by Theorem 0.9.8

$$\mathbf{A}^{-1} = \begin{pmatrix} 1 & -1 \\ -1 & 2 \end{pmatrix}, \qquad \mathbf{D}^{-1} = \begin{pmatrix} 1 & -2 \\ 0 & 1 \end{pmatrix}.$$

Then $\mathbf{A}^{-1}\mathbf{B} = \begin{pmatrix} -1 & -1 \\ 3 & 2 \end{pmatrix}$ and $-\mathbf{A}^{-1}\mathbf{B}\mathbf{D}^{-1} = -\begin{pmatrix} -1 & 1 \\ 3 & -4 \end{pmatrix} = \begin{pmatrix} 1 & -1 \\ -3 & 4 \end{pmatrix}$. By Theo-

rem 7.1.5 (c),

$$\mathbf{M}^{-1} = \begin{pmatrix} 1 & -1 & 1 & -1 \\ -1 & 2 & -3 & 4 \\ 0 & 0 & 1 & -2 \\ 0 & 0 & 0 & 1 \end{pmatrix}.$$

Check the top-right block of $\mathbf{M}\mathbf{M}^{-1}$: $\mathbf{A}(-\mathbf{A}^{-1}\mathbf{B}\mathbf{D}^{-1}) + \mathbf{B}\mathbf{D}^{-1} = \begin{pmatrix} 2 & 1 \\ 1 & 1 \end{pmatrix}\begin{pmatrix} 1 & -1 \\ -3 & 4 \end{pmatrix} + \begin{pmatrix} 1 & 0 \\ 2 & 1 \end{pmatrix}\begin{pmatrix} 1 & -2 \\ 0 & 1 \end{pmatrix} = \begin{pmatrix} -1 & 2 \\ -2 & 3 \end{pmatrix} + \begin{pmatrix} 1 & -2 \\ 2 & -3 \end{pmatrix} = 0$, as it must be.

Exercise B3: A projection in an adapted basis.

Let $\mathbf{P} = \begin{pmatrix} 0 & 1 & -1 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \in M_3(\mathbb{R})$, $U = \operatorname{span}((1,1,0),(0,1,1))$ and $W = \operatorname{span}(\mathbf{e}_1)$.

(a) Show that $\mathbf{P}^2 = \mathbf{P}$, that $\mathbf{P}\mathbf{u} = \mathbf{u}$ for $\mathbf{u} \in U$ and $\mathbf{P}\mathbf{e}_1 = \mathbf{0}$, and that $\mathbb{R}^3 = U \oplus W$.

(b) Let $\mathcal{B} = ((1,1,0),(0,1,1),\mathbf{e}_1)$. Use Theorem 7.1.6 to write down $[T_{\mathbf{P}}]_{\mathcal{B}}$ without computing, and confirm it as $\mathbf{S}^{-1}\mathbf{P}\mathbf{S}$, where $\mathbf{S}$ has the vectors of $\mathcal{B}$ as columns.

(c) Hence find $\mathbf{P}^{100}$ and $\operatorname{tr}\mathbf{P}$.

Solution.

(a) Multiplying, $\mathbf{P}^2$ has rows $(0,1,-1)$, $(0,1,0)$, $(0,0,1)$, so $\mathbf{P}^2 = \mathbf{P}$. Also $\mathbf{P}(1,1,0) = (1,1,0)$, $\mathbf{P}(0,1,1) = (0,1,1)$ and $\mathbf{P}\mathbf{e}_1 = \mathbf{0}$ (the first column is zero), so $\mathbf{P}$ fixes every vector of U by linearity. The three vectors of $\mathcal{B}$ are the columns of $\mathbf{S} = \begin{pmatrix} 1 & 0 & 1 \\ 1 & 1 & 0 \\ 0 & 1 & 0 \end{pmatrix}$, and expanding along the last column, $\det\mathbf{S} = 1\cdot(1-0) = 1 \neq 0$. So $\mathbf{S}$ is invertible (Theorem 6.5.2), its columns form a basis of $\mathbb{R}^3$ (Theorem 2.4.4), and $\mathbb{R}^3 = U \oplus W$ by Theorem 1.7.5.

(b) $T_{\mathbf{P}}$ maps U into U (as the identity) and W into W (as zero). By Theorem 7.1.6, $[T_{\mathbf{P}}]_{\mathcal{B}} = \mathbf{I}_2 \oplus (0) = \operatorname{diag}(1,1,0)$. By Theorem 3.7.3, $[T_{\mathbf{P}}]_{\mathcal{B}} = \mathbf{S}^{-1}\mathbf{P}\mathbf{S}$. Here $\mathbf{S}^{-1} = \begin{pmatrix} 0 & 1 & -1 \\ 0 & 0 & 1 \\ 1 & -1 & 1 \end{pmatrix}$ (check $\mathbf{S}\mathbf{S}^{-1} = \mathbf{I}_3$), and $\mathbf{P}\mathbf{S}$ has columns $\mathbf{P}(1,1,0) = (1,1,0)$, $\mathbf{P}(0,1,1) = (0,1,1)$, $\mathbf{P}\mathbf{e}_1 = \mathbf{0}$, so $\mathbf{S}^{-1}\mathbf{P}\mathbf{S} = \mathbf{S}^{-1}\begin{pmatrix} 1 & 0 & 0 \\ 1 & 1 & 0 \\ 0 & 1 & 0 \end{pmatrix} = \operatorname{diag}(1,1,0)$.

(c) $\mathbf{P} = \mathbf{S}\operatorname{diag}(1,1,0)\mathbf{S}^{-1}$, so $\mathbf{P}^{100} = \mathbf{S}\operatorname{diag}(1,1,0)^{100}\mathbf{S}^{-1} = \mathbf{S}\operatorname{diag}(1,1,0)\mathbf{S}^{-1} = \mathbf{P}$ by Theorem 7.1.4 (b) (or directly from $\mathbf{P}^2 = \mathbf{P}$). By Theorem 3.7.5, $\operatorname{tr}\mathbf{P} = \operatorname{tr}\operatorname{diag}(1,1,0) = 2$, which matches $0+1+1$.

7.1.7.3 C. Going deeper

Exercise C1: Square-zero matrices of half rank.

Let $n \geq 1$.

(a) For $\mathbf{X} \in M_n(F)$, let $\mathbf{N}_\mathbf{X} = \begin{pmatrix} 0 & \mathbf{X} \\ 0 & 0 \end{pmatrix} \in M_{2n}(F)$. Show that $\mathbf{N}_\mathbf{X}^2 = 0$ and that $\operatorname{rank} \mathbf{N}_\mathbf{X} = \operatorname{rank} \mathbf{X}$.

(b) Let V have dimension $2n$, and let $T \in \mathcal{L}(V)$ satisfy $T^2 = 0$ and $\operatorname{rank} T = n$. Show that $\operatorname{im} T = \ker T$. Choose $\mathbf{w}_1, \ldots, \mathbf{w}_n$ with $(T\mathbf{w}_1, \ldots, T\mathbf{w}_n)$ a basis of $\operatorname{im} T$, and put $\mathbf{u}_i = T\mathbf{w}_i$. Prove that $\mathcal{B} = (\mathbf{u}_1, \ldots, \mathbf{u}_n, \mathbf{w}_1, \ldots, \mathbf{w}_n)$ is a basis of V and that $[T]_\mathcal{B} = \mathbf{N}_{\mathbf{I}_n}$.

(c) Deduce that for every invertible $\mathbf{X} \in M_n(F)$, the matrix $\mathbf{N}_\mathbf{X}$ is similar to $\mathbf{N}_{\mathbf{I}_n}$.

Hint: for the independence in (b), apply T.

Solution.

(a) By Theorem 7.1.1, $\mathbf{N}_\mathbf{X}^2 = \begin{pmatrix} 0 \cdot 0 + \mathbf{X} \cdot 0 & 0 \cdot \mathbf{X} + \mathbf{X} \cdot 0 \\ 0 & 0 \end{pmatrix} = 0$. The first n columns of $\mathbf{N}_\mathbf{X}$ are zero, and column $n + j$ is $\begin{pmatrix} \mathbf{x}_j \\ \mathbf{0} \end{pmatrix}$, where $\mathbf{x}_j$ is column j of $\mathbf{X}$. A combination $\sum_j c_j \begin{pmatrix} \mathbf{x}_j \\ \mathbf{0} \end{pmatrix}$ is zero exactly when $\sum_j c_j \mathbf{x}_j = \mathbf{0}$, so a list of these columns is independent exactly when the corresponding columns of $\mathbf{X}$ are. Hence $\dim \operatorname{col}(\mathbf{N}_\mathbf{X}) = \dim \operatorname{col}(\mathbf{X})$, that is, $\operatorname{rank} \mathbf{N}_\mathbf{X} = \operatorname{rank} \mathbf{X}$.

(b) If $\mathbf{v} = T\mathbf{x} \in \operatorname{im} T$, then $T\mathbf{v} = T^2\mathbf{x} = \mathbf{0}$, so $\operatorname{im} T \subseteq \ker T$. By Theorem 3.3.1, $\dim \ker T = 2n - n = n = \dim \operatorname{im} T$, so $\operatorname{im} T = \ker T$ by Theorem 1.6.8. The vectors $\mathbf{w}_i$ exist because $(T\mathbf{w}_1, \ldots, T\mathbf{w}_n)$ can be any basis of $\operatorname{im} T$, each of whose vectors is T of something.
Let $\sum_i a_i \mathbf{u}_i + \sum_i b_i \mathbf{w}_i = \mathbf{0}$. Applying T, and using $T\mathbf{u}_i = T^2\mathbf{w}_i = \mathbf{0}$, gives $\sum_i b_i \mathbf{u}_i = \mathbf{0}$. The $\mathbf{u}_i$ form a basis of $\operatorname{im} T$, so all $b_i = 0$, and then $\sum_i a_i \mathbf{u}_i = \mathbf{0}$ gives all $a_i = 0$. So $\mathcal{B}$ is a linearly independent list of $2n = \dim V$ vectors, hence a basis (Theorem 1.6.4). Since $T\mathbf{u}_i = \mathbf{0}$ and $T\mathbf{w}_i = \mathbf{u}_i$, column $i \le n$ of $[T]_\mathcal{B}$ is zero and column $n + i$ is $\mathbf{e}_i$. So $[T]_\mathcal{B} = \begin{pmatrix} 0 & \mathbf{I}_n \\ 0 & 0 \end{pmatrix} = \mathbf{N}_{\mathbf{I}_n}$.

(c) If $\mathbf{X}$ is invertible, then by (a) the operator $T = T_{\mathbf{N}_\mathbf{X}}$ on F^{2n} satisfies $T^2 = 0$ and $\operatorname{rank} T = \operatorname{rank} \mathbf{N}_\mathbf{X} = \operatorname{rank} \mathbf{X} = n$ (Theorem 3.6.5, and Theorem 2.4.4 for $\operatorname{rank} \mathbf{X} = n$). By (b) there is a basis $\mathcal{B}$ with $[T]_\mathcal{B} = \mathbf{N}_{\mathbf{I}_n}$. The matrix of T in the standard basis is $\mathbf{N}_\mathbf{X}$, so $\mathbf{N}_\mathbf{X}$ and $\mathbf{N}_{\mathbf{I}_n}$ are similar by Theorem 3.7.4.

Exercise C2: Powers of block triangular matrices.

Let $\mathbf{A} \in M_k(F)$, $\mathbf{D} \in M_l(F)$ and $\mathbf{B} \in M_{k \times l}(F)$, and let $\mathbf{M} = \begin{pmatrix} \mathbf{A} & \mathbf{B} \\ 0 & \mathbf{D} \end{pmatrix}$.

(a) Prove that for every $j \ge 1$,

$$\mathbf{M}^j = \begin{pmatrix} \mathbf{A}^j & \mathbf{S}_j \\ 0 & \mathbf{D}^j \end{pmatrix}, \qquad \mathbf{S}_j = \sum_{i=0}^{j-1} \mathbf{A}^i \mathbf{B} \mathbf{D}^{j-1-i}.$$

(b) Deduce that if $\mathbf{D} = 0$, then $\mathbf{M}^j = \begin{pmatrix} \mathbf{A}^j & \mathbf{A}^{j-1}\mathbf{B} \\ 0 & 0 \end{pmatrix}$ for $j \ge 1$, and that if moreover $\mathbf{A}^r = 0$, then $\mathbf{M}^{r+1} = 0$.

(c) For $\mathbf{A} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$, $\mathbf{B} = \begin{pmatrix} 1 \\ 1 \end{pmatrix}$ and $\mathbf{D} = (0)$, find the least j with $\mathbf{M}^j = 0$.

Solution.

(a) By induction on j. For $j = 1$, $\mathbf{S}_1 = \mathbf{A}^0\mathbf{B}\mathbf{D}^0 = \mathbf{B}$. Suppose the formula holds for j. By Theorem 7.1.5 (a),

$$\mathbf{M}^{j+1} = \mathbf{M}^j\mathbf{M} = \begin{pmatrix} \mathbf{A}^j\mathbf{A} & \mathbf{A}^j\mathbf{B} + \mathbf{S}_j\mathbf{D} \\ 0 & \mathbf{D}^j\mathbf{D} \end{pmatrix},$$

and $\mathbf{A}^j\mathbf{B} + \mathbf{S}_j\mathbf{D} = \mathbf{A}^j\mathbf{B}\mathbf{D}^0 + \sum_{i=0}^{j-1} \mathbf{A}^i\mathbf{B}\mathbf{D}^{j-i} = \sum_{i=0}^{j} \mathbf{A}^i\mathbf{B}\mathbf{D}^{j-i} = \mathbf{S}_{j+1}$. This completes the induction.

(b) If $\mathbf{D} = 0$, every term of $\mathbf{S}_j$ with $j - 1 - i \geq 1$ contains a factor $\mathbf{D} = 0$, and only $i = j - 1$ survives, with $\mathbf{D}^0 = \mathbf{I}_l$. So $\mathbf{S}_j = \mathbf{A}^{j-1}\mathbf{B}$ and $\mathbf{D}^j = 0$. If also $\mathbf{A}^r = 0$, then $\mathbf{M}^{r+1}$ has blocks $\mathbf{A}^{r+1} = 0$ and $\mathbf{A}^r\mathbf{B} = 0$, so $\mathbf{M}^{r+1} = 0$.

(c) Here $\mathbf{A}^2 = 0$, so $\mathbf{M}^3 = 0$ by (b). But $\mathbf{M}^2 = \begin{pmatrix} \mathbf{A}^2 & \mathbf{A}\mathbf{B} \\ 0 & 0 \end{pmatrix}$ with $\mathbf{A}\mathbf{B} = \begin{pmatrix} 1 \\ 0 \end{pmatrix} \neq \mathbf{0}$, so $\mathbf{M}^2 \neq 0$; and $\mathbf{M} \neq 0$. The least such j is 3. Explicitly, $\mathbf{M} = \begin{pmatrix} 0 & 1 & 1 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{pmatrix}$ and $\mathbf{M}^2 = \mathbf{E}_{13}$.

7.2 Rank and Block Matrices

Rank is the most robust number attached to a matrix, and Chapters 2 and 3 found several inequalities for it: the rank of a product is at most the rank of each factor, and Sylvester's inequality bounds it from below. Those proofs worked with subspaces. This section proves rank inequalities by a different and very mechanical method. We place the matrices we care about as blocks of one bigger matrix, and then change that matrix by block row and column operations, which never change the rank, until its rank can be read off. The method gives short proofs of the Frobenius inequality and of identities such as $\operatorname{rank}(\mathbf{I}_m - \mathbf{A}\mathbf{B}) + n = \operatorname{rank}(\mathbf{I}_n - \mathbf{B}\mathbf{A}) + m$, which are awkward to reach with subspaces alone.

7.2.1 Three basic inequalities

We start with what the shape of a block matrix alone says about its rank. Write $\begin{pmatrix} \mathbf{A} & \mathbf{B} \end{pmatrix}$ for the matrix obtained by placing $\mathbf{B}$ to the right of $\mathbf{A}$ (same number of rows), and $\begin{pmatrix} \mathbf{A} \\ \mathbf{C} \end{pmatrix}$ for $\mathbf{C}$ below $\mathbf{A}$ (same number of columns). In these results the blocks need **not** be square.

Theorem 7.2.1 — Rank Inequalities for Block Matrices

Let $\mathbf{A} \in M_{m\times k}(F)$, $\mathbf{B} \in M_{m\times l}(F)$, $\mathbf{C} \in M_{p\times k}(F)$ and $\mathbf{D} \in M_{p\times l}(F)$.

(a) $\max(\operatorname{rank}\mathbf{A}, \operatorname{rank}\mathbf{B}) \leq \operatorname{rank}\begin{pmatrix} \mathbf{A} & \mathbf{B} \end{pmatrix} \leq \operatorname{rank}\mathbf{A} + \operatorname{rank}\mathbf{B}$, and likewise $\max(\operatorname{rank}\mathbf{A}, \operatorname{rank}\mathbf{C}) \leq$

$$\operatorname{rank}\begin{pmatrix}\mathbf{A}\\ \mathbf{C}\end{pmatrix} \le \operatorname{rank}\mathbf{A} + \operatorname{rank}\mathbf{C}.$$

(b) $\operatorname{rank}\begin{pmatrix}\mathbf{A} & 0\\ 0 & \mathbf{D}\end{pmatrix} = \operatorname{rank}\mathbf{A} + \operatorname{rank}\mathbf{D}.$

(c) $\operatorname{rank}\begin{pmatrix}\mathbf{A} & \mathbf{B}\\ 0 & \mathbf{D}\end{pmatrix} \ge \operatorname{rank}\mathbf{A} + \operatorname{rank}\mathbf{D}$ and $\operatorname{rank}\begin{pmatrix}\mathbf{A} & 0\\ \mathbf{C} & \mathbf{D}\end{pmatrix} \ge \operatorname{rank}\mathbf{A} + \operatorname{rank}\mathbf{D}.$

Idea. Rank is the dimension of the column space, so look at columns. In (a) the columns of $\begin{pmatrix}\mathbf{A} & \mathbf{B}\end{pmatrix}$ are those of $\mathbf{A}$ together with those of $\mathbf{B}$, and dimensions of sums are at most sums of dimensions. In (b) the columns coming from $\mathbf{A}$ and from $\mathbf{D}$ live in two subspaces that meet only in $\mathbf{0}$. In (c) we cannot use the column space of $\mathbf{B}$, which is unknown, so instead we pick independent columns of $\mathbf{A}$ and of $\mathbf{D}$ and show that the columns of the big matrix standing above them are still independent: the zero block lets us peel off the $\mathbf{D}$-part first.

Proof. For $\mathbf{y} \in F^m$ and $\mathbf{z} \in F^p$, write $\begin{pmatrix}\mathbf{y}\\ \mathbf{z}\end{pmatrix} \in F^{m+p}$ for the stacked vector.

(a) The columns of $\begin{pmatrix}\mathbf{A} & \mathbf{B}\end{pmatrix}$ are the columns of $\mathbf{A}$ followed by the columns of $\mathbf{B}$, so its column space is $\operatorname{col}(\mathbf{A}) + \operatorname{col}(\mathbf{B})$ by Proposition 1.7.2. It contains $\operatorname{col}(\mathbf{A})$ and $\operatorname{col}(\mathbf{B})$, which gives the lower bound by Theorem 1.6.7, and by Theorem 1.7.3

$$\operatorname{rank}\begin{pmatrix}\mathbf{A} & \mathbf{B}\end{pmatrix} = \operatorname{rank}\mathbf{A} + \operatorname{rank}\mathbf{B} - \dim(\operatorname{col}\mathbf{A} \cap \operatorname{col}\mathbf{B}) \le \operatorname{rank}\mathbf{A} + \operatorname{rank}\mathbf{B}.$$

For the stacked matrix, Proposition 7.1.2 gives $\begin{pmatrix}\mathbf{A}\\ \mathbf{C}\end{pmatrix}^{\top} = \begin{pmatrix}\mathbf{A}^{\top} & \mathbf{C}^{\top}\end{pmatrix}$, and a matrix and its transpose have the same rank (Theorem 2.5.5). Apply the first part to $\mathbf{A}^{\top}$ and $\mathbf{C}^{\top}$.

(b) Let $\mathbf{M} = \begin{pmatrix}\mathbf{A} & 0\\ 0 & \mathbf{D}\end{pmatrix}$. Its first k columns are $\begin{pmatrix}\mathbf{a}_j\\ \mathbf{0}\end{pmatrix}$ and its last l columns are $\begin{pmatrix}\mathbf{0}\\ \mathbf{d}_q\end{pmatrix}$, where $\mathbf{a}_j$, $\mathbf{d}_q$ are the columns of $\mathbf{A}$, $\mathbf{D}$. So $\operatorname{col}(\mathbf{M}) = Y + Z$ with $Y = \{\begin{pmatrix}\mathbf{y}\\ \mathbf{0}\end{pmatrix} : \mathbf{y} \in \operatorname{col}\mathbf{A}\}$ and $Z = \{\begin{pmatrix}\mathbf{0}\\ \mathbf{z}\end{pmatrix} : \mathbf{z} \in \operatorname{col}\mathbf{D}\}$. A vector in $Y \cap Z$ has both parts zero, so $Y \cap Z = \{\mathbf{0}\}$. The map $\mathbf{y} \mapsto \begin{pmatrix}\mathbf{y}\\ \mathbf{0}\end{pmatrix}$ is linear and injective from $\operatorname{col}\mathbf{A}$ onto Y, so $\dim Y = \operatorname{rank}\mathbf{A}$ (Theorem 3.5.4); likewise $\dim Z = \operatorname{rank}\mathbf{D}$. By Theorem 1.7.3, $\operatorname{rank}\mathbf{M} = \operatorname{rank}\mathbf{A} + \operatorname{rank}\mathbf{D} - 0$.

(c) Let $\mathbf{M} = \begin{pmatrix}\mathbf{A} & \mathbf{B}\\ 0 & \mathbf{D}\end{pmatrix}$, $r = \operatorname{rank}\mathbf{A}$ and $s = \operatorname{rank}\mathbf{D}$. By Theorem 2.5.2 there are columns $\mathbf{a}_{j_1}, \dots, \mathbf{a}_{j_r}$ of $\mathbf{A}$ that are linearly independent, and columns $\mathbf{d}_{q_1}, \dots, \mathbf{d}_{q_s}$ of $\mathbf{D}$ that are linearly independent. The corresponding columns of $\mathbf{M}$ are $\begin{pmatrix}\mathbf{a}_{j_i}\\ \mathbf{0}\end{pmatrix}$ and $\begin{pmatrix}\mathbf{b}_{q_i}\\ \mathbf{d}_{q_i}\end{pmatrix}$, where $\mathbf{b}_q$ is column q of $\mathbf{B}$. Let

$$\sum_{i=1}^{r} \alpha_i \begin{pmatrix}\mathbf{a}_{j_i}\\ \mathbf{0}\end{pmatrix} + \sum_{i=1}^{s} \beta_i \begin{pmatrix}\mathbf{b}_{q_i}\\ \mathbf{d}_{q_i}\end{pmatrix} = \mathbf{0}.$$

The last p entries give $\sum_i \beta_i \mathbf{d}_{q_i} = \mathbf{0}$, so all $\beta_i = 0$. The first m entries then

give $\sum_i \alpha_i \mathbf{a}_{j_i} = \mathbf{0}$, so all $\alpha_i = 0$. Hence $\operatorname{col}(\mathbf{M})$ contains $r+s$ linearly independent vectors, and $\operatorname{rank}\mathbf{M} \geq r+s$ by Theorem 1.6.3. For the lower triangular shape, $\begin{pmatrix} \mathbf{A} & 0 \\ \mathbf{C} & \mathbf{D} \end{pmatrix}^\top = \begin{pmatrix} \mathbf{A}^\top & \mathbf{C}^\top \\ 0 & \mathbf{D}^\top \end{pmatrix}$ by Proposition 7.1.2; apply the first case and Theorem 2.5.5.

■

All three inequalities, the two in (a) and the one in (c), can be strict, and small witnesses show it. For $\mathbf{A} = \mathbf{B} = (1)$, $\operatorname{rank}\begin{pmatrix} 1 & 1 \end{pmatrix} = 1 < 2$: the two column spaces overlap. For $\mathbf{A} = \mathbf{e}_1$ and $\mathbf{B} = \mathbf{e}_2$ in F^2, $\operatorname{rank}\begin{pmatrix} \mathbf{e}_1 & \mathbf{e}_2 \end{pmatrix} = \operatorname{rank}\mathbf{I}_2 = 2 > \max(1,1)$: each block adds something the other lacks. For $\mathbf{A} = \mathbf{D} = (0)$ and $\mathbf{B} = (1)$, $\operatorname{rank}\begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} = 1 > 0+0$: the off-diagonal block contributes rank of its own. The proof of (a) says exactly when the upper bound is attained: $\operatorname{rank}\begin{pmatrix} \mathbf{A} & \mathbf{B} \end{pmatrix} = \operatorname{rank}\mathbf{A} + \operatorname{rank}\mathbf{B}$ if and only if $\operatorname{col}\mathbf{A} \cap \operatorname{col}\mathbf{B} = \{\mathbf{0}\}$.

Warning. **The ranks of the four blocks do not determine the rank of the whole.** Over $\mathbb{Q}$, $\begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix}$ and $\begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}$ have all four 1×1 blocks of rank 1, but ranks 1 and 2. Only special shapes, like the zero blocks in (b) and (c), turn block ranks into information about the whole matrix.

Quick check. Without computing, find rank $\begin{pmatrix} 1 & 2 & 0 & 0 & 0 \\ 2 & 4 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 3 \\ 0 & 0 & 0 & 1 & 5 \end{pmatrix}$.

Solution. With row partition $2,2$ and column partition $2,3$, the matrix is $\begin{pmatrix} \mathbf{A} & 0 \\ 0 & \mathbf{D} \end{pmatrix}$ with $\mathbf{A} = \begin{pmatrix} 1 & 2 \\ 2 & 4 \end{pmatrix}$ of rank 1 (the second row is twice the first) and $\mathbf{D} = \begin{pmatrix} 1 & 0 & 3 \\ 0 & 1 & 5 \end{pmatrix}$ of rank 2 (the first two columns are $\mathbf{e}_1, \mathbf{e}_2$). By Theorem 7.2.1 (b), the rank is $1+2=3$.

7.2.2 Block elimination

Gaussian elimination changes a matrix by row operations, which are multiplications by invertible matrices on the left, and the rank never changes. The same is true when the "rows" are whole block rows and the multipliers are matrices. The matrices that do this are the block triangular matrices with identity blocks on the diagonal from Theorem 7.1.5, together with block swaps.

Fix a partition of $\mathbf{M} = \begin{pmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{C} & \mathbf{D} \end{pmatrix} \in M_{(m+p)\times(k+l)}(F)$ with $\mathbf{A} \in M_{m\times k}(F)$. For matrices $\mathbf{X} \in M_{m\times p}(F)$ and $\mathbf{Y} \in M_{k\times l}(F)$, Theorem 7.1.1 gives

$$\begin{pmatrix} \mathbf{I}_m & \mathbf{X} \\ 0 & \mathbf{I}_p \end{pmatrix}\begin{pmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{C} & \mathbf{D} \end{pmatrix} = \begin{pmatrix} \mathbf{A}+\mathbf{XC} & \mathbf{B}+\mathbf{XD} \\ \mathbf{C} & \mathbf{D} \end{pmatrix},$$
$$\begin{pmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{C} & \mathbf{D} \end{pmatrix}\begin{pmatrix} \mathbf{I}_k & \mathbf{Y} \\ 0 & \mathbf{I}_l \end{pmatrix} = \begin{pmatrix} \mathbf{A} & \mathbf{AY}+\mathbf{B} \\ \mathbf{C} & \mathbf{CY}+\mathbf{D} \end{pmatrix}.$$

In words: multiplying on the **left** adds $\mathbf{X}$ times block row 2 to block row 1, with $\mathbf{X}$ on the left

of the row; multiplying on the **right** adds block column 1 times $\mathbf{Y}$ to block column 2, with $\mathbf{Y}$ on the right of the column. The lower triangular multipliers $\begin{pmatrix} \mathbf{I}_m & 0 \\ \mathbf{X}' & \mathbf{I}_p \end{pmatrix}$ and $\begin{pmatrix} \mathbf{I}_k & 0 \\ \mathbf{Y}' & \mathbf{I}_l \end{pmatrix}$ act the same way in the other direction. Sides matter: the multiplier sits on the side of the product where the matrix operation happens.

Theorem 7.2.2 — Block Elimination Preserves Rank

Let $\mathbf{M} = \begin{pmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{C} & \mathbf{D} \end{pmatrix}$ be as above.

(a) For all $\mathbf{X} \in M_{m\times p}(F)$, $\mathbf{X}' \in M_{p\times m}(F)$, $\mathbf{Y} \in M_{k\times l}(F)$ and $\mathbf{Y}' \in M_{l\times k}(F)$, the matrices

$$\begin{pmatrix} \mathbf{I}_m & \mathbf{X} \\ 0 & \mathbf{I}_p \end{pmatrix}, \quad \begin{pmatrix} \mathbf{I}_m & 0 \\ \mathbf{X}' & \mathbf{I}_p \end{pmatrix}, \quad \begin{pmatrix} \mathbf{I}_k & \mathbf{Y} \\ 0 & \mathbf{I}_l \end{pmatrix}, \quad \begin{pmatrix} \mathbf{I}_k & 0 \\ \mathbf{Y}' & \mathbf{I}_l \end{pmatrix}$$

are invertible, and so are the block swaps $\begin{pmatrix} 0 & \mathbf{I}_p \\ \mathbf{I}_m & 0 \end{pmatrix} \in M_{m+p}(F)$ and $\begin{pmatrix} 0 & \mathbf{I}_k \\ \mathbf{I}_l & 0 \end{pmatrix} \in M_{k+l}(F)$. Hence multiplying $\mathbf{M}$ on the left or right by any product of such matrices does not change its rank. The swaps give $\begin{pmatrix} 0 & \mathbf{I}_p \\ \mathbf{I}_m & 0 \end{pmatrix}\mathbf{M} = \begin{pmatrix} \mathbf{C} & \mathbf{D} \\ \mathbf{A} & \mathbf{B} \end{pmatrix}$ and $\mathbf{M}\begin{pmatrix} 0 & \mathbf{I}_k \\ \mathbf{I}_l & 0 \end{pmatrix} = \begin{pmatrix} \mathbf{B} & \mathbf{A} \\ \mathbf{D} & \mathbf{C} \end{pmatrix}$.

(b) If $\operatorname{col}(\mathbf{B}) \subseteq \operatorname{col}(\mathbf{A})$, or if $\operatorname{row}(\mathbf{B}) \subseteq \operatorname{row}(\mathbf{D})$, then $\operatorname{rank}\begin{pmatrix} \mathbf{A} & \mathbf{B} \\ 0 & \mathbf{D} \end{pmatrix} = \operatorname{rank}\mathbf{A} + \operatorname{rank}\mathbf{D}$.

Proof.

(a) By Theorem 7.1.5 (c), with identity blocks on the diagonal, $\begin{pmatrix} \mathbf{I}_m & \mathbf{X} \\ 0 & \mathbf{I}_p \end{pmatrix}$ has inverse $\begin{pmatrix} \mathbf{I}_m & -\mathbf{X} \\ 0 & \mathbf{I}_p \end{pmatrix}$; the lower triangular case follows by transposing (Proposition 7.1.2, Theorem 0.9.7). In the swap $\mathbf{S} = \begin{pmatrix} 0 & \mathbf{I}_p \\ \mathbf{I}_m & 0 \end{pmatrix}$ the row partition is p, m and the column partition is m, p. Let $\mathbf{S}' = \begin{pmatrix} 0 & \mathbf{I}_m \\ \mathbf{I}_p & 0 \end{pmatrix}$, with row partition m, p and column partition p, m. These are conformable, and Theorem 7.1.1 gives $\mathbf{S}'\mathbf{S} = \begin{pmatrix} \mathbf{I}_m & 0 \\ 0 & \mathbf{I}_p \end{pmatrix} = \mathbf{I}_{m+p}$, so $\mathbf{S}$ is invertible by Theorem 2.4.5; the other swap is the same with k, l in place of m, p. The two displayed products are Theorem 7.1.1. Rank is unchanged by invertible factors on either side (Theorem 2.5.9).

(b) Suppose $\operatorname{col}(\mathbf{B}) \subseteq \operatorname{col}(\mathbf{A})$. Each column $\mathbf{b}_q$ of $\mathbf{B}$ is then $\mathbf{A}\mathbf{y}_q$ for some $\mathbf{y}_q \in F^k$ (Definition 2.5.1, Theorem 0.9.3). Let $\mathbf{Y} \in M_{k\times l}(F)$ have columns $\mathbf{y}_q$, so that $\mathbf{AY} = \mathbf{B}$ by Theorem 0.9.2. By the computation before the theorem,

$$\begin{pmatrix} \mathbf{A} & \mathbf{B} \\ 0 & \mathbf{D} \end{pmatrix}\begin{pmatrix} \mathbf{I}_k & -\mathbf{Y} \\ 0 & \mathbf{I}_l \end{pmatrix} = \begin{pmatrix} \mathbf{A} & -\mathbf{AY} + \mathbf{B} \\ 0 & \mathbf{D} \end{pmatrix} = \begin{pmatrix} \mathbf{A} & 0 \\ 0 & \mathbf{D} \end{pmatrix},$$

and (a) together with Theorem 7.2.1 (b) gives the claim. If $\operatorname{row}(\mathbf{B}) \subseteq \operatorname{row}(\mathbf{D})$, the same argument applied to rows gives $\mathbf{B} = \mathbf{XD}$ for some $\mathbf{X} \in M_{m\times p}(F)$, and

$$\begin{pmatrix} \mathbf{I}_m & -\mathbf{X} \\ 0 & \mathbf{I}_p \end{pmatrix} \begin{pmatrix} \mathbf{A} & \mathbf{B} \\ 0 & \mathbf{D} \end{pmatrix} = \begin{pmatrix} \mathbf{A} & 0 \\ 0 & \mathbf{D} \end{pmatrix}.$$

■

Part (b) is the typical use of (a): a block that is a multiple of a neighboring block can be cleared, exactly as an entry below a pivot is cleared in Gaussian elimination. The zero block of Theorem 7.2.1 (c) is what lets the cleared matrix fall apart into a direct sum.

7.2.3 Frobenius's inequality by blocks

Recall Sylvester's rank inequality (Theorem 3.8.5): for $\mathbf{A} \in M_{m\times n}(F)$ and $\mathbf{B} \in M_{n\times p}(F)$, $\operatorname{rank}(\mathbf{AB}) \geq \operatorname{rank}\mathbf{A} + \operatorname{rank}\mathbf{B} - n$. In Exercise (C1: Frobenius's rank inequality) we met a stronger statement, Frobenius's inequality, and proved it by comparing intersections of subspaces with a null space. Here is a proof in which nothing is chosen: we write down one block matrix whose rank we know, and eliminate.

Theorem 7.2.3 — Frobenius's Rank Inequality

Let $\mathbf{A} \in M_{m\times n}(F)$, $\mathbf{B} \in M_{n\times p}(F)$ and $\mathbf{C} \in M_{p\times q}(F)$. Then

$$\operatorname{rank}(\mathbf{ABC}) + \operatorname{rank}\mathbf{B} \geq \operatorname{rank}(\mathbf{AB}) + \operatorname{rank}(\mathbf{BC}).$$

Idea. The left side is the rank of $\begin{pmatrix} \mathbf{ABC} & 0 \\ 0 & \mathbf{B} \end{pmatrix}$, by Theorem 7.2.1 (b). The right side is a lower bound for any block triangular matrix with diagonal blocks $\mathbf{AB}$ and $\mathbf{BC}$, by part (c). So we want to turn the first matrix into the second by block elimination. Found backwards: $\mathbf{A}$ times the second block row puts $\mathbf{AB}$ into the top-right corner; then the second block column times $\mathbf{C}$ cancels $\mathbf{ABC}$ and puts $\mathbf{BC}$ into the bottom-left corner. A swap of the two block columns finishes the job.

Proof. Let $\mathbf{P} = \begin{pmatrix} \mathbf{ABC} & 0 \\ 0 & \mathbf{B} \end{pmatrix}$, with row partition m, n and column partition q, p. By Theorem 7.2.1 (b), $\operatorname{rank}\mathbf{P} = \operatorname{rank}(\mathbf{ABC}) + \operatorname{rank}\mathbf{B}$. By Theorem 7.1.1,

$$\begin{pmatrix} \mathbf{I}_m & \mathbf{A} \\ 0 & \mathbf{I}_n \end{pmatrix} \mathbf{P} = \begin{pmatrix} \mathbf{ABC} & \mathbf{AB} \\ 0 & \mathbf{B} \end{pmatrix},$$

$$\begin{pmatrix} \mathbf{ABC} & \mathbf{AB} \\ 0 & \mathbf{B} \end{pmatrix} \begin{pmatrix} \mathbf{I}_q & 0 \\ -\mathbf{C} & \mathbf{I}_p \end{pmatrix} = \begin{pmatrix} \mathbf{ABC} - \mathbf{ABC} & \mathbf{AB} \\ -\mathbf{BC} & \mathbf{B} \end{pmatrix} = \begin{pmatrix} 0 & \mathbf{AB} \\ -\mathbf{BC} & \mathbf{B} \end{pmatrix}.$$

Multiplying on the right by the block swap $\begin{pmatrix} 0 & \mathbf{I}_q \\ \mathbf{I}_p & 0 \end{pmatrix}$ exchanges the two block columns and gives $\mathbf{Q} = \begin{pmatrix} \mathbf{AB} & 0 \\ \mathbf{B} & -\mathbf{BC} \end{pmatrix}$. By Theorem 7.2.2 (a), $\operatorname{rank}\mathbf{Q} = \operatorname{rank}\mathbf{P}$. By Theorem 7.2.1 (c), $\operatorname{rank}\mathbf{Q} \geq \operatorname{rank}(\mathbf{AB}) + \operatorname{rank}(-\mathbf{BC}) = \operatorname{rank}(\mathbf{AB}) + \operatorname{rank}(\mathbf{BC})$, where $\operatorname{rank}(-\mathbf{BC}) = \operatorname{rank}(\mathbf{BC})$ because $-\mathbf{BC}$ and $\mathbf{BC}$ have the same column space. Hence $\operatorname{rank}(\mathbf{ABC}) + \operatorname{rank}\mathbf{B} \geq \operatorname{rank}(\mathbf{AB}) + \operatorname{rank}(\mathbf{BC})$.

■

Taking $\mathbf{B} = \mathbf{I}_n$ gives $\operatorname{rank}(\mathbf{AC}) + n \geq \operatorname{rank}\mathbf{A} + \operatorname{rank}\mathbf{C}$ for $\mathbf{A} \in M_{m\times n}(F)$ and $\mathbf{C} \in M_{n\times q}(F)$, which is Sylvester's inequality again. Taking $\mathbf{A} = \mathbf{I}_n$ or $\mathbf{C} = \mathbf{I}_p$ gives an equality and no information, as it should. The inequality says that multiplying by $\mathbf{A}$ on the left loses at least as much rank from $\mathbf{BC}$ as from $\mathbf{B}$: the rank lost is $\operatorname{rank}(\mathbf{BC}) - \operatorname{rank}(\mathbf{ABC}) \leq \operatorname{rank}\mathbf{B} - \operatorname{rank}(\mathbf{AB})$. A smaller column space has less to lose.

7.2.4 A worked example: $\mathbf{I} - \mathbf{AB}$ and $\mathbf{I} - \mathbf{BA}$

Products in the two orders, $\mathbf{AB}$ and $\mathbf{BA}$, are different matrices of possibly different sizes, and Chapter 3 showed that even their ranks can differ. Yet $\mathbf{I} - \mathbf{AB}$ and $\mathbf{I} - \mathbf{BA}$ are tightly linked. The block matrix that links them contains $\mathbf{I}_m$, $\mathbf{A}$, $\mathbf{B}$ and $\mathbf{I}_n$, and each identity block can be used as a pivot to clear its neighbors.

Example. (Rank of $\mathbf{I} - \mathbf{AB}$ versus $\mathbf{I} - \mathbf{BA}$)

Let $\mathbf{A} \in M_{m\times n}(F)$ and $\mathbf{B} \in M_{n\times m}(F)$.

(a) Prove that $\operatorname{rank}(\mathbf{I}_m - \mathbf{AB}) + n = \operatorname{rank}(\mathbf{I}_n - \mathbf{BA}) + m$.

(b) Deduce that for $m = n$, $\operatorname{rank}(\mathbf{I}_n - \mathbf{AB}) = \operatorname{rank}(\mathbf{I}_n - \mathbf{BA})$, and $\mathbf{I}_n - \mathbf{AB}$ is invertible if and only if $\mathbf{I}_n - \mathbf{BA}$ is.

(c) Check (a) for $\mathbf{A} = \begin{pmatrix} 1 & 1 & 0 \\ 0 & 1 & 1 \end{pmatrix}$ and $\mathbf{B} = \begin{pmatrix} 1 & 0 \\ 0 & 0 \\ 0 & 1 \end{pmatrix}$ over $\mathbb{Q}$.

Solution.

(a) Let $\mathbf{M} = \begin{pmatrix} \mathbf{I}_m & \mathbf{A} \\ \mathbf{B} & \mathbf{I}_n \end{pmatrix} \in M_{m+n}(F)$, with partition m, n for rows and columns. We eliminate in two different ways.
Using $\mathbf{I}_m$ as the pivot. Subtract $\mathbf{B}$ times block row 1 from block row 2, then subtract block column 1 times $\mathbf{A}$ from block column 2. By Theorem 7.1.1,

$$\begin{pmatrix} \mathbf{I}_m & 0 \\ -\mathbf{B} & \mathbf{I}_n \end{pmatrix} \mathbf{M} = \begin{pmatrix} \mathbf{I}_m & \mathbf{A} \\ 0 & \mathbf{I}_n - \mathbf{BA} \end{pmatrix},$$
$$\begin{pmatrix} \mathbf{I}_m & \mathbf{A} \\ 0 & \mathbf{I}_n - \mathbf{BA} \end{pmatrix} \begin{pmatrix} \mathbf{I}_m & -\mathbf{A} \\ 0 & \mathbf{I}_n \end{pmatrix} = \begin{pmatrix} \mathbf{I}_m & 0 \\ 0 & \mathbf{I}_n - \mathbf{BA} \end{pmatrix}.$$

By Theorem 7.2.2 (a) and Theorem 7.2.1 (b), $\operatorname{rank}\mathbf{M} = m + \operatorname{rank}(\mathbf{I}_n - \mathbf{BA})$.
Using $\mathbf{I}_n$ as the pivot. Subtract $\mathbf{A}$ times block row 2 from block row 1, then subtract block column 2 times $\mathbf{B}$ from block column 1:

$$\begin{pmatrix} \mathbf{I}_m & -\mathbf{A} \\ 0 & \mathbf{I}_n \end{pmatrix} \mathbf{M} = \begin{pmatrix} \mathbf{I}_m - \mathbf{AB} & 0 \\ \mathbf{B} & \mathbf{I}_n \end{pmatrix},$$
$$\begin{pmatrix} \mathbf{I}_m - \mathbf{AB} & 0 \\ \mathbf{B} & \mathbf{I}_n \end{pmatrix} \begin{pmatrix} \mathbf{I}_m & 0 \\ -\mathbf{B} & \mathbf{I}_n \end{pmatrix} = \begin{pmatrix} \mathbf{I}_m - \mathbf{AB} & 0 \\ 0 & \mathbf{I}_n \end{pmatrix}.$$

So $\operatorname{rank}\mathbf{M} = \operatorname{rank}(\mathbf{I}_m - \mathbf{AB}) + n$ in the same way. Comparing the two expressions for $\operatorname{rank}\mathbf{M}$ proves (a).

(b) For $m = n$ the two added terms are equal and cancel. A square matrix is invertible exactly when its rank is n (Theorem 2.4.4), so $\mathbf{I}_n - \mathbf{AB}$ is invertible if and only if $\mathbf{I}_n - \mathbf{BA}$ is.

(c) Here $\mathbf{AB} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} = \mathbf{I}_2$, so $\operatorname{rank}(\mathbf{I}_2 - \mathbf{AB}) = 0$, and

$$\mathbf{BA} = \begin{pmatrix} 1 & 1 & 0 \\ 0 & 0 & 0 \\ 0 & 1 & 1 \end{pmatrix}, \qquad \mathbf{I}_3 - \mathbf{BA} = \begin{pmatrix} 0 & -1 & 0 \\ 0 & 1 & 0 \\ 0 & -1 & 0 \end{pmatrix},$$

which has rank 1. Indeed $0 + 3 = 1 + 2$. So $\mathbf{AB} = \mathbf{I}_2$ while $\mathbf{BA} \neq \mathbf{I}_3$, and the identity accounts for the difference exactly: $\mathbf{I}_3 - \mathbf{BA}$ has rank $3 - 2 = 1$.

The trick is worth naming. **To compare two expressions, find one block matrix from which both can be obtained by elimination, and compute its rank twice.** Section 3 does the same with determinants and inverses, and the pair $\mathbf{I} - \mathbf{AB}$, $\mathbf{I} - \mathbf{BA}$ returns there as Sylvester's determinant identity.

7.2.5 Exercises

7.2.5.1 A. Check your understanding

Exercise A1.

(a) State the three inequalities of Theorem 7.2.1.

(b) True or false: $\operatorname{rank} \begin{pmatrix} \mathbf{A} & \mathbf{B} \\ 0 & \mathbf{D} \end{pmatrix} = \operatorname{rank} \mathbf{A} + \operatorname{rank} \mathbf{D}$ for all blocks of compatible sizes. Justify your answer.

(c) Which matrix do you multiply $\begin{pmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{C} & \mathbf{D} \end{pmatrix}$ by, and on which side, to replace $\mathbf{C}$ by $\mathbf{C} - \mathbf{XA}$?

(d) True or false: $\operatorname{rank} \begin{pmatrix} \mathbf{A} & \mathbf{B} \end{pmatrix} = \operatorname{rank} \mathbf{A} + \operatorname{rank} \mathbf{B}$ whenever $\mathbf{A}$ and $\mathbf{B}$ have the same number of rows. Justify your answer.

(e) State Frobenius's inequality, and explain how Sylvester's inequality follows from it.

Solution.

(a) $\max(\operatorname{rank} \mathbf{A}, \operatorname{rank} \mathbf{B}) \leq \operatorname{rank} \begin{pmatrix} \mathbf{A} & \mathbf{B} \end{pmatrix} \leq \operatorname{rank} \mathbf{A} + \operatorname{rank} \mathbf{B}$ (and the same for stacked blocks); $\operatorname{rank} \begin{pmatrix} \mathbf{A} & 0 \\ 0 & \mathbf{D} \end{pmatrix} = \operatorname{rank} \mathbf{A} + \operatorname{rank} \mathbf{D}$; and both block triangular shapes have rank at least $\operatorname{rank} \mathbf{A} + \operatorname{rank} \mathbf{D}$.

(b) False. $\begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$ with 1×1 blocks has rank 1, but $\operatorname{rank}(0) + \operatorname{rank}(0) = 0$. Only $\geq$ holds in general.

(c) Multiply on the left by $\begin{pmatrix} \mathbf{I} & 0 \\ -\mathbf{X} & \mathbf{I} \end{pmatrix}$: block row 2 becomes $\begin{pmatrix} \mathbf{C} - \mathbf{XA} & \mathbf{D} - \mathbf{XB} \end{pmatrix}$ by Theorem 7.1.1. The rank does not change (Theorem 7.2.2).

(d) False. $\begin{pmatrix} 1 & 1 \end{pmatrix}$ has rank 1, not 1+1. Equality holds exactly when $\operatorname{col} \mathbf{A} \cap \operatorname{col} \mathbf{B} = \{\mathbf{0}\}$.

(e) $\operatorname{rank}(\mathbf{ABC}) + \operatorname{rank}\mathbf{B} \geq \operatorname{rank}(\mathbf{AB}) + \operatorname{rank}(\mathbf{BC})$ for matrices of compatible sizes. With $\mathbf{B} = \mathbf{I}_n$ it reads $\operatorname{rank}(\mathbf{AC}) + n \geq \operatorname{rank}\mathbf{A} + \operatorname{rank}\mathbf{C}$, which is Sylvester's inequality.

7.2.5.2 B. Practice

Exercise B1: Ranks of block matrices.

Let $\mathbf{A} = \begin{pmatrix} 1 & 2 \\ 2 & 4 \end{pmatrix}$ and $\mathbf{D} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$ in $M_2(\mathbb{Q})$. Find the rank of each 4×4 matrix, citing the result you use. In which case is the lower bound of Theorem 7.2.1 (c) strict?

(a) $\mathbf{M}_1 = \begin{pmatrix} \mathbf{A} & 0 \\ 0 & \mathbf{D} \end{pmatrix}$.

(b) $\mathbf{M}_2 = \begin{pmatrix} \mathbf{A} & \mathbf{B} \\ 0 & \mathbf{D} \end{pmatrix}$ with $\mathbf{B} = \begin{pmatrix} 1 & 3 \\ 2 & 6 \end{pmatrix}$.

(c) $\mathbf{M}_3 = \begin{pmatrix} \mathbf{A} & \mathbf{I}_2 \\ 0 & 0 \end{pmatrix}$.

Solution. $\operatorname{rank}\mathbf{A} = 1$, since the second row is twice the first and $\mathbf{A} \neq 0$; $\operatorname{rank}\mathbf{D} = 2$, since $\det\mathbf{D} = 1 \neq 0$.

(a) By Theorem 7.2.1 (b), $\operatorname{rank}\mathbf{M}_1 = 1 + 2 = 3$.

(b) The columns of $\mathbf{B}$ are $(1,2)$ and $(3,6) = 3(1,2)$, and $(1,2)$ is the first column of $\mathbf{A}$. So $\operatorname{col}\mathbf{B} \subseteq \operatorname{col}\mathbf{A}$, and by Theorem 7.2.2 (b), $\operatorname{rank}\mathbf{M}_2 = 1 + 2 = 3$. (Explicitly $\mathbf{B} = \mathbf{AY}$ with $\mathbf{Y} = \begin{pmatrix} 1 & 3 \\ 0 & 0 \end{pmatrix}$.)

(c) The lower bound is $\operatorname{rank}\mathbf{A} + \operatorname{rank}0 = 1$. But the last two columns of $\mathbf{M}_3$ are $\mathbf{e}_1, \mathbf{e}_2$, and every column lies in $\operatorname{span}(\mathbf{e}_1, \mathbf{e}_2)$, so $\operatorname{rank}\mathbf{M}_3 = 2$. This is the strict case: the block $\mathbf{I}_2$ is not a multiple of $\mathbf{A}$ or of the zero block.

Exercise B2: Shifted products.

Let $\mathbf{A} \in M_{m\times n}(F)$, $\mathbf{B} \in M_{n\times m}(F)$ and $c \in F$ with $c \neq 0$.

(a) By adapting Example (Rank of $\mathbf{I} - \mathbf{AB}$ versus $\mathbf{I} - \mathbf{BA}$), prove that $\operatorname{rank}(c\mathbf{I}_m - \mathbf{AB}) + n = \operatorname{rank}(c\mathbf{I}_n - \mathbf{BA}) + m$.

(b) Check (a) over $\mathbb{Q}$ for $c = 2$, $\mathbf{A} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \\ 1 & 0 \end{pmatrix}$ and $\mathbf{B} = \begin{pmatrix} 1 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix}$.

(c) Show by an example with $m = 1$, $n = 2$ that (a) can fail for $c = 0$.

Solution.

(a) Since $c \neq 0$, put $\mathbf{A}' = c^{-1}\mathbf{A}$. Then $c\mathbf{I}_m - \mathbf{AB} = c(\mathbf{I}_m - \mathbf{A}'\mathbf{B})$ and $c\mathbf{I}_n - \mathbf{BA} = c(\mathbf{I}_n - \mathbf{BA}')$. Multiplying a matrix by the non-zero scalar c does not change its column space, hence not its rank. By Example (Rank of $\mathbf{I} - \mathbf{AB}$ versus $\mathbf{I} - \mathbf{BA}$)

(a) applied to $\mathbf{A}'$ and $\mathbf{B}$,

$$\begin{aligned}\operatorname{rank}(c\mathbf{I}_m - \mathbf{AB}) + n &= \operatorname{rank}(\mathbf{I}_m - \mathbf{A}'\mathbf{B}) + n \\ &= \operatorname{rank}(\mathbf{I}_n - \mathbf{BA}') + m \\ &= \operatorname{rank}(c\mathbf{I}_n - \mathbf{BA}) + m.\end{aligned}$$

(b) Here $m = 3$, $n = 2$, and

$$2\mathbf{I}_3 - \mathbf{AB} = \begin{pmatrix} 1 & -1 & -1 \\ 0 & 1 & 0 \\ -1 & 0 & 1 \end{pmatrix}, \qquad 2\mathbf{I}_2 - \mathbf{BA} = \begin{pmatrix} 0 & -1 \\ 0 & 1 \end{pmatrix},$$

since $\mathbf{AB} = \begin{pmatrix} 1 & 1 & 1 \\ 0 & 1 & 0 \\ 1 & 0 & 1 \end{pmatrix}$ and $\mathbf{BA} = \begin{pmatrix} 2 & 1 \\ 0 & 1 \end{pmatrix}$. In the first matrix, row 1 equals $-(\text{row } 2) - (\text{row } 3)$, and rows 2 and 3 are not multiples of each other, so its rank is 2 (Theorem 2.5.5). The second has rank 1. Indeed $2 + 2 = 1 + 3$.

(c) For $c = 0$ the identity would say $\operatorname{rank}(\mathbf{AB}) + n = \operatorname{rank}(\mathbf{BA}) + m$. Take $\mathbf{A} = \begin{pmatrix} 1 & 0 \end{pmatrix}$ and $\mathbf{B} = \begin{pmatrix} 1 \\ 0 \end{pmatrix}$: $\mathbf{AB} = (1)$ has rank 1, and $\mathbf{BA} = \mathbf{E}_{11} \in M_2(F)$ has rank 1, but $1 + 2 \neq 1 + 1$.

Exercise B3: Idempotents by blocks.

Let $\mathbf{A} \in M_n(F)$.

(a) Starting from $\begin{pmatrix} \mathbf{A} & 0 \\ 0 & \mathbf{I}_n - \mathbf{A} \end{pmatrix}$, use block elimination to prove

$$\operatorname{rank} \mathbf{A} + \operatorname{rank}(\mathbf{I}_n - \mathbf{A}) = n + \operatorname{rank}(\mathbf{A} - \mathbf{A}^2).$$

(b) Deduce that $\mathbf{A}^2 = \mathbf{A}$ if and only if $\operatorname{rank} \mathbf{A} + \operatorname{rank}(\mathbf{I}_n - \mathbf{A}) = n$.

(c) Compare (b) with what Chapter 3 says about projections.

Hint: first add block row 1 to block row 2, then add block column 2 to block column 1.

Solution.

(a) Write $\mathbf{I} = \mathbf{I}_n$. By Theorem 7.1.1, each step being multiplication by one of the matrices of Theorem 7.2.2 (a):

$$\begin{aligned}\begin{pmatrix} \mathbf{A} & 0 \\ 0 & \mathbf{I} - \mathbf{A} \end{pmatrix} &\xrightarrow{\text{row}_2 + \text{row}_1} \begin{pmatrix} \mathbf{A} & 0 \\ \mathbf{A} & \mathbf{I} - \mathbf{A} \end{pmatrix} \\ &\xrightarrow{\text{col}_1 + \text{col}_2} \begin{pmatrix} \mathbf{A} & 0 \\ \mathbf{I} & \mathbf{I} - \mathbf{A} \end{pmatrix} \\ &\xrightarrow{\text{row}_1 - \mathbf{A}\,\text{row}_2} \begin{pmatrix} 0 & \mathbf{A}^2 - \mathbf{A} \\ \mathbf{I} & \mathbf{I} - \mathbf{A} \end{pmatrix} \\ &\xrightarrow{\text{col}_2 - \text{col}_1(\mathbf{I} - \mathbf{A})} \begin{pmatrix} 0 & \mathbf{A}^2 - \mathbf{A} \\ \mathbf{I} & 0 \end{pmatrix}.\end{aligned}$$

The multipliers are, in order, $\begin{pmatrix}\mathbf{I} & 0\\ \mathbf{I} & \mathbf{I}\end{pmatrix}$ on the left, $\begin{pmatrix}\mathbf{I} & 0\\ \mathbf{I} & \mathbf{I}\end{pmatrix}$ on the right, $\begin{pmatrix}\mathbf{I} & -\mathbf{A}\\ 0 & \mathbf{I}\end{pmatrix}$ on the left and $\begin{pmatrix}\mathbf{I} & -(\mathbf{I}-\mathbf{A})\\ 0 & \mathbf{I}\end{pmatrix}$ on the right. In the third step the top row becomes $\begin{pmatrix}\mathbf{A}-\mathbf{AI} & 0-\mathbf{A}(\mathbf{I}-\mathbf{A})\end{pmatrix} = \begin{pmatrix}0 & \mathbf{A}^2-\mathbf{A}\end{pmatrix}$, and in the fourth the bottom-right block becomes $(\mathbf{I}-\mathbf{A})-\mathbf{I}(\mathbf{I}-\mathbf{A})=0$. Swapping the block columns (Theorem 7.2.2 (a)) gives $\begin{pmatrix}\mathbf{A}^2-\mathbf{A} & 0\\ 0 & \mathbf{I}\end{pmatrix}$, of rank $\operatorname{rank}(\mathbf{A}^2-\mathbf{A})+n$ by Theorem 7.2.1 (b). The first matrix has rank $\operatorname{rank}\mathbf{A}+\operatorname{rank}(\mathbf{I}-\mathbf{A})$, and rank is unchanged throughout. Since $\mathbf{A}^2-\mathbf{A}=-(\mathbf{A}-\mathbf{A}^2)$ has the same rank as $\mathbf{A}-\mathbf{A}^2$, (a) follows.

(b) By (a), $\operatorname{rank}\mathbf{A}+\operatorname{rank}(\mathbf{I}-\mathbf{A})=n$ if and only if $\operatorname{rank}(\mathbf{A}-\mathbf{A}^2)=0$, that is, $\mathbf{A}-\mathbf{A}^2=0$.

(c) If $\mathbf{A}^2=\mathbf{A}$, then $T_{\mathbf{A}}$ is a projection (Definition 3.10.1), so $F^n=\operatorname{im}T_{\mathbf{A}}\oplus\ker T_{\mathbf{A}}$ by Theorem 3.10.1, with $\ker T_{\mathbf{A}}=\operatorname{col}(\mathbf{I}-\mathbf{A})$ (a vector $\mathbf{v}$ with $\mathbf{Av}=\mathbf{0}$ equals $(\mathbf{I}-\mathbf{A})\mathbf{v}$, and conversely $\mathbf{A}(\mathbf{I}-\mathbf{A})=\mathbf{A}-\mathbf{A}^2=0$). So $\operatorname{rank}\mathbf{A}+\operatorname{rank}(\mathbf{I}-\mathbf{A})=\dim\operatorname{im}T_{\mathbf{A}}+\dim\ker T_{\mathbf{A}}=n$, which is the forward direction of (b). The block argument also gives the converse, and it never mentions subspaces.

7.2.5.3 C. Going deeper

Exercise C1: The rank of $\mathbf{A}-\mathbf{ABA}$.

Let $\mathbf{A}\in M_{m\times n}(F)$ and $\mathbf{B}\in M_{n\times m}(F)$.

(a) Verify, by block multiplication, the following chain, in which each arrow is multiplication by an invertible block triangular matrix:

$$\begin{pmatrix}\mathbf{A} & 0\\ 0 & \mathbf{I}_n-\mathbf{BA}\end{pmatrix}\to\begin{pmatrix}\mathbf{A} & \mathbf{A}\\ 0 & \mathbf{I}_n-\mathbf{BA}\end{pmatrix}\to\begin{pmatrix}\mathbf{A} & \mathbf{A}\\ \mathbf{BA} & \mathbf{I}_n\end{pmatrix}$$
$$\to\begin{pmatrix}\mathbf{A}-\mathbf{ABA} & \mathbf{A}\\ 0 & \mathbf{I}_n\end{pmatrix}\to\begin{pmatrix}\mathbf{A}-\mathbf{ABA} & 0\\ 0 & \mathbf{I}_n\end{pmatrix}.$$

Name each multiplier and the side it acts on.

(b) Deduce that $\operatorname{rank}(\mathbf{A}-\mathbf{ABA})=\operatorname{rank}\mathbf{A}+\operatorname{rank}(\mathbf{I}_n-\mathbf{BA})-n$.

(c) Suppose $\mathbf{ABA}=\mathbf{A}$. Show that $\mathbf{BA}$ is idempotent and that $\operatorname{rank}(\mathbf{BA})=\operatorname{rank}\mathbf{A}$.

Hint for (c): use (b), then Exercise (B3: Idempotents by blocks).

Solution.

(a) The partitions are m,n for rows and n,n for columns. By Theorem 7.1.1:

1. Right multiplication by $\begin{pmatrix}\mathbf{I}_n & \mathbf{I}_n\\ 0 & \mathbf{I}_n\end{pmatrix}$ adds block column 1 to block column 2: $\begin{pmatrix}\mathbf{A} & \mathbf{A}+0\\ 0 & 0+(\mathbf{I}_n-\mathbf{BA})\end{pmatrix}$.
2. Left multiplication by $\begin{pmatrix}\mathbf{I}_m & 0\\ \mathbf{B} & \mathbf{I}_n\end{pmatrix}$ adds $\mathbf{B}$ times block row 1 to block row 2: the new row is $\begin{pmatrix}\mathbf{BA} & \mathbf{BA}+\mathbf{I}_n-\mathbf{BA}\end{pmatrix}=\begin{pmatrix}\mathbf{BA} & \mathbf{I}_n\end{pmatrix}$.
3. Right multiplication by $\begin{pmatrix}\mathbf{I}_n & 0\\ -\mathbf{BA} & \mathbf{I}_n\end{pmatrix}$ subtracts block column 2 times $\mathbf{BA}$ from

block column 1: the new column is $\begin{pmatrix} \mathbf{A}-\mathbf{ABA} \\ \mathbf{BA}-\mathbf{I}_n\mathbf{BA} \end{pmatrix} = \begin{pmatrix} \mathbf{A}-\mathbf{ABA} \\ 0 \end{pmatrix}$.

4. Left multiplication by $\begin{pmatrix} \mathbf{I}_m & -\mathbf{A} \\ 0 & \mathbf{I}_n \end{pmatrix}$ subtracts $\mathbf{A}$ times block row 2 from block row 1: the new row is $\begin{pmatrix} \mathbf{A}-\mathbf{ABA}-\mathbf{A}\cdot 0 & \mathbf{A}-\mathbf{AI}_n \end{pmatrix} = \begin{pmatrix} \mathbf{A}-\mathbf{ABA} & 0 \end{pmatrix}$.

All four multipliers are invertible by Theorem 7.2.2 (a).

(b) By Theorem 7.2.2 (a) the first and last matrices have the same rank, and by Theorem 7.2.1 (b) these ranks are $\operatorname{rank}\mathbf{A}+\operatorname{rank}(\mathbf{I}_n-\mathbf{BA})$ and $\operatorname{rank}(\mathbf{A}-\mathbf{ABA})+n$. Rearranging gives the formula.

(c) $(\mathbf{BA})^2 = \mathbf{B}(\mathbf{ABA}) = \mathbf{BA}$, so $\mathbf{BA}$ is idempotent. By (b), $0 = \operatorname{rank}(\mathbf{A}-\mathbf{ABA}) = \operatorname{rank}\mathbf{A} + \operatorname{rank}(\mathbf{I}_n - \mathbf{BA}) - n$, so $\operatorname{rank}(\mathbf{I}_n - \mathbf{BA}) = n - \operatorname{rank}\mathbf{A}$. By Exercise (B3: Idempotents by blocks) (b) applied to the idempotent $\mathbf{BA}$, $\operatorname{rank}(\mathbf{BA}) = n - \operatorname{rank}(\mathbf{I}_n - \mathbf{BA}) = \operatorname{rank}\mathbf{A}$.

Exercise C2: Involutions and the field.

Let $\mathbf{A} \in M_n(F)$.

(a) Suppose the characteristic of F is not 2. Starting from $\begin{pmatrix} \mathbf{A}-\mathbf{I}_n & 0 \\ 0 & \mathbf{A}+\mathbf{I}_n \end{pmatrix}$, prove that

$$\operatorname{rank}(\mathbf{A}-\mathbf{I}_n) + \operatorname{rank}(\mathbf{A}+\mathbf{I}_n) = n + \operatorname{rank}(\mathbf{A}^2-\mathbf{I}_n).$$

(b) Deduce that if $\mathbf{A}^2 = \mathbf{I}_n$ (and $\operatorname{char} F \neq 2$), then $\operatorname{rank}(\mathbf{A}-\mathbf{I}_n) + \operatorname{rank}(\mathbf{A}+\mathbf{I}_n) = n$.

(c) Show that (b) fails over $\mathbb{F}_2$, and point to the step of (a) that breaks.

Hint for (a): add block column 2 to block column 1, and subtract block row 2 from block row 1; then $-2\mathbf{I}_n$ is an invertible pivot.

Solution.

(a) Write $\mathbf{I} = \mathbf{I}_n$ and $\mathbf{P} = \mathbf{A}+\mathbf{I}$. Since $\operatorname{char} F \neq 2$, $2 \neq 0$ in F, so $\frac{1}{2}$ exists and $-2\mathbf{I}$ is invertible. By Theorem 7.1.1, with each multiplier from Theorem 7.2.2 (a):

$$\begin{pmatrix} \mathbf{A}-\mathbf{I} & 0 \\ 0 & \mathbf{P} \end{pmatrix} \xrightarrow{\text{col}_1+\text{col}_2} \begin{pmatrix} \mathbf{A}-\mathbf{I} & 0 \\ \mathbf{P} & \mathbf{P} \end{pmatrix} \xrightarrow{\text{row}_1-\text{row}_2} \begin{pmatrix} -2\mathbf{I} & -\mathbf{P} \\ \mathbf{P} & \mathbf{P} \end{pmatrix}$$
$$\xrightarrow{\text{col}_2-\text{col}_1\cdot\frac{1}{2}\mathbf{P}} \begin{pmatrix} -2\mathbf{I} & 0 \\ \mathbf{P} & \mathbf{P}-\frac{1}{2}\mathbf{P}^2 \end{pmatrix}$$
$$\xrightarrow{\text{row}_2+\frac{1}{2}\mathbf{P}\,\text{row}_1} \begin{pmatrix} -2\mathbf{I} & 0 \\ 0 & \mathbf{P}-\frac{1}{2}\mathbf{P}^2 \end{pmatrix}.$$

In the second step $(\mathbf{A}-\mathbf{I})-\mathbf{P} = -2\mathbf{I}$; in the third, $-\mathbf{P}-(-2\mathbf{I})\frac{1}{2}\mathbf{P} = 0$ and $\mathbf{P}-\mathbf{P}\cdot\frac{1}{2}\mathbf{P} = \mathbf{P}-\frac{1}{2}\mathbf{P}^2$; in the fourth, $\mathbf{P}+\frac{1}{2}\mathbf{P}(-2\mathbf{I}) = 0$. Finally

$$\mathbf{P}-\tfrac{1}{2}\mathbf{P}^2 = \tfrac{1}{2}\mathbf{P}(2\mathbf{I}-\mathbf{P}) = \tfrac{1}{2}(\mathbf{A}+\mathbf{I})(\mathbf{I}-\mathbf{A}) = \tfrac{1}{2}(\mathbf{I}-\mathbf{A}^2),$$

where the product $(\mathbf{A}+\mathbf{I})(\mathbf{I}-\mathbf{A}) = \mathbf{I}-\mathbf{A}+\mathbf{A}-\mathbf{A}^2$ expands by distributivity. The first matrix has rank $\operatorname{rank}(\mathbf{A}-\mathbf{I}) + \operatorname{rank}(\mathbf{A}+\mathbf{I})$ and the last has rank $n+$

$\operatorname{rank}(\frac{1}{2}(\mathbf{I}-\mathbf{A}^2)) = n+\operatorname{rank}(\mathbf{A}^2-\mathbf{I})$ by Theorem 7.2.1 (b), non-zero scalar multiples having the same column space. Rank is unchanged throughout.

(b) If $\mathbf{A}^2 = \mathbf{I}_n$, then $\operatorname{rank}(\mathbf{A}^2 - \mathbf{I}_n) = 0$.

(c) Over $\mathbb{F}_2$, take $\mathbf{A} = \mathbf{I}_n$. Then $\mathbf{A}^2 = \mathbf{I}_n$, but $\mathbf{A} - \mathbf{I}_n = 0$ and $\mathbf{A} + \mathbf{I}_n = 2\mathbf{I}_n = 0$, so the left side is $0 \neq n$. The step that breaks is the pivot: $-2\mathbf{I}_n = 0$ is not invertible, and $\frac{1}{2}$ does not exist. (Chapter 3's decomposition of an involution into ± 1 parts, Theorem 3.10.5, needs the same hypothesis.)

7.3 Schur Complements

Section 1 inverted block triangular matrices, and Section 2 cleared blocks without changing the rank. A general block matrix $\begin{pmatrix}\mathbf{A} & \mathbf{B}\\ \mathbf{C} & \mathbf{D}\end{pmatrix}$ has no zero block to help, but when one diagonal block is invertible, a single step of block elimination creates one. What is left in the opposite corner is a new matrix, the Schur complement, and it carries everything that the invertible block does not: the determinant, the rank and the inverse of the whole matrix can all be read off from the block and its complement. This section introduces it, derives these formulas, uses the two complements of one matrix to prove the Sherman–Morrison–Woodbury formula, and ends with the determinant of a block matrix whose lower blocks commute, over every field.

7.3.1 Eliminating a block

Suppose we must solve a linear system whose unknowns come in two groups, $\mathbf{x} \in F^k$ and $\mathbf{y} \in F^l$:

$$\begin{pmatrix}\mathbf{A} & \mathbf{B}\\ \mathbf{C} & \mathbf{D}\end{pmatrix}\begin{pmatrix}\mathbf{x}\\ \mathbf{y}\end{pmatrix} = \begin{pmatrix}\mathbf{f}\\ \mathbf{g}\end{pmatrix}, \qquad \text{that is,} \qquad \begin{aligned}\mathbf{A}\mathbf{x} + \mathbf{B}\mathbf{y} &= \mathbf{f},\\ \mathbf{C}\mathbf{x} + \mathbf{D}\mathbf{y} &= \mathbf{g},\end{aligned}$$

with $\mathbf{A} \in M_k(F)$ invertible. Do what we would do for two equations in two numbers: solve the first equation for $\mathbf{x}$, and substitute. The first equation gives $\mathbf{x} = \mathbf{A}^{-1}(\mathbf{f} - \mathbf{B}\mathbf{y})$. Substituting into the second,

$$\mathbf{C}\mathbf{A}^{-1}\mathbf{f} - \mathbf{C}\mathbf{A}^{-1}\mathbf{B}\mathbf{y} + \mathbf{D}\mathbf{y} = \mathbf{g}, \qquad \text{so} \qquad (\mathbf{D} - \mathbf{C}\mathbf{A}^{-1}\mathbf{B})\,\mathbf{y} = \mathbf{g} - \mathbf{C}\mathbf{A}^{-1}\mathbf{f}.$$

The unknown $\mathbf{x}$ has disappeared, and $\mathbf{y}$ solves a smaller system whose matrix is $\mathbf{D} - \mathbf{C}\mathbf{A}^{-1}\mathbf{B}$. Once $\mathbf{y}$ is known, $\mathbf{x} = \mathbf{A}^{-1}(\mathbf{f} - \mathbf{B}\mathbf{y})$. So the big system is solvable for every right-hand side exactly when the small matrix $\mathbf{D} - \mathbf{C}\mathbf{A}^{-1}\mathbf{B}$ allows it, and this matrix will keep appearing.

For $k = l = 1$ we have met it before: $d - cb/a = (ad - bc)/a$ is the determinant divided by the pivot a, which is what Gaussian elimination leaves in the corner after clearing the entry c.

The Schur complement of an invertible block is what remains in the opposite corner after that block has been used to eliminate its row and column.

Definition 7.3.1 — Schur Complement

Let $\mathbf{M} = \begin{pmatrix}\mathbf{A} & \mathbf{B}\\ \mathbf{C} & \mathbf{D}\end{pmatrix} \in M_{(k+p)\times(k+l)}(F)$ be a block matrix with $\mathbf{A} \in M_k(F)$, $\mathbf{B} \in M_{k\times l}(F)$, $\mathbf{C} \in M_{p\times k}(F)$ and $\mathbf{D} \in M_{p\times l}(F)$, where $k, p, l \geq 1$.

(a) If $\mathbf{A}$ is **invertible**, the **Schur complement of $\mathbf{A}$ in $\mathbf{M}$** is

$$\mathbf{M}/\mathbf{A} \coloneqq \mathbf{D} - \mathbf{C}\mathbf{A}^{-1}\mathbf{B} \in M_{p\times l}(F).$$

(b) Symmetrically, if $\mathbf{M} = \begin{pmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{C} & \mathbf{D} \end{pmatrix}$ with $\mathbf{D} \in M_l(F)$ **invertible**, $\mathbf{A} \in M_{m\times k}(F)$, $\mathbf{B} \in M_{m\times l}(F)$ and $\mathbf{C} \in M_{l\times k}(F)$, the **Schur complement of $\mathbf{D}$ in $\mathbf{M}$** is $\mathbf{M}/\mathbf{D} \coloneqq \mathbf{A} - \mathbf{B}\mathbf{D}^{-1}\mathbf{C} \in M_{m\times k}(F)$.

In words, clause by clause. The block whose complement we take must be **square and invertible**, since its inverse appears in the formula; the other blocks may be rectangular. The complement has the size of the **opposite corner**: $\mathbf{M}/\mathbf{A}$ has the shape of $\mathbf{D}$, and $\mathbf{M}/\mathbf{D}$ has the shape of $\mathbf{A}$. In $\mathbf{C}\mathbf{A}^{-1}\mathbf{B}$ the factors come in the only order the sizes allow: $\mathbf{C}$ is $p \times k$, $\mathbf{A}^{-1}$ is $k \times k$, $\mathbf{B}$ is $k \times l$. A way to remember it: go from the corner $\mathbf{D}$ to $\mathbf{A}$ along its row ($\mathbf{C}$), invert, and come back along its column ($\mathbf{B}$).

Well-definedness. $\mathbf{M}/\mathbf{A}$ depends on $\mathbf{M}$ and on the chosen partition, which says which corner is $\mathbf{A}$. The inverse $\mathbf{A}^{-1}$ is unique (Theorem 0.9.7), so there is no other choice to make.

Examples.

- **Scalars.** For $\mathbf{M} = \begin{pmatrix} a & b \\ c & d \end{pmatrix}$ with $a \neq 0$, $\mathbf{M}/a = d - ca^{-1}b = (ad - bc)/a$. In particular $a \cdot (\mathbf{M}/a) = \det \mathbf{M}$.
- **An identity corner.** If $\mathbf{A} = \mathbf{I}_k$, then $\mathbf{M}/\mathbf{I}_k = \mathbf{D} - \mathbf{C}\mathbf{B}$. No inversion is needed at all.
- **Block triangular.** If $\mathbf{C} = 0$, then $\mathbf{M}/\mathbf{A} = \mathbf{D}$: nothing needs to be eliminated.
- **$\mathbf{A}$ 3×3 example.** For $\mathbf{M} = \left(\begin{array}{cc|c} 2 & 1 & 1 \\ 1 & 1 & 0 \\ \hline 3 & 1 & 4 \end{array}\right)$ over $\mathbb{Q}$, $\mathbf{A} = \begin{pmatrix} 2 & 1 \\ 1 & 1 \end{pmatrix}$ has $\mathbf{A}^{-1} = \begin{pmatrix} 1 & -1 \\ -1 & 2 \end{pmatrix}$, and $\mathbf{C}\mathbf{A}^{-1} = \begin{pmatrix} 3 & 1 \end{pmatrix}\mathbf{A}^{-1} = \begin{pmatrix} 2 & -1 \end{pmatrix}$, so $\mathbf{M}/\mathbf{A} = 4 - \begin{pmatrix} 2 & -1 \end{pmatrix}\begin{pmatrix} 1 \\ 0 \end{pmatrix} = (2)$. This 1×1 complement is the last pivot of Gaussian elimination on $\mathbf{M}$: subtracting $\frac{1}{2}$ row 1 from row 2 and $\frac{3}{2}$ row 1 from row 3 gives the rows $(0, \frac{1}{2}, -\frac{1}{2})$ and $(0, -\frac{1}{2}, \frac{5}{2})$, and adding the first of these to the second gives $(0, 0, 2)$.

Non-example by minimal change. For $\mathbf{M} = \begin{pmatrix} 1 & 1 \\ 1 & 0 \end{pmatrix}$, $\mathbf{M}/(1) = 0 - 1 \cdot 1 \cdot 1 = (-1)$. Change the corner entry 1 to 0: $\mathbf{M}' = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$. The blocks $\mathbf{B}$, $\mathbf{C}$, $\mathbf{D}$ and the partition are unchanged, and $\mathbf{M}'$ is still invertible, but $\mathbf{M}'/(0)$ is **not defined**, because the clause "$\mathbf{A}$ is invertible" fails. Here $\mathbf{M}'/\mathbf{D}$ is not defined either, since $\mathbf{D} = (0)$.

Why this definition. The formula is read off from the elimination in the hook, so the question is only about the name and the hypotheses. "Complement" refers to position: $\mathbf{M}/\mathbf{A}$ sits in the corner complementary to $\mathbf{A}$. The quotient notation $\mathbf{M}/\mathbf{A}$ is suggested by the first example, $\det(\mathbf{M}/a) = \det \mathbf{M}/\det a$, and the determinant formula below shows that this holds for blocks of every size. Invertibility of $\mathbf{A}$ cannot be dropped, since $\mathbf{A}^{-1}$ is in the formula; the price is that some invertible matrices, like $\mathbf{M}'$, have no Schur complement for a given partition.

Warning. **$\mathbf{M}$ can be invertible while $\mathbf{A}$ is not.** For $\mathbf{M}' = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$, neither corner is invertible, so neither Schur complement exists for the partition $1, 1$. Before using a formula below, check that the block you invert is invertible. If it is not, try the other

corner $(\mathbf{M}/\mathbf{D})$, a different partition, or first permute rows: $\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} \mathbf{M}' = \mathbf{I}_2$. The same issue appears in Gaussian elimination as a zero pivot.

Quick check. Let $\mathbf{M} = \left(\begin{array}{c|cc} 2 & 4 & 2 \\ \hline 1 & 3 & 5 \\ 3 & 1 & 0 \end{array}\right)$ with partition $1, 2$. Compute $\mathbf{M}/(2)$.

Solution. Here $\mathbf{A} = (2)$, $\mathbf{B} = \begin{pmatrix} 4 & 2 \end{pmatrix}$, $\mathbf{C} = \begin{pmatrix} 1 \\ 3 \end{pmatrix}$, $\mathbf{D} = \begin{pmatrix} 3 & 5 \\ 1 & 0 \end{pmatrix}$. Then $\mathbf{CA}^{-1}\mathbf{B} = \frac{1}{2}\begin{pmatrix} 4 & 2 \\ 12 & 6 \end{pmatrix} = \begin{pmatrix} 2 & 1 \\ 6 & 3 \end{pmatrix}$, so $\mathbf{M}/(2) = \begin{pmatrix} 1 & 4 \\ -5 & -3 \end{pmatrix}$. These are exactly the entries left in rows 2, 3 after clearing column 1 with the pivot 2.

7.3.2 The block LDU factorization

The elimination of the hook, written with matrices, factors $\mathbf{M}$ into a lower block triangular matrix, a block diagonal matrix and an upper block triangular matrix. Everything else in this section follows from this factorization.

Theorem 7.3.1 — Block LDU Factorization

Let $\mathbf{M} = \begin{pmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{C} & \mathbf{D} \end{pmatrix}$ be partitioned as in Definition 7.3.1.

(a) If $\mathbf{A} \in M_k(F)$ is invertible, then

$$\mathbf{M} = \begin{pmatrix} \mathbf{I}_k & 0 \\ \mathbf{CA}^{-1} & \mathbf{I}_p \end{pmatrix} \begin{pmatrix} \mathbf{A} & 0 \\ 0 & \mathbf{M}/\mathbf{A} \end{pmatrix} \begin{pmatrix} \mathbf{I}_k & \mathbf{A}^{-1}\mathbf{B} \\ 0 & \mathbf{I}_l \end{pmatrix}.$$

(b) If $\mathbf{D} \in M_l(F)$ is invertible, then

$$\mathbf{M} = \begin{pmatrix} \mathbf{I}_m & \mathbf{BD}^{-1} \\ 0 & \mathbf{I}_l \end{pmatrix} \begin{pmatrix} \mathbf{M}/\mathbf{D} & 0 \\ 0 & \mathbf{D} \end{pmatrix} \begin{pmatrix} \mathbf{I}_k & 0 \\ \mathbf{D}^{-1}\mathbf{C} & \mathbf{I}_l \end{pmatrix}.$$

Idea. The left factor in (a) records the row operation "subtract $\mathbf{CA}^{-1}$ times block row 1 from block row 2", which turns $\mathbf{C}$ into 0 and $\mathbf{D}$ into $\mathbf{M}/\mathbf{A}$. The right factor records the column operation "subtract block column 1 times $\mathbf{A}^{-1}\mathbf{B}$ from block column 2", which turns $\mathbf{B}$ into 0. Undoing both operations gives the factorization. To prove it we need not retrace the elimination: multiplying out is enough.

Proof.

(a) Write $\mathbf{S} = \mathbf{M}/\mathbf{A} = \mathbf{D} - \mathbf{CA}^{-1}\mathbf{B}$. The sizes are conformable throughout. By Theorem 7.1.1,

$$\begin{pmatrix} \mathbf{A} & 0 \\ 0 & \mathbf{S} \end{pmatrix} \begin{pmatrix} \mathbf{I}_k & \mathbf{A}^{-1}\mathbf{B} \\ 0 & \mathbf{I}_l \end{pmatrix} = \begin{pmatrix} \mathbf{A} & \mathbf{AA}^{-1}\mathbf{B} \\ 0 & \mathbf{S} \end{pmatrix} = \begin{pmatrix} \mathbf{A} & \mathbf{B} \\ 0 & \mathbf{S} \end{pmatrix},$$

and then

$$\begin{pmatrix} \mathbf{I}_k & 0 \\ \mathbf{C}\mathbf{A}^{-1} & \mathbf{I}_p \end{pmatrix} \begin{pmatrix} \mathbf{A} & \mathbf{B} \\ 0 & \mathbf{S} \end{pmatrix} = \begin{pmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{C}\mathbf{A}^{-1}\mathbf{A} & \mathbf{C}\mathbf{A}^{-1}\mathbf{B} + \mathbf{S} \end{pmatrix} = \begin{pmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{C} & \mathbf{D} \end{pmatrix},$$

since $\mathbf{C}\mathbf{A}^{-1}\mathbf{A} = \mathbf{C}$ and $\mathbf{C}\mathbf{A}^{-1}\mathbf{B} + (\mathbf{D} - \mathbf{C}\mathbf{A}^{-1}\mathbf{B}) = \mathbf{D}$. By associativity (Theorem 0.9.4) the triple product equals $\mathbf{M}$.

(b) Write $\mathbf{S}' = \mathbf{M}/\mathbf{D} = \mathbf{A} - \mathbf{B}\mathbf{D}^{-1}\mathbf{C}$. By Theorem 7.1.1,

$$\begin{pmatrix} \mathbf{S}' & 0 \\ 0 & \mathbf{D} \end{pmatrix} \begin{pmatrix} \mathbf{I}_k & 0 \\ \mathbf{D}^{-1}\mathbf{C} & \mathbf{I}_l \end{pmatrix} = \begin{pmatrix} \mathbf{S}' & 0 \\ \mathbf{C} & \mathbf{D} \end{pmatrix},$$
$$\begin{pmatrix} \mathbf{I}_m & \mathbf{B}\mathbf{D}^{-1} \\ 0 & \mathbf{I}_l \end{pmatrix} \begin{pmatrix} \mathbf{S}' & 0 \\ \mathbf{C} & \mathbf{D} \end{pmatrix} = \begin{pmatrix} \mathbf{S}' + \mathbf{B}\mathbf{D}^{-1}\mathbf{C} & \mathbf{B}\mathbf{D}^{-1}\mathbf{D} \\ \mathbf{C} & \mathbf{D} \end{pmatrix} = \mathbf{M}.$$

■

The outer factors are block triangular with identity blocks on the diagonal. They are invertible, with inverses obtained by changing the sign of the off-diagonal block (Theorem 7.1.5), and they have determinant 1. So, up to these harmless factors, $\mathbf{M}$ **is** the block diagonal matrix $\mathbf{A} \oplus (\mathbf{M}/\mathbf{A})$ when $\mathbf{A}$ and $\mathbf{D}$ are square. Determinant, rank and invertibility cannot tell the difference.

7.3.3 Determinant and rank

The outer factors of Theorem 7.3.1 do not change the determinant or the rank, so both can be read off from the middle factor.

Theorem 7.3.2 — Schur Determinant Formula

Let $\mathbf{M} = \begin{pmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{C} & \mathbf{D} \end{pmatrix} \in M_{k+l}(F)$ with $\mathbf{A} \in M_k(F)$, $\mathbf{D} \in M_l(F)$ and $k, l \geq 1$.

(a) If $\mathbf{A}$ is invertible, then $\det \mathbf{M} = \det \mathbf{A} \cdot \det(\mathbf{M}/\mathbf{A})$.

(b) If $\mathbf{D}$ is invertible, then $\det \mathbf{M} = \det \mathbf{D} \cdot \det(\mathbf{M}/\mathbf{D})$.

Proof.

(a) By Theorem 7.3.1 (a), $\mathbf{M} = Ł\,(\mathbf{A} \oplus (\mathbf{M}/\mathbf{A}))\,\mathbf{U}$ with $Ł = \begin{pmatrix} \mathbf{I}_k & 0 \\ \mathbf{C}\mathbf{A}^{-1} & \mathbf{I}_l \end{pmatrix}$ and $\mathbf{U} = \begin{pmatrix} \mathbf{I}_k & \mathbf{A}^{-1}\mathbf{B} \\ 0 & \mathbf{I}_l \end{pmatrix}$. Here $p = l$ because $\mathbf{M}$ is square, so $\mathbf{M}/\mathbf{A} \in M_l(F)$. By Theorem 6.8.4, $\det Ł = \det \mathbf{I}_k \det \mathbf{I}_l = 1$, $\det \mathbf{U} = 1$, and $\det(\mathbf{A} \oplus (\mathbf{M}/\mathbf{A})) = \det \mathbf{A} \det(\mathbf{M}/\mathbf{A})$. By Theorem 6.5.4,

$$\det \mathbf{M} = \det Ł \cdot \det \mathbf{A} \det(\mathbf{M}/\mathbf{A}) \cdot \det \mathbf{U} = \det \mathbf{A} \det(\mathbf{M}/\mathbf{A}).$$

(b) The same argument with Theorem 7.3.1 (b), where $\mathbf{M}/\mathbf{D} \in M_k(F)$ because $\mathbf{M}$ is square.

■

This is the correct replacement for the false rule $\det \mathbf{M} = \det(\mathbf{AD} - \mathbf{BC})$ of Section 1: the determinant of $\mathbf{M}$ is that of $\mathbf{A}$ times that of the complement. For $k = l = 1$ it is $a\big(d - ca^{-1}b\big) = ad - bc$. Chapter 6 promised this, and it relies on Theorem 6.8.4 in exactly the form proved there, with square diagonal blocks.

Theorem 7.3.3 — Schur Rank Formula

Let $\mathbf{M} = \begin{pmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{C} & \mathbf{D} \end{pmatrix}$ be partitioned as in Definition 7.3.1. If $\mathbf{A} \in M_k(F)$ is invertible, then

$$\operatorname{rank} \mathbf{M} = k + \operatorname{rank}(\mathbf{M}/\mathbf{A}).$$

Symmetrically, if $\mathbf{D} \in M_l(F)$ is invertible, then $\operatorname{rank} \mathbf{M} = l + \operatorname{rank}(\mathbf{M}/\mathbf{D})$.

Proof. By Theorem 7.3.1 (a), $\mathbf{M} = \text{Ł} \begin{pmatrix} \mathbf{A} & 0 \\ 0 & \mathbf{M}/\mathbf{A} \end{pmatrix} \mathbf{U}$, where Ł and $\mathbf{U}$ are invertible by Theorem 7.2.2 (a). By Theorem 2.5.9, $\operatorname{rank} \mathbf{M}$ equals the rank of the middle factor, which is $\operatorname{rank} \mathbf{A} + \operatorname{rank}(\mathbf{M}/\mathbf{A}) = k + \operatorname{rank}(\mathbf{M}/\mathbf{A})$ by Theorem 7.2.1 (b) and Theorem 2.4.4. The second statement follows in the same way from Theorem 7.3.1 (b). ∎

In words: an invertible block of size k contributes exactly k to the rank, and all the remaining rank sits in its complement. For example, in Example (Rank of $\mathbf{I} - \mathbf{AB}$ versus $\mathbf{I} - \mathbf{BA}$) the matrix $\begin{pmatrix} \mathbf{I}_m & \mathbf{A} \\ \mathbf{B} & \mathbf{I}_n \end{pmatrix}$ has the two complements $\mathbf{I}_n - \mathbf{BA}$ and $\mathbf{I}_m - \mathbf{AB}$, and the theorem gives both expressions for its rank at once.

7.3.4 Inverting a block matrix

Since $\mathbf{A} \oplus (\mathbf{M}/\mathbf{A})$ is invertible exactly when $\mathbf{M}/\mathbf{A}$ is, the factorization also inverts $\mathbf{M}$: invert the three factors and multiply them in the reverse order.

Theorem 7.3.4 — Block Inverse Formula

Let $\mathbf{M} = \begin{pmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{C} & \mathbf{D} \end{pmatrix} \in M_{k+l}(F)$ with $\mathbf{A} \in M_k(F)$ and $\mathbf{D} \in M_l(F)$.

(a) Suppose $\mathbf{A}$ is invertible, and let $\mathbf{S} = \mathbf{M}/\mathbf{A}$. Then $\mathbf{M}$ is invertible if and only if $\mathbf{S}$ is invertible, and in that case

$$\mathbf{M}^{-1} = \begin{pmatrix} \mathbf{A}^{-1} + \mathbf{A}^{-1}\mathbf{B}\mathbf{S}^{-1}\mathbf{C}\mathbf{A}^{-1} & -\mathbf{A}^{-1}\mathbf{B}\mathbf{S}^{-1} \\ -\mathbf{S}^{-1}\mathbf{C}\mathbf{A}^{-1} & \mathbf{S}^{-1} \end{pmatrix}.$$

In particular the lower-right $l \times l$ block of $\mathbf{M}^{-1}$ is $(\mathbf{M}/\mathbf{A})^{-1}$.

(b) Suppose $\mathbf{D}$ is invertible, and let $\mathbf{S}' = \mathbf{M}/\mathbf{D}$. Then $\mathbf{M}$ is invertible if and only if $\mathbf{S}'$ is invertible, and in that case

$$\mathbf{M}^{-1} = \begin{pmatrix} \mathbf{S}'^{-1} & -\mathbf{S}'^{-1}\mathbf{B}\mathbf{D}^{-1} \\ -\mathbf{D}^{-1}\mathbf{C}\mathbf{S}'^{-1} & \mathbf{D}^{-1} + \mathbf{D}^{-1}\mathbf{C}\mathbf{S}'^{-1}\mathbf{B}\mathbf{D}^{-1} \end{pmatrix}.$$

In particular the upper-left $k \times k$ block of $\mathbf{M}^{-1}$ is $(\mathbf{M}/\mathbf{D})^{-1}$.

Proof.

(a) By Theorem 7.3.3, $\operatorname{rank}\mathbf{M} = k + \operatorname{rank}\mathbf{S}$. So $\operatorname{rank}\mathbf{M} = k+l$ if and only if $\operatorname{rank}\mathbf{S} = l$, and by Theorem 2.4.4 this says that $\mathbf{M}$ is invertible if and only if $\mathbf{S}$ is.
Suppose $\mathbf{S}$ is invertible. In Theorem 7.3.1 (a), $\mathbf{M} = Ł(\mathbf{A} \oplus \mathbf{S})\mathbf{U}$, where $Ł^{-1} = \begin{pmatrix} \mathbf{I}_k & 0 \\ -\mathbf{C}\mathbf{A}^{-1} & \mathbf{I}_l \end{pmatrix}$ and $\mathbf{U}^{-1} = \begin{pmatrix} \mathbf{I}_k & -\mathbf{A}^{-1}\mathbf{B} \\ 0 & \mathbf{I}_l \end{pmatrix}$ by Theorem 7.1.5, and $(\mathbf{A} \oplus \mathbf{S})^{-1} = \mathbf{A}^{-1} \oplus \mathbf{S}^{-1}$ by Theorem 7.1.4 (c). By Theorem 0.9.7 (3), $\mathbf{M}^{-1} = \mathbf{U}^{-1}(\mathbf{A}^{-1} \oplus \mathbf{S}^{-1})Ł^{-1}$. By Theorem 7.1.1,

$$\mathbf{U}^{-1}(\mathbf{A}^{-1} \oplus \mathbf{S}^{-1}) = \begin{pmatrix} \mathbf{A}^{-1} & -\mathbf{A}^{-1}\mathbf{B}\mathbf{S}^{-1} \\ 0 & \mathbf{S}^{-1} \end{pmatrix},$$

$$\begin{pmatrix} \mathbf{A}^{-1} & -\mathbf{A}^{-1}\mathbf{B}\mathbf{S}^{-1} \\ 0 & \mathbf{S}^{-1} \end{pmatrix} \begin{pmatrix} \mathbf{I}_k & 0 \\ -\mathbf{C}\mathbf{A}^{-1} & \mathbf{I}_l \end{pmatrix}$$
$$= \begin{pmatrix} \mathbf{A}^{-1} + \mathbf{A}^{-1}\mathbf{B}\mathbf{S}^{-1}\mathbf{C}\mathbf{A}^{-1} & -\mathbf{A}^{-1}\mathbf{B}\mathbf{S}^{-1} \\ -\mathbf{S}^{-1}\mathbf{C}\mathbf{A}^{-1} & \mathbf{S}^{-1} \end{pmatrix}.$$

(b) The equivalence follows from the second statement of Theorem 7.3.3 in the same way. By Theorem 7.3.1 (b), $\mathbf{M}^{-1} = \begin{pmatrix} \mathbf{I}_k & 0 \\ -\mathbf{D}^{-1}\mathbf{C} & \mathbf{I}_l \end{pmatrix} (\mathbf{S}'^{-1} \oplus \mathbf{D}^{-1}) \begin{pmatrix} \mathbf{I}_k & -\mathbf{B}\mathbf{D}^{-1} \\ 0 & \mathbf{I}_l \end{pmatrix}$, and

$$\begin{pmatrix} \mathbf{I}_k & 0 \\ -\mathbf{D}^{-1}\mathbf{C} & \mathbf{I}_l \end{pmatrix} \begin{pmatrix} \mathbf{S}'^{-1} & 0 \\ 0 & \mathbf{D}^{-1} \end{pmatrix} = \begin{pmatrix} \mathbf{S}'^{-1} & 0 \\ -\mathbf{D}^{-1}\mathbf{C}\mathbf{S}'^{-1} & \mathbf{D}^{-1} \end{pmatrix},$$

whose product with $\begin{pmatrix} \mathbf{I}_k & -\mathbf{B}\mathbf{D}^{-1} \\ 0 & \mathbf{I}_l \end{pmatrix}$ is the displayed matrix by Theorem 7.1.1.

■

Nobody should memorize these blocks. Remember instead that $\mathbf{M}^{-1}$ is the product of three easy inverses in reverse order, and that the corner opposite $\mathbf{A}$ in $\mathbf{M}^{-1}$ is the inverse of the complement of $\mathbf{A}$.

Example. (A 4×4 Inverse through a 2×2 Schur Complement)

Invert

$$\mathbf{M} = \left(\begin{array}{cc|cc} 1 & 1 & 0 & -1 \\ 1 & 2 & -1 & -1 \\ \hline -1 & -1 & 1 & 1 \\ 0 & 1 & 0 & -1 \end{array}\right) \in M_4(\mathbb{Q})$$

using Theorem 7.3.4, and find $\det\mathbf{M}$.

Solution. The blocks are $\mathbf{A} = \begin{pmatrix} 1 & 1 \\ 1 & 2 \end{pmatrix}$, $\mathbf{B} = \begin{pmatrix} 0 & -1 \\ -1 & -1 \end{pmatrix}$, $\mathbf{C} = \begin{pmatrix} -1 & -1 \\ 0 & 1 \end{pmatrix}$, $\mathbf{D} = \begin{pmatrix} 1 & 1 \\ 0 & -1 \end{pmatrix}$.

Step 1: invert $\mathbf{A}$. $\det\mathbf{A} = 1$, so $\mathbf{A}^{-1} = \begin{pmatrix} 2 & -1 \\ -1 & 1 \end{pmatrix}$ by Theorem 0.9.8.

Step 2: the two "half" products.

$$\mathbf{CA}^{-1} = \begin{pmatrix} -1 & 0 \\ -1 & 1 \end{pmatrix}, \qquad \mathbf{A}^{-1}\mathbf{B} = \begin{pmatrix} 1 & -1 \\ -1 & 0 \end{pmatrix}, \qquad \mathbf{CA}^{-1}\mathbf{B} = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}.$$

Step 3: the complement and its inverse. $\mathbf{S} = \mathbf{M}/\mathbf{A} = \mathbf{D} - \mathbf{CA}^{-1}\mathbf{B} = \begin{pmatrix} 1 & 0 \\ 1 & -1 \end{pmatrix}$. Its determinant is $-1 \neq 0$, so $\mathbf{M}$ is invertible by Theorem 7.3.4 (a), and $\mathbf{S}^{-1} = \begin{pmatrix} 1 & 0 \\ 1 & -1 \end{pmatrix} = \mathbf{S}$ by Theorem 0.9.8. By Theorem 7.3.2, $\det \mathbf{M} = \det \mathbf{A} \det \mathbf{S} = -1$.

Step 4: the blocks of $\mathbf{M}^{-1}$. Using Step 2,

$$-\mathbf{A}^{-1}\mathbf{B}\mathbf{S}^{-1} = -\begin{pmatrix} 1 & -1 \\ -1 & 0 \end{pmatrix}\begin{pmatrix} 1 & 0 \\ 1 & -1 \end{pmatrix} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix},$$
$$-\mathbf{S}^{-1}\mathbf{C}\mathbf{A}^{-1} = -\begin{pmatrix} 1 & 0 \\ 1 & -1 \end{pmatrix}\begin{pmatrix} -1 & 0 \\ -1 & 1 \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix},$$

and $\mathbf{A}^{-1}+\mathbf{A}^{-1}\mathbf{B}\mathbf{S}^{-1}\mathbf{C}\mathbf{A}^{-1} = \mathbf{A}^{-1}+(\mathbf{A}^{-1}\mathbf{B}\mathbf{S}^{-1})(\mathbf{C}\mathbf{A}^{-1}) = \begin{pmatrix} 2 & -1 \\ -1 & 1 \end{pmatrix}+\begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}\begin{pmatrix} -1 & 0 \\ -1 & 1 \end{pmatrix} = \begin{pmatrix} 2 & -1 \\ -1 & 1 \end{pmatrix} + \begin{pmatrix} -1 & 1 \\ 1 & 0 \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$. Hence

$$\mathbf{M}^{-1} = \left(\begin{array}{cc|cc} 1 & 0 & 0 & -1 \\ 0 & 1 & 1 & 0 \\ \hline 1 & 0 & 1 & 0 \\ 0 & 1 & 1 & -1 \end{array}\right).$$

Check one row: row 1 of $\mathbf{M}$ times column 1 of $\mathbf{M}^{-1}$ is $1+0+0+0=1$, and times column 3 is $0+1+0-1=0$. All the work was with 2×2 matrices, and only two of them had to be inverted.

Remark. When $\mathbf{M}$ is real symmetric, $\mathbf{M}/\mathbf{A}$ is again symmetric, and Chapter 12 uses Schur complements to test whether $\mathbf{M}$ is positive definite one block at a time. Chapter 23 reads Gaussian elimination itself as a sequence of Schur complements of 1×1 pivots, which is the point of view behind block algorithms in numerical linear algebra.

7.3.5 The Sherman–Morrison–Woodbury formula

Chapter 6 proved the Matrix Determinant Lemma, $\det(\mathbf{I}_n + \mathbf{uv}^\top) = 1 + \mathbf{v}^\top\mathbf{u}$ (Theorem 6.8.5), by bordering $\mathbf{I}_n + \mathbf{uv}^\top$ into a larger block matrix. There is a matching statement about inverses: if we already know $\mathbf{A}^{-1}$ and change $\mathbf{A}$ by a low-rank term $\mathbf{UCV}$, the new inverse should cost only a small inversion. The trick is to find one block matrix that has $\mathbf{A}$ in one corner and $\mathbf{A}+\mathbf{UCV}$ as a Schur complement, and then to compute its inverse twice.

Theorem 7.3.5 — Sherman–Morrison–Woodbury Formula

Let $n, k \geq 1$, let $\mathbf{A} \in M_n(F)$ and $\mathbf{C} \in M_k(F)$ be invertible, and let $\mathbf{U} \in M_{n\times k}(F)$ and $\mathbf{V} \in M_{k\times n}(F)$. Put $\mathbf{W} = \mathbf{C}^{-1} + \mathbf{VA}^{-1}\mathbf{U} \in M_k(F)$.

(a) $\mathbf{A}+\mathbf{UCV}$ is invertible if and only if $\mathbf{W}$ is invertible.

(b) In that case

$$\begin{aligned}(\mathbf{A}+\mathbf{UCV})^{-1} &= \mathbf{A}^{-1}-\mathbf{A}^{-1}\mathbf{U}\,\mathbf{W}^{-1}\,\mathbf{V}\mathbf{A}^{-1}\\ &= \mathbf{A}^{-1}-\mathbf{A}^{-1}\mathbf{U}\big(\mathbf{C}^{-1}+\mathbf{V}\mathbf{A}^{-1}\mathbf{U}\big)^{-1}\mathbf{V}\mathbf{A}^{-1}.\end{aligned}$$

(c) $\det(\mathbf{A}+\mathbf{UCV}) = \det\mathbf{A}\cdot\det\mathbf{C}\cdot\det\mathbf{W}$.

Idea. Look for a block matrix whose two Schur complements are $\mathbf{A}+\mathbf{UCV}$ and something involving $\mathbf{W}$. The complement of the lower-right corner of $\mathbf{M}=\begin{pmatrix}\mathbf{A}&\mathbf{U}\\ \mathbf{V}&\mathbf{D}\end{pmatrix}$ is $\mathbf{A}-\mathbf{UD}^{-1}\mathbf{V}$, which is $\mathbf{A}+\mathbf{UCV}$ when $\mathbf{D}^{-1}=-\mathbf{C}$, that is, $\mathbf{D}=-\mathbf{C}^{-1}$. The complement of the upper-left corner is then $-\mathbf{C}^{-1}-\mathbf{V}\mathbf{A}^{-1}\mathbf{U}=-\mathbf{W}$. Now Theorem 7.3.4 computes the upper-left block of $\mathbf{M}^{-1}$ in two ways: as $(\mathbf{M}/\mathbf{D})^{-1}=(\mathbf{A}+\mathbf{UCV})^{-1}$, and from the formula in terms of $\mathbf{A}$ and $\mathbf{M}/\mathbf{A}$. Setting them equal is the Woodbury formula. The determinant formula of the previous subsection, used twice, gives (c).

Proof. Let $\mathbf{D}=-\mathbf{C}^{-1}$, which is invertible with $\mathbf{D}^{-1}=-\mathbf{C}$ by Theorem 0.9.7 (2) and (5), and let $\mathbf{M}=\begin{pmatrix}\mathbf{A}&\mathbf{U}\\ \mathbf{V}&\mathbf{D}\end{pmatrix}\in M_{n+k}(F)$. By Definition 7.3.1,

$$\begin{aligned}\mathbf{M}/\mathbf{A} &= \mathbf{D}-\mathbf{V}\mathbf{A}^{-1}\mathbf{U} = -\mathbf{C}^{-1}-\mathbf{V}\mathbf{A}^{-1}\mathbf{U} = -\mathbf{W},\\ \mathbf{M}/\mathbf{D} &= \mathbf{A}-\mathbf{U}\mathbf{D}^{-1}\mathbf{V} = \mathbf{A}+\mathbf{UCV}.\end{aligned}$$

(a) By Theorem 7.3.4 (a) and (b), $\mathbf{M}$ is invertible if and only if $-\mathbf{W}$ is, and if and only if $\mathbf{A}+\mathbf{UCV}$ is. Since $-\mathbf{W}$ is invertible exactly when $\mathbf{W}$ is (Theorem 0.9.7 (5)), this proves (a).

(b) Suppose $\mathbf{W}$ is invertible, so $\mathbf{M}$ is invertible, and $(-\mathbf{W})^{-1}=-\mathbf{W}^{-1}$. The upper-left $n\times n$ block of $\mathbf{M}^{-1}$ is $(\mathbf{M}/\mathbf{D})^{-1}=(\mathbf{A}+\mathbf{UCV})^{-1}$ by Theorem 7.3.4 (b). By Theorem 7.3.4 (a), applied to $\mathbf{M}$, whose blocks are $\mathbf{A},\mathbf{U},\mathbf{V},\mathbf{D}$, and with $\mathbf{S}=\mathbf{M}/\mathbf{A}=-\mathbf{W}$, the same block is

$$\mathbf{A}^{-1}+\mathbf{A}^{-1}\mathbf{U}(-\mathbf{W})^{-1}\mathbf{V}\mathbf{A}^{-1} = \mathbf{A}^{-1}-\mathbf{A}^{-1}\mathbf{U}\mathbf{W}^{-1}\mathbf{V}\mathbf{A}^{-1}.$$

The two expressions are the same block of the same matrix, so they are equal.

(c) By Theorem 7.3.2 (a) and (b), $\det\mathbf{A}\det(-\mathbf{W})=\det\mathbf{M}=\det\mathbf{D}\det(\mathbf{A}+\mathbf{UCV})$. Multiplying a $k\times k$ matrix by -1 multiplies each of its k rows by -1, so by Theorem 6.5.1 $\det(-\mathbf{W})=(-1)^k\det\mathbf{W}$ and $\det\mathbf{D}=(-1)^k\det(\mathbf{C}^{-1})=(-1)^k(\det\mathbf{C})^{-1}$, using Corollary 6.5.6. Hence $\det\mathbf{A}\,(-1)^k\det\mathbf{W}=(-1)^k(\det\mathbf{C})^{-1}\det(\mathbf{A}+\mathbf{UCV})$. Multiplying both sides by $(-1)^k\det\mathbf{C}$ gives (c).

■

The formula is useful when k is much smaller than n and $\mathbf{A}^{-1}$ is already known or easy (diagonal, say): the only new inversion is of the $k\times k$ matrix $\mathbf{W}$. The most common case is a rank-one update, $k=1$ and $\mathbf{C}=(1)$.

Corollary 7.3.6 — Sherman–Morrison Formula

Let $\mathbf{A} \in M_n(F)$ be invertible and $\mathbf{u}, \mathbf{v} \in F^n$. Then $\mathbf{A} + \mathbf{u}\mathbf{v}^\top$ is invertible if and only if $1 + \mathbf{v}^\top \mathbf{A}^{-1}\mathbf{u} \neq 0$, and in that case

$$(\mathbf{A} + \mathbf{u}\mathbf{v}^\top)^{-1} = \mathbf{A}^{-1} - \frac{\mathbf{A}^{-1}\mathbf{u}\,\mathbf{v}^\top\mathbf{A}^{-1}}{1 + \mathbf{v}^\top\mathbf{A}^{-1}\mathbf{u}}.$$

Moreover $\det(\mathbf{A} + \mathbf{u}\mathbf{v}^\top) = \det\mathbf{A}\,(1 + \mathbf{v}^\top\mathbf{A}^{-1}\mathbf{u})$.

Proof. Apply Theorem 7.3.5 with $k = 1$, $\mathbf{C} = (1)$, $\mathbf{U} = \mathbf{u}$ and $\mathbf{V} = \mathbf{v}^\top$. Then $\mathbf{W} = (1 + \mathbf{v}^\top\mathbf{A}^{-1}\mathbf{u})$ is a 1×1 matrix, invertible exactly when its entry is non-zero, with inverse the reciprocal. Multiplying by a 1×1 matrix is multiplying by its entry, which gives the displayed formula; and $\det\mathbf{W}$ is the entry itself. ∎

For example, over $\mathbb{Q}$ let $\mathbf{A} = \operatorname{diag}(1, -1)$, so $\mathbf{A}^{-1} = \mathbf{A}$, and $\mathbf{u} = (1, 1)$. For $\mathbf{v} = (2, 1)$, $\mathbf{A}^{-1}\mathbf{u} = (1, -1)$, $\mathbf{v}^\top\mathbf{A}^{-1} = \begin{pmatrix} 2 & -1 \end{pmatrix}$ and $1 + \mathbf{v}^\top\mathbf{A}^{-1}\mathbf{u} = 1 + (2 - 1) = 2 \neq 0$. So $\mathbf{A} + \mathbf{u}\mathbf{v}^\top = \begin{pmatrix} 3 & 1 \\ 2 & 0 \end{pmatrix}$ has determinant $\det\mathbf{A} \cdot 2 = -2$, and

$$\begin{aligned}(\mathbf{A} + \mathbf{u}\mathbf{v}^\top)^{-1} &= \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} - \frac{1}{2}\begin{pmatrix} 1 \\ -1 \end{pmatrix}\begin{pmatrix} 2 & -1 \end{pmatrix} \\ &= \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} - \begin{pmatrix} 1 & -\frac{1}{2} \\ -1 & \frac{1}{2} \end{pmatrix} = \begin{pmatrix} 0 & \frac{1}{2} \\ 1 & -\frac{3}{2} \end{pmatrix},\end{aligned}$$

which agrees with Theorem 0.9.8. For $\mathbf{v} = (1, 2)$ instead, $1 + \mathbf{v}^\top\mathbf{A}^{-1}\mathbf{u} = 1 + (1 - 2) = 0$, and indeed $\mathbf{A} + \mathbf{u}\mathbf{v}^\top = \begin{pmatrix} 2 & 2 \\ 1 & 1 \end{pmatrix}$ is not invertible.

With $\mathbf{A} = \mathbf{I}_n$, the determinant statement is the Matrix Determinant Lemma of Chapter 6, now obtained as a special case of a formula about general low-rank updates, and it matches Exercise (C3: Rank-one updates of an invertible matrix).

7.3.6 Commuting blocks

Section 1 warned that $\det\begin{pmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{C} & \mathbf{D} \end{pmatrix} \neq \det(\mathbf{AD} - \mathbf{BC})$ in general. With the Schur complement we can see what goes wrong and what extra hypothesis repairs it. Take all four blocks in $M_n(F)$ and suppose $\mathbf{D}$ is invertible. By Theorem 7.3.2 (b),

$$\begin{aligned}\det\mathbf{M} &= \det\mathbf{D}\,\det(\mathbf{A} - \mathbf{B}\mathbf{D}^{-1}\mathbf{C}) \\ &= \det\big((\mathbf{A} - \mathbf{B}\mathbf{D}^{-1}\mathbf{C})\mathbf{D}\big) = \det(\mathbf{AD} - \mathbf{B}\mathbf{D}^{-1}\mathbf{CD}),\end{aligned}$$

using Theorem 6.5.4. If $\mathbf{C}$ and $\mathbf{D}$ commute, then $\mathbf{D}^{-1}\mathbf{CD} = \mathbf{D}^{-1}\mathbf{DC} = \mathbf{C}$, and the right side is $\det(\mathbf{AD} - \mathbf{BC})$. So commuting is exactly what lets $\mathbf{D}^{-1}$ cancel. The real question is how to remove the hypothesis that $\mathbf{D}$ is invertible, which is not needed for the conclusion to make sense.

Over $\mathbb{R}$ one could perturb: $\mathbf{D} + t\mathbf{I}_n$ is invertible for all but finitely many t, both sides are polynomials in t, and polynomials that agree at infinitely many points are equal. Over a finite field such as $\mathbb{F}_2$ there may be no invertible perturbation at all. We use instead a perturbation

by an **indeterminate**: replace $\mathbf{D}$ by $\mathbf{D}+x\mathbf{I}_n$, a matrix with entries in $F[x]$. Its determinant is a monic polynomial, hence not the zero polynomial, and that is all the cancellation needs. First we record that evaluating polynomial entries commutes with matrix operations.

For $\mathbf{N}=(n_{ij})$ with entries in $F[x]$ and $c\in F$, write $\mathbf{N}(c)=(n_{ij}(c))$ for the matrix over F obtained by evaluating every entry at c. A matrix over F is a matrix over $F[x]$ with constant entries, and then $\mathbf{N}(c)=\mathbf{N}$.

Lemma 7.3.7 — Evaluating a Matrix of Polynomials

Let $c\in F$, and let $\mathbf{N},\mathbf{N}'$ be matrices with entries in $F[x]$ of sizes for which the operations below are defined. Then $(\mathbf{N}+\mathbf{N}')(c)=\mathbf{N}(c)+\mathbf{N}'(c)$, $(\mathbf{N}\mathbf{N}')(c)=\mathbf{N}(c)\mathbf{N}'(c)$, and, for square $\mathbf{N}$, $(\det\mathbf{N})(c)=\det\big(\mathbf{N}(c)\big)$.

Proof. By Theorem 0.8.5, evaluation at c sends sums of polynomials to sums, products to products, and constants to themselves. The (i,j)-entry of $\mathbf{N}+\mathbf{N}'$ is $n_{ij}+n'_{ij}$ and that of $\mathbf{N}\mathbf{N}'$ is $\sum_l n_{il}n'_{lj}$, so evaluating gives the corresponding entries of $\mathbf{N}(c)+\mathbf{N}'(c)$ and $\mathbf{N}(c)\mathbf{N}'(c)$. The determinant $\det\mathbf{N}$ is the Leibniz sum $\sum_\sigma \operatorname{sgn}(\sigma)\prod_j n_{\sigma(j)j}$ of Definition 6.4.1, computed in $F[x]$, and evaluating it term by term gives the Leibniz sum for $\mathbf{N}(c)$. This is the argument of Lemma 6.10.1. ∎

Theorem 7.3.8 — Determinant with Commuting Blocks

Let $n\ge 1$ and $\mathbf{A},\mathbf{B},\mathbf{C},\mathbf{D}\in M_n(F)$ over **any** field F. If $\mathbf{C}\mathbf{D}=\mathbf{D}\mathbf{C}$, then

$$\det\begin{pmatrix}\mathbf{A}&\mathbf{B}\\ \mathbf{C}&\mathbf{D}\end{pmatrix}=\det(\mathbf{A}\mathbf{D}-\mathbf{B}\mathbf{C}).$$

Idea. ① Work over the commutative ring $F[x]$, replacing $\mathbf{D}$ by $\mathbf{D}_x=\mathbf{D}+x\mathbf{I}_n$, which still commutes with $\mathbf{C}$. ② Multiply $\mathbf{M}_x=\begin{pmatrix}\mathbf{A}&\mathbf{B}\\ \mathbf{C}&\mathbf{D}_x\end{pmatrix}$ on the right by $\begin{pmatrix}\mathbf{D}_x&0\\ -\mathbf{C}&\mathbf{I}_n\end{pmatrix}$: the lower-left block becomes $\mathbf{C}\mathbf{D}_x-\mathbf{D}_x\mathbf{C}=0$ and the upper-left block becomes $\mathbf{A}\mathbf{D}_x-\mathbf{B}\mathbf{C}$. This is the Schur computation above with $\mathbf{D}^{-1}$ cleared from the denominators. ③ Take determinants: $\det\mathbf{M}_x\det\mathbf{D}_x=\det(\mathbf{A}\mathbf{D}_x-\mathbf{B}\mathbf{C})\det\mathbf{D}_x$. ④ Cancel $\det\mathbf{D}_x$, which is legal because it is a non-zero polynomial and $F[x]$ has no zero divisors. ⑤ Set $x=0$. Each step uses only determinant facts that Chapter 6 proved over commutative rings.

Proof. Regard $\mathbf{A},\mathbf{B},\mathbf{C},\mathbf{D}$ as matrices over $F[x]$ with constant entries, and let $\mathbf{D}_x=\mathbf{D}+x\mathbf{I}_n$. The proofs of Theorem 0.9.4 use only the ring axioms, so they hold for matrices over $F[x]$; in particular

$$\mathbf{C}\mathbf{D}_x=\mathbf{C}\mathbf{D}+x\mathbf{C}=\mathbf{D}\mathbf{C}+x\mathbf{C}=\mathbf{D}_x\mathbf{C},$$

using the hypothesis $\mathbf{C}\mathbf{D}=\mathbf{D}\mathbf{C}$. Let

$$\mathbf{M}_x=\begin{pmatrix}\mathbf{A}&\mathbf{B}\\ \mathbf{C}&\mathbf{D}_x\end{pmatrix},\qquad \mathbf{R}=\begin{pmatrix}\mathbf{D}_x&0\\ -\mathbf{C}&\mathbf{I}_n\end{pmatrix},$$

both in $M_{2n}(F[x])$. By Theorem 7.1.1, which holds over $F[x]$ by the remark following it,

$$\mathbf{M}_x\mathbf{R} = \begin{pmatrix} \mathbf{A}\mathbf{D}_x - \mathbf{B}\mathbf{C} & \mathbf{B} \\ \mathbf{C}\mathbf{D}_x - \mathbf{D}_x\mathbf{C} & \mathbf{D}_x \end{pmatrix} = \begin{pmatrix} \mathbf{A}\mathbf{D}_x - \mathbf{B}\mathbf{C} & \mathbf{B} \\ 0 & \mathbf{D}_x \end{pmatrix}.$$

By the remarks in Chapter 6 §5 and §8, Theorem 6.5.4 and Theorem 6.8.4 hold over the commutative ring $F[x]$. Hence $\det(\mathbf{M}_x\mathbf{R}) = \det \mathbf{M}_x \det \mathbf{R}$, with $\det \mathbf{R} = \det \mathbf{D}_x \det \mathbf{I}_n = \det \mathbf{D}_x$, and $\det(\mathbf{M}_x\mathbf{R}) = \det(\mathbf{A}\mathbf{D}_x - \mathbf{B}\mathbf{C}) \det \mathbf{D}_x$. So, in $F[x]$,

$$\det \mathbf{M}_x \cdot \det \mathbf{D}_x = \det(\mathbf{A}\mathbf{D}_x - \mathbf{B}\mathbf{C}) \cdot \det \mathbf{D}_x. \qquad (*)$$

Now $\mathbf{D}_x = x\mathbf{I}_n - (-\mathbf{D})$, so $\det \mathbf{D}_x = p_{-\mathbf{D}}(x)$ is the characteristic polynomial of $-\mathbf{D} \in M_n(F)$ (Definition 6.10.1). By Theorem 6.10.2 it is monic of degree n, so $\det \mathbf{D}_x \neq 0$ in $F[x]$. By Corollary 0.8.4 (2), we may cancel it from $(*)$:

$$\det \mathbf{M}_x = \det(\mathbf{A}\mathbf{D}_x - \mathbf{B}\mathbf{C}) \quad \text{in } F[x].$$

Finally evaluate both sides at 0. By Lemma 7.3.7, $(\det \mathbf{M}_x)(0) = \det(\mathbf{M}_x(0)) = \det \mathbf{M}$, since $\mathbf{D}_x(0) = \mathbf{D}$; and $(\mathbf{A}\mathbf{D}_x - \mathbf{B}\mathbf{C})(0) = \mathbf{A}\mathbf{D} - \mathbf{B}\mathbf{C}$, so $(\det(\mathbf{A}\mathbf{D}_x - \mathbf{B}\mathbf{C}))(0) = \det(\mathbf{A}\mathbf{D} - \mathbf{B}\mathbf{C})$. Hence $\det \mathbf{M} = \det(\mathbf{A}\mathbf{D} - \mathbf{B}\mathbf{C})$.

■

The cancellation in $F[x]$ is the heart of the argument, so it is worth being precise about why it is legal. Over F we cannot divide by $\det \mathbf{D}$ when it is 0. Over $F[x]$ we still cannot divide, since $\det \mathbf{D}_x$ usually has no inverse, but we do not need to: cancellation only needs "$pq = pr$ and $p \neq 0$ imply $q = r$", and this holds in $F[x]$ because a product of non-zero polynomials is non-zero (Corollary 0.8.4). The perturbation $x\mathbf{I}_n$ makes $\det \mathbf{D}_x$ non-zero **as a polynomial** even when every value $\det(\mathbf{D} + c\mathbf{I}_n)$ with $c \in F$ is zero. For example, over $\mathbb{F}_2$, let $\mathbf{D} = \mathbf{E}_{22} = \operatorname{diag}(0, 1)$. Then $\det(\mathbf{D} + 0\mathbf{I}_2) = 0$ and $\det(\mathbf{D} + \mathbf{I}_2) = \det \operatorname{diag}(1, 0) = 0$, because $1 + 1 = 0$ in $\mathbb{F}_2$; no scalar shift makes $\mathbf{D}$ invertible. But $\det(\mathbf{D} + x\mathbf{I}_2) = x(x + 1) = x^2 + x$ is not the zero polynomial.

For example, over $\mathbb{Q}$, let $\mathbf{A} = \begin{pmatrix} 1 & 2 \\ 0 & 1 \end{pmatrix}$, $\mathbf{B} = \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix}$, $\mathbf{D} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$ and $\mathbf{C} = 2\mathbf{I}_2 + \mathbf{D} = \begin{pmatrix} 2 & 1 \\ 0 & 2 \end{pmatrix}$, which commutes with $\mathbf{D}$. Here $\mathbf{D}$ is not invertible, so the Schur route is closed. The theorem gives $\det \mathbf{M} = \det(\mathbf{A}\mathbf{D} - \mathbf{B}\mathbf{C}) = \det \begin{pmatrix} -2 & 0 \\ -2 & -3 \end{pmatrix} = 6$.

Warning. **Which blocks commute decides which product appears.** The hypothesis $\mathbf{C}\mathbf{D} = \mathbf{D}\mathbf{C}$ gives $\det(\mathbf{A}\mathbf{D} - \mathbf{B}\mathbf{C})$. If instead $\mathbf{A}$ and $\mathbf{C}$ commute, the correct formula is $\det(\mathbf{A}\mathbf{D} - \mathbf{C}\mathbf{B})$ (Exercise (C3: When **A** and **C** commute)), with $\mathbf{C}$ and $\mathbf{B}$ in the other order. The two can differ: for the blocks $\mathbf{A} = \mathbf{I}_2$, $\mathbf{B} = \mathbf{E}_{12}$, $\mathbf{C} = \mathbf{E}_{21}$, $\mathbf{D} = \mathbf{E}_{11}$ of the warning in Section 1, $\mathbf{A}$ commutes with $\mathbf{C}$ but $\mathbf{C}$ does not commute with $\mathbf{D}$; indeed $\det \mathbf{M} = -1 = \det(\mathbf{E}_{11} - \mathbf{E}_{22}) = \det(\mathbf{A}\mathbf{D} - \mathbf{C}\mathbf{B})$, while $\det(\mathbf{A}\mathbf{D} - \mathbf{B}\mathbf{C}) = 0$.

7.3.7 Exercises

7.3.7.1 A. Check your understanding

Exercise A1.

(a) Define the Schur complement $\mathbf{M}/\mathbf{A}$, including the hypothesis on $\mathbf{A}$ and the size of $\mathbf{M}/\mathbf{A}$.

(b) State the block LDU factorization of $\mathbf{M}$ in terms of $\mathbf{A}$ and $\mathbf{M}/\mathbf{A}$.

(c) True or false: if $\mathbf{M} = \begin{pmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{C} & \mathbf{D} \end{pmatrix}$ is invertible and $\mathbf{A}$ is square, then $\mathbf{A}$ is invertible. Justify your answer.

(d) If $\mathbf{A}$ is invertible and $\mathbf{M}$ is invertible, which block of $\mathbf{M}^{-1}$ is $(\mathbf{M}/\mathbf{A})^{-1}$?

(e) True or false: for all $\mathbf{A}, \mathbf{B}, \mathbf{C}, \mathbf{D} \in M_n(F)$ with $\mathbf{CD} = \mathbf{DC}$, $\det \begin{pmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{C} & \mathbf{D} \end{pmatrix} = \det(\mathbf{AD} - \mathbf{BC})$, even if $\mathbf{D}$ is not invertible and $F = \mathbb{F}_2$. Justify your answer.

Solution.

(a) For $\mathbf{M} = \begin{pmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{C} & \mathbf{D} \end{pmatrix}$ with $\mathbf{A} \in M_k(F)$ **invertible**, $\mathbf{B} \in M_{k\times l}(F)$, $\mathbf{C} \in M_{p\times k}(F)$, $\mathbf{D} \in M_{p\times l}(F)$: $\mathbf{M}/\mathbf{A} = \mathbf{D} - \mathbf{C}\mathbf{A}^{-1}\mathbf{B} \in M_{p\times l}(F)$, the size of $\mathbf{D}$ (Definition 7.3.1).

(b) $\mathbf{M} = \begin{pmatrix} \mathbf{I}_k & 0 \\ \mathbf{C}\mathbf{A}^{-1} & \mathbf{I}_p \end{pmatrix} \begin{pmatrix} \mathbf{A} & 0 \\ 0 & \mathbf{M}/\mathbf{A} \end{pmatrix} \begin{pmatrix} \mathbf{I}_k & \mathbf{A}^{-1}\mathbf{B} \\ 0 & \mathbf{I}_l \end{pmatrix}$ (Theorem 7.3.1).

(c) False. $\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$ is invertible, but $\mathbf{A} = (0)$ is not.

(d) The lower-right block, in the position of $\mathbf{D}$ (Theorem 7.3.4 (a)).

(e) True. Theorem 7.3.8 holds over every field and needs no invertibility; its proof cancels the non-zero polynomial $\det(\mathbf{D} + x\mathbf{I}_n)$ in $F[x]$.

7.3.7.2 B. Practice

Exercise B1: A Schur complement, a determinant and a rank.

Let

$$\mathbf{M} = \left(\begin{array}{cc|cc} 2 & 1 & 1 & 0 \\ 1 & 1 & 3 & 1 \\ \hline 1 & 2 & 9 & 5 \\ 0 & 1 & 6 & 4 \end{array}\right) \in M_4(\mathbb{Q}).$$

Compute $\mathbf{M}/\mathbf{A}$ for the upper-left block $\mathbf{A}$. Hence find $\det \mathbf{M}$ and $\operatorname{rank} \mathbf{M}$, and decide whether $\mathbf{M}$ is invertible.

Solution. $\mathbf{A} = \begin{pmatrix} 2 & 1 \\ 1 & 1 \end{pmatrix}$ has $\det \mathbf{A} = 1$, so $\mathbf{A}^{-1} = \begin{pmatrix} 1 & -1 \\ -1 & 2 \end{pmatrix}$ (Theorem 0.9.8). With $\mathbf{B} = \begin{pmatrix} 1 & 0 \\ 3 & 1 \end{pmatrix}$, $\mathbf{C} = \begin{pmatrix} 1 & 2 \\ 0 & 1 \end{pmatrix}$, $\mathbf{D} = \begin{pmatrix} 9 & 5 \\ 6 & 4 \end{pmatrix}$:

$$\mathbf{C}\mathbf{A}^{-1} = \begin{pmatrix} -1 & 3 \\ -1 & 2 \end{pmatrix}, \qquad \mathbf{C}\mathbf{A}^{-1}\mathbf{B} = \begin{pmatrix} 8 & 3 \\ 5 & 2 \end{pmatrix}, \qquad \mathbf{M}/\mathbf{A} = \begin{pmatrix} 1 & 2 \\ 1 & 2 \end{pmatrix}.$$

By Theorem 7.3.2, $\det \mathbf{M} = \det \mathbf{A} \det(\mathbf{M}/\mathbf{A}) = 1 \cdot 0 = 0$. By Theorem 7.3.3, $\operatorname{rank} \mathbf{M} = 2 + \operatorname{rank}(\mathbf{M}/\mathbf{A}) = 2 + 1 = 3$, since $\mathbf{M}/\mathbf{A}$ is non-zero with equal rows. So $\mathbf{M}$ is not invertible (Theorem 2.4.4).

Exercise B2: A rank-one update.

Let $\mathbf{A} = \operatorname{diag}(1, 2, 4) \in M_3(\mathbb{Q})$, $\mathbf{u} = (1, 1, 1)$ and $\mathbf{v} = (1, -1, 2)$. Use Corollary 7.3.6 to find $\det(\mathbf{A} + \mathbf{u}\mathbf{v}^\top)$ and $(\mathbf{A} + \mathbf{u}\mathbf{v}^\top)^{-1}$, and check one entry.

Solution. $\mathbf{A}^{-1} = \operatorname{diag}(1, \frac{1}{2}, \frac{1}{4})$, so $\mathbf{A}^{-1}\mathbf{u} = (1, \frac{1}{2}, \frac{1}{4})$ and $\mathbf{v}^\top\mathbf{A}^{-1} = \begin{pmatrix} 1 & -\frac{1}{2} & \frac{1}{2} \end{pmatrix}$. Then $\mathbf{v}^\top\mathbf{A}^{-1}\mathbf{u} = 1 - \frac{1}{2} + \frac{1}{2} = 1$, so $1 + \mathbf{v}^\top\mathbf{A}^{-1}\mathbf{u} = 2 \neq 0$. By Corollary 7.3.6, $\mathbf{A} + \mathbf{u}\mathbf{v}^\top$ is invertible, $\det(\mathbf{A} + \mathbf{u}\mathbf{v}^\top) = 8 \cdot 2 = 16$, and

$$\begin{aligned}(\mathbf{A} + \mathbf{u}\mathbf{v}^\top)^{-1} &= \operatorname{diag}\left(1, \tfrac{1}{2}, \tfrac{1}{4}\right) - \frac{1}{2}\begin{pmatrix} 1 \\ \frac{1}{2} \\ \frac{1}{4} \end{pmatrix}\begin{pmatrix} 1 & -\frac{1}{2} & \frac{1}{2} \end{pmatrix} \\ &= \begin{pmatrix} 1 & 0 & 0 \\ 0 & \frac{1}{2} & 0 \\ 0 & 0 & \frac{1}{4} \end{pmatrix} - \begin{pmatrix} \frac{1}{2} & -\frac{1}{4} & \frac{1}{4} \\ \frac{1}{4} & -\frac{1}{8} & \frac{1}{8} \\ \frac{1}{8} & -\frac{1}{16} & \frac{1}{16} \end{pmatrix} \\ &= \begin{pmatrix} \frac{1}{2} & \frac{1}{4} & -\frac{1}{4} \\ -\frac{1}{4} & \frac{5}{8} & -\frac{1}{8} \\ -\frac{1}{8} & \frac{1}{16} & \frac{3}{16} \end{pmatrix}.\end{aligned}$$

Check: $\mathbf{A}+\mathbf{u}\mathbf{v}^\top = \begin{pmatrix} 2 & -1 & 2 \\ 1 & 1 & 2 \\ 1 & -1 & 6 \end{pmatrix}$, and its row 1 times column 1 of the answer is $1+\frac{1}{4}-\frac{1}{4} = 1$, times column 2 is $\frac{1}{2} - \frac{5}{8} + \frac{1}{8} = 0$.

Exercise B3: Identity corners.

Let $\mathbf{B} \in M_{k\times l}(F)$, $\mathbf{C} \in M_{l\times k}(F)$ and $\mathbf{M} = \begin{pmatrix} \mathbf{I}_k & \mathbf{B} \\ \mathbf{C} & \mathbf{I}_l \end{pmatrix}$.

(a) Show that $\mathbf{M}$ is invertible if and only if $\mathbf{S} = \mathbf{I}_l - \mathbf{C}\mathbf{B}$ is, and write down $\mathbf{M}^{-1}$ in terms of $\mathbf{S}^{-1}$.

(b) Deduce the inverse of $\begin{pmatrix} \mathbf{I}_k & \mathbf{B} \\ 0 & \mathbf{I}_l \end{pmatrix}$.

(c) For $\mathbf{B} = \begin{pmatrix} 1 \\ 2 \end{pmatrix}$ and $\mathbf{C} = \begin{pmatrix} 1 & 1 \end{pmatrix}$ over $\mathbb{Q}$, compute $\mathbf{M}^{-1}$.

Solution.

(a) The block $\mathbf{I}_k$ is invertible and $\mathbf{M}/\mathbf{I}_k = \mathbf{I}_l - \mathbf{C}\mathbf{I}_k^{-1}\mathbf{B} = \mathbf{I}_l - \mathbf{C}\mathbf{B}$. By Theorem 7.3.4 (a), $\mathbf{M}$ is invertible if and only if $\mathbf{I}_l - \mathbf{C}\mathbf{B}$ is, and then, with $\mathbf{A}^{-1} = \mathbf{I}_k$,

$$\mathbf{M}^{-1} = \begin{pmatrix} \mathbf{I}_k + \mathbf{B}\mathbf{S}^{-1}\mathbf{C} & -\mathbf{B}\mathbf{S}^{-1} \\ -\mathbf{S}^{-1}\mathbf{C} & \mathbf{S}^{-1} \end{pmatrix}.$$

(b) With $\mathbf{C} = 0$, $\mathbf{S} = \mathbf{I}_l - \mathbf{C}\mathbf{B} = \mathbf{I}_l$ and $\mathbf{S}^{-1} = \mathbf{I}_l$, so the inverse is $\begin{pmatrix} \mathbf{I}_k & -\mathbf{B} \\ 0 & \mathbf{I}_l \end{pmatrix}$, in agreement with Theorem 7.1.5.

(c) $\mathbf{C}\mathbf{B} = (3)$, so $\mathbf{S} = \mathbf{I}_1 - \mathbf{C}\mathbf{B} = (-2)$ and $\mathbf{S}^{-1} = (-\frac{1}{2})$. Then $\mathbf{B}\mathbf{S}^{-1}\mathbf{C} = -\frac{1}{2}\begin{pmatrix} 1 & 1 \\ 2 & 2 \end{pmatrix}$,

$-\mathbf{B}\mathbf{S}^{-1} = \begin{pmatrix}\frac{1}{2}\\ 1\end{pmatrix}$ and $-\mathbf{S}^{-1}\mathbf{C} = \begin{pmatrix}\frac{1}{2} & \frac{1}{2}\end{pmatrix}$, so

$$\mathbf{M}^{-1} = \begin{pmatrix}\frac{1}{2} & -\frac{1}{2} & \frac{1}{2}\\ -1 & 0 & 1\\ \frac{1}{2} & \frac{1}{2} & -\frac{1}{2}\end{pmatrix}, \qquad \mathbf{M} = \begin{pmatrix}1 & 0 & 1\\ 0 & 1 & 2\\ 1 & 1 & 1\end{pmatrix}.$$

Check: row 3 of $\mathbf{M}$ times column 3 of $\mathbf{M}^{-1}$ is $\frac{1}{2} + 1 - \frac{1}{2} = 1$, and times column 1 is $\frac{1}{2} - 1 + \frac{1}{2} = 0$.

7.3.7.3 C. Going deeper

Exercise C1: Sylvester's determinant identity.

Let $\mathbf{A} \in M_{m\times n}(F)$ and $\mathbf{B} \in M_{n\times m}(F)$ with $m, n \geq 1$.

(a) Compute both Schur complements of the identity blocks in $\mathbf{M} = \begin{pmatrix}\mathbf{I}_m & -\mathbf{A}\\ \mathbf{B} & \mathbf{I}_n\end{pmatrix}$, and deduce
$$\det(\mathbf{I}_m + \mathbf{AB}) = \det(\mathbf{I}_n + \mathbf{BA}).$$

(b) Deduce that for every non-zero $c \in F$, $\det(c\mathbf{I}_m - \mathbf{AB}) = c^{m-n}\det(c\mathbf{I}_n - \mathbf{BA})$.

(c) Deduce Theorem 6.8.5 from (a).

Solution.

(a) Both identity blocks are invertible. By Definition 7.3.1,
$$\mathbf{M}/\mathbf{I}_m = \mathbf{I}_n - \mathbf{B}\mathbf{I}_m^{-1}(-\mathbf{A}) = \mathbf{I}_n + \mathbf{BA},$$
$$\mathbf{M}/\mathbf{I}_n = \mathbf{I}_m - (-\mathbf{A})\mathbf{I}_n^{-1}\mathbf{B} = \mathbf{I}_m + \mathbf{AB}.$$
By Theorem 7.3.2 (a) and (b), $\det\mathbf{M} = \det\mathbf{I}_m \det(\mathbf{I}_n+\mathbf{BA})$ and $\det\mathbf{M} = \det\mathbf{I}_n \det(\mathbf{I}_m+\mathbf{AB})$. Hence $\det(\mathbf{I}_m + \mathbf{AB}) = \det(\mathbf{I}_n + \mathbf{BA})$.

(b) Let $\mathbf{A}' = -c^{-1}\mathbf{A}$. Then $c\mathbf{I}_m - \mathbf{AB} = c(\mathbf{I}_m + \mathbf{A}'\mathbf{B})$ and $c\mathbf{I}_n - \mathbf{BA} = c(\mathbf{I}_n + \mathbf{BA}')$. Multiplying an $m\times m$ matrix by c multiplies each of its m rows by c, so it multiplies the determinant by c^m (Theorem 6.5.1). By (a) applied to $\mathbf{A}'$ and $\mathbf{B}$,
$$\begin{aligned}\det(c\mathbf{I}_m - \mathbf{AB}) &= c^m\det(\mathbf{I}_m + \mathbf{A}'\mathbf{B}) = c^m\det(\mathbf{I}_n + \mathbf{BA}')\\ &= c^m c^{-n}\det(c\mathbf{I}_n - \mathbf{BA}) = c^{m-n}\det(c\mathbf{I}_n - \mathbf{BA}).\end{aligned}$$

(c) Let $\mathbf{u}, \mathbf{v} \in F^n$, and apply (a) with the sizes m, n there replaced by $n, 1$: $\mathbf{A} = \mathbf{u} \in M_{n\times 1}(F)$ and $\mathbf{B} = \mathbf{v}^\top \in M_{1\times n}(F)$. Then $\det(\mathbf{I}_n+\mathbf{u}\mathbf{v}^\top) = \det(\mathbf{I}_1+\mathbf{v}^\top\mathbf{u}) = 1+\mathbf{v}^\top\mathbf{u}$, because the determinant of a 1×1 matrix is its entry.

Exercise C2: Pivots as Schur complements.

Let $\mathbf{A} \in M_n(F)$, and for $1 \leq k \leq n$ let $\mathbf{A}_k$ be its leading principal submatrix (the top-left $k\times k$ corner), as in Exercise (C1: Leading principal submatrices).

(a) Suppose $\mathbf{A}_{k-1}$ is invertible, where $2 \leq k \leq n$, and write $\mathbf{A}_k = \begin{pmatrix}\mathbf{A}_{k-1} & \mathbf{b}\\ \mathbf{c}^\top & d\end{pmatrix}$. Show

that $s_k \coloneqq \mathbf{A}_k/\mathbf{A}_{k-1}$ is the scalar $d - \mathbf{c}^\top \mathbf{A}_{k-1}^{-1}\mathbf{b}$, and that $\det \mathbf{A}_k = \det \mathbf{A}_{k-1} \cdot s_k$.

(b) Suppose $\mathbf{A}_1, \dots, \mathbf{A}_n$ are all invertible, and put $s_1 = a_{11}$. Prove that $\det \mathbf{A}_k = s_1 s_2 \cdots s_k$ for every k, and that every s_k is non-zero.

(c) Keep the hypothesis of (b). In the proof of Exercise (C1: Leading principal submatrices) (c), the last pivot is $z = d - \mathbf{x}^\top \mathbf{y}$ with $\mathbf{y} = \text{Ł}'^{-1}\mathbf{b}$ and $\mathbf{x}^\top = \mathbf{c}^\top \mathbf{U}'^{-1}$. Show that $z = \mathbf{A}_n/\mathbf{A}_{n-1}$. Deduce that the diagonal entries of $\mathbf{U}$ in the LU factorization are $u_{kk} = \det \mathbf{A}_k / \det \mathbf{A}_{k-1}$, with $\det \mathbf{A}_0 \coloneqq 1$.

(d) Check (c) for $\mathbf{A} = \begin{pmatrix} 2 & 1 & 1 \\ 4 & 3 & 3 \\ 8 & 7 & 9 \end{pmatrix}$ over $\mathbb{Q}$.

Solution.

(a) With the partition $k-1, 1$, Definition 7.3.1 gives the 1×1 matrix $\mathbf{A}_k/\mathbf{A}_{k-1} = d - \mathbf{c}^\top \mathbf{A}_{k-1}^{-1}\mathbf{b}$, which we identify with its entry. By Theorem 7.3.2 (a), $\det \mathbf{A}_k = \det \mathbf{A}_{k-1} \det(s_k) = \det \mathbf{A}_{k-1} \cdot s_k$.

(b) By induction on k. For $k = 1$, $\det \mathbf{A}_1 = a_{11} = s_1$. If $\det \mathbf{A}_{k-1} = s_1 \cdots s_{k-1}$, then by (a), which applies since $\mathbf{A}_{k-1}$ is invertible, $\det \mathbf{A}_k = s_1 \cdots s_{k-1} s_k$. Since $\mathbf{A}_k$ is invertible, $\det \mathbf{A}_k \neq 0$ (Theorem 6.5.2), so no factor s_k is zero (Theorem 0.7.1 (d)).

(c) $\mathbf{A}_{n-1} = \text{Ł}'\mathbf{U}'$ with both factors invertible, so $\mathbf{A}_{n-1}^{-1} = \mathbf{U}'^{-1}\text{Ł}'^{-1}$ (Theorem 0.9.7 (3)) and $\mathbf{x}^\top \mathbf{y} = \mathbf{c}^\top \mathbf{U}'^{-1}\text{Ł}'^{-1}\mathbf{b} = \mathbf{c}^\top \mathbf{A}_{n-1}^{-1}\mathbf{b}$. Hence $z = d - \mathbf{c}^\top \mathbf{A}_{n-1}^{-1}\mathbf{b} = \mathbf{A}_n/\mathbf{A}_{n-1} = s_n$ by (a). The same construction applied to $\mathbf{A}_k$ (whose LU factors are the top-left corners $\text{Ł}_k, \mathbf{U}_k$ of $\text{Ł}, \mathbf{U}$, by Exercise (C1: Leading principal submatrices) (a) and Theorem 2.6.5) shows $u_{kk} = s_k$ for every k. By (a) and (b), $s_k = \det \mathbf{A}_k / \det \mathbf{A}_{k-1}$, with $s_1 = \det \mathbf{A}_1 / 1$.

(d) $\det \mathbf{A}_1 = 2$, $\det \mathbf{A}_2 = 6 - 4 = 2$, and expanding, $\det \mathbf{A}_3 = 2(27 - 21) - 1(36 - 24) + 1(28 - 24) = 12 - 12 + 4 = 4$. The predicted pivots are 2, $2/2 = 1$, $4/2 = 2$. Elimination gives $\text{Ł} = \begin{pmatrix} 1 & 0 & 0 \\ 2 & 1 & 0 \\ 4 & 3 & 1 \end{pmatrix}$ and $\mathbf{U} = \begin{pmatrix} 2 & 1 & 1 \\ 0 & 1 & 1 \\ 0 & 0 & 2 \end{pmatrix}$: subtract 2 and 4 times row 1 to get rows $(0, 1, 1)$ and $(0, 3, 5)$, then 3 times the new row 2 to get $(0, 0, 2)$. The diagonal of $\mathbf{U}$ is $2, 1, 2$, as predicted.

Exercise C3: When A and C commute.

Let $n \geq 1$ and $\mathbf{A}, \mathbf{B}, \mathbf{C}, \mathbf{D} \in M_n(F)$ with $\mathbf{AC} = \mathbf{CA}$, and $\mathbf{M} = \begin{pmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{C} & \mathbf{D} \end{pmatrix}$.

(a) Assume $\mathbf{A}$ is invertible. Use Theorem 7.3.2 to prove $\det \mathbf{M} = \det(\mathbf{AD} - \mathbf{CB})$.

(b) Remove the assumption that $\mathbf{A}$ is invertible, over any field, by adapting the proof of Theorem 7.3.8 with $\mathbf{A}_x = \mathbf{A} + x\mathbf{I}_n$.

(c) For $\mathbf{A} = \mathbf{I}_2$, $\mathbf{B} = \mathbf{E}_{12}$, $\mathbf{C} = \mathbf{E}_{21}$, $\mathbf{D} = \mathbf{E}_{11}$ in $M_2(\mathbb{Q})$, check that $\mathbf{AC} = \mathbf{CA}$, and compare $\det \mathbf{M}$, $\det(\mathbf{AD} - \mathbf{CB})$ and $\det(\mathbf{AD} - \mathbf{BC})$.

Hint for (b): multiply $\mathbf{M}_x$ on the left by a block matrix that clears the lower-left block.

Solution.

(a) By Theorem 7.3.2 (a) and Theorem 6.5.4,

$$\begin{aligned}\det \mathbf{M} &= \det \mathbf{A} \det(\mathbf{D} - \mathbf{C}\mathbf{A}^{-1}\mathbf{B}) \\ &= \det\left(\mathbf{A}(\mathbf{D} - \mathbf{C}\mathbf{A}^{-1}\mathbf{B})\right) = \det(\mathbf{A}\mathbf{D} - \mathbf{A}\mathbf{C}\mathbf{A}^{-1}\mathbf{B}).\end{aligned}$$

Since $\mathbf{A}\mathbf{C} = \mathbf{C}\mathbf{A}$, $\mathbf{A}\mathbf{C}\mathbf{A}^{-1} = \mathbf{C}\mathbf{A}\mathbf{A}^{-1} = \mathbf{C}$, so $\det \mathbf{M} = \det(\mathbf{A}\mathbf{D} - \mathbf{C}\mathbf{B})$.

(b) Let $\mathbf{A}_x = \mathbf{A} + x\mathbf{I}_n$ over $F[x]$. Then $\mathbf{A}_x\mathbf{C} = \mathbf{A}\mathbf{C} + x\mathbf{C} = \mathbf{C}\mathbf{A} + x\mathbf{C} = \mathbf{C}\mathbf{A}_x$. Let $\mathbf{M}_x = \begin{pmatrix} \mathbf{A}_x & \mathbf{B} \\ \mathbf{C} & \mathbf{D} \end{pmatrix}$ and Ł $= \begin{pmatrix} \mathbf{I}_n & 0 \\ -\mathbf{C} & \mathbf{A}_x \end{pmatrix}$. By Theorem 7.1.1 over $F[x]$,

$$Ł\mathbf{M}_x = \begin{pmatrix} \mathbf{A}_x & \mathbf{B} \\ -\mathbf{C}\mathbf{A}_x + \mathbf{A}_x\mathbf{C} & -\mathbf{C}\mathbf{B} + \mathbf{A}_x\mathbf{D} \end{pmatrix} = \begin{pmatrix} \mathbf{A}_x & \mathbf{B} \\ 0 & \mathbf{A}_x\mathbf{D} - \mathbf{C}\mathbf{B} \end{pmatrix}.$$

By Theorem 6.5.4 and Theorem 6.8.4 over $F[x]$ (Chapter 6 §5 and §8), $\det \mathbf{A}_x \det \mathbf{M}_x = \det \mathbf{A}_x \det(\mathbf{A}_x\mathbf{D} - \mathbf{C}\mathbf{B})$, using $\det Ł = \det \mathbf{I}_n \det \mathbf{A}_x$. As in the proof of Theorem 7.3.8, $\det \mathbf{A}_x = p_{-\mathbf{A}}(x)$ is monic, hence non-zero, and Corollary 0.8.4 (2) gives $\det \mathbf{M}_x = \det(\mathbf{A}_x\mathbf{D} - \mathbf{C}\mathbf{B})$. Evaluating at $x = 0$ with Lemma 7.3.7 gives $\det \mathbf{M} = \det(\mathbf{A}\mathbf{D} - \mathbf{C}\mathbf{B})$.

(c) $\mathbf{A}\mathbf{C} = \mathbf{C} = \mathbf{C}\mathbf{A}$, since $\mathbf{A} = \mathbf{I}_2$. As computed in Section 1, $\det \mathbf{M} = -1$. Also $\mathbf{A}\mathbf{D} - \mathbf{C}\mathbf{B} = \mathbf{E}_{11} - \mathbf{E}_{21}\mathbf{E}_{12} = \mathbf{E}_{11} - \mathbf{E}_{22} = \operatorname{diag}(1, -1)$, with determinant -1, in agreement with (b). But $\mathbf{A}\mathbf{D} - \mathbf{B}\mathbf{C} = \mathbf{E}_{11} - \mathbf{E}_{12}\mathbf{E}_{21} = \mathbf{E}_{11} - \mathbf{E}_{11} = 0$, with determinant 0. So with $\mathbf{A}\mathbf{C} = \mathbf{C}\mathbf{A}$ the product must be taken as $\mathbf{C}\mathbf{B}$, not $\mathbf{B}\mathbf{C}$; here $\mathbf{C}\mathbf{D} = \mathbf{E}_{21} \neq 0 = \mathbf{D}\mathbf{C}$, so Theorem 7.3.8 does not apply.

7.4 The Kronecker Product

So far the unknown in a matrix equation has been a vector: $\mathbf{A}\mathbf{x} = \mathbf{b}$. Many natural questions have a matrix as the unknown instead. Which matrices commute with a given $\mathbf{A}$? Which $\mathbf{X}$ solve $\mathbf{A}\mathbf{X} + \mathbf{X}\mathbf{B} = \mathbf{C}$? Such an equation is still linear in the entries of $\mathbf{X}$, so in principle it is an ordinary linear system. The trouble is bookkeeping: we need to know what the coefficient matrix of that system is. This section builds it from $\mathbf{A}$ and $\mathbf{B}$ with one operation, the Kronecker product, and turns matrix equations into systems we already know how to solve.

7.4.1 From a matrix equation to a linear system

Take $\mathbf{A}, \mathbf{B} \in M_2(F)$ and an unknown $\mathbf{X} = (x_{ij}) \in M_2(F)$, and look at the equation $\mathbf{A}\mathbf{X}\mathbf{B} = \mathbf{C}$. By Definition 0.9.9, applied twice,

$$(\mathbf{A}\mathbf{X}\mathbf{B})_{rs} = \sum_{i=1}^{2}\sum_{j=1}^{2} a_{ri}\, x_{ij}\, b_{js}.$$

So each entry of $\mathbf{A}\mathbf{X}\mathbf{B}$ is a linear combination of the four unknowns $x_{11}, x_{21}, x_{12}, x_{22}$, and the coefficient of x_{ij} in entry (r, s) is the product $b_{js}a_{ri}$: **an entry of B times an entry of A**. Writing the four equations as a 4×4 system, every coefficient is such a product. For instance, if we list the unknowns column by column as $(x_{11}, x_{21}, x_{12}, x_{22})$ and the equations in the same order, the first row of the coefficient matrix is

$$\begin{pmatrix} b_{11}a_{11} & b_{11}a_{12} & b_{21}a_{11} & b_{21}a_{12} \end{pmatrix}.$$

The left half of this row is b_{11} times row 1 of $\mathbf{A}$, and the right half is b_{21} times row 1 of $\mathbf{A}$.

That is a recurring pattern: a big matrix whose entries are all the products of the entries of two small matrices, arranged in blocks. It deserves a name.

7.4.2 The Kronecker product

The Kronecker product of $\mathbf{A}$ *and* $\mathbf{B}$ *is the block matrix obtained by replacing each entry* a_{ij} *of* $\mathbf{A}$ *by the block* $a_{ij}\mathbf{B}$.

Definition 7.4.1 — Kronecker product

Let $\mathbf{A} = (a_{ij}) \in M_{m\times n}(F)$ and $\mathbf{B} = (b_{kl}) \in M_{p\times q}(F)$, of **any** sizes. The **Kronecker product** of $\mathbf{A}$ and $\mathbf{B}$ is the $mp \times nq$ block matrix

$$\mathbf{A}\otimes\mathbf{B} \coloneqq \begin{pmatrix} a_{11}\mathbf{B} & a_{12}\mathbf{B} & \cdots & a_{1n}\mathbf{B} \\ a_{21}\mathbf{B} & a_{22}\mathbf{B} & \cdots & a_{2n}\mathbf{B} \\ \vdots & \vdots & & \vdots \\ a_{m1}\mathbf{B} & a_{m2}\mathbf{B} & \cdots & a_{mn}\mathbf{B} \end{pmatrix} \in M_{mp\times nq}(F),$$

with m rows and n columns of blocks, each block of size $p \times q$ (Definition 7.1.1).

In words: the outer layout is the layout of $\mathbf{A}$, and the inner pattern of every block is $\mathbf{B}$. The sizes multiply, rows with rows and columns with columns. No condition on the sizes is needed, unlike for an ordinary product.

To work with single entries we need to know where each product $a_{ij}b_{kl}$ sits. Block (i, j) occupies rows $(i-1)p+1, \ldots, ip$ and columns $(j-1)q+1, \ldots, jq$. Inside it, entry (k, l) is $a_{ij}b_{kl}$. So

$$(\mathbf{A}\otimes\mathbf{B})_{(i-1)p+k,\ (j-1)q+l} = a_{ij}\,b_{kl} \qquad (1\le i\le m,\ 1\le j\le n,\ 1\le k\le p,\ 1\le l\le q). \tag{$*$}$$

Every entry is reached exactly once. Division with remainder writes each row index $r \in \{1, \ldots, mp\}$ uniquely as $r = (i-1)p + k$ with $1 \le i \le m$ and $1 \le k \le p$ (divide $r-1$ by p), and likewise for columns. So $(*)$ is a complete description of $\mathbf{A}\otimes\mathbf{B}$, and it is the formula we use in proofs. In words, the rows of $\mathbf{A}\otimes\mathbf{B}$ are labeled by pairs (row of $\mathbf{A}$, row of $\mathbf{B}$) in dictionary order, and the columns by pairs (column of $\mathbf{A}$, column of $\mathbf{B}$) in dictionary order.

Examples.

1. **$\mathbf{A}$ 2×2 example.** With $\mathbf{A} = \begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix}$ and $\mathbf{B} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$,

$$\mathbf{A}\otimes\mathbf{B} = \begin{pmatrix} 1\mathbf{B} & 2\mathbf{B} \\ 3\mathbf{B} & 4\mathbf{B} \end{pmatrix} = \begin{pmatrix} 0 & 1 & 0 & 2 \\ 1 & 0 & 2 & 0 \\ 0 & 3 & 0 & 4 \\ 3 & 0 & 4 & 0 \end{pmatrix}.$$

   Check one entry against $(*)$: row $3 = (2-1)\cdot 2 + 1$ and column $2 = (1-1)\cdot 2 + 2$ give $a_{21}b_{12} = 3 \cdot 1 = 3$, as displayed.
2. **Vectors.** For column vectors $\mathbf{u} \in F^m$ and $\mathbf{v} \in F^p$ (so $n = q = 1$), $\mathbf{u}\otimes\mathbf{v} \in F^{mp}$ lists all products u_iv_k in dictionary order. In particular, for standard basis vectors, $\mathbf{e}_i \otimes \mathbf{e}_k =$

$\mathbf{e}_{(i-1)p+k} \in F^{mp}$: the only non-zero product is $1 \cdot 1$ in position $(i-1)p+k$. For a column $\mathbf{u} \in F^m$ and a row $\mathbf{v}^\top$, $\mathbf{u} \otimes \mathbf{v}^\top$ is the $m \times p$ matrix with entries $u_i v_k$, which is the outer product $\mathbf{u}\mathbf{v}^\top$ of Corollary 7.1.3.

3. **Identity blocks.** $\mathbf{I}_n \otimes \mathbf{B}$ has $\mathbf{B}$ in each diagonal block and zero blocks elsewhere, so it is the block diagonal matrix $\mathbf{B} \oplus \cdots \oplus \mathbf{B}$ with n copies of $\mathbf{B}$ (Definition 7.1.2). By contrast, $\mathbf{A} \otimes \mathbf{I}_m$ replaces each entry a_{ij} by the $m \times m$ block $a_{ij}\mathbf{I}_m$. Taking both, $\mathbf{I}_n \otimes \mathbf{I}_m = \mathbf{I}_{nm}$: by $(*)$ its entries are $\delta_{ij}\delta_{kl}$, which is 1 exactly when the row and column labels (i,k) and (j,l) agree.
4. **The degenerate case 1×1.** If $\mathbf{A} = (a)$ is 1×1, then $\mathbf{A} \otimes \mathbf{B} = a\mathbf{B}$; if $\mathbf{B} = (b)$, then $\mathbf{A} \otimes \mathbf{B} = b\mathbf{A}$. So a 1×1 factor behaves like a scalar, and $(1) \otimes \mathbf{B} = \mathbf{B}$. This case is worth keeping in mind: it shows that the Kronecker product extends scalar multiplication, which is why it is bilinear below.

Non-example by minimal change. Swap the two factors of Example 1:

$$\mathbf{B} \otimes \mathbf{A} = \begin{pmatrix} 0\mathbf{A} & 1\mathbf{A} \\ 1\mathbf{A} & 0\mathbf{A} \end{pmatrix} = \begin{pmatrix} 0 & 0 & 1 & 2 \\ 0 & 0 & 3 & 4 \\ 1 & 2 & 0 & 0 \\ 3 & 4 & 0 & 0 \end{pmatrix}.$$

It has the same size and the same multiset of entries, since both list all products $a_{ij}b_{kl}$. What fails is the position formula $(*)$: in $\mathbf{B} \otimes \mathbf{A}$ the **outer** layout comes from $\mathbf{B}$, so the products sit in different places. For instance, the $(1,2)$-entry is $a_{11}b_{12} = 1$ in $\mathbf{A} \otimes \mathbf{B}$ but $b_{11}a_{12} = 0$ in $\mathbf{B} \otimes \mathbf{A}$.

Why this definition. The dictionary order in $(*)$ is a convention, and the other order would simply give $\mathbf{B} \otimes \mathbf{A}$. We fix it because it makes the block picture true: the Kronecker product is literally "$\mathbf{A}$ with entries replaced by blocks", so block multiplication (Theorem 7.1.1) applies to it directly. The symbol $\otimes$ anticipates the tensor product of Chapter 14, of which this is the matrix version.

> *Warning.* **The Kronecker product is not commutative, and it is not the ordinary product.** The two matrices in Example 1 and the non-example differ, so $\mathbf{A} \otimes \mathbf{B} \neq \mathbf{B} \otimes \mathbf{A}$ in general, even for square matrices of the same size. Also do not confuse $\mathbf{A} \otimes \mathbf{B}$ with $\mathbf{AB}$: for $\mathbf{A}, \mathbf{B} \in M_2(F)$, $\mathbf{AB}$ is 2×2 while $\mathbf{A} \otimes \mathbf{B}$ is 4×4, and $\mathbf{A} \otimes \mathbf{B}$ is defined for all sizes. We will see below that $\mathbf{A} \otimes \mathbf{B}$ and $\mathbf{B} \otimes \mathbf{A}$ are always **similar** when $\mathbf{A}$ and $\mathbf{B}$ are square, so they share rank, trace and determinant, but they are not equal.

7.4.3 Algebraic properties

The Kronecker product interacts well with every operation we have. The most useful rule is the one connecting it to ordinary multiplication: multiply the two left factors together and the two right factors together.

Theorem 7.4.1 — Properties of the Kronecker Product

Let $c \in F$. Whenever the sizes make each side defined:

(a) **(Bilinearity)** $(\mathbf{A} + \mathbf{A}') \otimes \mathbf{B} = \mathbf{A} \otimes \mathbf{B} + \mathbf{A}' \otimes \mathbf{B}$, $\mathbf{A} \otimes (\mathbf{B} + \mathbf{B}') = \mathbf{A} \otimes \mathbf{B} + \mathbf{A} \otimes \mathbf{B}'$, and $(c\mathbf{A}) \otimes \mathbf{B} = c(\mathbf{A} \otimes \mathbf{B}) = \mathbf{A} \otimes (c\mathbf{B})$.

(b) **(Associativity)** $(\mathbf{A} \otimes \mathbf{B}) \otimes \mathbf{C} = \mathbf{A} \otimes (\mathbf{B} \otimes \mathbf{C})$ for all $\mathbf{A} \in M_{m \times n}(F)$, $\mathbf{B} \in M_{p \times q}(F)$,

$\mathbf{C} \in M_{r\times s}(F)$.

(c) **(Mixed product rule)** For $\mathbf{A} \in M_{m\times n}(F)$, $\mathbf{C} \in M_{n\times t}(F)$, $\mathbf{B} \in M_{p\times q}(F)$ and $\mathbf{D} \in M_{q\times u}(F)$,
$$(\mathbf{A} \otimes \mathbf{B})(\mathbf{C} \otimes \mathbf{D}) = (\mathbf{AC}) \otimes (\mathbf{BD}).$$

(d) **(Transpose)** $(\mathbf{A} \otimes \mathbf{B})^\top = \mathbf{A}^\top \otimes \mathbf{B}^\top$.

(e) **(Inverse)** If $\mathbf{A} \in M_n(F)$ and $\mathbf{B} \in M_m(F)$ are invertible, then $\mathbf{A} \otimes \mathbf{B}$ is invertible and $(\mathbf{A} \otimes \mathbf{B})^{-1} = \mathbf{A}^{-1} \otimes \mathbf{B}^{-1}$.

Idea. Parts (a), (b) and (d) are entry checks with $(*)$. For (c), both factors on the left are block matrices, and the columns of blocks of $\mathbf{A} \otimes \mathbf{B}$ (n of them, each q wide) match the rows of blocks of $\mathbf{C} \otimes \mathbf{D}$ (n of them, each q tall). So we may multiply blockwise, and each block of the product is a sum $\sum_j (a_{ij}\mathbf{B})(c_{jk}\mathbf{D})$ in which the scalars come out. Part (e) is (c) with $\mathbf{C} = \mathbf{A}^{-1}$, $\mathbf{D} = \mathbf{B}^{-1}$.

Proof.

(a) By $(*)$, the entry of $(\mathbf{A}+\mathbf{A}')\otimes\mathbf{B}$ in position $((i-1)p+k, (j-1)q+l)$ is $(a_{ij}+a'_{ij})b_{kl} = a_{ij}b_{kl} + a'_{ij}b_{kl}$, which is the entry of $\mathbf{A} \otimes \mathbf{B} + \mathbf{A}' \otimes \mathbf{B}$ in the same position. The other identities are checked the same way, using $(ca_{ij})b_{kl} = c(a_{ij}b_{kl}) = a_{ij}(cb_{kl})$.

(b) Both sides are $mpr \times nqs$. Let $1 \le i \le m$, $1 \le k \le p$, $1 \le t \le r$, and similarly j, l, u for columns. Applying $(*)$ twice, the entry of $(\mathbf{A}\otimes\mathbf{B})\otimes\mathbf{C}$ in row $\big((i-1)p+k-1\big)r+t$ and column $\big((j-1)q+l-1\big)s+u$ is $(\mathbf{A} \otimes \mathbf{B})_{(i-1)p+k,\,(j-1)q+l}\; c_{tu} = a_{ij}b_{kl}c_{tu}$. Likewise the entry of $\mathbf{A} \otimes (\mathbf{B} \otimes \mathbf{C})$ in row $(i-1)pr + (k-1)r + t$ and column $(j-1)qs + (l-1)s + u$ is $a_{ij}(\mathbf{B} \otimes \mathbf{C})_{(k-1)r+t,\,(l-1)s+u} = a_{ij}b_{kl}c_{tu}$. Since $\big((i-1)p + k - 1\big)r + t = (i-1)pr + (k-1)r + t$, and similarly for columns, the two matrices have the same entry in every position; every position arises from exactly one choice of indices, by division with remainder. Hence they are equal.

(c) Partition $\mathbf{A} \otimes \mathbf{B}$ into m rows and n columns of blocks as in Definition 7.4.1, each block $p \times q$, and $\mathbf{C} \otimes \mathbf{D}$ into n rows and t columns of blocks, each $q \times u$. The column partition of the first matrix (n parts of size q) equals the row partition of the second, so the partitions are conformable, and by Theorem 7.1.1 the (i, k) block of the product is
$$\sum_{j=1}^{n} (a_{ij}\mathbf{B})(c_{jk}\mathbf{D}) = \sum_{j=1}^{n} a_{ij}c_{jk}\,\mathbf{BD} = (\mathbf{AC})_{ik}\,\mathbf{BD},$$
where the first equality uses Theorem 0.9.4 (4) and the second uses Definition 0.9.9. This is the (i, k) block of $(\mathbf{AC}) \otimes (\mathbf{BD})$, a matrix partitioned into m rows and t columns of $p \times u$ blocks. So the two matrices agree block by block, hence entry by entry.

(d) $(\mathbf{A} \otimes \mathbf{B})^\top$ is $nq \times mp$. By Definition 0.9.10 and $(*)$, its entry in row $(j-1)q + l$ and column $(i-1)p+k$ is $(\mathbf{A}\otimes\mathbf{B})_{(i-1)p+k,\,(j-1)q+l} = a_{ij}b_{kl} = (\mathbf{A}^\top)_{ji}(\mathbf{B}^\top)_{lk}$, which by $(*)$ is the entry of $\mathbf{A}^\top \otimes \mathbf{B}^\top$ in the same position.

(e) By (c) and Example 3, $(\mathbf{A}\otimes\mathbf{B})(\mathbf{A}^{-1}\otimes\mathbf{B}^{-1}) = (\mathbf{A}\mathbf{A}^{-1})\otimes(\mathbf{B}\mathbf{B}^{-1}) = \mathbf{I}_n\otimes\mathbf{I}_m = \mathbf{I}_{nm}$, and similarly $(\mathbf{A}^{-1}\otimes\mathbf{B}^{-1})(\mathbf{A}\otimes\mathbf{B}) = \mathbf{I}_{nm}$. By Definition 0.9.13, $\mathbf{A}\otimes\mathbf{B}$ is invertible with inverse $\mathbf{A}^{-1} \otimes \mathbf{B}^{-1}$.

■

The mixed product rule is the engine of everything that follows. One immediate consequence splits a Kronecker product of square matrices into two simpler factors: for $\mathbf{A} \in M_n(F)$ and $\mathbf{B} \in M_m(F)$,

$$\mathbf{A} \otimes \mathbf{B} = (\mathbf{A}\mathbf{I}_n) \otimes (\mathbf{I}_m\mathbf{B}) = (\mathbf{A} \otimes \mathbf{I}_m)(\mathbf{I}_n \otimes \mathbf{B}), \tag{$**$}$$

and in the same way $\mathbf{A} \otimes \mathbf{B} = (\mathbf{I}_n \otimes \mathbf{B})(\mathbf{A} \otimes \mathbf{I}_m)$. So $\mathbf{A} \otimes \mathbf{I}_m$ and $\mathbf{I}_n \otimes \mathbf{B}$ commute, even though $\mathbf{A}$ and $\mathbf{B}$ have nothing to do with each other.

For example, with $\mathbf{A} = \begin{pmatrix} 1 & -1 \\ 0 & 2 \end{pmatrix}$, $\mathbf{B} = \begin{pmatrix} 2 & 1 \\ 1 & 1 \end{pmatrix}$, $\mathbf{C} = \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix}$ and $\mathbf{D} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$, multiplying two 4×4 matrices directly gives

$$(\mathbf{A} \otimes \mathbf{B})(\mathbf{C} \otimes \mathbf{D}) = \begin{pmatrix} 2 & 1 & -2 & -1 \\ 1 & 1 & -1 & -1 \\ 0 & 0 & 4 & 2 \\ 0 & 0 & 2 & 2 \end{pmatrix} \begin{pmatrix} 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 1 \\ 1 & 0 & 1 & 0 \end{pmatrix} = \begin{pmatrix} 0 & 0 & -1 & -2 \\ 0 & 0 & -1 & -1 \\ 2 & 4 & 2 & 4 \\ 2 & 2 & 2 & 2 \end{pmatrix},$$

while the rule needs only two 2×2 products, $\mathbf{AC} = \begin{pmatrix} 0 & -1 \\ 2 & 2 \end{pmatrix}$ and $\mathbf{BD} = \begin{pmatrix} 1 & 2 \\ 1 & 1 \end{pmatrix}$, whose Kronecker product is the same matrix.

7.4.4 Swapping the factors

The warning said that $\mathbf{A} \otimes \mathbf{B}$ and $\mathbf{B} \otimes \mathbf{A}$ differ. They differ only in the order in which rows and columns are labeled: $\mathbf{A} \otimes \mathbf{B}$ uses (index of $\mathbf{A}$, index of $\mathbf{B}$) in dictionary order, $\mathbf{B} \otimes \mathbf{A}$ the reverse order. Relabeling rows and columns by the same permutation is conjugation by a permutation matrix, and that is what the next result makes precise.

First, a fact about permutation matrices. Recall that for $\sigma \in S_N$, the permutation matrix $\mathbf{P}_\sigma$ has j-th column $\mathbf{e}_{\sigma(j)}$, and $\mathbf{P}_\sigma^{-1} = \mathbf{P}_\sigma^{\top}$ (Definition 2.6.2, Lemma 2.6.6). For every $\mathbf{M} \in M_N(F)$,

$$\left(\mathbf{P}_\sigma^{\top}\mathbf{M}\mathbf{P}_\sigma\right)_{rs} = \mathbf{M}_{\sigma(r)\,\sigma(s)} \qquad (1 \le r, s \le N). \tag{$\dagger$}$$

Indeed, by Theorem 0.9.2 column s of $\mathbf{M}\mathbf{P}_\sigma$ is $\mathbf{M}\mathbf{e}_{\sigma(s)}$, which is column $\sigma(s)$ of $\mathbf{M}$. Row r of $\mathbf{P}_\sigma^{\top}$ is $\mathbf{e}_{\sigma(r)}^{\top}$, so by the same theorem row r of $\mathbf{P}_\sigma^{\top}Ł$ is row $\sigma(r)$ of Ł, for any $Ł \in M_N(F)$. Combining the two gives ($\dagger$).

Proposition 7.4.2 — Swapping the Factors Is a Permutation Similarity

Let $n, m \ge 1$. There is a permutation matrix $\mathbf{P} \in M_{nm}(F)$, depending only on n and m, such that

$$\mathbf{B} \otimes \mathbf{A} = \mathbf{P}^{-1}(\mathbf{A} \otimes \mathbf{B})\mathbf{P} \qquad \text{for all } \mathbf{A} \in M_n(F),\ \mathbf{B} \in M_m(F).$$

In particular $\mathbf{A} \otimes \mathbf{B} \sim \mathbf{B} \otimes \mathbf{A}$, and $\mathbf{I}_m \otimes \mathbf{A} = \mathbf{P}^{-1}(\mathbf{A} \otimes \mathbf{I}_m)\mathbf{P}$.

Proof. Every $r \in \{1, \dots, nm\}$ can be written uniquely as $r = (k-1)n+i$ with $1 \le k \le m$ and $1 \le i \le n$. Define $\sigma(r) := (i-1)m+k$. As (k, i) runs over all pairs, so does (i, k), and each value $(i-1)m+k$ is taken by exactly one pair; hence σ is a bijection of $\{1, \dots, nm\}$, that is, $\sigma \in S_{nm}$. Put $\mathbf{P} = \mathbf{P}_\sigma$.

Let $r = (k-1)n + i$ and $s = (l-1)n + j$. By $(*)$ applied to $\mathbf{B} \otimes \mathbf{A}$, $(\mathbf{B} \otimes \mathbf{A})_{rs} = b_{kl}a_{ij}$.

By $(*)$ applied to $\mathbf{A}\otimes\mathbf{B}$,

$$(\mathbf{A}\otimes\mathbf{B})_{\sigma(r)\,\sigma(s)} = (\mathbf{A}\otimes\mathbf{B})_{(i-1)m+k,\;(j-1)m+l} = a_{ij}b_{kl}.$$

So by $(\dagger)$, $\mathbf{P}_\sigma^{\top}(\mathbf{A}\otimes\mathbf{B})\mathbf{P}_\sigma$ and $\mathbf{B}\otimes\mathbf{A}$ agree in every entry, and $\mathbf{P}_\sigma^{\top} = \mathbf{P}_\sigma^{-1}$ by Lemma 2.6.6 (b). The last claim is the case $\mathbf{B} = \mathbf{I}_m$.

■

For example, when $n = m = 2$, σ fixes 1 and 4 and swaps 2 and 3, so $\mathbf{P}$ is the elementary matrix $\mathbf{P}_{23}$: conjugating by it swaps rows $2,3$ and columns $2,3$. Doing this to $\mathbf{A}\otimes\mathbf{B}$ in Example 1 does give $\mathbf{B}\otimes\mathbf{A}$, as a direct check shows. For rectangular $\mathbf{A}\in M_{m\times n}(F)$ and $\mathbf{B}\in M_{p\times q}(F)$, the same argument gives $\mathbf{B}\otimes\mathbf{A} = \mathbf{P}_\sigma^{\top}(\mathbf{A}\otimes\mathbf{B})\mathbf{P}_\tau$ with one permutation for the rows and another for the columns.

7.4.5 Rank, trace and determinant

Each of the three basic numbers attached to a matrix behaves multiplicatively. The formulas for trace and rank are what one would guess. The determinant is subtler, because the sizes enter as exponents.

Theorem 7.4.3 — Rank, Trace and Determinant of a Kronecker Product

(a) For $\mathbf{A}\in M_{m\times n}(F)$ and $\mathbf{B}\in M_{p\times q}(F)$, $\operatorname{rank}(\mathbf{A}\otimes\mathbf{B}) = \operatorname{rank}\mathbf{A}\cdot\operatorname{rank}\mathbf{B}$.

(b) For $\mathbf{A}\in M_n(F)$ and $\mathbf{B}\in M_m(F)$, $\operatorname{tr}(\mathbf{A}\otimes\mathbf{B}) = \operatorname{tr}\mathbf{A}\cdot\operatorname{tr}\mathbf{B}$.

(c) For $\mathbf{A}\in M_n(F)$ and $\mathbf{B}\in M_m(F)$, $\det(\mathbf{A}\otimes\mathbf{B}) = (\det\mathbf{A})^m\,(\det\mathbf{B})^n$.

Idea. For rank, bring both factors to rank normal form, $\mathbf{A} = \mathbf{Q}\mathbf{N}_r\mathbf{P}$ and $\mathbf{B} = \mathbf{Q}'\mathbf{N}_s\mathbf{P}'$. The mixed product rule moves the invertible factors outside, where they do not change rank, and $\mathbf{N}_r\otimes\mathbf{N}_s$ visibly has rank rs. Trace is a sum over diagonal entries, and the diagonal entries of $\mathbf{A}\otimes\mathbf{B}$ are the products $a_{ii}b_{kk}$. For the determinant, split $\mathbf{A}\otimes\mathbf{B} = (\mathbf{A}\otimes\mathbf{I}_m)(\mathbf{I}_n\otimes\mathbf{B})$ by $(**)$. The second factor is block diagonal with n copies of $\mathbf{B}$. The first is not, but by Proposition 7.4.2 it is similar to $\mathbf{I}_m\otimes\mathbf{A}$, which is block diagonal with m copies of $\mathbf{A}$.

Proof.

(a) Let $r = \operatorname{rank}\mathbf{A}$ and $s = \operatorname{rank}\mathbf{B}$. By Theorem 3.8.3 (b) and Definition 3.8.1, there are invertible $\mathbf{Q}_1,\mathbf{P}_1,\mathbf{Q}_2,\mathbf{P}_2$ with $\mathbf{N}_r = \mathbf{Q}_1\mathbf{A}\mathbf{P}_1$ and $\mathbf{N}_s = \mathbf{Q}_2\mathbf{B}\mathbf{P}_2$, where $\mathbf{N}_r\in M_{m\times n}(F)$ and $\mathbf{N}_s\in M_{p\times q}(F)$ have $\mathbf{I}_r$, $\mathbf{I}_s$ in the top left corner and zeros elsewhere. Hence $\mathbf{A} = \mathbf{Q}_1^{-1}\mathbf{N}_r\mathbf{P}_1^{-1}$ and $\mathbf{B} = \mathbf{Q}_2^{-1}\mathbf{N}_s\mathbf{P}_2^{-1}$, and by Theorem 7.4.1 (c), used twice,

$$\mathbf{A}\otimes\mathbf{B} = (\mathbf{Q}_1^{-1}\otimes\mathbf{Q}_2^{-1})(\mathbf{N}_r\otimes\mathbf{N}_s)(\mathbf{P}_1^{-1}\otimes\mathbf{P}_2^{-1}).$$

The outer factors are invertible by Theorem 7.4.1 (e), so $\operatorname{rank}(\mathbf{A}\otimes\mathbf{B}) = \operatorname{rank}(\mathbf{N}_r\otimes\mathbf{N}_s)$ by Theorem 2.5.9.
By $(*)$, the entry of $\mathbf{N}_r\otimes\mathbf{N}_s$ in position $((i-1)p+k,(j-1)q+l)$ is 1 if $i=j\le r$ and $k=l\le s$, and 0 otherwise. So for each of the rs pairs (i,k) with $i\le r$, $k\le s$, column $(i-1)q+k$ equals $\mathbf{e}_{(i-1)p+k}$, and every other column is zero. Distinct pairs

give distinct standard basis vectors, so these rs columns are linearly independent and span the column space. Hence $\operatorname{rank}(\mathbf{N}_r \otimes \mathbf{N}_s) = rs$ by Definition 2.5.4, which proves (a). (If $r = 0$ or $s = 0$, the matrix is zero and both sides are 0.)

(b) By $(*)$ with $p = q = m$, the diagonal entries of $\mathbf{A} \otimes \mathbf{B}$ are those with $(i-1)m + k = (j-1)m + l$, that is $i = j$ and $k = l$ by uniqueness of division with remainder, and they equal $a_{ii}b_{kk}$. By Definition 0.9.12,

$$\operatorname{tr}(\mathbf{A} \otimes \mathbf{B}) = \sum_{i=1}^{n}\sum_{k=1}^{m} a_{ii}b_{kk} = \Big(\sum_{i=1}^{n} a_{ii}\Big)\Big(\sum_{k=1}^{m} b_{kk}\Big) = \operatorname{tr}\mathbf{A} \cdot \operatorname{tr}\mathbf{B}.$$

(c) First, a block diagonal matrix $\mathbf{M}_1 \oplus \cdots \oplus \mathbf{M}_t$ with square blocks $\mathbf{M}_1, \ldots, \mathbf{M}_t$ has determinant $\det \mathbf{M}_1 \cdots \det \mathbf{M}_t$. For $t = 1$ there is nothing to prove, and for $t \geq 2$ the matrix is $\mathbf{M}_1 \oplus (\mathbf{M}_2 \oplus \cdots \oplus \mathbf{M}_t)$, so Theorem 7.1.4 (d) (or Theorem 6.8.4) and induction on t give the claim.

By Example 3, $\mathbf{I}_n \otimes \mathbf{B} = \mathbf{B} \oplus \cdots \oplus \mathbf{B}$ with n blocks, so $\det(\mathbf{I}_n \otimes \mathbf{B}) = (\det \mathbf{B})^n$. Likewise $\mathbf{I}_m \otimes \mathbf{A} = \mathbf{A} \oplus \cdots \oplus \mathbf{A}$ with m blocks, so $\det(\mathbf{I}_m \otimes \mathbf{A}) = (\det \mathbf{A})^m$. By Proposition 7.4.2, $\mathbf{A} \otimes \mathbf{I}_m$ is similar to $\mathbf{I}_m \otimes \mathbf{A}$, so $\det(\mathbf{A} \otimes \mathbf{I}_m) = (\det \mathbf{A})^m$ by Corollary 6.5.7. Finally, by $(**)$ and Theorem 6.5.4,

$$\det(\mathbf{A} \otimes \mathbf{B}) = \det(\mathbf{A} \otimes \mathbf{I}_m)\det(\mathbf{I}_n \otimes \mathbf{B}) = (\det \mathbf{A})^m (\det \mathbf{B})^n.$$

■

The exponents are easy to get backwards, and a size count fixes them. In $\mathbf{A} \otimes \mathbf{B}$ with $\mathbf{A} \in M_n(F)$, $\mathbf{B} \in M_m(F)$, the matrix $\mathbf{A}$ is "used" m times (once for each index of $\mathbf{B}$), so $\det \mathbf{A}$ appears to the power m, the size of the **other** factor. For $\mathbf{A} = c\mathbf{I}_n$ and $\mathbf{B} = \mathbf{I}_m$, $\mathbf{A} \otimes \mathbf{B} = c\mathbf{I}_{nm}$ has determinant $c^{nm} = (c^n)^m = (\det \mathbf{A})^m$, which confirms the exponent.

For the matrices of the example after Theorem 7.4.1, $\det \mathbf{A} = 2$, $\det \mathbf{B} = 1$, $\operatorname{tr}\mathbf{A} = 3$ and $\operatorname{tr}\mathbf{B} = 3$, so $\det(\mathbf{A} \otimes \mathbf{B}) = 2^2 \cdot 1^2 = 4$, $\operatorname{tr}(\mathbf{A} \otimes \mathbf{B}) = 9$, and $\operatorname{rank}(\mathbf{A} \otimes \mathbf{B}) = 2 \cdot 2 = 4$. Directly, the diagonal of $\mathbf{A} \otimes \mathbf{B}$ is $2, 1, 4, 2$, with sum 9.

Quick check. Let $\mathbf{A} \in M_2(\mathbb{R})$ have $\operatorname{tr}\mathbf{A} = 4$, $\det \mathbf{A} = 3$, and let $\mathbf{B} \in M_3(\mathbb{R})$ have $\operatorname{tr}\mathbf{B} = 2$, $\det \mathbf{B} = -1$. Find $\operatorname{tr}(\mathbf{A} \otimes \mathbf{B})$, $\det(\mathbf{A} \otimes \mathbf{B})$ and $\det(\mathbf{B} \otimes \mathbf{A})$.

Solution. By Theorem 7.4.3, $\operatorname{tr}(\mathbf{A} \otimes \mathbf{B}) = 4 \cdot 2 = 8$ and $\det(\mathbf{A} \otimes \mathbf{B}) = (\det \mathbf{A})^3 (\det \mathbf{B})^2 = 27 \cdot 1 = 27$. With the roles swapped, $\det(\mathbf{B} \otimes \mathbf{A}) = (\det \mathbf{B})^2 (\det \mathbf{A})^3 = 27$, as it must be since $\mathbf{B} \otimes \mathbf{A} \sim \mathbf{A} \otimes \mathbf{B}$ (Proposition 7.4.2). The common wrong answer $(\det \mathbf{A})^2 (\det \mathbf{B})^3 = -9$ puts each matrix's own size in its exponent.

7.4.6 Vectorization

We return to the question of the opening: turning a matrix equation into a linear system. For that we need to flatten the unknown matrix into a column, in an order that matches $(*)$.

To vectorize a matrix is to stack its columns into one long column.

Definition 7.4.2 — Vectorization

Let $\mathbf{X} = (x_{ij}) \in M_{m\times n}(F)$ have columns $\mathbf{x}_1, \dots, \mathbf{x}_n \in F^m$. Its **vectorization** is the column vector

$$\operatorname{vec}\mathbf{X} := \begin{pmatrix} \mathbf{x}_1 \\ \mathbf{x}_2 \\ \vdots \\ \mathbf{x}_n \end{pmatrix} \in F^{mn},$$

whose entry in position $(j-1)m + i$ is x_{ij}, for $1 \le i \le m$, $1 \le j \le n$.

For example, $\operatorname{vec}\begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix} = (1, 3, 2, 4)$, read down the first column and then down the second. For a column $\mathbf{x} \in F^m$ (the case $n = 1$), $\operatorname{vec}\mathbf{x} = \mathbf{x}$. The map $\operatorname{vec}\colon M_{m\times n}(F) \to F^{mn}$ is linear, since each entry of $\operatorname{vec}\mathbf{X}$ is an entry of $\mathbf{X}$, and bijective, since it only rearranges entries; so it is an isomorphism. It sends the matrix unit $\mathbf{E}_{ij}$ to $\mathbf{e}_{(j-1)m+i} = \mathbf{e}_j \otimes \mathbf{e}_i$ (Example 2, with the index of the column first). More generally, $\operatorname{vec}(\mathbf{u}\mathbf{v}^\top) = \mathbf{v} \otimes \mathbf{u}$ for $\mathbf{u} \in F^m$ and $\mathbf{v} \in F^n$: column j of $\mathbf{u}\mathbf{v}^\top$ is $v_j\mathbf{u}$.

Two conventions are in use, and they differ. Some books stack the **rows** instead, which exchanges the roles of the two factors in the next theorem. We always stack columns.

Theorem 7.4.4 — The vec Identity

Let $\mathbf{A} \in M_{k\times m}(F)$, $\mathbf{X} \in M_{m\times n}(F)$ and $\mathbf{B} \in M_{n\times l}(F)$. Then

$$\operatorname{vec}(\mathbf{A}\mathbf{X}\mathbf{B}) = (\mathbf{B}^\top \otimes \mathbf{A}) \operatorname{vec}\mathbf{X}.$$

Idea. Both sides are columns in F^{kl}. We compare one entry, using the formula for a triple product on the left and $(*)$ on the right. The factor $\mathbf{A}$ acts on the row index of $\mathbf{X}$, which is the inner index in vec; the factor $\mathbf{B}$ acts on the column index, which is the outer index. That is why $\mathbf{B}$ comes first, and it enters transposed because it multiplies $\mathbf{X}$ from the right.

Proof. Both sides lie in F^{kl}: $\mathbf{A}\mathbf{X}\mathbf{B} \in M_{k\times l}(F)$, and $\mathbf{B}^\top \otimes \mathbf{A} \in M_{lk\times nm}(F)$ acts on $\operatorname{vec}\mathbf{X} \in F^{mn}$. Fix $1 \le r \le k$ and $1 \le s \le l$, and consider position $(s-1)k + r$. By Definition 7.4.2 and Definition 0.9.9 applied twice, the left side has entry

$$(\mathbf{A}\mathbf{X}\mathbf{B})_{rs} = \sum_{i=1}^{m}\sum_{j=1}^{n} a_{ri}\, x_{ij}\, b_{js}.$$

On the right, write the column index $c \in \{1, \dots, nm\}$ of $\mathbf{B}^\top \otimes \mathbf{A}$ uniquely as $c = (j-1)m + i$ with $1 \le j \le n$, $1 \le i \le m$. By $(*)$, $(\mathbf{B}^\top \otimes \mathbf{A})_{(s-1)k+r,\ (j-1)m+i} = (\mathbf{B}^\top)_{sj}\, a_{ri} = b_{js}\, a_{ri}$, and by Definition 7.4.2 the c-th entry of $\operatorname{vec}\mathbf{X}$ is x_{ij}. Hence the entry of the right side in position $(s-1)k + r$ is

$$\sum_{c=1}^{nm} (\mathbf{B}^\top \otimes \mathbf{A})_{(s-1)k+r,\ c}\, (\operatorname{vec}\mathbf{X})_c = \sum_{j=1}^{n}\sum_{i=1}^{m} b_{js}\, a_{ri}\, x_{ij},$$

which equals the left side. As (r, s) ranges over all pairs, $(s-1)k + r$ ranges over all positions, so the two vectors are equal.

■

Taking $\mathbf{B} = \mathbf{I}_n$ or $\mathbf{A} = \mathbf{I}_m$ gives the two one-sided forms, which are used most often:

$$\operatorname{vec}(\mathbf{AX}) = (\mathbf{I}_n \otimes \mathbf{A})\operatorname{vec}\mathbf{X}, \qquad \operatorname{vec}(\mathbf{XB}) = (\mathbf{B}^{\top} \otimes \mathbf{I}_m)\operatorname{vec}\mathbf{X}.$$

The first says that multiplying $\mathbf{X}$ by $\mathbf{A}$ on the left multiplies each column of $\mathbf{X}$ by $\mathbf{A}$: $\mathbf{I}_n \otimes \mathbf{A} = \mathbf{A} \oplus \cdots \oplus \mathbf{A}$ acts on the stacked columns one at a time.

Now every linear matrix equation built from products becomes a linear system. The most important one is the **Sylvester equation**

$$\mathbf{AX} + \mathbf{XB} = \mathbf{C}, \qquad \mathbf{A} \in M_m(F),\ \mathbf{B} \in M_n(F),\ \mathbf{C} \in M_{m\times n}(F),$$

for an unknown $\mathbf{X} \in M_{m\times n}(F)$. Applying vec, which is linear, and the two one-sided forms,

$$\left(\mathbf{I}_n \otimes \mathbf{A} + \mathbf{B}^{\top} \otimes \mathbf{I}_m\right)\operatorname{vec}\mathbf{X} = \operatorname{vec}\mathbf{C}.$$

So the Sylvester equation has **exactly one** solution for every $\mathbf{C}$ if and only if the $mn \times mn$ matrix $\mathbf{I}_n \otimes \mathbf{A} + \mathbf{B}^{\top} \otimes \mathbf{I}_m$ is invertible (Theorem 2.4.4, transported through the isomorphism vec). The equation $\mathbf{AX} = \mathbf{XA}$ of the opening, which describes the matrices commuting with $\mathbf{A}$, is the case $\mathbf{B} = -\mathbf{A}$, $\mathbf{C} = 0$: its solutions form the null space of $\mathbf{I}_m \otimes \mathbf{A} - \mathbf{A}^{\top} \otimes \mathbf{I}_m$.

Example. (A Sylvester Equation as a Linear System)

Solve $\mathbf{AX} + \mathbf{XB} = \mathbf{C}$ over $\mathbb{Q}$, where

$$\mathbf{A} = \begin{pmatrix} 1 & 1 \\ 0 & 2 \end{pmatrix}, \qquad \mathbf{B} = \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix}, \qquad \mathbf{C} = \begin{pmatrix} 1 & -1 \\ 1 & 3 \end{pmatrix}.$$

Solution. Here $m = n = 2$. Compute the two Kronecker products from Definition 7.4.1:

$$\mathbf{I}_2 \otimes \mathbf{A} = \begin{pmatrix} 1 & 1 & 0 & 0 \\ 0 & 2 & 0 & 0 \\ 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 2 \end{pmatrix}, \qquad \mathbf{B}^{\top} \otimes \mathbf{I}_2 = \begin{pmatrix} 1\mathbf{I}_2 & 1\mathbf{I}_2 \\ 0\mathbf{I}_2 & 1\mathbf{I}_2 \end{pmatrix} = \begin{pmatrix} 1 & 0 & 1 & 0 \\ 0 & 1 & 0 & 1 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}.$$

With $\operatorname{vec}\mathbf{X} = (x_{11}, x_{21}, x_{12}, x_{22})$ and $\operatorname{vec}\mathbf{C} = (1, 1, -1, 3)$, the system $(\mathbf{I}_2 \otimes \mathbf{A} + \mathbf{B}^{\top} \otimes \mathbf{I}_2)\operatorname{vec}\mathbf{X} = \operatorname{vec}\mathbf{C}$ is

$$\begin{pmatrix} 2 & 1 & 1 & 0 \\ 0 & 3 & 0 & 1 \\ 0 & 0 & 2 & 1 \\ 0 & 0 & 0 & 3 \end{pmatrix} \begin{pmatrix} x_{11} \\ x_{21} \\ x_{12} \\ x_{22} \end{pmatrix} = \begin{pmatrix} 1 \\ 1 \\ -1 \\ 3 \end{pmatrix}.$$

The coefficient matrix is upper triangular with non-zero diagonal entries $2, 3, 2, 3$, so its determinant is $36 \neq 0$ (Theorem 6.4.6) and the solution is unique. Back substitution gives $x_{22} = 1$; then $2x_{12} + 1 = -1$, so $x_{12} = -1$; then $3x_{21} + 1 = 1$, so $x_{21} = 0$; then $2x_{11} + 0 - 1 = 1$, so $x_{11} = 1$. Hence

$$\mathbf{X} = \begin{pmatrix} 1 & -1 \\ 0 & 1 \end{pmatrix}.$$

Check: $\mathbf{AX} = \begin{pmatrix} 1 & 0 \\ 0 & 2 \end{pmatrix}$ and $\mathbf{XB} = \begin{pmatrix} 0 & -1 \\ 1 & 1 \end{pmatrix}$, whose sum is $\mathbf{C}$. As a check on the bookkeeping, row 1 of the system is the $(1,1)$ entry of $\mathbf{AX}+\mathbf{XB}$, namely $(x_{11}+x_{21})+(x_{11}+x_{12})$.

In this example the coefficient matrix came out triangular, with diagonal entries $a_{ii}+b_{jj}$. That is no accident when $\mathbf{A}$ is upper triangular and $\mathbf{B}$ lower triangular, as Exercise (C2: Kronecker sums) below shows. In general, whether $\mathbf{I}_n\otimes\mathbf{A}+\mathbf{B}^{\top}\otimes\mathbf{I}_m$ is invertible depends on the eigenvalues of $\mathbf{A}$ and $\mathbf{B}$: over $\mathbb{C}$, the equation $\mathbf{AX}-\mathbf{XB}=\mathbf{C}$ is uniquely solvable for every $\mathbf{C}$ exactly when $\mathbf{A}$ and $\mathbf{B}$ have no common eigenvalue. That criterion needs eigenvalues and is proved in Chapter 11, and its quantitative form appears in Chapter 19.

Warning. **Keep the order and the transpose in** $\operatorname{vec}(\mathbf{AXB}) = (\mathbf{B}^{\top}\otimes\mathbf{A})\operatorname{vec}\mathbf{X}$**.** Both $\mathbf{A}\otimes\mathbf{B}^{\top}$ and $\mathbf{B}\otimes\mathbf{A}$ look plausible, and both are wrong. With $\mathbf{X}=\mathbf{E}_{11}\in M_2(F)$, $\mathbf{A}=\mathbf{I}_2$ and $\mathbf{B}=\mathbf{E}_{21}$, we get $\mathbf{AXB}=\mathbf{E}_{11}\mathbf{E}_{21}=0$, and indeed $(\mathbf{B}^{\top}\otimes\mathbf{I}_2)\,\mathbf{e}_1=(\mathbf{E}_{12}\otimes\mathbf{I}_2)\mathbf{e}_1=\mathbf{0}$, because the first column of $\mathbf{E}_{12}\otimes\mathbf{I}_2$ is zero. But $(\mathbf{B}\otimes\mathbf{I}_2)\,\mathbf{e}_1=(\mathbf{E}_{21}\otimes\mathbf{I}_2)\mathbf{e}_1=\mathbf{e}_3\neq\mathbf{0}$. So $\mathbf{B}\otimes\mathbf{A}$ fails. A similar test with $\mathbf{A}=\mathbf{E}_{12}$, $\mathbf{X}=\mathbf{E}_{21}$, $\mathbf{B}=\mathbf{I}_2$ refutes $\mathbf{A}\otimes\mathbf{B}^{\top}$. If a formula is in doubt, test it on matrix units.

The Kronecker product is the coordinate shadow of a basis-free construction: the tensor product of linear maps, in Chapter 14, whose matrix in suitable bases is exactly $\mathbf{A}\otimes\mathbf{B}$. The dictionary order in $(*)$ will reappear there as an ordering of a basis $\mathbf{v}_i\otimes\mathbf{w}_k$.

7.4.7 Exercises

7.4.7.1 A. Check your understanding

Exercise A1.

(a) Define $\mathbf{A}\otimes\mathbf{B}$ for $\mathbf{A}\in M_{m\times n}(F)$ and $\mathbf{B}\in M_{p\times q}(F)$, and state its size.

(b) True or false: for all $\mathbf{A},\mathbf{B}\in M_2(F)$, $\mathbf{A}\otimes\mathbf{B}=\mathbf{B}\otimes\mathbf{A}$. Justify your answer.

(c) State the mixed product rule, including the conditions on the sizes.

(d) True or false: $\det(\mathbf{A}\otimes\mathbf{B})=\det\mathbf{A}\det\mathbf{B}$ for all $\mathbf{A},\mathbf{B}\in M_2(\mathbb{R})$. Justify your answer.

(e) State the vec identity, and name the matrix $\mathbf{M}$ with $\operatorname{vec}(\mathbf{XB})=\mathbf{M}\operatorname{vec}\mathbf{X}$ for $\mathbf{X}\in M_{m\times n}(F)$, $\mathbf{B}\in M_n(F)$.

Solution.

(a) $\mathbf{A}\otimes\mathbf{B}$ is the $mp\times nq$ block matrix with (i,j) block $a_{ij}\mathbf{B}$ (Definition 7.4.1); equivalently, its entry in position $((i-1)p+k,(j-1)q+l)$ is $a_{ij}b_{kl}$.

(b) False. For $\mathbf{A}=\begin{pmatrix}1&2\\3&4\end{pmatrix}$ and $\mathbf{B}=\begin{pmatrix}0&1\\1&0\end{pmatrix}$, the $(1,2)$ entry of $\mathbf{A}\otimes\mathbf{B}$ is $a_{11}b_{12}=1$ and that of $\mathbf{B}\otimes\mathbf{A}$ is $b_{11}a_{12}=0$. The two are similar (Proposition 7.4.2), not equal.

(c) If $\mathbf{A}\in M_{m\times n}(F)$, $\mathbf{C}\in M_{n\times t}(F)$, $\mathbf{B}\in M_{p\times q}(F)$ and $\mathbf{D}\in M_{q\times u}(F)$, then $(\mathbf{A}\otimes\mathbf{B})(\mathbf{C}\otimes\mathbf{D})=(\mathbf{AC})\otimes(\mathbf{BD})$ (Theorem 7.4.1 (c)). The conditions are exactly that $\mathbf{AC}$ and $\mathbf{BD}$ are defined.

(d) False. By Theorem 7.4.3, $\det(\mathbf{A}\otimes\mathbf{B})=(\det\mathbf{A})^2(\det\mathbf{B})^2$. For $\mathbf{A}=\mathbf{B}=2\mathbf{I}_2$,

$\mathbf{A} \otimes \mathbf{B} = 4\mathbf{I}_4$ has determinant 256, while $\det \mathbf{A} \det \mathbf{B} = 16$.

(e) $\operatorname{vec}(\mathbf{AXB}) = (\mathbf{B}^\top \otimes \mathbf{A}) \operatorname{vec} \mathbf{X}$ (Theorem 7.4.4). With $\mathbf{A} = \mathbf{I}_m$, $\mathbf{M} = \mathbf{B}^\top \otimes \mathbf{I}_m$.

7.4.7.2 B. Practice

Exercise B1: Computing with Kronecker products.

Let $\mathbf{A} = \begin{pmatrix} 2 & 0 \\ 1 & -1 \end{pmatrix}$ and $\mathbf{B} = \begin{pmatrix} 1 & 1 \\ 0 & 3 \end{pmatrix}$ over $\mathbb{Q}$.

(a) Write out $\mathbf{A} \otimes \mathbf{B}$ and $\mathbf{B} \otimes \mathbf{A}$.

(b) Compute tr, det and rank of $\mathbf{A} \otimes \mathbf{B}$ from Theorem 7.4.3, and check the trace directly.

(c) Compute $\mathbf{A}^2 \otimes \mathbf{B}^2$ and use it to write down $(\mathbf{A} \otimes \mathbf{B})^2$ without multiplying 4×4 matrices. Justify the step.

(d) Hence find $(\mathbf{A} \otimes \mathbf{B})^{-1}$.

Solution.

(a) By Definition 7.4.1,

$$\mathbf{A} \otimes \mathbf{B} = \begin{pmatrix} 2\mathbf{B} & 0\mathbf{B} \\ 1\mathbf{B} & -1\mathbf{B} \end{pmatrix} = \begin{pmatrix} 2 & 2 & 0 & 0 \\ 0 & 6 & 0 & 0 \\ 1 & 1 & -1 & -1 \\ 0 & 3 & 0 & -3 \end{pmatrix},$$

$$\mathbf{B} \otimes \mathbf{A} = \begin{pmatrix} 1\mathbf{A} & 1\mathbf{A} \\ 0\mathbf{A} & 3\mathbf{A} \end{pmatrix} = \begin{pmatrix} 2 & 0 & 2 & 0 \\ 1 & -1 & 1 & -1 \\ 0 & 0 & 6 & 0 \\ 0 & 0 & 3 & -3 \end{pmatrix}.$$

(b) $\operatorname{tr} \mathbf{A} = 1$, $\operatorname{tr} \mathbf{B} = 4$, $\det \mathbf{A} = -2$, $\det \mathbf{B} = 3$, and both have rank 2. By Theorem 7.4.3, $\operatorname{tr}(\mathbf{A} \otimes \mathbf{B}) = 4$, $\det(\mathbf{A} \otimes \mathbf{B}) = (-2)^2 \cdot 3^2 = 36$ and $\operatorname{rank}(\mathbf{A} \otimes \mathbf{B}) = 4$. Directly, the diagonal of $\mathbf{A} \otimes \mathbf{B}$ is $2, 6, -1, -3$, with sum 4.

(c) By the mixed product rule (Theorem 7.4.1 (c)) with $\mathbf{C} = \mathbf{A}$ and $\mathbf{D} = \mathbf{B}$, $(\mathbf{A} \otimes \mathbf{B})^2 = \mathbf{A}^2 \otimes \mathbf{B}^2$. Here $\mathbf{A}^2 = \begin{pmatrix} 4 & 0 \\ 1 & 1 \end{pmatrix}$ and $\mathbf{B}^2 = \begin{pmatrix} 1 & 4 \\ 0 & 9 \end{pmatrix}$, so

$$(\mathbf{A} \otimes \mathbf{B})^2 = \begin{pmatrix} 4\mathbf{B}^2 & 0 \\ \mathbf{B}^2 & \mathbf{B}^2 \end{pmatrix} = \begin{pmatrix} 4 & 16 & 0 & 0 \\ 0 & 36 & 0 & 0 \\ 1 & 4 & 1 & 4 \\ 0 & 9 & 0 & 9 \end{pmatrix}.$$

(d) $\mathbf{A}^{-1} = \frac{1}{-2} \begin{pmatrix} -1 & 0 \\ -1 & 2 \end{pmatrix} = \begin{pmatrix} \frac{1}{2} & 0 \\ \frac{1}{2} & -1 \end{pmatrix}$ and $\mathbf{B}^{-1} = \frac{1}{3} \begin{pmatrix} 3 & -1 \\ 0 & 1 \end{pmatrix}$ by Theorem 0.9.8. By Theorem 7.4.1 (e),

$$(\mathbf{A} \otimes \mathbf{B})^{-1} = \mathbf{A}^{-1} \otimes \mathbf{B}^{-1} = \begin{pmatrix} \frac{1}{2}\mathbf{B}^{-1} & 0 \\ \frac{1}{2}\mathbf{B}^{-1} & -\mathbf{B}^{-1} \end{pmatrix} = \begin{pmatrix} \frac{1}{2} & -\frac{1}{6} & 0 & 0 \\ 0 & \frac{1}{6} & 0 & 0 \\ \frac{1}{2} & -\frac{1}{6} & -1 & \frac{1}{3} \\ 0 & \frac{1}{6} & 0 & -\frac{1}{3} \end{pmatrix}.$$

Multiplying by $\mathbf{A} \otimes \mathbf{B}$ gives $\mathbf{I}_4$.

Exercise B2: One-sided equations.

Let $\mathbf{A} \in M_m(F)$ and $\mathbf{C} \in M_{m\times n}(F)$, and consider $\mathbf{AX} = \mathbf{C}$ for $\mathbf{X} \in M_{m\times n}(F)$.

(a) Write the equation in the form $\mathbf{M}\operatorname{vec}\mathbf{X} = \operatorname{vec}\mathbf{C}$, and describe $\mathbf{M}$ as a block matrix.

(b) Explain why the system splits into n separate systems, one for each column of $\mathbf{X}$.

(c) Hence show that $\mathbf{AX} = \mathbf{C}$ has exactly one solution for every $\mathbf{C}$ if and only if $\mathbf{A}$ is invertible.

(d) Solve $\mathbf{XA} = \mathbf{C}$ over $\mathbb{Q}$ by the same method, where $\mathbf{A} = \begin{pmatrix} 1 & 2 \\ 1 & 3 \end{pmatrix}$ and $\mathbf{C} = \begin{pmatrix} 3 & 7 \\ 0 & 1 \end{pmatrix}$.

Solution.

(a) By Theorem 7.4.4 with $\mathbf{B} = \mathbf{I}_n$, $\operatorname{vec}(\mathbf{AX}) = (\mathbf{I}_n \otimes \mathbf{A})\operatorname{vec}\mathbf{X}$, so $\mathbf{M} = \mathbf{I}_n \otimes \mathbf{A} = \mathbf{A} \oplus \cdots \oplus \mathbf{A}$, with n blocks.

(b) Write $\operatorname{vec}\mathbf{X}$ and $\operatorname{vec}\mathbf{C}$ as stacks of the columns $\mathbf{x}_j$ and $\mathbf{c}_j$. By Theorem 7.1.1, $(\mathbf{A} \oplus \cdots \oplus \mathbf{A})\operatorname{vec}\mathbf{X}$ is the stack of the $\mathbf{A}\mathbf{x}_j$. So the system says $\mathbf{A}\mathbf{x}_j = \mathbf{c}_j$ for $j = 1, \ldots, n$, and the unknowns of different columns never meet.

(c) ($\Leftarrow$) If $\mathbf{A}$ is invertible, then $\mathbf{AX} = \mathbf{C}$ forces $\mathbf{X} = \mathbf{A}^{-1}\mathbf{C}$, and this $\mathbf{X}$ is a solution. ($\Rightarrow$) Suppose $\mathbf{AX} = \mathbf{C}$ is solvable for every $\mathbf{C}$. Given $\mathbf{c} \in F^m$, take $\mathbf{C}$ with every column equal to $\mathbf{c}$; by (b), a solution gives $\mathbf{x}$ with $\mathbf{Ax} = \mathbf{c}$. So $\mathbf{Ax} = \mathbf{c}$ is solvable for every $\mathbf{c}$, and $\mathbf{A}$ is invertible by Theorem 2.4.4 ((e) $\Rightarrow$ (a)).

(d) By Theorem 7.4.4 with the left factor $\mathbf{I}_2$, $\operatorname{vec}(\mathbf{XA}) = (\mathbf{A}^\top \otimes \mathbf{I}_2)\operatorname{vec}\mathbf{X}$. With $\mathbf{A}^\top = \begin{pmatrix} 1 & 1 \\ 2 & 3 \end{pmatrix}$, $\operatorname{vec}\mathbf{X} = (x_{11}, x_{21}, x_{12}, x_{22})$ and $\operatorname{vec}\mathbf{C} = (3, 0, 7, 1)$, the system is

$$\begin{pmatrix} 1 & 0 & 1 & 0 \\ 0 & 1 & 0 & 1 \\ 2 & 0 & 3 & 0 \\ 0 & 2 & 0 & 3 \end{pmatrix} \begin{pmatrix} x_{11} \\ x_{21} \\ x_{12} \\ x_{22} \end{pmatrix} = \begin{pmatrix} 3 \\ 0 \\ 7 \\ 1 \end{pmatrix}.$$

This time the system splits by the **rows** of $\mathbf{X}$: equations $1, 3$ involve only x_{11}, x_{12}, and equations $2, 4$ only x_{21}, x_{22}. From $x_{11} + x_{12} = 3$ and $2x_{11} + 3x_{12} = 7$ we get $x_{12} = 1$, $x_{11} = 2$. From $x_{21} + x_{22} = 0$ and $2x_{21} + 3x_{22} = 1$ we get $x_{22} = 1$, $x_{21} = -1$. Hence

$$\mathbf{X} = \begin{pmatrix} 2 & 1 \\ -1 & 1 \end{pmatrix}.$$

Check: $\mathbf{XA} = \begin{pmatrix} 2+1 & 4+3 \\ -1+1 & -2+3 \end{pmatrix} = \begin{pmatrix} 3 & 7 \\ 0 & 1 \end{pmatrix} = \mathbf{C}$.

Exercise B3: Which identities hold?.

Determine which of the following statements hold for **all** $\mathbf{A}, \mathbf{B}, \mathbf{C} \in M_2(\mathbb{R})$. Justify your answer.

(a) $(\mathbf{A}\otimes\mathbf{B})(\mathbf{A}\otimes\mathbf{B}) = \mathbf{A}^2\otimes\mathbf{B}^2$.
(b) $(\mathbf{A}+\mathbf{B})\otimes\mathbf{C} = \mathbf{A}\otimes\mathbf{C}+\mathbf{B}\otimes\mathbf{C}$.
(c) $(\mathbf{A}\otimes\mathbf{B})^\top = \mathbf{B}^\top\otimes\mathbf{A}^\top$.
(d) $\mathbf{A}\otimes\mathbf{B} = 0$ implies $\mathbf{A} = 0$ or $\mathbf{B} = 0$.
(e) $\operatorname{tr}(\mathbf{A}\otimes\mathbf{B}) = \operatorname{tr}(\mathbf{B}\otimes\mathbf{A})$.
(f) $\mathbf{A}\otimes\mathbf{B}+\mathbf{B}\otimes\mathbf{A} = 2(\mathbf{A}\otimes\mathbf{B})$.

Solution.

(a) Holds, by the mixed product rule (Theorem 7.4.1 (c)).
(b) Holds, by bilinearity (Theorem 7.4.1 (a)).
(c) Fails. By Theorem 7.4.1 (d), $(\mathbf{A}\otimes\mathbf{B})^\top = \mathbf{A}^\top\otimes\mathbf{B}^\top$, and this differs from $\mathbf{B}^\top\otimes\mathbf{A}^\top$ in general. Take $\mathbf{A} = \begin{pmatrix}1 & 3\\ 2 & 4\end{pmatrix}$ and $\mathbf{B} = \begin{pmatrix}0 & 1\\ 1 & 0\end{pmatrix} = \mathbf{B}^\top$. By $(*)$, the $(1,2)$ entry of $\mathbf{A}^\top\otimes\mathbf{B}^\top$ is $(\mathbf{A}^\top)_{11}b_{12} = 1$, while that of $\mathbf{B}^\top\otimes\mathbf{A}^\top$ is $b_{11}(\mathbf{A}^\top)_{12} = 0$. Unlike $(\mathbf{AB})^\top = \mathbf{B}^\top\mathbf{A}^\top$, the order of the factors does not reverse.
(d) Holds. If $\mathbf{A}\neq 0$ and $\mathbf{B}\neq 0$, then $\operatorname{rank}\mathbf{A}\geq 1$ and $\operatorname{rank}\mathbf{B}\geq 1$, so $\operatorname{rank}(\mathbf{A}\otimes\mathbf{B})\geq 1$ by Theorem 7.4.3 (a), and $\mathbf{A}\otimes\mathbf{B}\neq 0$. (Directly: if $a_{ij}\neq 0$ and $b_{kl}\neq 0$, the entry $a_{ij}b_{kl}$ of $\mathbf{A}\otimes\mathbf{B}$ is non-zero.)
(e) Holds: both equal $\operatorname{tr}\mathbf{A}\operatorname{tr}\mathbf{B}$ by Theorem 7.4.3 (b).
(f) Fails, since it is equivalent to $\mathbf{B}\otimes\mathbf{A} = \mathbf{A}\otimes\mathbf{B}$, which is false for the matrices of Example 1 after Definition 7.4.1 (see the non-example there).

7.4.7.3 C. Going deeper

Exercise C1: When is a Kronecker product invertible?.

(a) Let $\mathbf{A}\in M_n(F)$ and $\mathbf{B}\in M_m(F)$. Prove that $\mathbf{A}\otimes\mathbf{B}$ is invertible if and only if both $\mathbf{A}$ and $\mathbf{B}$ are invertible.
(b) Let $\mathbf{A}\in M_{m\times n}(F)$ and $\mathbf{B}\in M_{p\times q}(F)$ with $mp = nq$, so that $\mathbf{A}\otimes\mathbf{B}$ is square. Prove that if $m\neq n$, then $\mathbf{A}\otimes\mathbf{B}$ is **not** invertible.
(c) Give an example of a 2×1 matrix $\mathbf{A}$ and a 1×2 matrix $\mathbf{B}$ for which $\mathbf{A}\otimes\mathbf{B}$ is a non-zero 2×2 matrix, and compute its rank.

Solution.

(a) By Theorem 7.4.3 (c), $\det(\mathbf{A}\otimes\mathbf{B}) = (\det\mathbf{A})^m(\det\mathbf{B})^n$. In a field a product is non-zero if and only if each factor is, so this is non-zero if and only if $\det\mathbf{A}\neq 0$ and $\det\mathbf{B}\neq 0$ (here $n,m\geq 1$). By Theorem 6.5.2, applied to all three matrices, $\mathbf{A}\otimes\mathbf{B}$ is invertible if and only if $\mathbf{A}$ and $\mathbf{B}$ are.
(b) Suppose $m<n$. Since $mp = nq$ and $m<n$, we get $p>q$. By Theorem 7.4.3 (a) and the bound $\operatorname{rank}\mathbf{M}\leq$ (number of rows) and $\leq$ (number of columns),

$$\operatorname{rank}(\mathbf{A}\otimes\mathbf{B}) = \operatorname{rank}\mathbf{A}\operatorname{rank}\mathbf{B}\leq m\cdot q < n\cdot q = nq,$$

so the $nq\times nq$ matrix $\mathbf{A}\otimes\mathbf{B}$ is not invertible (Theorem 2.4.4). If $m>n$, then $p<q$, and $\operatorname{rank}\mathbf{A}\operatorname{rank}\mathbf{B}\leq n\cdot p < m\cdot p = mp = nq$ in the same way.

(c) Take $\mathbf{A} = \begin{pmatrix}1\\2\end{pmatrix}$ and $\mathbf{B} = \begin{pmatrix}3 & 1\end{pmatrix}$. Then $\mathbf{A}\otimes\mathbf{B} = \begin{pmatrix}1\mathbf{B}\\2\mathbf{B}\end{pmatrix} = \begin{pmatrix}3 & 1\\6 & 2\end{pmatrix}$, the outer product $\mathbf{AB}$, of rank $1\cdot 1 = 1$: its second row is twice its first. So it is square and non-zero but singular, as (b) predicts.

Exercise C2: Kronecker sums.

Let $\mathbf{A}\in M_n(F)$ and $\mathbf{B}\in M_m(F)$, and put $\mathbf{K} \coloneqq \mathbf{A}\otimes\mathbf{I}_m + \mathbf{I}_n\otimes\mathbf{B}\in M_{nm}(F)$.

(a) Prove that $(\mathbf{A}\otimes\mathbf{I}_m)(\mathbf{I}_n\otimes\mathbf{B}) = (\mathbf{I}_n\otimes\mathbf{B})(\mathbf{A}\otimes\mathbf{I}_m)$, and deduce that $\mathbf{K}^2 = \mathbf{A}^2\otimes\mathbf{I}_m + 2(\mathbf{A}\otimes\mathbf{B}) + \mathbf{I}_n\otimes\mathbf{B}^2$.

(b) Show that for $\mathbf{X}\in M_{m\times n}(F)$, $\operatorname{vec}(\mathbf{BX}+\mathbf{XA}^\top) = \mathbf{K}\operatorname{vec}\mathbf{X}$.

(c) Suppose $\mathbf{A}$ and $\mathbf{B}$ are upper triangular. Prove that $\mathbf{K}$ is upper triangular with diagonal entries $a_{ii}+b_{kk}$, and deduce that $\mathbf{BX}+\mathbf{XA}^\top = \mathbf{C}$ has exactly one solution for every $\mathbf{C}\in M_{m\times n}(F)$ if and only if $a_{ii}+b_{kk}\neq 0$ for all i,k.

(d) For $\mathbf{A} = \begin{pmatrix}1 & 2\\0 & -1\end{pmatrix}$ and $\mathbf{B} = \begin{pmatrix}1 & 0\\0 & 3\end{pmatrix}$ over $\mathbb{Q}$, decide whether $\mathbf{BX}+\mathbf{XA}^\top = \mathbf{C}$ is solvable for every $\mathbf{C}$. If not, find a $\mathbf{C}$ with no solution.

Solution.

(a) By the mixed product rule, both products equal $(\mathbf{A}\mathbf{I}_n)\otimes(\mathbf{I}_m\mathbf{B}) = (\mathbf{I}_n\mathbf{A})\otimes(\mathbf{B}\mathbf{I}_m) = \mathbf{A}\otimes\mathbf{B}$, as in $(**)$. Expanding $\mathbf{K}^2$ by distributivity (Theorem 0.9.4) gives $(\mathbf{A}\otimes\mathbf{I}_m)^2 + (\mathbf{A}\otimes\mathbf{I}_m)(\mathbf{I}_n\otimes\mathbf{B}) + (\mathbf{I}_n\otimes\mathbf{B})(\mathbf{A}\otimes\mathbf{I}_m) + (\mathbf{I}_n\otimes\mathbf{B})^2$. The middle terms are both $\mathbf{A}\otimes\mathbf{B}$, and the outer ones are $\mathbf{A}^2\otimes\mathbf{I}_m$ and $\mathbf{I}_n\otimes\mathbf{B}^2$ by the mixed product rule.

(b) By Theorem 7.4.4, $\operatorname{vec}(\mathbf{BXI}_n) = (\mathbf{I}_n\otimes\mathbf{B})\operatorname{vec}\mathbf{X}$ and $\operatorname{vec}(\mathbf{I}_m\mathbf{XA}^\top) = ((\mathbf{A}^\top)^\top\otimes\mathbf{I}_m)\operatorname{vec}\mathbf{X} = (\mathbf{A}\otimes\mathbf{I}_m)\operatorname{vec}\mathbf{X}$. Add, using linearity of vec.

(c) By $(*)$, the entry of $\mathbf{A}\otimes\mathbf{I}_m$ in position $((i-1)m+k,(j-1)m+l)$ is $a_{ij}\delta_{kl}$, which is zero unless $i\le j$ and $k=l$; in that case $(i-1)m+k\le(j-1)m+l$. The entry of $\mathbf{I}_n\otimes\mathbf{B}$ there is $\delta_{ij}b_{kl}$, zero unless $i=j$ and $k\le l$, and again the row index is at most the column index. So both are upper triangular, hence so is $\mathbf{K}$. On the diagonal, $i=j$ and $k=l$, and the entry is $a_{ii}+b_{kk}$. By Theorem 6.4.6, $\det\mathbf{K} = \prod_{i,k}(a_{ii}+b_{kk})$. By (b), the equation is $\mathbf{K}\operatorname{vec}\mathbf{X} = \operatorname{vec}\mathbf{C}$, and since vec is an isomorphism, it has exactly one solution for every $\mathbf{C}$ if and only if $\mathbf{K}$ is invertible (Theorem 2.4.4), that is $\det\mathbf{K}\neq 0$ (Theorem 6.5.2), that is every $a_{ii}+b_{kk}\neq 0$.

(d) The diagonal entries $a_{ii}+b_{kk}$ are $1+1=2$, $1+3=4$, $-1+1=0$, $-1+3=2$, so by (c) the equation is not solvable for every $\mathbf{C}$. Explicitly,

$$\mathbf{K} = \begin{pmatrix}1\mathbf{I}_2 & 2\mathbf{I}_2\\0\mathbf{I}_2 & -1\mathbf{I}_2\end{pmatrix} + \begin{pmatrix}\mathbf{B} & 0\\0 & \mathbf{B}\end{pmatrix} = \begin{pmatrix}2 & 0 & 2 & 0\\0 & 4 & 0 & 2\\0 & 0 & 0 & 0\\0 & 0 & 0 & 2\end{pmatrix},$$

whose third row is zero. So $\mathbf{K}\operatorname{vec}\mathbf{X}$ always has third entry 0, and any $\mathbf{C}$ with $(\operatorname{vec}\mathbf{C})_3 = c_{12}\neq 0$ has no solution, for example $\mathbf{C} = \mathbf{E}_{12}$. (Directly: the $(1,2)$ entry of $\mathbf{BX}+\mathbf{XA}^\top$ is $x_{12} + (x_{11}a_{21} + x_{12}a_{22}) = x_{12} - x_{12} = 0$.)

7.5 Commutators and Trace-Zero Matrices

The expression $\mathbf{AB}-\mathbf{BA}$ has come up several times already. In Chapter 0 its trace was 0, which showed that $\mathbf{AB}-\mathbf{BA}=\mathbf{I}_n$ is impossible over $\mathbb{R}$ (Exercise (C1: $\mathbf{AB}-\mathbf{BA}=\mathbf{I}$ is impossible, or is it?)). In Chapter 3 the same trace argument showed that the relation $DS-SD=\mathrm{id}$ between differentiation and multiplication by x on $F[x]$ has no finite-dimensional analogue in characteristic 0 (Exercise (C1: The Heisenberg relation)). Both arguments use one direction only: every matrix of the form $\mathbf{AB}-\mathbf{BA}$ has trace zero. This section asks whether the converse holds. Is every trace-zero matrix of the form $\mathbf{AB}-\mathbf{BA}$? The answer is yes over a field of characteristic 0, and the proof is a good example of the block techniques of this chapter: move the matrix into a convenient shape by a similarity, one row and column at a time, and then solve an equation that has become entrywise.

Which fields. Commutators, their basic rules, the first similarity lemma and the final theorem on spans work over **every** field F. The lemma on zero diagonals and Shoda's theorem assume that F has **characteristic** 0. We point out exactly where that hypothesis is used, and what happens in characteristic p.

7.5.1 Commutators

Two matrices $\mathbf{A}$ and $\mathbf{B}$ commute when $\mathbf{AB}=\mathbf{BA}$, and most pairs do not. The difference $\mathbf{AB}-\mathbf{BA}$ measures the failure, and it keeps recurring: in the trace arguments above, in the relation between differentiation and multiplication by x, and in the description of trace-like functionals (Exercise (C2: The trace is the only trace-like functional)). So we give it a name.

The commutator of two matrices is the amount by which they fail to commute.

Definition 7.5.1 — Commutator

Let $n\geq 1$ and $\mathbf{A},\mathbf{B}\in M_n(F)$. The **commutator** of $\mathbf{A}$ and $\mathbf{B}$ is

$$[\mathbf{A},\mathbf{B}]\coloneqq\mathbf{AB}-\mathbf{BA}\in M_n(F).$$

A matrix $\mathbf{C}\in M_n(F)$ is **a commutator** if $\mathbf{C}=[\mathbf{X},\mathbf{Y}]$ for **some** $\mathbf{X},\mathbf{Y}\in M_n(F)$. For operators $S,T\in\mathcal{L}(V)$ on a vector space V, we write likewise $[S,T]\coloneqq ST-TS\in\mathcal{L}(V)$.

In words: $[\mathbf{A},\mathbf{B}]$ is "$\mathbf{A}$ then $\mathbf{B}$" minus "$\mathbf{B}$ then $\mathbf{A}$", in that order, and it is the zero matrix exactly when $\mathbf{A}$ and $\mathbf{B}$ commute. The second sentence of the definition is about a single matrix: being a commutator means that **there exist** two matrices whose commutator it is, and it says nothing about which ones.

Examples.

1. **Degenerate cases.** $[\mathbf{A},\mathbf{A}]=0$ and $[\mathbf{A},c\mathbf{I}_n]=c\mathbf{A}-c\mathbf{A}=0$ for every $c\in F$. So the zero matrix is a commutator, in many ways. In $M_1(F)=F$ every commutator is $ab-ba=0$, so for $n=1$ the only commutator is 0; this is the smallest case, and it already matches the trace condition, since the only 1×1 matrix of trace 0 is (0).
2. **Matrix units.** Recall that $\mathbf{E}_{ij}\mathbf{E}_{kl}$ is $\mathbf{E}_{il}$ if $j=k$ and 0 otherwise (Definition 0.9.9). So

for $i \neq k$,

$$[\mathbf{E}_{ij}, \mathbf{E}_{jk}] = \mathbf{E}_{ik} - 0 = \mathbf{E}_{ik}, \qquad \text{and} \qquad [\mathbf{E}_{ij}, \mathbf{E}_{ji}] = \mathbf{E}_{ii} - \mathbf{E}_{jj} \quad (i \neq j).$$

For instance $[\mathbf{E}_{12}, \mathbf{E}_{21}] = \operatorname{diag}(1, -1)$ in $M_2(F)$, and $[\mathbf{E}_{11}, \mathbf{E}_{12}] = \mathbf{E}_{12}$. Both have trace 0.

3. **Operators on an infinite-dimensional space.** On $F[x]$, with D differentiation and S multiplication by x, Exercise (C1: The Heisenberg relation) (a) shows $[D, S] = \mathrm{id}$. So the identity **is** a commutator of operators on $F[x]$. This does not contradict anything, because there is no trace on $\mathcal{L}(F[x])$: the trace was defined only on finite-dimensional spaces (Definition 3.10.2).

Non-example by minimal change. Change the minus sign to a plus: $\mathbf{AB} + \mathbf{BA}$. It is still linear in $\mathbf{A}$ and in $\mathbf{B}$, and it is still built from the two products $\mathbf{AB}$ and $\mathbf{BA}$. What is lost is the trace: $\operatorname{tr}(\mathbf{AB}+\mathbf{BA}) = 2\operatorname{tr}(\mathbf{AB})$, which has no reason to vanish. For example $\mathbf{E}_{12}\mathbf{E}_{21}+\mathbf{E}_{21}\mathbf{E}_{12} = \mathbf{E}_{11}+\mathbf{E}_{22} = \mathbf{I}_2$, with trace 2. It also no longer detects commuting: $\mathbf{AA}+\mathbf{AA} = 2\mathbf{A}^2$ is non-zero for $\mathbf{A} = \mathbf{I}_n$ over $\mathbb{Q}$, although $\mathbf{A}$ commutes with itself.

Why this definition. The order in $\mathbf{AB} - \mathbf{BA}$ is a convention; the other order gives $[\mathbf{B}, \mathbf{A}] = -[\mathbf{A}, \mathbf{B}]$, which is a commutator too. The notion is invariant under a change of basis: a similarity applied to $\mathbf{X}$ and $\mathbf{Y}$ applies to $[\mathbf{X}, \mathbf{Y}]$. So "being a commutator" is a property of the operator $\mathbf{x} \mapsto \mathbf{Cx}$, not of the basis used to write $\mathbf{C}$, and we are free to choose a convenient basis. This is what the proof of the main theorem exploits.

The basic rules are collected here.

Proposition 7.5.1 — Rules for Commutators

Let $\mathbf{A}, \mathbf{A}', \mathbf{B} \in M_n(F)$, $c \in F$, and let $\mathbf{P} \in M_n(F)$ be invertible. Then:

(a) $[\mathbf{A} + \mathbf{A}', \mathbf{B}] = [\mathbf{A}, \mathbf{B}] + [\mathbf{A}', \mathbf{B}]$, $[c\mathbf{A}, \mathbf{B}] = c[\mathbf{A}, \mathbf{B}]$, and $[\mathbf{B}, \mathbf{A}] = -[\mathbf{A}, \mathbf{B}]$; in particular the commutator is linear in each slot.

(b) $\mathbf{P}^{-1}[\mathbf{A}, \mathbf{B}]\mathbf{P} = [\mathbf{P}^{-1}\mathbf{AP}, \mathbf{P}^{-1}\mathbf{BP}]$.

(c) $\operatorname{tr}[\mathbf{A}, \mathbf{B}] = 0$.

Proof.

(a) By Theorem 0.9.4, $(\mathbf{A} + \mathbf{A}')\mathbf{B} - \mathbf{B}(\mathbf{A} + \mathbf{A}') = (\mathbf{AB} - \mathbf{BA}) + (\mathbf{A}'\mathbf{B} - \mathbf{BA}')$ and $(c\mathbf{A})\mathbf{B} - \mathbf{B}(c\mathbf{A}) = c(\mathbf{AB} - \mathbf{BA})$. The last identity is $\mathbf{BA} - \mathbf{AB} = -(\mathbf{AB} - \mathbf{BA})$. Linearity in the second slot follows from the first slot and antisymmetry.

(b) Inserting $\mathbf{PP}^{-1} = \mathbf{I}_n$, $\mathbf{P}^{-1}\mathbf{ABP} = (\mathbf{P}^{-1}\mathbf{AP})(\mathbf{P}^{-1}\mathbf{BP})$, and likewise for $\mathbf{BA}$. Subtract, using distributivity.

(c) By Theorem 0.9.6 (1) and (3), $\operatorname{tr}(\mathbf{AB} - \mathbf{BA}) = \operatorname{tr}(\mathbf{AB}) - \operatorname{tr}(\mathbf{BA}) = 0$.

■

So every commutator lies in the subspace of trace-zero matrices of Example (Trace-Free Matrices). The question of this section is whether it fills that subspace.

7.5.2 The identity in characteristic p

Rule (c) is the whole content of the Heisenberg exercises: if $[\mathbf{X}, \mathbf{Y}] = \mathbf{I}_n$, then $n \cdot 1 = \operatorname{tr} \mathbf{I}_n = 0$, which is impossible when F has characteristic 0 (Definition 0.7.2). The obstruction is the number $n \cdot 1$, not the identity matrix itself. In characteristic p, the $p \times p$ identity has trace $p \cdot 1 = 0$, and the obstruction disappears. In fact the pair D, S of Example 3 survives in a finite form.

Example. (The Identity as a Commutator in Characteristic p)

Let F have prime characteristic p (for instance $F = \mathbb{F}_p$). Let $\mathbf{D}_p \in M_p(F)$ have $(k, k+1)$-entry $k \cdot 1$ for $1 \le k \le p-1$, and let $\mathbf{S}_p \in M_p(F)$ have $(k+1, k)$-entry 1 for $1 \le k \le p-1$, all other entries 0. Show that $[\mathbf{D}_p, \mathbf{S}_p] = \mathbf{I}_p$.

Solution. The columns of these matrices describe differentiation and multiplication by x on the list $1, x, \dots, x^{p-1}$, where x^p is replaced by 0. By Theorem 0.9.2, $\mathbf{S}_p \mathbf{e}_k = \mathbf{e}_{k+1}$ for $k < p$ and $\mathbf{S}_p \mathbf{e}_p = \mathbf{0}$, while $\mathbf{D}_p \mathbf{e}_1 = \mathbf{0}$ and $\mathbf{D}_p \mathbf{e}_k = (k-1)\mathbf{e}_{k-1}$ for $k \ge 2$. Hence

$$\mathbf{D}_p \mathbf{S}_p \mathbf{e}_k = k\, \mathbf{e}_k \ (k < p), \quad \mathbf{D}_p \mathbf{S}_p \mathbf{e}_p = \mathbf{0}, \qquad \mathbf{S}_p \mathbf{D}_p \mathbf{e}_k = (k-1)\, \mathbf{e}_k \ (1 \le k \le p),$$

where for $k = 1$ we used $\mathbf{S}_p \mathbf{D}_p \mathbf{e}_1 = \mathbf{0} = 0\, \mathbf{e}_1$. Subtracting, $[\mathbf{D}_p, \mathbf{S}_p]\mathbf{e}_k = \mathbf{e}_k$ for $k < p$, and $[\mathbf{D}_p, \mathbf{S}_p]\mathbf{e}_p = -(p-1)\mathbf{e}_p = (1-p)\mathbf{e}_p = \mathbf{e}_p$, because $p \cdot 1 = 0$ in F (Definition 0.7.2, Lemma 0.7.4). So every column of $[\mathbf{D}_p, \mathbf{S}_p]$ is the corresponding column of $\mathbf{I}_p$. For $p = 2$ this is the pair of Exercise (C1: The Heisenberg relation) (d), transposed.

Warning. **"The identity is never a commutator" is a statement about characteristic 0.** The trace test says that a commutator has trace 0, and $\operatorname{tr} \mathbf{I}_n = n \cdot 1$. Over $\mathbb{R}$ this is $n \neq 0$; over $\mathbb{F}_p$ it is 0 whenever p divides n, and then the test is silent. The example above shows that $\mathbf{I}_p$ really is a commutator over $\mathbb{F}_p$. Whenever an argument ends with "$n \cdot 1 = 0$, contradiction", check which fields it covers.

7.5.3 Trace-zero matrices with zero diagonal

We want to write a given trace-zero $\mathbf{A}$ as $[\mathbf{X}, \mathbf{Y}]$. Look first at the easiest choice of $\mathbf{X}$, a diagonal matrix $\mathbf{X} = \operatorname{diag}(x_1, \dots, x_n)$. For any $\mathbf{Y} = (y_{ij})$, Definition 0.9.9 gives $(\mathbf{XY})_{ij} = x_i y_{ij}$ and $(\mathbf{YX})_{ij} = y_{ij} x_j$, so

$$[\mathbf{X}, \mathbf{Y}]_{ij} = (x_i - x_j)\, y_{ij}. \tag{$*$}$$

The diagonal entries of $[\mathbf{X}, \mathbf{Y}]$ are all 0, and each off-diagonal entry can be anything, provided $x_i \neq x_j$. So a diagonal $\mathbf{X}$ with distinct entries produces **exactly** the matrices with zero diagonal. A trace-zero matrix need not have zero diagonal, but by Proposition 7.5.1 (b) we may replace $\mathbf{A}$ by any matrix similar to it. The plan is therefore:

① find a similarity that makes the diagonal of $\mathbf{A}$ zero; ② solve $(*)$ entrywise.

Step ① is the heart of the matter. We do it one diagonal entry at a time, starting with the $(1,1)$-entry.

A matrix is **scalar** if it equals $\lambda \mathbf{I}_n$ for some $\lambda \in F$. A scalar matrix is similar only to itself, since $\mathbf{P}^{-1}(\lambda \mathbf{I}_n)\mathbf{P} = \lambda \mathbf{I}_n$, so its diagonal cannot be changed. Every other matrix can at least be given a zero in the corner. This first lemma holds over every field.

Lemma 7.5.2 — A Non-Scalar Matrix Has a Similar Matrix with Zero Corner

Let F be any field, let $n \geq 2$, and let $\mathbf{A} \in M_n(F)$ be **not** scalar. Then there is an invertible $\mathbf{P} \in M_n(F)$ such that the first column of $\mathbf{P}^{-1}\mathbf{A}\mathbf{P}$ is $\mathbf{e}_2$. In particular

$$\mathbf{P}^{-1}\mathbf{A}\mathbf{P} = \begin{pmatrix} 0 & \mathbf{r}^{\top} \\ \mathbf{e}_1 & \mathbf{A}_1 \end{pmatrix}$$

for some $\mathbf{r} \in F^{n-1}$ and $\mathbf{A}_1 \in M_{n-1}(F)$ with $\operatorname{tr}\mathbf{A}_1 = \operatorname{tr}\mathbf{A}$, where $\mathbf{e}_1 \in F^{n-1}$.

Idea. Work backwards from the goal. The first column of $\mathbf{P}^{-1}\mathbf{A}\mathbf{P}$ is the coordinate vector of $\mathbf{A}\mathbf{p}_1$ in the basis formed by the columns $\mathbf{p}_1, \dots, \mathbf{p}_n$ of $\mathbf{P}$. For it to be $\mathbf{e}_2$, we need $\mathbf{A}\mathbf{p}_1 = \mathbf{p}_2$. So we want a vector $\mathbf{v}$ such that $\mathbf{v}$ and $\mathbf{A}\mathbf{v}$ are independent, and then we build a basis starting $\mathbf{v}, \mathbf{A}\mathbf{v}$. Such a $\mathbf{v}$ exists unless $\mathbf{A}$ sends every vector to a multiple of itself, and a short argument shows that this forces $\mathbf{A}$ to be scalar.

Proof. We first show that there is $\mathbf{v} \in F^n$ with $(\mathbf{v}, \mathbf{A}\mathbf{v})$ linearly independent. Suppose not. Then for every $\mathbf{v} \neq \mathbf{0}$ there are $a, b \in F$, not both zero, with $a\mathbf{v} + b\mathbf{A}\mathbf{v} = \mathbf{0}$. If $b = 0$, then $a \neq 0$ and $a\mathbf{v} = \mathbf{0}$, which forces $\mathbf{v} = \mathbf{0}$ (Theorem 1.1.9), a contradiction; so $b \neq 0$ and $\mathbf{A}\mathbf{v} = \lambda_{\mathbf{v}}\mathbf{v}$ with $\lambda_{\mathbf{v}} = -a/b$. Apply this to $\mathbf{e}_i$, $\mathbf{e}_j$ and $\mathbf{e}_i + \mathbf{e}_j$ for $i \neq j$:

$$\lambda_{\mathbf{e}_i+\mathbf{e}_j}\mathbf{e}_i + \lambda_{\mathbf{e}_i+\mathbf{e}_j}\mathbf{e}_j = \mathbf{A}(\mathbf{e}_i + \mathbf{e}_j) = \mathbf{A}\mathbf{e}_i + \mathbf{A}\mathbf{e}_j = \lambda_{\mathbf{e}_i}\mathbf{e}_i + \lambda_{\mathbf{e}_j}\mathbf{e}_j.$$

Since $\mathbf{e}_i, \mathbf{e}_j$ are linearly independent, comparing coefficients (Theorem 1.4.3) gives $\lambda_{\mathbf{e}_i} = \lambda_{\mathbf{e}_i+\mathbf{e}_j} = \lambda_{\mathbf{e}_j}$. Hence all $\lambda_{\mathbf{e}_i}$ equal a common λ, so $\mathbf{A}\mathbf{e}_i = \lambda\mathbf{e}_i$ for every i, and by Theorem 0.9.2 the columns of $\mathbf{A}$ are those of $\lambda\mathbf{I}_n$. So $\mathbf{A} = \lambda\mathbf{I}_n$ is scalar, contrary to the hypothesis.

Take such a $\mathbf{v}$. By Theorem 1.6.5, the independent list $(\mathbf{v}, \mathbf{A}\mathbf{v})$ extends to a basis $(\mathbf{v}, \mathbf{A}\mathbf{v}, \mathbf{w}_3, \dots, \mathbf{w}_n)$ of F^n. Let $\mathbf{P}$ be the matrix with these columns; it is invertible by Theorem 2.4.4. Then $\mathbf{P}\mathbf{e}_1 = \mathbf{v}$ and $\mathbf{P}\mathbf{e}_2 = \mathbf{A}\mathbf{v}$ (Theorem 0.9.3), so the first column of $\mathbf{P}^{-1}\mathbf{A}\mathbf{P}$ is

$$\mathbf{P}^{-1}\mathbf{A}\mathbf{P}\mathbf{e}_1 = \mathbf{P}^{-1}\mathbf{A}\mathbf{v} = \mathbf{P}^{-1}\mathbf{P}\mathbf{e}_2 = \mathbf{e}_2.$$

Partitioning $\mathbf{P}^{-1}\mathbf{A}\mathbf{P}$ after the first row and column gives the displayed form. Finally, $\operatorname{tr}(\mathbf{P}^{-1}\mathbf{A}\mathbf{P}) = \operatorname{tr}\mathbf{A}$ by Theorem 3.7.5, and $\operatorname{tr}(\mathbf{P}^{-1}\mathbf{A}\mathbf{P}) = 0 + \operatorname{tr}\mathbf{A}_1$ by Definition 0.9.12, so $\operatorname{tr}\mathbf{A}_1 = \operatorname{tr}\mathbf{A}$.

■

Quick check. Over $\mathbb{Q}$, let $\mathbf{A} = \begin{pmatrix} 2 & 1 \\ 0 & -2 \end{pmatrix}$. Using $\mathbf{v} = \mathbf{e}_2$ in the proof of Lemma 7.5.2, find $\mathbf{P}$ and $\mathbf{P}^{-1}\mathbf{A}\mathbf{P}$, and check that its diagonal is zero.

Solution. $\mathbf{A}\mathbf{e}_2 = (1, -2)$, which is not a multiple of $\mathbf{e}_2$, so $(\mathbf{e}_2, \mathbf{A}\mathbf{e}_2)$ is independent and already a basis of $\mathbb{Q}^2$. Then $\mathbf{P} = \begin{pmatrix} 0 & 1 \\ 1 & -2 \end{pmatrix}$, with $\det\mathbf{P} = -1$ and $\mathbf{P}^{-1} = \begin{pmatrix} 2 & 1 \\ 1 & 0 \end{pmatrix}$. We

get $\mathbf{AP} = \begin{pmatrix} 1 & 0 \\ -2 & 4 \end{pmatrix}$ and $\mathbf{P}^{-1}\mathbf{AP} = \begin{pmatrix} 0 & 4 \\ 1 & 0 \end{pmatrix}$. The first column is $\mathbf{e}_2$, as the lemma promises; the $(2,2)$-entry is 0 as well, because the trace is 0 and trace is a similarity invariant.

The lemma controls one diagonal entry and hands us a smaller matrix $\mathbf{A}_1$ with the same trace. That is exactly the setting for induction on the size. The only thing that can stop the induction is a scalar $\mathbf{A}_1$, and here the trace saves us, provided the field has characteristic 0.

Lemma 7.5.3 — Trace Zero Means Similar to Zero Diagonal

Let F be a field of **characteristic** 0, let $n \geq 1$, and let $\mathbf{A} \in M_n(F)$ with $\operatorname{tr}\mathbf{A} = 0$. Then $\mathbf{A}$ is similar to a matrix all of whose diagonal entries are 0.

Idea. Induction on n. If $\mathbf{A}$ is scalar, $\mathbf{A} = \lambda\mathbf{I}_n$ with $n\lambda = 0$, and characteristic 0 forces $\lambda = 0$: then $\mathbf{A} = 0$ already has zero diagonal. Otherwise, Lemma 7.5.2 puts a 0 in the corner and leaves a trace-zero block $\mathbf{A}_1$ of size $n-1$. The induction hypothesis conjugates $\mathbf{A}_1$ by some $\mathbf{Q}$ into zero diagonal. Conjugating the whole matrix by the block diagonal matrix $(1) \oplus \mathbf{Q}$ does this to the lower block without disturbing the corner.

Proof. We use induction on n (Theorem 0.2.7). For $n = 1$, $\mathbf{A} = (\operatorname{tr}\mathbf{A}) = (0)$, which has zero diagonal.

Let $n \geq 2$, and assume the statement for trace-zero matrices of size $n - 1$.

Case 1: $\mathbf{A}$ *is scalar,* say $\mathbf{A} = \lambda\mathbf{I}_n$. Then $0 = \operatorname{tr}\mathbf{A} = n \cdot \lambda = (n \cdot 1)\lambda$ by Definition 0.9.12 and Lemma 0.7.4. Since F has characteristic 0 and $n \geq 1$, $n \cdot 1 \neq 0$ (Definition 0.7.2), so $\lambda = 0$. Hence $\mathbf{A} = 0$, which has zero diagonal and is similar to itself.

Case 2: $\mathbf{A}$ *is not scalar.* By Lemma 7.5.2 there is an invertible $\mathbf{P}$ with

$$\mathbf{M} := \mathbf{P}^{-1}\mathbf{AP} = \begin{pmatrix} 0 & \mathbf{r}^\top \\ \mathbf{e}_1 & \mathbf{A}_1 \end{pmatrix}, \qquad \operatorname{tr}\mathbf{A}_1 = \operatorname{tr}\mathbf{A} = 0.$$

By the induction hypothesis there is an invertible $\mathbf{Q} \in M_{n-1}(F)$ such that $\mathbf{Z}_1 := \mathbf{Q}^{-1}\mathbf{A}_1\mathbf{Q}$ has zero diagonal. Let $\mathbf{R} = (1) \oplus \mathbf{Q} = \begin{pmatrix} 1 & \mathbf{0}^\top \\ \mathbf{0} & \mathbf{Q} \end{pmatrix}$. By Theorem 7.1.4, $\mathbf{R}$ is invertible with $\mathbf{R}^{-1} = (1) \oplus \mathbf{Q}^{-1}$. By Theorem 7.1.1,

$$\begin{aligned} \mathbf{R}^{-1}\mathbf{MR} &= \begin{pmatrix} 1 & \mathbf{0}^\top \\ \mathbf{0} & \mathbf{Q}^{-1} \end{pmatrix} \begin{pmatrix} 0 & \mathbf{r}^\top \\ \mathbf{e}_1 & \mathbf{A}_1 \end{pmatrix} \begin{pmatrix} 1 & \mathbf{0}^\top \\ \mathbf{0} & \mathbf{Q} \end{pmatrix} \\ &= \begin{pmatrix} 0 & \mathbf{r}^\top\mathbf{Q} \\ \mathbf{Q}^{-1}\mathbf{e}_1 & \mathbf{Q}^{-1}\mathbf{A}_1\mathbf{Q} \end{pmatrix} = \begin{pmatrix} 0 & \mathbf{r}^\top\mathbf{Q} \\ \mathbf{Q}^{-1}\mathbf{e}_1 & \mathbf{Z}_1 \end{pmatrix}. \end{aligned}$$

Its $(1,1)$-entry is 0, and its other diagonal entries are those of $\mathbf{Z}_1$, which are 0. Since $\mathbf{R}^{-1}\mathbf{MR} = (\mathbf{PR})^{-1}\mathbf{A}(\mathbf{PR})$ by Theorem 0.9.7 (3), and $\mathbf{PR}$ is invertible, $\mathbf{A}$ is similar to a matrix with zero diagonal. This completes the induction.

■

Remark. The characteristic was used only in Case 1, and only through $k \cdot 1 \neq 0$ for the sizes $k = 2, \ldots, n$ that the induction passes through. So the lemma holds, with the same

proof, whenever F has characteristic 0 or characteristic $p > n$. Some hypothesis on the characteristic is needed: for $n = p$, over $\mathbb{F}_p$, the matrix $\mathbf{I}_p$ has trace $p \cdot 1 = 0$, but it is scalar, so it is similar only to itself, and its diagonal entries are 1. The same happens for $\lambda \mathbf{I}_n$ with $\lambda \neq 0$ whenever p divides n.

7.5.4 Shoda's theorem

With a zero diagonal available, the diagonal choice of $\mathbf{X}$ in $(*)$ finishes the job. All we need are n distinct scalars for the diagonal of $\mathbf{X}$, and characteristic 0 provides them.

Theorem 7.5.4 — Shoda's Theorem

Let F be a field of **characteristic** 0, let $n \geq 1$, and let $\mathbf{A} \in M_n(F)$. Then $\mathbf{A}$ is a commutator, that is $\mathbf{A} = [\mathbf{X}, \mathbf{Y}]$ for some $\mathbf{X}, \mathbf{Y} \in M_n(F)$, if and only if $\operatorname{tr} \mathbf{A} = 0$.

Idea. One direction is Proposition 7.5.1 (c). For the other: ① by Lemma 7.5.3, $\mathbf{A} = \mathbf{PZP}^{-1}$ with $\mathbf{Z}$ of zero diagonal; ② take $\mathbf{X}_0 = \operatorname{diag}(0, 1, \ldots, n-1)$, whose entries are distinct in characteristic 0; ③ solve $[\mathbf{X}_0, \mathbf{Y}_0] = \mathbf{Z}$ entrywise with $(*)$, dividing by $x_i - x_j \neq 0$; ④ conjugate back with Proposition 7.5.1 (b).

Proof. ($\Rightarrow$) If $\mathbf{A} = [\mathbf{X}, \mathbf{Y}]$, then $\operatorname{tr} \mathbf{A} = 0$ by Proposition 7.5.1 (c).

($\Leftarrow$) Suppose $\operatorname{tr} \mathbf{A} = 0$. By Lemma 7.5.3 there is an invertible $\mathbf{P}$ such that $\mathbf{Z} = (z_{ij}) \coloneqq \mathbf{P}^{-1}\mathbf{AP}$ has $z_{ii} = 0$ for all i.

For $1 \leq i \leq n$ let $x_i \coloneqq (i-1) \cdot 1 \in F$, and $\mathbf{X}_0 \coloneqq \operatorname{diag}(x_1, \ldots, x_n)$. For $i < j$, Lemma 0.7.4 gives $x_j - x_i = (j - i) \cdot 1$, which is non-zero because $j - i \geq 1$ and F has characteristic 0 (Definition 0.7.2). So the x_i are distinct, and we may define $\mathbf{Y}_0 = (y_{ij}) \in M_n(F)$ by

$$y_{ij} \coloneqq \frac{z_{ij}}{x_i - x_j} \quad (i \neq j), \qquad y_{ii} \coloneqq 0.$$

By $(*)$, $[\mathbf{X}_0, \mathbf{Y}_0]_{ij} = (x_i - x_j) y_{ij} = z_{ij}$ for $i \neq j$, and $[\mathbf{X}_0, \mathbf{Y}_0]_{ii} = 0 = z_{ii}$. Hence $[\mathbf{X}_0, \mathbf{Y}_0] = \mathbf{Z}$.

Let $\mathbf{X} = \mathbf{PX}_0\mathbf{P}^{-1}$ and $\mathbf{Y} = \mathbf{PY}_0\mathbf{P}^{-1}$. Applying Proposition 7.5.1 (b) with the invertible matrix $\mathbf{P}^{-1}$,

$$[\mathbf{X}, \mathbf{Y}] = [\mathbf{PX}_0\mathbf{P}^{-1}, \mathbf{PY}_0\mathbf{P}^{-1}] = \mathbf{P}[\mathbf{X}_0, \mathbf{Y}_0]\mathbf{P}^{-1} = \mathbf{PZP}^{-1} = \mathbf{A}.$$

This proves that $\mathbf{A}$ is a commutator.

■

The proof used characteristic 0 twice: in the lemma, to rule out non-zero scalar blocks of trace zero, and here, to find n distinct diagonal entries. The second use needs only $(j - i) \cdot 1 \neq 0$ for $1 \leq j - i \leq n - 1$, and with the remark after Lemma 7.5.3, the same proof works whenever the characteristic of F is 0 or larger than n. Neither use is essential for the **theorem**. In fact the statement "a square matrix over a field is a commutator if and only if its trace is 0" is true over **every** field. The proof in positive characteristic needs a different normal form and more work, and we do not give it. Example (The Identity as a Commutator in Characteristic p) is a small

instance: $\mathbf{I}_p$ over $\mathbb{F}_p$ is a commutator, although Lemma 7.5.3 fails for it.

The proof is constructive, and it is worth running once in full.

Example. (Writing a Trace-Zero 3×3 Matrix as a Commutator)

Over $\mathbb{Q}$, write $\mathbf{A} = \begin{pmatrix} 1 & 2 & 0 \\ 0 & 1 & 1 \\ 1 & 0 & -2 \end{pmatrix}$ as a commutator $[\mathbf{X}, \mathbf{Y}]$.

Solution. The trace is $1 + 1 - 2 = 0$. We follow the proofs step by step.

First corner. $\mathbf{A}$ is not scalar. Take $\mathbf{v} = \mathbf{e}_1$; then $\mathbf{Av} = (1, 0, 1)$ is not a multiple of $\mathbf{e}_1$. Extend $(\mathbf{e}_1, \mathbf{Ae}_1)$ by $\mathbf{e}_2$, which is not in their span, to a basis, and let

$$\mathbf{P}_1 = \begin{pmatrix} 1 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix}, \qquad \mathbf{M} = \mathbf{P}_1^{-1}\mathbf{A}\mathbf{P}_1 = \begin{pmatrix} 0 & 2 & 2 \\ 1 & -1 & 0 \\ 0 & 1 & 1 \end{pmatrix}.$$

(To check $\mathbf{M}$ without inverting, verify $\mathbf{P}_1\mathbf{M} = \mathbf{A}\mathbf{P}_1$: both equal $\begin{pmatrix} 1 & 1 & 2 \\ 0 & 1 & 1 \\ 1 & -1 & 0 \end{pmatrix}$.) The first column is $\mathbf{e}_2$, and the lower block is $\mathbf{A}_1 = \begin{pmatrix} -1 & 0 \\ 1 & 1 \end{pmatrix}$, with trace 0.

Second corner. $\mathbf{A}_1$ is not scalar. With $\mathbf{w} = \mathbf{e}_1 \in \mathbb{Q}^2$, $\mathbf{A}_1\mathbf{w} = (-1, 1)$ is independent of $\mathbf{e}_1$, so

$$\mathbf{Q} = \begin{pmatrix} 1 & -1 \\ 0 & 1 \end{pmatrix}, \qquad \mathbf{Q}^{-1} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}, \qquad \mathbf{Z}_1 = \mathbf{Q}^{-1}\mathbf{A}_1\mathbf{Q} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}.$$

Assemble. With $\mathbf{r}^\top = (2, 2)$, the proof of Lemma 7.5.3 gives $\mathbf{r}^\top\mathbf{Q} = (2, 0)$ and $\mathbf{Q}^{-1}\mathbf{e}_1 = \mathbf{e}_1$, so for $\mathbf{P} = \mathbf{P}_1\big((1) \oplus \mathbf{Q}\big)$,

$$\mathbf{P} = \begin{pmatrix} 1 & 1 & -1 \\ 0 & 0 & 1 \\ 0 & 1 & -1 \end{pmatrix}, \qquad \mathbf{Z} = \mathbf{P}^{-1}\mathbf{A}\mathbf{P} = \begin{pmatrix} 0 & 2 & 0 \\ 1 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix}, \qquad \mathbf{P}^{-1} = \begin{pmatrix} 1 & 0 & -1 \\ 0 & 1 & 1 \\ 0 & 1 & 0 \end{pmatrix}.$$

Solve entrywise. With $\mathbf{X}_0 = \operatorname{diag}(0, 1, 2)$, the rule $y_{ij} = z_{ij}/(x_i - x_j)$ gives $y_{12} = \frac{2}{-1} = -2$, $y_{21} = \frac{1}{1} = 1$, $y_{23} = \frac{1}{-1} = -1$, $y_{32} = \frac{1}{1} = 1$, and $y_{13} = y_{31} = 0$:

$$\mathbf{Y}_0 = \begin{pmatrix} 0 & -2 & 0 \\ 1 & 0 & -1 \\ 0 & 1 & 0 \end{pmatrix}.$$

Conjugate back. $\mathbf{X} = \mathbf{P}\mathbf{X}_0\mathbf{P}^{-1}$ and $\mathbf{Y} = \mathbf{P}\mathbf{Y}_0\mathbf{P}^{-1}$ are

$$\mathbf{X} = \begin{pmatrix} 0 & -1 & 1 \\ 0 & 2 & 0 \\ 0 & -1 & 1 \end{pmatrix}, \qquad \mathbf{Y} = \begin{pmatrix} 1 & -4 & -4 \\ 0 & 1 & 1 \\ 1 & -2 & -2 \end{pmatrix}.$$

Check: $\mathbf{XY} = \begin{pmatrix} 1 & -3 & -3 \\ 0 & 2 & 2 \\ 1 & -3 & -3 \end{pmatrix}$ and $\mathbf{YX} = \begin{pmatrix} 0 & -5 & -3 \\ 0 & 1 & 1 \\ 0 & -3 & -1 \end{pmatrix}$, and $\mathbf{XY} - \mathbf{YX} = \mathbf{A}$.

Nothing about these $\mathbf{X}$ and $\mathbf{Y}$ is unique. Adding to $\mathbf{Y}$ any matrix that commutes with $\mathbf{X}$, for instance a polynomial in $\mathbf{X}$, gives another solution, by Proposition 7.5.1 (a).

7.5.5 The span of the commutators

Shoda's theorem is about single commutators. A weaker question, with an easier answer that holds over **every** field, is which matrices are **sums** of commutators. Since the trace-zero matrices form a subspace and contain all commutators, the span of the commutators lies inside it. Matrix units show that it is all of it.

Theorem 7.5.5 — Commutators Span the Trace-Zero Matrices

Let F be any field and $n \geq 1$. The span of all commutators $[\mathbf{X}, \mathbf{Y}]$ with $\mathbf{X}, \mathbf{Y} \in M_n(F)$ is the subspace $\{\mathbf{A} \in M_n(F) : \operatorname{tr} \mathbf{A} = 0\}$. More precisely, every trace-zero matrix is a linear combination of the commutators

$$\mathbf{E}_{ij} = [\mathbf{E}_{ii}, \mathbf{E}_{ij}] \ (i \neq j) \qquad \text{and} \qquad \mathbf{E}_{ii} - \mathbf{E}_{nn} = [\mathbf{E}_{in}, \mathbf{E}_{ni}] \ (1 \leq i \leq n-1).$$

Proof. Let $W = \{\mathbf{A} \in M_n(F) : \operatorname{tr} \mathbf{A} = 0\}$, a subspace by Example (Trace-Free Matrices). By Proposition 7.5.1 (c), every commutator lies in W, so their span is contained in W (Theorem 1.3.1, the span being the smallest subspace containing them).

For the reverse inclusion, the displayed identities hold by Example 2 after Definition 7.5.1: for $i \neq j$, $[\mathbf{E}_{ii}, \mathbf{E}_{ij}] = \mathbf{E}_{ij}$, and for $i < n$, $[\mathbf{E}_{in}, \mathbf{E}_{ni}] = \mathbf{E}_{ii} - \mathbf{E}_{nn}$. Now let $\mathbf{A} = (a_{ij}) \in W$. Writing $\mathbf{A}$ in the basis of matrix units (Example (Standard Bases)) and using $a_{nn} = -\sum_{i<n} a_{ii}$,

$$\mathbf{A} = \sum_{i \neq j} a_{ij}\mathbf{E}_{ij} + \sum_{i=1}^{n-1} a_{ii}\mathbf{E}_{ii} + a_{nn}\mathbf{E}_{nn} = \sum_{i \neq j} a_{ij}\mathbf{E}_{ij} + \sum_{i=1}^{n-1} a_{ii}\,(\mathbf{E}_{ii} - \mathbf{E}_{nn}).$$

So $\mathbf{A}$ is a linear combination of commutators, hence lies in their span. (For $n = 1$, $W = \{0\}$ and both sides are $\{0\}$.)

■

The theorem lists $n(n-1)+(n-1) = n^2-1$ commutators spanning the trace-zero matrices. Since $\operatorname{tr}\colon M_n(F) \to F$ is onto ($\operatorname{tr}(c\mathbf{E}_{11}) = c$), the Rank–Nullity Theorem (Theorem 3.3.1) gives that its kernel has dimension n^2-1, so by Theorem 1.6.4 (b) these commutators form a basis of it. Over a field of characteristic 0, Shoda's theorem says much more: the sum of commutators produced here can always be collapsed into a single commutator. In general the set of commutators is not obviously closed under addition, and that is exactly what makes Shoda's theorem a theorem.

Warning. **The span of a set is not the set.** Theorem 7.5.5 shows that every trace-zero matrix is a **sum** of commutators, over any field, by a two-line argument. It does not show that every trace-zero matrix **is** a commutator. For comparison, in $M_2(F)$ the

matrices of rank at most 1 span everything (the four matrix units have rank 1), yet $\mathbf{I}_2$ has rank 2: a set can span a subspace without filling it. For commutators it happens that the set does fill the subspace, but the proof needs the similarity argument of Lemma 7.5.3, not just matrix units.

The span theorem gives a clean proof of a fact from Chapter 3: a linear functional φ on $M_n(F)$ with $\varphi(\mathbf{AB}) = \varphi(\mathbf{BA})$ is a multiple of the trace. Such a φ kills every commutator, hence their span, which is the kernel of the trace; Exercise (C1: Trace-like functionals, again) below completes the argument.

7.5.6 Exercises

7.5.6.1 A. Check your understanding

Exercise A1.

(a) Define the commutator $[\mathbf{A}, \mathbf{B}]$, and state what it means for a matrix to be a commutator.

(b) State Shoda's theorem, including the hypothesis on the field.

(c) True or false: $[\mathbf{A}, \mathbf{B}] = [\mathbf{B}, \mathbf{A}]$ for all $\mathbf{A}, \mathbf{B} \in M_n(F)$. Justify your answer.

(d) True or false: over every field, every trace-zero matrix is similar to a matrix with zero diagonal. Justify your answer.

(e) Name the two places where the proof of Shoda's theorem uses characteristic 0.

(f) Explain why Theorem 7.5.5 does not by itself prove Shoda's theorem.

Solution.

(a) $[\mathbf{A}, \mathbf{B}] = \mathbf{AB} - \mathbf{BA}$ (Definition 7.5.1). A matrix $\mathbf{C} \in M_n(F)$ is a commutator if $\mathbf{C} = [\mathbf{X}, \mathbf{Y}]$ for some $\mathbf{X}, \mathbf{Y} \in M_n(F)$.

(b) If F has characteristic 0 and $\mathbf{A} \in M_n(F)$, then $\mathbf{A} = [\mathbf{X}, \mathbf{Y}]$ for some $\mathbf{X}, \mathbf{Y} \in M_n(F)$ if and only if $\operatorname{tr} \mathbf{A} = 0$ (Theorem 7.5.4).

(c) False. $[\mathbf{B}, \mathbf{A}] = -[\mathbf{A}, \mathbf{B}]$ (Proposition 7.5.1 (a)), so equality holds only when $[\mathbf{A}, \mathbf{B}] = 0$. For example $[\mathbf{E}_{12}, \mathbf{E}_{21}] = \operatorname{diag}(1, -1)$ and $[\mathbf{E}_{21}, \mathbf{E}_{12}] = \operatorname{diag}(-1, 1)$ over $\mathbb{Q}$.

(d) False. Over $\mathbb{F}_2$, $\mathbf{I}_2$ has trace $1 + 1 = 0$, but it is scalar, so every matrix similar to it equals $\mathbf{P}^{-1}\mathbf{I}_2\mathbf{P} = \mathbf{I}_2$, whose diagonal entries are 1.

(e) In Lemma 7.5.3, to conclude from $(n \cdot 1)\lambda = 0$ that a trace-zero scalar matrix $\lambda \mathbf{I}_n$ is 0; and in Theorem 7.5.4, to find n distinct scalars $x_i = (i-1) \cdot 1$ so that we can divide by $x_i - x_j$.

(f) It says every trace-zero matrix is a **linear combination** of commutators. Shoda's theorem says it is a **single** commutator. A sum of commutators need not visibly be a commutator, since $[\mathbf{X}, \mathbf{Y}] + [\mathbf{X}', \mathbf{Y}']$ has no evident expression as $[\mathbf{X}'', \mathbf{Y}'']$.

7.5.6.2 B. Practice

Exercise B1: A 2×2 commutator.

Over $\mathbb{Q}$, let $\mathbf{A} = \begin{pmatrix} 3 & -2 \\ 1 & -3 \end{pmatrix}$.

(a) Using $\mathbf{v} = \mathbf{e}_1$ as in Lemma 7.5.2, find an invertible $\mathbf{P}$ such that $\mathbf{Z} = \mathbf{P}^{-1}\mathbf{A}\mathbf{P}$ has zero diagonal.

(b) With $\mathbf{X}_0 = \operatorname{diag}(0, 1)$, find $\mathbf{Y}_0$ with $[\mathbf{X}_0, \mathbf{Y}_0] = \mathbf{Z}$.

(c) Hence write $\mathbf{A} = [\mathbf{X}, \mathbf{Y}]$, and check your answer by multiplying out.

Solution.

(a) $\operatorname{tr}\mathbf{A} = 0$, and $\mathbf{A}\mathbf{e}_1 = (3, 1)$ is not a multiple of $\mathbf{e}_1$, so $(\mathbf{e}_1, \mathbf{A}\mathbf{e}_1)$ is a basis of $\mathbb{Q}^2$. Let $\mathbf{P} = \begin{pmatrix} 1 & 3 \\ 0 & 1 \end{pmatrix}$, so $\mathbf{P}^{-1} = \begin{pmatrix} 1 & -3 \\ 0 & 1 \end{pmatrix}$. Then $\mathbf{A}\mathbf{P} = \begin{pmatrix} 3 & 7 \\ 1 & 0 \end{pmatrix}$ and

$$\mathbf{Z} = \mathbf{P}^{-1}\mathbf{A}\mathbf{P} = \begin{pmatrix} 0 & 7 \\ 1 & 0 \end{pmatrix}.$$

The first column is $\mathbf{e}_2$ by Lemma 7.5.2, and the $(2,2)$-entry is 0 because the trace is 0.

(b) By $(*)$, $[\mathbf{X}_0, \mathbf{Y}]_{12} = (0 - 1)y_{12}$ and $[\mathbf{X}_0, \mathbf{Y}]_{21} = (1 - 0)y_{21}$, while the diagonal of $[\mathbf{X}_0, \mathbf{Y}]$ is zero. So $y_{12} = -7$, $y_{21} = 1$, and we may take $y_{11} = y_{22} = 0$: $\mathbf{Y}_0 = \begin{pmatrix} 0 & -7 \\ 1 & 0 \end{pmatrix}$.

(c) By the proof of Theorem 7.5.4, $\mathbf{X} = \mathbf{P}\mathbf{X}_0\mathbf{P}^{-1}$ and $\mathbf{Y} = \mathbf{P}\mathbf{Y}_0\mathbf{P}^{-1}$:

$$\mathbf{X} = \begin{pmatrix} 0 & 3 \\ 0 & 1 \end{pmatrix}\begin{pmatrix} 1 & -3 \\ 0 & 1 \end{pmatrix} = \begin{pmatrix} 0 & 3 \\ 0 & 1 \end{pmatrix}, \qquad \mathbf{Y} = \begin{pmatrix} 3 & -7 \\ 1 & 0 \end{pmatrix}\begin{pmatrix} 1 & -3 \\ 0 & 1 \end{pmatrix} = \begin{pmatrix} 3 & -16 \\ 1 & -3 \end{pmatrix},$$

using $\mathbf{P}\mathbf{X}_0 = \begin{pmatrix} 0 & 3 \\ 0 & 1 \end{pmatrix}$ and $\mathbf{P}\mathbf{Y}_0 = \begin{pmatrix} 3 & -7 \\ 1 & 0 \end{pmatrix}$. *Check:* $\mathbf{X}\mathbf{Y} = \begin{pmatrix} 3 & -9 \\ 1 & -3 \end{pmatrix}$, $\mathbf{Y}\mathbf{X} = \begin{pmatrix} 0 & -7 \\ 0 & 0 \end{pmatrix}$, and $\mathbf{X}\mathbf{Y} - \mathbf{Y}\mathbf{X} = \begin{pmatrix} 3 & -2 \\ 1 & -3 \end{pmatrix} = \mathbf{A}$.

Exercise B2: A commutator over $\mathbb{F}_2$.

Work over $\mathbb{F}_2$, and let $\mathbf{A} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$.

(a) Show that $\operatorname{tr}\mathbf{A} = 0$ and that $\mathbf{A}$ is not scalar.

(b) Explain why $\mathbf{v} = \mathbf{e}_1$ cannot be used in Lemma 7.5.2, and use $\mathbf{v} = \mathbf{e}_2$ instead to find $\mathbf{P}$ with $\mathbf{P}^{-1}\mathbf{A}\mathbf{P}$ of zero diagonal.

(c) The field $\mathbb{F}_2$ has exactly two elements. Use them as the diagonal of $\mathbf{X}_0$ to write $\mathbf{A}$ as a commutator, by hand.

(d) Explain why the same method cannot write $\mathbf{I}_2 \in M_2(\mathbb{F}_2)$ as a commutator, and recall a pair $\mathbf{X}, \mathbf{Y}$ that does.

Solution.

(a) $\operatorname{tr}\mathbf{A} = 1 + 1 = 0$ in $\mathbb{F}_2$. $\mathbf{A}$ has a non-zero off-diagonal entry, while every scalar matrix has zero off-diagonal entries.

(b) $\mathbf{A}\mathbf{e}_1 = \mathbf{e}_1$, so $(\mathbf{e}_1, \mathbf{A}\mathbf{e}_1)$ is dependent. With $\mathbf{v} = \mathbf{e}_2$, $\mathbf{A}\mathbf{e}_2 = (1,1)$, which is not a multiple of $\mathbf{e}_2$, so $(\mathbf{e}_2, \mathbf{A}\mathbf{e}_2)$ is a basis. Let $\mathbf{P} = \begin{pmatrix} 0 & 1 \\ 1 & 1 \end{pmatrix}$; since $\det\mathbf{P} = -1 = 1$, $\mathbf{P}^{-1} = \begin{pmatrix} 1 & 1 \\ 1 & 0 \end{pmatrix}$ (check: $\mathbf{P}\mathbf{P}^{-1} = \begin{pmatrix} 1 & 0 \\ 2 & 1 \end{pmatrix} = \mathbf{I}_2$ in $\mathbb{F}_2$). Then $\mathbf{A}\mathbf{P} = \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix}$ and $\mathbf{Z} = \mathbf{P}^{-1}\mathbf{A}\mathbf{P} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$.

(c) Take $\mathbf{X}_0 = \operatorname{diag}(0,1)$. By $(*)$, $[\mathbf{X}_0, \mathbf{Y}]_{12} = (0-1)y_{12} = y_{12}$ (as $-1 = 1$) and $[\mathbf{X}_0, \mathbf{Y}]_{21} = y_{21}$. So $\mathbf{Y}_0 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$ gives $[\mathbf{X}_0, \mathbf{Y}_0] = \mathbf{Z}$. Conjugating back, $\mathbf{P}\mathbf{X}_0 = \begin{pmatrix} 0 & 1 \\ 0 & 1 \end{pmatrix}$ and $\mathbf{P}\mathbf{Y}_0 = \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix}$, so

$$\mathbf{X} = \mathbf{P}\mathbf{X}_0\mathbf{P}^{-1} = \begin{pmatrix} 1 & 0 \\ 1 & 0 \end{pmatrix}, \qquad \mathbf{Y} = \mathbf{P}\mathbf{Y}_0\mathbf{P}^{-1} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}.$$

Check: $\mathbf{X}\mathbf{Y} = \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix}$, $\mathbf{Y}\mathbf{X} = \begin{pmatrix} 2 & 0 \\ 1 & 0 \end{pmatrix} = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix}$, so $[\mathbf{X}, \mathbf{Y}] = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix} = \mathbf{A}$. (Here $\mathbf{Y} = \mathbf{A}$: indeed $[\mathbf{X}, \mathbf{A}] = \mathbf{A}$.)

(d) The method writes $\mathbf{Z} = \mathbf{P}^{-1}\mathbf{I}_2\mathbf{P}$ as $[\mathbf{X}_0, \mathbf{Y}_0]$ with $\mathbf{X}_0$ diagonal, and by $(*)$ such a commutator has zero diagonal. But $\mathbf{I}_2$ is scalar, so $\mathbf{P}^{-1}\mathbf{I}_2\mathbf{P} = \mathbf{I}_2$ for every invertible $\mathbf{P}$, and its diagonal entries are 1. So the method cannot start. Nevertheless $\mathbf{I}_2$ is a commutator: with $\mathbf{X} = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix}$ and $\mathbf{Y} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$, $[\mathbf{X}, \mathbf{Y}] = \operatorname{diag}(-1, 1) = \mathbf{I}_2$ in $\mathbb{F}_2$ (Exercise (C1: The Heisenberg relation) (d), or Example (The Identity as a Commutator in Characteristic p) with $p = 2$).

Exercise B3: Commuting with a diagonal matrix.

Let F be any field, let $d_1, \dots, d_n \in F$ be **distinct**, let $\mathbf{D} = \operatorname{diag}(d_1, \dots, d_n)$, and define $L\colon M_n(F) \to M_n(F)$ by $L(\mathbf{X}) = [\mathbf{D}, \mathbf{X}]$.

(a) Show that L is linear.

(b) Prove that $\ker L$ is the set of diagonal matrices and $\operatorname{im} L$ is the set of matrices with zero diagonal.

(c) Check that your answer to (b) agrees with the Rank–Nullity Theorem.

(d) Hence decide whether $\begin{pmatrix} 0 & 1 & 2 \\ 3 & 0 & 4 \\ 5 & 6 & 0 \end{pmatrix} \in M_3(\mathbb{Q})$ is a commutator with $\mathbf{X} = \operatorname{diag}(1,2,3)$, and if so find $\mathbf{Y}$.

Solution.

(a) By Proposition 7.5.1 (a), $[\mathbf{D}, \mathbf{X} + \mathbf{X}'] = [\mathbf{D}, \mathbf{X}] + [\mathbf{D}, \mathbf{X}']$ and $[\mathbf{D}, c\mathbf{X}] = c[\mathbf{D}, \mathbf{X}]$.

(b) By $(*)$, $L(\mathbf{X})_{ij} = (d_i - d_j)x_{ij}$. Since $d_i - d_j \neq 0$ for $i \neq j$, $L(\mathbf{X}) = 0$ if and only

if $x_{ij} = 0$ for all $i \neq j$, that is, $\mathbf{X}$ is diagonal. Every $L(\mathbf{X})$ has zero diagonal. Conversely, if $\mathbf{Z}$ has zero diagonal, the matrix $\mathbf{Y}$ with $y_{ij} = z_{ij}/(d_i - d_j)$ for $i \neq j$ and $y_{ii} = 0$ satisfies $L(\mathbf{Y}) = \mathbf{Z}$. So $\operatorname{im} L$ is exactly the set of zero-diagonal matrices.

(c) The diagonal matrices have basis $\mathbf{E}_{11}, \dots, \mathbf{E}_{nn}$, so nullity $L = n$. The zero-diagonal matrices have basis $\mathbf{E}_{ij}$ $(i \neq j)$, so $\operatorname{rank} L = n^2 - n$. Their sum is $n^2 = \dim M_n(F)$, as Theorem 3.3.1 requires.

(d) Yes, since the matrix has zero diagonal and $1, 2, 3$ are distinct. With $d = (1, 2, 3)$, $y_{ij} = z_{ij}/(d_i - d_j)$ gives

$$\mathbf{Y} = \begin{pmatrix} 0 & \frac{1}{-1} & \frac{2}{-2} \\ \frac{3}{1} & 0 & \frac{4}{-1} \\ \frac{5}{2} & \frac{6}{1} & 0 \end{pmatrix} = \begin{pmatrix} 0 & -1 & -1 \\ 3 & 0 & -4 \\ \frac{5}{2} & 6 & 0 \end{pmatrix},$$

and by (b), $[\operatorname{diag}(1, 2, 3), \mathbf{Y}]$ is the given matrix.

7.5.6.3 C. Going deeper

Exercise C1: Trace-like functionals, again.

Let F be any field, $n \geq 1$, and let $\varphi\colon M_n(F) \to F$ be linear with $\varphi(\mathbf{AB}) = \varphi(\mathbf{BA})$ for all $\mathbf{A}, \mathbf{B} \in M_n(F)$.

(a) Prove that φ vanishes on every trace-zero matrix.

(b) Deduce that $\varphi = c \operatorname{tr}$, where $c = \varphi(\mathbf{E}_{11})$.

(c) Suppose F has characteristic 0 and, in addition, $\varphi(\mathbf{I}_n) = n \cdot 1$. Deduce that $\varphi = \operatorname{tr}$.

(d) Show that the conclusion of (c) fails over $\mathbb{F}_p$ when $n = p$.

Hint: for (a), use Theorem 7.5.5.

Solution.

(a) For all $\mathbf{X}, \mathbf{Y}$, $\varphi([\mathbf{X}, \mathbf{Y}]) = \varphi(\mathbf{XY}) - \varphi(\mathbf{YX}) = 0$ by linearity and the hypothesis. So the kernel of φ, a subspace, contains every commutator, hence their span (Theorem 1.3.1), which is the set of trace-zero matrices by Theorem 7.5.5.

(b) Let $\mathbf{A} \in M_n(F)$. Since $\operatorname{tr} \mathbf{E}_{11} = 1$, the matrix $\mathbf{A} - (\operatorname{tr} \mathbf{A})\mathbf{E}_{11}$ has trace 0 (Theorem 0.9.6 (1)), so by (a) and linearity,

$$0 = \varphi\big(\mathbf{A} - (\operatorname{tr} \mathbf{A})\mathbf{E}_{11}\big) = \varphi(\mathbf{A}) - (\operatorname{tr} \mathbf{A})\, \varphi(\mathbf{E}_{11}).$$

Hence $\varphi(\mathbf{A}) = c \operatorname{tr} \mathbf{A}$ with $c = \varphi(\mathbf{E}_{11})$. This recovers Exercise (C2: The trace is the only trace-like functional) by a different route: the matrix-unit computations are now packaged in Theorem 7.5.5.

(c) By (b), $n \cdot 1 = \varphi(\mathbf{I}_n) = c \operatorname{tr} \mathbf{I}_n = c\,(n \cdot 1)$. Since F has characteristic 0, $n \cdot 1 \neq 0$, so $c = 1$ and $\varphi = \operatorname{tr}$.

(d) Over $\mathbb{F}_p$ with $n = p$, take $\varphi = 0$. It is linear, satisfies $\varphi(\mathbf{AB}) = 0 = \varphi(\mathbf{BA})$, and $\varphi(\mathbf{I}_p) = 0 = p \cdot 1$. But $\varphi \neq \operatorname{tr}$, since $\operatorname{tr} \mathbf{E}_{11} = 1$. The step that fails is canceling $n \cdot 1 = 0$ in (c).

Exercise C2: When A commutes with [A, B].

Let F be a field of characteristic 0, let $\mathbf{A}, \mathbf{B} \in M_n(F)$, put $\mathbf{C} = [\mathbf{A}, \mathbf{B}]$, and suppose that $\mathbf{AC} = \mathbf{CA}$. The goal is to prove that $\mathbf{C}$ is **nilpotent**, that is, $\mathbf{C}^s = 0$ for some $s \geq 1$.

(a) Prove that $\mathbf{C}^k = [\mathbf{A}, \mathbf{BC}^{k-1}]$ for every $k \geq 1$. Deduce that $\operatorname{tr} \mathbf{C}^k = 0$ for every $k \geq 1$.

(b) Show that there are an integer $s \geq 1$ and $g \in F[x]$ with $g(0) \neq 0$ such that $\mathbf{C}^s g(\mathbf{C}) = 0$.

(c) Let $U = \operatorname{col}(\mathbf{C}^s)$ and $r = \dim U$, and suppose $r \geq 1$. Extend a basis of U to a basis of F^n, and let $\mathbf{P}$ be the matrix with these columns. Show that

$$\mathbf{P}^{-1}\mathbf{C}\mathbf{P} = \begin{pmatrix} \mathbf{D} & * \\ 0 & \mathbf{N} \end{pmatrix}, \qquad \mathbf{D} \in M_r(F),$$

with $\mathbf{N}^s = 0$ and $g(\mathbf{D}) = 0$.

(d) Write $g = g_0 + xh$ with $g_0 = g(0) \neq 0$. Show that $\mathbf{I}_r$ is a linear combination of $\mathbf{D}^s, \mathbf{D}^{s+1}, \ldots, \mathbf{D}^d$ for some $d \geq s$, and use (a) to reach a contradiction.

(e) Conclude that $\mathbf{C}^s = 0$.

Hint: in (c), compare the columns of $\mathbf{P}^{-1}\mathbf{C}^k\mathbf{P}$ for $k = 1$ and $k = s$ with the coordinates of vectors of U; in (d), take traces.

Solution.

(a) First, $\mathbf{C}^{k-1}\mathbf{A} = \mathbf{AC}^{k-1}$ for all $k \geq 1$, by induction on k from $\mathbf{CA} = \mathbf{AC}$. Hence

$$\begin{aligned}[\mathbf{A}, \mathbf{BC}^{k-1}] &= \mathbf{ABC}^{k-1} - \mathbf{BC}^{k-1}\mathbf{A} = \mathbf{ABC}^{k-1} - \mathbf{BAC}^{k-1} \\ &= (\mathbf{AB} - \mathbf{BA})\mathbf{C}^{k-1} = \mathbf{C}^k.\end{aligned}$$

By Proposition 7.5.1 (c), $\operatorname{tr} \mathbf{C}^k = 0$.

(b) By Theorem 5.7.2 there is a non-zero $f \in F[x]$ with $f(\mathbf{C}) = 0$. Let $t \geq 0$ be the largest integer with x^t dividing f, and write $f = x^t g$; then $x \nmid g$, so $g(0) \neq 0$ by Theorem 5.1.3. Put $s = t + 1 \geq 1$. By Theorem 0.9.9, $\mathbf{C}^s g(\mathbf{C}) = \mathbf{C}\, f(\mathbf{C}) = 0$.

(c) Let $\mathbf{P}$ have columns $\mathbf{p}_1, \ldots, \mathbf{p}_n$, where $(\mathbf{p}_1, \ldots, \mathbf{p}_r)$ is a basis of U; $\mathbf{P}$ is invertible by Theorem 2.4.4. For any $k \geq 1$, column j of $\mathbf{P}^{-1}\mathbf{C}^k\mathbf{P}$ is $\mathbf{P}^{-1}(\mathbf{C}^k\mathbf{p}_j)$, the vector $\mathbf{c}$ with $\mathbf{Pc} = \mathbf{C}^k\mathbf{p}_j$, that is, the coefficients of $\mathbf{C}^k\mathbf{p}_j$ in terms of $\mathbf{p}_1, \ldots, \mathbf{p}_n$ (Theorem 0.9.3). If $\mathbf{y} \in U$, then $\mathbf{y} = \mathbf{C}^s\mathbf{z}$ and $\mathbf{Cy} = \mathbf{C}^s(\mathbf{Cz}) \in U$, so $\mathbf{C}$ maps U into U; hence for $j \leq r$ the vector $\mathbf{Cp}_j$ is a combination of $\mathbf{p}_1, \ldots, \mathbf{p}_r$, and column j of $\mathbf{P}^{-1}\mathbf{CP}$ has zeros below row r. This gives the block form. By Theorem 7.1.1 and induction on k, $(\mathbf{P}^{-1}\mathbf{CP})^k = \begin{pmatrix} \mathbf{D}^k & * \\ 0 & \mathbf{N}^k \end{pmatrix}$, and by Proposition 3.7.6 (c) this is $\mathbf{P}^{-1}\mathbf{C}^k\mathbf{P}$; more generally $\mathbf{P}^{-1}q(\mathbf{C})\mathbf{P} = \begin{pmatrix} q(\mathbf{D}) & * \\ 0 & q(\mathbf{N}) \end{pmatrix}$ for every $q \in F[x]$.

For $k = s$, every vector $\mathbf{C}^s\mathbf{p}_j$ lies in U, so every column of $\mathbf{P}^{-1}\mathbf{C}^s\mathbf{P}$ is zero below row r, and $\mathbf{N}^s = 0$. For $q = g$: for $j \leq r$, $\mathbf{p}_j \in U$ is $\mathbf{C}^s\mathbf{z}$ for some $\mathbf{z}$, so $g(\mathbf{C})\mathbf{p}_j = g(\mathbf{C})\mathbf{C}^s\mathbf{z} = \mathbf{0}$ by (b) and Theorem 0.9.9. So the first r columns of $\mathbf{P}^{-1}g(\mathbf{C})\mathbf{P}$ are zero, and in particular $g(\mathbf{D}) = 0$.

(d) From $g(\mathbf{D}) = g_0\mathbf{I}_r + \mathbf{D}h(\mathbf{D}) = 0$ we get $\mathbf{I}_r = \mathbf{D}\, h_1(\mathbf{D})$ with $h_1 = -g_0^{-1}h$. Since

polynomials in $\mathbf{D}$ commute (Theorem 0.9.9),

$$\mathbf{I}_r = \big(\mathbf{D}\, h_1(\mathbf{D})\big)^s = \mathbf{D}^s\, h_1(\mathbf{D})^s = \sum_{k=s}^{d} c_k \mathbf{D}^k$$

for some $c_k \in F$, as every term of $x^s h_1(x)^s$ has degree at least s. For $k \geq s$, $\mathbf{N}^k = \mathbf{N}^s \mathbf{N}^{k-s} = 0$, so by (c), Theorem 3.7.5 and Definition 0.9.12, $\operatorname{tr} \mathbf{C}^k = \operatorname{tr}(\mathbf{P}^{-1}\mathbf{C}^k\mathbf{P}) = \operatorname{tr} \mathbf{D}^k + \operatorname{tr} \mathbf{N}^k = \operatorname{tr} \mathbf{D}^k$. Taking traces,

$$r \cdot 1 = \operatorname{tr} \mathbf{I}_r = \sum_{k=s}^{d} c_k \operatorname{tr} \mathbf{D}^k = \sum_{k=s}^{d} c_k \operatorname{tr} \mathbf{C}^k = 0$$

by (a). But $r \geq 1$ and F has characteristic 0, so $r \cdot 1 \neq 0$, a contradiction.

(e) By (d), $r = 0$, so $\operatorname{col}(\mathbf{C}^s) = \{\mathbf{0}\}$ and $\mathbf{C}^s = 0$. For example, with $\mathbf{A} = \mathbf{E}_{12} + \mathbf{E}_{23}$ and $\mathbf{B} = \operatorname{diag}(0, 1, 2)$ in $M_3(\mathbb{Q})$, $\mathbf{C} = [\mathbf{A}, \mathbf{B}] = \mathbf{E}_{12} + \mathbf{E}_{23} = \mathbf{A}$, which commutes with $\mathbf{A}$, and indeed $\mathbf{C}^3 = 0$. In Chapter 8 the statement "$\operatorname{tr} \mathbf{C}^k = 0$ for all $k \geq 1$ forces nilpotency in characteristic 0" becomes a statement about eigenvalues.

Chapter 8

Eigenvalues and Diagonalization

Chapter 3 showed that one operator has many matrices, one for each basis, and asked how simple the matrix can be made. This chapter answers the first half of that question. The simplest possible matrix is diagonal, and a matrix of an operator is diagonal exactly when every basis vector is only stretched, never turned. Such vectors are **eigenvectors**, and the stretching factors are **eigenvalues**.

Not every operator has enough eigenvectors, and the chapter explains precisely when it does. Two polynomials carry the information: the characteristic polynomial from Chapter 6 and the **minimal polynomial**, the smallest polynomial that kills the operator. The Cayley–Hamilton Theorem ties them together. When eigenvectors run short, operators over $\mathbb{C}$ can still be made triangular, and the space splits into pieces on which the operator is easier to understand. The chapter ends with what diagonalization is for: powers of matrices, linear recurrences such as the Fibonacci numbers, and the long-run behavior of Markov chains.

What you need. From Chapter 3, the matrix of a linear map, change of basis and similarity (Definition 3.6.1, Theorem 3.7.3, Theorem 3.7.4), and quotient spaces (Definition 3.9.3). From Chapter 5, polynomials of an operator, the ideal of polynomials that kill it, and the kernel splitting lemma (Theorem 5.7.1, Theorem 5.7.3, Theorem 5.7.5), and the Fundamental Theorem of Algebra (Theorem 5.5.1). From Chapter 6, the characteristic polynomial and the adjugate (Definition 6.10.1, Theorem 6.6.2). From Chapter 7, block triangular matrices (Theorem 7.1.7).

8.0.1 Roadmap

- **Invariant subspaces.** Subspaces an operator maps into themselves, and the block triangular matrices they produce.
- **Eigenvalues and eigenvectors.** Directions that are only stretched; eigenvalues as roots of the characteristic polynomial; every complex operator has one.
- **Algebraic and geometric multiplicity.** Two ways to count a repeated eigenvalue, and why the second never exceeds the first.
- **Diagonalization.** Exactly when an operator has a basis of eigenvectors, and how to compute with one.
- **The minimal polynomial.** The monic polynomial of least degree that kills an operator, and why its roots are the eigenvalues.
- **The Cayley–Hamilton Theorem.** Every square matrix satisfies its own characteristic polynomial.

- **Triangularization.** An operator has a triangular matrix exactly when its characteristic polynomial splits.
- **Primary decomposition.** The factorization of the minimal polynomial splits the space, and decides diagonalizability.
- **Commuting operators.** Operators that commute share eigenvectors, and can be triangularized or diagonalized together.
- **Spectral mapping, AB and BA.** Eigenvalues of polynomials in an operator, and why **AB** and **BA** share their non-zero eigenvalues.
- **Powers, recurrences and Markov chains.** Diagonalization at work.

8.0.2 Named moves

- **Ask when the matrix is diagonal.** Unwinding the columns of a diagonal matrix gives the eigenvector equation $T\mathbf{v} = \lambda\mathbf{v}$.
- **Eigenvalue means a kernel.** λ is an eigenvalue exactly when $T - \lambda I$ is not injective.
- **Apply $T - \lambda I$ to a relation.** Kills one eigenvector and shortens a dependence, the heart of "distinct eigenvalues give independent eigenvectors".
- **Turn a relation into a divisibility.** If $p(T) = 0$, then the minimal polynomial divides p.
- **One eigenvector, extend, recurse.** Split off an eigenvector, pass to the quotient, and use induction on dimension.
- **Search inside an eigenspace.** A commuting operator maps each eigenspace into itself, so look for a common eigenvector there.

8.1 Invariant Subspaces

Chapter 3 raised a question it could not answer: given an operator T on a finite-dimensional space, how simple can its matrix $[T]_{\mathcal{B}}$ be made by choosing the basis $\mathcal{B}$ well? Chapter 7 found the first piece of an answer. A zero block in the lower-left corner of $[T]_{\mathcal{B}}$ appears exactly when the first few basis vectors span a subspace that T maps into itself. This section gives that property a name, collects the standard examples, and shows that it can fail badly: some operators map almost no subspace into itself. It ends by recording how such subspaces cut an operator, and its characteristic polynomial, into smaller pieces. The next section looks at the smallest non-zero case, a line, and finds eigenvectors there.

8.1.1 Subspaces an operator maps into itself

After a vector space we studied its subspaces, and after linear maps their kernels and images. For an operator $T \in \mathcal{L}(V)$, the domain and the codomain are the same space, so a new question makes sense: which subspaces of V are compatible with T?

Here is the result that makes the question worth asking. Let V be finite-dimensional, $T \in \mathcal{L}(V)$, and U a subspace with $\{\mathbf{0}\} \neq U \neq V$. Take a basis $(\mathbf{u}_1, \ldots, \mathbf{u}_k)$ of U and extend it to a basis $\mathcal{B} = (\mathbf{u}_1, \ldots, \mathbf{u}_k, \mathbf{w}_1, \ldots, \mathbf{w}_l)$ of V. By Theorem 7.1.7, the lower-left $l \times k$ block of $[T]_{\mathcal{B}}$ is zero **if and only if** $T\mathbf{u} \in U$ for every $\mathbf{u} \in U$. For example, the cyclic shift $T(x, y, z) = (y, z, x)$ on $\mathbb{R}^3$ keeps the plane $x + y + z = 0$ in place, and in Example (A Plane Mapped into Itself) this produced a matrix with a zero corner. The property "T maps U into U" is what we need to

control, so it gets a name.

A subspace is invariant under T when T never moves a vector of the subspace out of it.

Definition 8.1.1 — Invariant Subspace

Let V be a vector space over F and $T \in \mathcal{L}(V)$. A subspace U of V is **invariant under** T, or **T-invariant**, if

$$T\mathbf{u} \in U \qquad \text{for every } \mathbf{u} \in U,$$

that is, if $T(U) \subseteq U$.

In words: we start from a **subspace** U, not an arbitrary subset. We apply T to **every** vector of U, and each image must land back **in** U. Nothing is required of vectors outside U, and nothing says that a vector of U stays where it is: $T\mathbf{u}$ may be a different vector of U. The condition is an inclusion $T(U) \subseteq U$, not an equality.

Checking "for every $\mathbf{u} \in U$" looks like infinitely many checks. Linearity reduces it to finitely many when U has a finite spanning list.

Lemma 8.1.1 — Invariance Can Be Checked on a Spanning List

Let $T \in \mathcal{L}(V)$ and $U = \operatorname{span}(\mathbf{u}_1, \dots, \mathbf{u}_k)$. Then U is T-invariant if and only if $T\mathbf{u}_i \in U$ for each $i = 1, \dots, k$.

Proof. ($\Rightarrow$) Each $\mathbf{u}_i$ lies in U. ($\Leftarrow$) Let $\mathbf{u} = c_1\mathbf{u}_1 + \cdots + c_k\mathbf{u}_k \in U$. By Theorem 3.1.4, $T\mathbf{u} = c_1T\mathbf{u}_1 + \cdots + c_kT\mathbf{u}_k$, a linear combination of vectors of U, which lies in U because U is a subspace (Theorem 1.2.1). ∎

Examples.

- **The trivial subspaces.** For every $T \in \mathcal{L}(V)$, both $\{\mathbf{0}\}$ and V are T-invariant: $T\mathbf{0} = \mathbf{0}$ (Theorem 3.1.1), and $T\mathbf{v} \in V$ always. These are the degenerate cases, and they matter as a warning about what the word does **not** tell us: invariance carries information only for subspaces strictly between $\{\mathbf{0}\}$ and V. At the other extreme, for $T = c\,\mathrm{id}_V$ **every** subspace is invariant, since $c\mathbf{u} \in U$ whenever $\mathbf{u} \in U$.
- **Kernel and image.** $\ker T$ is invariant: if $\mathbf{u} \in \ker T$, then $T\mathbf{u} = \mathbf{0} \in \ker T$. So is $\operatorname{im} T$: if $\mathbf{w} \in \operatorname{im} T$, then $T\mathbf{w}$ is T of something, so $T\mathbf{w} \in \operatorname{im} T$. More generally, for every polynomial $p \in F[x]$, the subspaces $\ker p(T)$ and $\operatorname{im} p(T)$ are T-invariant, by Theorem 5.7.4 (b). For instance $\ker(T - c\,\mathrm{id}_V)$ is invariant for every scalar c.
- **A line in the plane.** Let $\mathbf{A} = \begin{pmatrix} 2 & 1 \\ 0 & 3 \end{pmatrix}$ act on $\mathbb{R}^2$. The line $\operatorname{span}(\mathbf{e}_1)$ is invariant, by Lemma 8.1.1, because $\mathbf{A}\mathbf{e}_1 = (2, 0) = 2\mathbf{e}_1 \in \operatorname{span}(\mathbf{e}_1)$. The line $\operatorname{span}((1, 1))$ is invariant as well, since $\mathbf{A}(1, 1) = (3, 3) = 3\,(1, 1)$.
- **Polynomials of bounded degree.** Let $D\colon F[x] \to F[x]$ be differentiation (Example (Differentiation)). For each $k \in \mathbb{N}$, the subspace $F[x]_{\le k}$ is D-invariant, because differentiating does not raise the degree. It is spanned by $1, x, \dots, x^k$, and $D(x^j) = jx^{j-1} \in F[x]_{\le k}$.

Non-example by minimal change. Keep $\mathbf{A} = \begin{pmatrix} 2 & 1 \\ 0 & 3 \end{pmatrix}$ and replace the line $\operatorname{span}(\mathbf{e}_1)$ by the line $\operatorname{span}(\mathbf{e}_2)$. It is still a subspace, and $\mathbf{A}\mathbf{e}_2 = (1, 3)$ is still some vector of $\mathbb{R}^2$. What fails is the clause "$T\mathbf{u} \in U$ for every $\mathbf{u} \in U$" at $\mathbf{u} = \mathbf{e}_2$: the vector $(1, 3)$ is not a multiple of $\mathbf{e}_2$. In the same way, $\operatorname{span}(x, x^2)$ inside $\mathbb{R}[x]_{\leq 3}$ is not D-invariant, because $D(x) = 1 \notin \operatorname{span}(x, x^2)$.

The examples with lines all have the same shape, which is worth recording now, because the whole next section grows out of it.

Proposition 8.1.2 — Invariant Lines

Let $T \in \mathcal{L}(V)$ and $\mathbf{v} \in V$ with $\mathbf{v} \neq \mathbf{0}$. Then $\operatorname{span}(\mathbf{v})$ is T-invariant if and only if $T\mathbf{v} = \lambda\mathbf{v}$ for some $\lambda \in F$.

Proof. By Lemma 8.1.1, $\operatorname{span}(\mathbf{v})$ is invariant if and only if $T\mathbf{v} \in \operatorname{span}(\mathbf{v})$, and $\operatorname{span}(\mathbf{v}) = \{\lambda\mathbf{v} : \lambda \in F\}$ by Definition 1.3.2.

■

So an invariant line is a line on which T acts by stretching with a single factor λ. Does every operator have one? Not over $\mathbb{R}$.

Example. (A Rotation Has No Invariant Lines)

Let $R\colon \mathbb{R}^2 \to \mathbb{R}^2$, $R(x, y) = (-y, x)$, be the rotation by a right angle. Find all R-invariant subspaces of $\mathbb{R}^2$.

Solution. A subspace U of $\mathbb{R}^2$ has $\dim U \in \{0, 1, 2\}$ by Theorem 1.6.7. If $\dim U = 0$, then $U = \{\mathbf{0}\}$; if $\dim U = 2$, then $U = \mathbb{R}^2$ by Theorem 1.6.8. Both are invariant.

Suppose $\dim U = 1$. A basis of U is a single vector $\mathbf{v} = (a, b) \neq \mathbf{0}$, and $U = \operatorname{span}(\mathbf{v})$. If U were invariant, then by Proposition 8.1.2 there would be $\lambda \in \mathbb{R}$ with $R\mathbf{v} = \lambda\mathbf{v}$, that is,

$$-b = \lambda a, \qquad a = \lambda b.$$

Substituting the first equation into the second gives $a = \lambda b = \lambda(-\lambda a) = -\lambda^2 a$, so $(1 + \lambda^2)a = 0$. Since λ is real, $1 + \lambda^2 \geq 1 > 0$, so $a = 0$. Then $b = -\lambda a = 0$ by the first equation, and $\mathbf{v} = \mathbf{0}$, a contradiction.

Hence the only R-invariant subspaces of $\mathbb{R}^2$ are $\{\mathbf{0}\}$ and $\mathbb{R}^2$. Geometrically, a quarter-turn moves every line through the origin onto the perpendicular line.

The same computation over $\mathbb{C}$ does not end in a contradiction: $1 + \lambda^2 = 0$ has the solutions $\lambda = \pm i$, and we will see in the next section that $\mathbb{C}^2$ does contain R-invariant lines. Whether invariant lines exist depends on the field.

Why this definition. Two variations suggest themselves, and both are worse.

- *Demand* $T(U) = U$. Then $\ker T$ would fail whenever T is not injective, since then $T(\ker T) = \{\mathbf{0}\} \neq \ker T$. But the kernel is exactly the kind of subspace that produces a zero block, and Theorem 7.1.7 needs only the inclusion.
- *Demand* $T\mathbf{u} = \mathbf{u}$ *for every* $\mathbf{u} \in U$. That says T acts as the identity on U, a far stronger

condition. The line $\operatorname{span}((1,1))$ above is invariant under $\mathbf{A}$, but $\mathbf{A}$ triples its vectors.

The name records that the subspace, as a whole, is unchanged in the sense that it is carried into itself; its individual vectors may move.

Warning. **Invariant does not mean fixed.** The vectors of a T-invariant subspace may move, as long as they stay inside it. For the swap $T(x,y)=(y,x)$ on $\mathbb{R}^2$, the whole plane is invariant, yet $T(1,0)=(0,1)\neq(1,0)$. Conversely, containing a fixed vector does not make a subspace invariant. For $T(x,y,z)=(x,z,y+z)$ on $\mathbb{R}^3$, the plane $z=0$ contains $\mathbf{e}_1$, and $T\mathbf{e}_1=\mathbf{e}_1$; but it also contains $\mathbf{e}_2$, and $T\mathbf{e}_2=\mathbf{e}_3$ leaves the plane.

Quick check. Let $T(x,y)=(x+y,y)$ on $\mathbb{R}^2$. Is the x-axis T-invariant? Is the y-axis?

Solution. By Lemma 8.1.1 it suffices to test one spanning vector. $T\mathbf{e}_1=(1,0)=\mathbf{e}_1$, which lies on the x-axis, so the x-axis is invariant. $T\mathbf{e}_2=(1,1)$, which is not a multiple of $\mathbf{e}_2$, so the y-axis is **not** invariant.

8.1.2 Restriction and the induced operator

An invariant subspace U lets us split T into two smaller operators. One lives on U: since T sends U into U, we may simply forget the rest of V. The other lives on the quotient V/U, which records what U cannot see. Chapter 7 met both in the proof of Theorem 7.1.7, and Chapter 3 constructed the second in Exercise (C2: The operator induced on a quotient). We now give them names.

Definition 8.1.2 — Restriction and Induced Operator

Let $T\in\mathcal{L}(V)$ and let U be a T-invariant subspace of V.

(a) The **restriction** of T to U is the operator $T|_U\colon U\to U$, $\mathbf{u}\mapsto T\mathbf{u}$.

(b) The **induced operator** (or quotient operator) on V/U is $\bar{T}\colon V/U\to V/U$, $\mathbf{v}+U\mapsto T\mathbf{v}+U$.

Well-definedness. For (a), the rule makes sense as a map **into** U only because U is invariant; it is linear because T is, and U carries the operations of V. For (b), the rule is phrased in terms of a representative $\mathbf{v}$ of the coset, so we must check that it does not depend on that choice. Suppose $\mathbf{v}+U=\mathbf{v}'+U$. Then $\mathbf{v}-\mathbf{v}'\in U$ (Lemma 3.9.3), so $T\mathbf{v}-T\mathbf{v}'=T(\mathbf{v}-\mathbf{v}')\in U$ by invariance, and hence $T\mathbf{v}+U=T\mathbf{v}'+U$. Linearity follows from the coset operations (Theorem 3.9.4): for instance $\bar{T}\big((\mathbf{v}+U)+(\mathbf{w}+U)\big)=\bar{T}(\mathbf{v}+\mathbf{w}+U)=T\mathbf{v}+T\mathbf{w}+U=\bar{T}(\mathbf{v}+U)+\bar{T}(\mathbf{w}+U)$, and scalars work the same way. Invariance was used exactly once in each part, which is where the hypothesis earns its place.

Examples.

- **Differentiation.** Let D act on $V=\mathbb{R}[x]_{\le 2}$ and $U=\mathbb{R}[x]_{\le 1}$, which is D-invariant. The restriction $D|_U$ is differentiation on $\mathbb{R}[x]_{\le 1}$. The quotient V/U has dimension 1 (Theorem 3.9.5), with basis x^2+U, and $\bar{D}(x^2+U)=2x+U=\mathbf{0}+U$, because $2x\in U$. So $\bar{D}=0$.
- **The cyclic shift.** For $T(x,y,z)=(y,z,x)$ and the plane U where $x+y+z=0$, Example (A Plane Mapped into Itself) showed that $\bar{T}$ is the identity of the line $\mathbb{R}^3/U$: the shift

permutes coordinates and so never changes their sum.

- **Degenerate cases.** For $U = V$, the restriction is T itself and V/V is the zero space. For $U = \{\mathbf{0}\}$, the restriction is the operator on the zero space, and $\bar{T}$ is T in disguise, since $\mathbf{v} + \{\mathbf{0}\}$ is just $\mathbf{v}$.

With these names, the matrix theorem of Chapter 7 reads as follows. We add the consequence for determinants and characteristic polynomials, which is what the rest of this chapter uses.

Theorem 8.1.3 — Invariant Subspaces and Block Triangular Matrices

Let V be finite-dimensional, $T \in \mathcal{L}(V)$, and U a subspace with $\{\mathbf{0}\} \neq U \neq V$. Let $\mathcal{B}_U = (\mathbf{u}_1, \dots, \mathbf{u}_k)$ be a basis of U, extended to a basis $\mathcal{B} = (\mathbf{u}_1, \dots, \mathbf{u}_k, \mathbf{w}_1, \dots, \mathbf{w}_l)$ of V, and put $\bar{\mathcal{B}} = (\mathbf{w}_1 + U, \dots, \mathbf{w}_l + U)$.

(a) U is T-invariant if and only if $[T]_{\mathcal{B}}$ has zero lower-left $l \times k$ block.

(b) In that case

$$[T]_{\mathcal{B}} = \begin{pmatrix} [T|_U]_{\mathcal{B}_U} & \mathbf{B} \\ 0 & [\bar{T}]_{\bar{\mathcal{B}}} \end{pmatrix}$$

for some $\mathbf{B} \in M_{k \times l}(F)$, and

$$\det T = \det(T|_U)\, \det \bar{T}, \qquad p_T = p_{T|_U}\, p_{\bar{T}}.$$

Proof. Part (a), and the block form in (b), are Theorem 7.1.7 in the language of Definition 8.1.1 and Definition 8.1.2; $\bar{\mathcal{B}}$ is a basis of V/U by Theorem 3.9.5.

Write $\mathbf{A} = [T|_U]_{\mathcal{B}_U} \in M_k(F)$ and $\mathbf{D} = [\bar{T}]_{\bar{\mathcal{B}}} \in M_l(F)$. By Definition 6.5.1 and Theorem 6.8.4, $\det T = \det [T]_{\mathcal{B}} = \det \mathbf{A} \det \mathbf{D} = \det(T|_U) \det \bar{T}$. For the characteristic polynomials,

$$x\mathbf{I}_{k+l} - [T]_{\mathcal{B}} = \begin{pmatrix} x\mathbf{I}_k - \mathbf{A} & -\mathbf{B} \\ 0 & x\mathbf{I}_l - \mathbf{D} \end{pmatrix}$$

is block upper triangular with square diagonal blocks, as a matrix over $F[x]$. The block triangular determinant holds over the commutative ring $F[x]$ (the remark after Theorem 6.8.4), so $\det(x\mathbf{I} - [T]_{\mathcal{B}}) = \det(x\mathbf{I}_k - \mathbf{A}) \det(x\mathbf{I}_l - \mathbf{D})$. By Definition 6.10.2, this says $p_T = p_{T|_U}\, p_{\bar{T}}$.

■

The theorem is the reason invariant subspaces matter. It splits the study of T into the study of two operators on smaller spaces, and every quantity that sees only the diagonal blocks splits with it. For differentiation on $\mathbb{R}[x]_{\le 2}$, in the basis $(1, x, x^2)$,

$$[D]_{\mathcal{B}} = \left(\begin{array}{cc|c} 0 & 1 & 0 \\ 0 & 0 & 2 \\ \hline 0 & 0 & 0 \end{array}\right),$$

with upper-left block $[D|_U] = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$, lower-right block $[\bar{D}] = (0)$, and $p_D = x^3 = x^2 \cdot x$. Section 7 of this chapter will run this splitting repeatedly, by induction on the dimension.

8.1.3 Sums, intersections and direct sums

Invariant subspaces can be combined. Sums and intersections of invariant subspaces are invariant, in contrast to many other properties, and the proof is one line each.

Proposition 8.1.4 — Sums and Intersections of Invariant Subspaces

Let $T \in \mathcal{L}(V)$ and let $U_1, \dots, U_k$ be T-invariant subspaces of V. Then $U_1 + \cdots + U_k$ and $U_1 \cap \cdots \cap U_k$ are T-invariant.

Proof. Both are subspaces, by Theorem 1.7.1 and Theorem 1.2.2. Let $\mathbf{u} = \mathbf{u}_1 + \cdots + \mathbf{u}_k$ with $\mathbf{u}_i \in U_i$. Then $T\mathbf{u} = T\mathbf{u}_1 + \cdots + T\mathbf{u}_k$ with $T\mathbf{u}_i \in U_i$ by invariance, so $T\mathbf{u} \in U_1 + \cdots + U_k$. If $\mathbf{u} \in U_1 \cap \cdots \cap U_k$, then $T\mathbf{u} \in U_i$ for each i, by invariance of each U_i, so $T\mathbf{u} \in U_1 \cap \cdots \cap U_k$.

■

When V is a **direct** sum of invariant subspaces, all the off-diagonal blocks vanish, not just one corner. Chapter 7 proved this for two summands (Theorem 7.1.6). The diagonalization theorem of Section 4 needs any number of summands.

Theorem 8.1.5 — Invariant Direct Sums and Block Diagonal Matrices

Let V be finite-dimensional with $V = U_1 \oplus \cdots \oplus U_k$, where each $U_i \neq \{\mathbf{0}\}$ has a basis $\mathcal{B}_i$ of length n_i. Let $\mathcal{B}$ be the list $\mathcal{B}_1, \dots, \mathcal{B}_k$ written one after another, and $T \in \mathcal{L}(V)$. Then $\mathcal{B}$ is a basis of V, and the following are equivalent:

(a) each U_i is T-invariant;

(b) $[T]_{\mathcal{B}}$ is block diagonal with respect to the partition $n_1, \dots, n_k$.

In that case

$$[T]_{\mathcal{B}} = [T|_{U_1}]_{\mathcal{B}_1} \oplus \cdots \oplus [T|_{U_k}]_{\mathcal{B}_k}, \qquad p_T = p_{T|_{U_1}} \cdots p_{T|_{U_k}}.$$

Idea. Read the matrix one block of columns at a time. The columns of block j are the coordinates of $T\mathbf{b}$ for the vectors $\mathbf{b}$ of $\mathcal{B}_j$. Such a $T\mathbf{b}$ lies in U_j exactly when all its coordinates outside block j vanish, because a vector of U_j is already a combination of $\mathcal{B}_j$, and coordinates are unique.

Proof. By Theorem 1.7.5 ((a) ⇒ (d)), $\mathcal{B}$ is a basis of V. Fix j and a vector $\mathbf{b}$ of $\mathcal{B}_j$; the column of $[T]_{\mathcal{B}}$ belonging to $\mathbf{b}$ is $[T\mathbf{b}]_{\mathcal{B}}$ (Definition 3.6.1). We claim: $T\mathbf{b} \in U_j$ if and only if the entries of this column outside the rows of block j are all 0. If $T\mathbf{b} \in U_j = \operatorname{span}(\mathcal{B}_j)$, then $T\mathbf{b}$ is a combination of $\mathcal{B}_j$ alone, which is a representation in the basis $\mathcal{B}$ with zero coefficients outside block j; by Theorem 1.5.1, it is **the** coordinate vector. Conversely, if those entries vanish, then $T\mathbf{b}$ is a combination of $\mathcal{B}_j$, so it lies in U_j.

(a) ⇒ (b). If U_j is invariant, then $T\mathbf{b} \in U_j$ for each $\mathbf{b}$ in $\mathcal{B}_j$, so by the claim every

block (i,j) with $i \neq j$ is zero. As j was arbitrary, $[T]_{\mathcal{B}}$ is block diagonal. Moreover the entries of column $\mathbf{b}$ in the rows of block j are the coordinates of $T\mathbf{b} = T|_{U_j}\mathbf{b}$ in $\mathcal{B}_j$, so the (j,j) block is $[T|_{U_j}]_{\mathcal{B}_j}$.

(b) $\Rightarrow$ (a). If the blocks (i,j) with $i \neq j$ vanish, the claim gives $T\mathbf{b} \in U_j$ for every $\mathbf{b}$ in $\mathcal{B}_j$, and U_j is invariant by Lemma 8.1.1.

Finally, $x\mathbf{I} - [T]_{\mathcal{B}}$ is block diagonal with diagonal blocks $x\mathbf{I}_{n_j} - [T|_{U_j}]_{\mathcal{B}_j}$. Its determinant over $F[x]$ is the product of the determinants of these blocks (the remark after Theorem 6.8.4, applied by induction on the number of blocks), which is $p_T = \prod_j p_{T|_{U_j}}$ by Definition 6.10.2.

■

So an operator that preserves each piece of a direct sum decomposition is, in a suitable basis, a list of independent smaller operators. The best possible case is a decomposition into invariant **lines**: then every block is 1×1, and $[T]_{\mathcal{B}}$ is diagonal. By Proposition 8.1.2, that happens exactly when V has a basis of vectors $\mathbf{v}$ with $T\mathbf{v} = \lambda\mathbf{v}$. This observation is the starting point of the next section.

A tempting shortcut is to assume that once one invariant subspace is found, a complement of it can be chosen invariant too, and the matrix becomes block diagonal. This fails.

Warning. **The complement of an invariant subspace need not be invariant.** Let $\mathbf{N} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$ act on F^2. The line $U = \operatorname{span}(\mathbf{e}_1)$ is invariant, since $\mathbf{N}\mathbf{e}_1 = \mathbf{0}$. Every complement of U is a line $W = \operatorname{span}((a,1))$ for some $a \in F$ (a line not equal to U contains a vector with second entry 1). But $\mathbf{N}(a,1) = (1,0)$, which is not a multiple of $(a,1)$. So **no** complement of U is $\mathbf{N}$-invariant, and no basis makes $[\mathbf{N}]$ block diagonal with two 1×1 blocks.

Quick check. Let U_1, U_2 be T-invariant. Must the union $U_1 \cup U_2$ be T-invariant? Must it even be a subspace?

Solution. The question has a trap: "invariant subspace" requires a subspace, and a union of two subspaces is usually not one (Proposition 1.2.3). For $T = \mathrm{id}_{\mathbb{R}^2}$, the two axes are invariant, but their union is not a subspace, so the word does not apply. The subspace that plays the role of the union is the sum $U_1 + U_2$, which is invariant by Proposition 8.1.4.

8.1.4 Exercises

8.1.4.1 A. Check your understanding

Exercise A1.

(a) Define what it means for a subspace U of V to be invariant under $T \in \mathcal{L}(V)$.

(b) True or false: for every $T \in \mathcal{L}(V)$, the subspaces $\ker T$ and $\operatorname{im} T$ are T-invariant. Justify your answer.

(c) True or false: if U is T-invariant, then $T\mathbf{u} = \mathbf{u}$ for every $\mathbf{u} \in U$. Justify your

answer.

(d) True or false: if U is invariant under S and under T, then U is invariant under $S+T$ and under ST. Justify your answer.

(e) For $\mathbf{v} \neq \mathbf{0}$, what condition on $T\mathbf{v}$ makes $\operatorname{span}(\mathbf{v})$ invariant?

(f) In a basis whose first k vectors form a basis of a T-invariant subspace U, which block of $[T]_{\mathcal{B}}$ is zero, and what are the two diagonal blocks?

Solution.

(a) U is T-invariant if $T\mathbf{u} \in U$ for every $\mathbf{u} \in U$ (Definition 8.1.1).

(b) True. If $\mathbf{u} \in \ker T$, then $T\mathbf{u} = \mathbf{0} \in \ker T$. If $\mathbf{w} \in \operatorname{im} T$, then $T\mathbf{w} \in \operatorname{im} T$ by definition of the image.

(c) False. For $T = 2\,\mathrm{id}_{\mathbb{R}^2}$, the subspace $\mathbb{R}^2$ is invariant, but $T\mathbf{e}_1 = 2\mathbf{e}_1 \neq \mathbf{e}_1$.

(d) True. For $\mathbf{u} \in U$, both $S\mathbf{u}$ and $T\mathbf{u}$ lie in U, so $(S+T)\mathbf{u} = S\mathbf{u} + T\mathbf{u} \in U$ since U is a subspace. Also $T\mathbf{u} \in U$, so $(ST)\mathbf{u} = S(T\mathbf{u}) \in U$ by invariance under S.

(e) $T\mathbf{v} = \lambda\mathbf{v}$ for some scalar λ (Proposition 8.1.2).

(f) The lower-left block is zero. The upper-left block is $[T|_U]_{\mathcal{B}_U}$ and the lower-right block is the matrix of the induced operator $\bar{T}$ on V/U (Theorem 8.1.3).

8.1.4.2 B. Practice

Exercise B1: All invariant subspaces of a diagonal matrix.

Let $\mathbf{A} = \operatorname{diag}(1, 2)$ act on $\mathbb{R}^2$. Find all $\mathbf{A}$-invariant subspaces of $\mathbb{R}^2$.

Solution. As in Example (A Rotation Has No Invariant Lines), a subspace of $\mathbb{R}^2$ is $\{\mathbf{0}\}$, $\mathbb{R}^2$, or a line $\operatorname{span}(\mathbf{v})$ with $\mathbf{v} = (a, b) \neq \mathbf{0}$. The first two are invariant. By Proposition 8.1.2, the line is invariant if and only if $\mathbf{A}\mathbf{v} = \lambda\mathbf{v}$ for some $\lambda \in \mathbb{R}$, that is,

$$a = \lambda a, \qquad 2b = \lambda b.$$

If $a \neq 0$, the first equation gives $\lambda = 1$, and then $2b = b$ gives $b = 0$; so $\mathbf{v}$ is a multiple of $\mathbf{e}_1$. If $a = 0$, then $b \neq 0$, the second equation gives $\lambda = 2$, and $\mathbf{v}$ is a multiple of $\mathbf{e}_2$. Conversely $\mathbf{A}\mathbf{e}_1 = \mathbf{e}_1$ and $\mathbf{A}\mathbf{e}_2 = 2\mathbf{e}_2$. Hence the invariant subspaces are exactly

$$\{\mathbf{0}\}, \qquad \operatorname{span}(\mathbf{e}_1), \qquad \operatorname{span}(\mathbf{e}_2), \qquad \mathbb{R}^2.$$

Compare with the identity $\mathbf{I}_2$, for which every line is invariant: changing one diagonal entry from 1 to 2 destroys all lines except the two axes.

Exercise B2: Kernels of $T - c\,\mathrm{id}$.

Let $T \in \mathcal{L}(V)$ and $c \in F$.

(a) Prove directly from the definition that $\ker(T - c\,\mathrm{id}_V)$ is T-invariant.

(b) Hence show that **every** subspace of $\ker(T - c\,\mathrm{id}_V)$ is T-invariant.

Solution.

(a) Let $K = \ker(T - c\,\mathrm{id}_V)$, a subspace by Theorem 3.2.1. For $\mathbf{u} \in K$ we have $T\mathbf{u} - c\mathbf{u} = \mathbf{0}$, that is, $T\mathbf{u} = c\mathbf{u}$. Since K is a subspace, $c\mathbf{u} \in K$. Hence $T\mathbf{u} \in K$, and K is T-invariant.

(b) Let W be a subspace of K and $\mathbf{w} \in W$. Since $\mathbf{w} \in K$, part (a) gives $T\mathbf{w} = c\mathbf{w}$, and $c\mathbf{w} \in W$ because W is a subspace. Hence W is T-invariant. (On K, T acts as c id, and for a scalar operator every subspace is invariant.)

Exercise B3: Invariance under differentiation.

Let D be differentiation on $V = \mathbb{R}[x]_{\le 3}$. Determine which of the following subspaces are D-invariant. Justify your answer.

(a) $U_1 = \mathrm{span}(1, x)$.

(b) $U_2 = \mathrm{span}(x, x^2)$.

(c) $U_3 = \{p \in V : p(0) = 0\}$.

(d) $U_4 = \mathrm{span}(x^2 + 2x,\ 2x + 2,\ 2)$.

(e) $U_5 = \mathrm{span}(1, x^2)$, the even polynomials in V.

Solution. We use Lemma 8.1.1 throughout.

(a) Invariant: $D(1) = 0 \in U_1$ and $D(x) = 1 \in U_1$.

(b) Not invariant: $D(x) = 1$, and $1 \notin \mathrm{span}(x, x^2)$ since every element of U_2 has constant term 0.

(c) Not invariant: $x \in U_3$, but $D(x) = 1$ and 1 evaluated at 0 is $1 \neq 0$.

(d) Invariant: $D(x^2 + 2x) = 2x + 2$, $D(2x + 2) = 2$ and $D(2) = 0$, all in U_4. (In fact $U_4 = \mathbb{R}[x]_{\le 2}$, since the three spanning polynomials have degrees $2, 1, 0$ and so are independent by Theorem 1.4.4.)

(e) Not invariant: $D(x^2) = 2x$, which is odd and non-zero, so it is not in $\mathrm{span}(1, x^2)$.

8.1.4.3 C. Going deeper

Exercise C1: A chain of invariant subspaces.

Let F be any field and

$$\mathbf{N} = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{pmatrix} \in M_3(F),$$

acting on F^3, so $\mathbf{N}\mathbf{e}_1 = \mathbf{0}$, $\mathbf{N}\mathbf{e}_2 = \mathbf{e}_1$, $\mathbf{N}\mathbf{e}_3 = \mathbf{e}_2$. Put $W_0 = \{\mathbf{0}\}$, $W_1 = \mathrm{span}(\mathbf{e}_1)$, $W_2 = \mathrm{span}(\mathbf{e}_1, \mathbf{e}_2)$, $W_3 = F^3$.

(a) Show that each W_j is $\mathbf{N}$-invariant.

(b) Let U be an $\mathbf{N}$-invariant subspace, and let j be the largest index such that some vector of U has a non-zero j-th entry (put $j = 0$ if $U = \{\mathbf{0}\}$). Prove that $U = W_j$.

(c) Deduce that the $\mathbf{N}$-invariant subspaces are exactly $W_0 \subset W_1 \subset W_2 \subset W_3$, and that any two of them are comparable under inclusion.

Hint: for (b), apply $\mathbf{N}$ *and* $\mathbf{N}^2$ *to a vector with non-zero* j*-th entry.*

Solution.

(a) W_0 and W_3 are invariant for every operator. By Lemma 8.1.1, W_1 is invariant since $\mathbf{N}\mathbf{e}_1 = \mathbf{0}$, and W_2 is invariant since $\mathbf{N}\mathbf{e}_1 = \mathbf{0}$ and $\mathbf{N}\mathbf{e}_2 = \mathbf{e}_1$ lie in W_2.

(b) If $U = \{\mathbf{0}\}$, then $j = 0$ and $U = W_0$. Otherwise $j \geq 1$. By the choice of j, every vector of U has entries 0 beyond position j, so $U \subseteq W_j$. Pick $\mathbf{v} = (a, b, c) \in U$ with non-zero j-th entry. We have $\mathbf{N}\mathbf{v} = (b, c, 0)$ and $\mathbf{N}^2\mathbf{v} = (c, 0, 0)$, and all of these lie in U by invariance.
Case $j = 3$. Here $c \neq 0$. Then $\mathbf{e}_1 = c^{-1}\mathbf{N}^2\mathbf{v} \in U$, $\mathbf{e}_2 = c^{-1}(\mathbf{N}\mathbf{v} - b\mathbf{e}_1) \in U$ and $\mathbf{e}_3 = c^{-1}(\mathbf{v} - a\mathbf{e}_1 - b\mathbf{e}_2) \in U$. So $W_3 \subseteq U$.
Case $j = 2$. Here $c = 0$ and $b \neq 0$. Then $\mathbf{e}_1 = b^{-1}\mathbf{N}\mathbf{v} \in U$ and $\mathbf{e}_2 = b^{-1}(\mathbf{v} - a\mathbf{e}_1) \in U$, so $W_2 \subseteq U$.
Case $j = 1$. Here $b = c = 0$ and $a \neq 0$, so $\mathbf{e}_1 = a^{-1}\mathbf{v} \in U$ and $W_1 \subseteq U$.
In each case $W_j \subseteq U \subseteq W_j$, so $U = W_j$.

(c) By (a) each W_j is invariant, and by (b) every invariant subspace is one of them. Since $W_0 \subset W_1 \subset W_2 \subset W_3$, any two are comparable. In particular $\mathbf{N}$ has exactly one invariant line, W_1, and exactly one invariant plane, W_2. Contrast Exercise (B1: All invariant subspaces of a diagonal matrix), where $\operatorname{diag}(1, 2)$ has two invariant lines (in the sense of Proposition 8.1.2), neither containing the other.

Exercise C2: Invariance under the inverse.

(a) Let V be finite-dimensional, $T \in \mathcal{L}(V)$ invertible, and U a T-invariant subspace. Prove that $T(U) = U$, and deduce that U is T^{-1}-invariant.

(b) Show that (a) fails without finite dimension. On $V = F^{\mathbb{Z}}$, the space of all functions $\mathbb{Z} \to F$ written as two-sided sequences $(s_n)_{n\in\mathbb{Z}}$, let $(Ss)_n = s_{n-1}$. Show that S is invertible, that $U = \{s : s_n = 0 \text{ for all } n < 0\}$ is S-invariant, and that U is **not** S^{-1}-invariant.

Hint: for (a), consider the restriction $T|_U$ *and its kernel.*

Solution.

(a) The restriction $T|_U \in \mathcal{L}(U)$ exists by invariance. Its kernel is $\ker T \cap U = \{\mathbf{0}\}$, since T is injective, so $T|_U$ is injective (Theorem 3.2.3). The space U is finite-dimensional (Theorem 1.6.7), so by Theorem 3.5.7, $T|_U$ is surjective onto U. That is, $T(U) = U$.
Now let $\mathbf{u} \in U$. By surjectivity of $T|_U$, there is $\mathbf{u}' \in U$ with $T\mathbf{u}' = \mathbf{u}$. Applying T^{-1} gives $T^{-1}\mathbf{u} = \mathbf{u}' \in U$. Hence U is T^{-1}-invariant.

(b) $V = F^{\mathbb{Z}}$ is a vector space with pointwise operations (Example (The Standard Vector Spaces)), and S is linear because it only re-indexes entries. Define $(S's)_n = s_{n+1}$. Then $(S'Ss)_n = (Ss)_{n+1} = s_n$ and $(SS's)_n = (S's)_{n-1} = s_n$, so S is invertible with $S^{-1} = S'$.

U is a subspace (the conditions $s_n = 0$ are preserved by sums and scalar multiples). If $s \in U$ and $n < 0$, then $n - 1 < 0$, so $(Ss)_n = s_{n-1} = 0$; thus $Ss \in U$, and U is S-invariant.

Let $\delta \in U$ be the sequence with $\delta_0 = 1$ and $\delta_n = 0$ for $n \neq 0$. Then $(S^{-1}\delta)_{-1} = \delta_0 = 1 \neq 0$, so $S^{-1}\delta \notin U$. Hence U is not S^{-1}-invariant. In (a), the step that breaks is "$T|_U$ injective, hence surjective", which needs finite dimension: here $S|_U$ is injective but its image misses δ.

8.2 Eigenvalues and Eigenvectors

The previous section ended with an observation: an operator has a diagonal matrix exactly when the space splits into invariant lines, and a line $\operatorname{span}(\mathbf{v})$ is invariant exactly when $T\mathbf{v}$ is a multiple of $\mathbf{v}$. This section turns that observation into the central notion of the chapter. We name the vectors that an operator only stretches, and the stretching factors. We find the factors as roots of the characteristic polynomial of Chapter 6, and we prove the two facts that everything later rests on: eigenvectors for different factors are independent, and over $\mathbb{C}$ every operator has at least one eigenvector.

8.2.1 When is a matrix diagonal?

Chapter 3 asked how simple $[T]_{\mathcal{B}}$ can be made by choosing $\mathcal{B}$. The simplest square matrices are the diagonal ones, so start with the wish and unwind it.

Let V be finite-dimensional with basis $\mathcal{B} = (\mathbf{v}_1, \dots, \mathbf{v}_n)$, and $T \in \mathcal{L}(V)$. By Definition 3.6.1, column j of $[T]_{\mathcal{B}}$ holds the coordinates of $T\mathbf{v}_j$. The matrix is $\operatorname{diag}(\lambda_1, \dots, \lambda_n)$ exactly when column j is $\lambda_j \mathbf{e}_j$ for each j, that is,

$$T\mathbf{v}_j = \lambda_j \mathbf{v}_j \qquad (j = 1, \dots, n).$$

So the wish forces an equation: every basis vector must be sent to a multiple of itself. We met this in Chapter 3, where the reflection $R(x, y) = (y, x)$ became $\operatorname{diag}(1, -1)$ in the basis $((1, 1), (1, -1))$ (Example (The reflection in a mirror-adapted basis)), precisely because $R(1, 1) = (1, 1)$ and $R(1, -1) = -(1, -1)$.

Where should we look for vectors with $T\mathbf{v} = \lambda\mathbf{v}$? Rewrite $\lambda\mathbf{v}$ as $\lambda \operatorname{id}_V(\mathbf{v})$. Then the equation says $(T - \lambda \operatorname{id}_V)\mathbf{v} = \mathbf{0}$: the vector lies in a **kernel**. Kernels are subspaces we know how to compute, so this rewriting is a plan, not just a restatement.

An eigenvector of T is a non-zero vector that T only stretches, and the eigenvalue is the stretching factor.

Definition 8.2.1 — Eigenvalue and Eigenvector

Let V be a vector space over F and $T \in \mathcal{L}(V)$. A scalar $\lambda \in F$ is an **eigenvalue** of T if there **exists** a **non-zero** vector $\mathbf{v} \in V$ with

$$T\mathbf{v} = \lambda\mathbf{v}.$$

Every **non-zero** $\mathbf{v} \in V$ with $T\mathbf{v} = \lambda\mathbf{v}$ is called **an eigenvector** of T for the eigenvalue λ.

For a matrix $\mathbf{A} \in M_n(F)$, the eigenvalues and eigenvectors of $\mathbf{A}$ are those of $T_{\mathbf{A}} \colon F^n \to F^n$: a scalar $\lambda \in F$ and a non-zero $\mathbf{v} \in F^n$ with $\mathbf{A}\mathbf{v} = \lambda\mathbf{v}$.

In words: an eigenvalue is a scalar **in the field** F over which V is a vector space. It qualifies if **some** non-zero vector is sent to λ times itself. The vector must be non-zero; the scalar may be anything, including 0. An eigenvector is a witness for its eigenvalue, and there are always many witnesses: if $\mathbf{v}$ is one, so is $c\mathbf{v}$ for every $c \neq 0$, since $T(c\mathbf{v}) = cT\mathbf{v} = \lambda(c\mathbf{v})$.

Well-definedness. An eigenvector determines its eigenvalue. If $T\mathbf{v} = \lambda\mathbf{v}$ and $T\mathbf{v} = \mu\mathbf{v}$ with $\mathbf{v} \neq \mathbf{0}$, then $(\lambda - \mu)\mathbf{v} = \mathbf{0}$, and Theorem 1.1.9 gives $\lambda = \mu$. So "the eigenvalue of $\mathbf{v}$" makes sense, while "the eigenvector of λ" does not.

The eigenvectors for one eigenvalue, together with $\mathbf{0}$, are exactly the kernel found above. That set is a subspace, and it deserves its own name.

Definition 8.2.2 — Eigenspace

Let $T \in \mathcal{L}(V)$ and $\lambda \in F$. The **eigenspace** of T for λ is

$$E_\lambda(T) \coloneqq \ker(T - \lambda \operatorname{id}_V) = \{\mathbf{v} \in V : T\mathbf{v} = \lambda\mathbf{v}\}.$$

For $\mathbf{A} \in M_n(F)$ we write $E_\lambda(\mathbf{A}) = E_\lambda(T_{\mathbf{A}}) = \operatorname{nul}(\mathbf{A} - \lambda\mathbf{I}_n)$.

$E_\lambda(T)$ is a subspace by Theorem 3.2.1, and it is T-invariant by Theorem 5.7.4 (b) with $p = x - \lambda$. It is defined for **every** $\lambda \in F$, and λ is an eigenvalue exactly when $E_\lambda(T) \neq \{\mathbf{0}\}$; in that case the eigenvectors for λ are the non-zero vectors of $E_\lambda(T)$. The eigenspace is the home of all eigenvectors for λ at once, and it is one of the invariant subspaces of the previous section: on it, T acts as λ id.

Examples.

- **Diagonal matrices.** Let $\mathbf{A} = \operatorname{diag}(d_1, \dots, d_n)$. Then $\mathbf{A}\mathbf{e}_j = d_j\mathbf{e}_j$ and $\mathbf{e}_j \neq \mathbf{0}$, so each d_j is an eigenvalue with eigenvector $\mathbf{e}_j$. The standard basis is a basis of eigenvectors, which is the observation we started from, read backwards.
- **Degenerate cases.** On $V \neq \{\mathbf{0}\}$, the identity has the eigenvalue 1 with $E_1(\operatorname{id}_V) = V$: **every** non-zero vector is an eigenvector. The zero operator has the eigenvalue 0 with $E_0 = V$. On $V = \{\mathbf{0}\}$, no operator has any eigenvalue, because there is no non-zero vector to be a witness. That last case matters: it is why the existence theorem later in this section must assume $V \neq \{\mathbf{0}\}$.
- **Projections.** Let $P \in \mathcal{L}(V)$ be a projection, $P^2 = P$ (Definition 3.10.1). If $P\mathbf{v} = \lambda\mathbf{v}$ with $\mathbf{v} \neq \mathbf{0}$, then $\lambda\mathbf{v} = P\mathbf{v} = P^2\mathbf{v} = P(\lambda\mathbf{v}) = \lambda^2\mathbf{v}$, so $(\lambda^2 - \lambda)\mathbf{v} = \mathbf{0}$ and $\lambda(\lambda - 1) = 0$ by Theorem 1.1.9. So the only possible eigenvalues are 0 and 1. By definition $E_0(P) = \ker P$. Also $E_1(P) = \operatorname{im} P$: a vector with $P\mathbf{v} = \mathbf{v}$ is in the image, and conversely P is the identity on $\operatorname{im} P$ by Theorem 3.10.1 (a). So a vector is fixed by P exactly when it is in the image, and killed exactly when it is in the kernel.
- **Differentiation of polynomials.** Let D act on $V = \mathbb{R}[x]_{\leq n}$ with $n \geq 1$. Suppose $Dp = \lambda p$ with $p \neq 0$. If $\lambda \neq 0$, then $\deg(\lambda p) = \deg p$, while Dp is either 0 or of degree $\deg p - 1$; neither equals $\deg p$ for $p \neq 0$. So $\lambda = 0$, and $E_0(D) = \ker D$ is the space of constant polynomials. Differentiation on $\mathbb{R}[x]_{\leq n}$ has exactly one eigenvalue, and its eigenvectors span only a line.

Non-example by minimal change. For $\mathbf{A} = \begin{pmatrix} 2 & 1 \\ 0 & 3 \end{pmatrix}$, the vector $\mathbf{e}_1$ is an eigenvector: $\mathbf{A}\mathbf{e}_1 = 2\mathbf{e}_1$. Move to the neighboring basis vector $\mathbf{e}_2$. It is still non-zero, and $\mathbf{A}\mathbf{e}_2 = (1, 3)$ is still a vector of $\mathbb{R}^2$. What fails is the equation $\mathbf{A}\mathbf{v} = \lambda\mathbf{v}$: no λ makes $(1, 3) = (0, \lambda)$. So $\mathbf{e}_2$ is not an eigenvector, and the line $\operatorname{span}(\mathbf{e}_2)$ is not invariant, as we saw in the previous section.

Why this definition. The clause "**non-zero**" is what gives the notion content. The zero vector satisfies $T\mathbf{0} = \lambda\mathbf{0}$ for **every** $\lambda \in F$, so if we allowed $\mathbf{v} = \mathbf{0}$, every scalar would be an eigenvalue of every operator. On the other hand we do **not** exclude $\lambda = 0$: the equation $T\mathbf{v} = 0\mathbf{v}$ says $\mathbf{v} \in \ker T$, and a non-zero kernel vector is exactly the kind of information we want to record. Requiring $\lambda \in F$, rather than in some larger field, makes the notion depend on the field, and this is deliberate: a real matrix may have no real eigenvalues, and then no real basis diagonalizes it. The prefix *eigen* is German for "own": an eigenvector is a direction that belongs to T, which T maps into itself.

Warning. **The eigenvalue may be 0; the eigenvector may not.** For $\mathbf{A} = \begin{pmatrix} 1 & 2 \\ 2 & 4 \end{pmatrix}$, the vector $(2, -1)$ satisfies $\mathbf{A}(2, -1) = (0, 0) = 0 \cdot (2, -1)$, so 0 is an eigenvalue. By contrast, $\mathbf{A}\mathbf{0} = 7 \cdot \mathbf{0}$ does **not** make 7 an eigenvalue. And say "**an** eigenvector for 0", never "the": $(2, -1)$, $(-4, 2)$ and $(200, -100)$ are all eigenvectors for 0.

Quick check. Let $T(x, y, z) = (x, z, y)$ on $\mathbb{R}^3$. Which of $\mathbf{e}_1$, $(0, 1, 1)$, $(0, 1, -1)$, $\mathbf{e}_2$ are eigenvectors of T, and for which eigenvalues?

Solution. $T\mathbf{e}_1 = \mathbf{e}_1$, so $\mathbf{e}_1$ is an eigenvector for 1. $T(0, 1, 1) = (0, 1, 1)$, an eigenvector for 1 as well. $T(0, 1, -1) = (0, -1, 1) = -(0, 1, -1)$, an eigenvector for -1. $T\mathbf{e}_2 = \mathbf{e}_3$, which is not a multiple of $\mathbf{e}_2$, so $\mathbf{e}_2$ is **not** an eigenvector. The three eigenvectors form a basis of $\mathbb{R}^3$, and in that basis $[T] = \operatorname{diag}(1, 1, -1)$.

8.2.2 Finding eigenvalues

The definition asks for a non-zero vector in $\ker(T - \lambda \operatorname{id}_V)$, a question about one λ at a time. In finite dimension, Chapters 3 and 6 turn it into a test that handles all λ at once. The last item is the one we compute with.

Theorem 8.2.1 — Characterizations of Eigenvalues

Let V be a finite-dimensional vector space over F with $\dim V = n \geq 1$, let $T \in \mathcal{L}(V)$ and $\lambda \in F$. The following are equivalent:

(a) λ is an eigenvalue of T;
(b) $E_\lambda(T) \neq \{\mathbf{0}\}$, that is, $T - \lambda \operatorname{id}_V$ is **not injective**;
(c) $T - \lambda \operatorname{id}_V$ is **not invertible**;
(d) $\det(\lambda \operatorname{id}_V - T) = 0$;
(e) $p_T(\lambda) = 0$.

In particular T has at most n eigenvalues. For $\mathbf{A} \in M_n(F)$: λ is an eigenvalue of $\mathbf{A}$ if and only if $p_{\mathbf{A}}(\lambda) = 0$, if and only if $\lambda\mathbf{I} - \mathbf{A}$ is not invertible.

Proof.

(a) $\Leftrightarrow$ (b). By Definition 8.2.1 and Definition 8.2.2, λ is an eigenvalue exactly when $E_\lambda(T) = \ker(T - \lambda\,\mathrm{id}_V)$ contains a non-zero vector. By Theorem 3.2.3, this happens exactly when $T - \lambda\,\mathrm{id}_V$ is not injective.

(b) $\Leftrightarrow$ (c). V is finite-dimensional, so by Theorem 3.5.7 ((a) $\Leftrightarrow$ (b)) an operator on V is invertible if and only if it is injective.

(c) $\Leftrightarrow$ (d). The operators $\lambda\,\mathrm{id}_V - T$ and $T - \lambda\,\mathrm{id}_V$ differ by the factor -1, so one is invertible exactly when the other is. By Theorem 6.5.8, $\lambda\,\mathrm{id}_V - T$ is invertible if and only if $\det(\lambda\,\mathrm{id}_V - T) \neq 0$.

(d) $\Leftrightarrow$ (e). Fix a basis $\mathcal{B}$ of V and put $\mathbf{A} = [T]_{\mathcal{B}}$. By Corollary 3.6.3, $[\lambda\,\mathrm{id}_V - T]_{\mathcal{B}} = \lambda\mathbf{I}_n - \mathbf{A}$, and by Theorem 3.6.5 (b), $\lambda\,\mathrm{id}_V - T$ is invertible if and only if $\lambda\mathbf{I}_n - \mathbf{A}$ is. By Theorem 6.10.4 ((a), (i) $\Leftrightarrow$ (ii)), $\lambda\mathbf{I}_n - \mathbf{A}$ is not invertible if and only if $p_{\mathbf{A}}(\lambda) = 0$, and $p_{\mathbf{A}} = p_T$ by Definition 6.10.2.

The bound on the number of eigenvalues is Theorem 6.10.4 (b) applied to $\mathbf{A}$, since by (e) the eigenvalues of T are the roots of $p_{\mathbf{A}}$ in F. The statement for matrices is the case $T = T_{\mathbf{A}}$, $\mathcal{B}$ standard, $[T_{\mathbf{A}}]_{\mathcal{B}} = \mathbf{A}$.

■

For matrices, this is Theorem 6.10.4 read in the new language: Chapter 6 found the scalars c with $c\mathbf{I} - \mathbf{A}$ singular, and those are the eigenvalues. It gives a procedure with two steps.

1. Compute $p_{\mathbf{A}}(x) = \det(x\mathbf{I} - \mathbf{A})$ and find its roots **in** F. These are the eigenvalues.
2. For each eigenvalue λ, solve the homogeneous system $(\mathbf{A} - \lambda\mathbf{I})\mathbf{x} = \mathbf{0}$ by elimination. Its solution set is $E_\lambda(\mathbf{A})$, and a basis of it lists "all" eigenvectors for λ (Theorem 2.5.4).

Example. (Eigenvalues and Eigenspaces of a 2×2 Matrix)

Find the eigenvalues and eigenspaces of $\mathbf{A} = \begin{pmatrix} 1 & 2 \\ 3 & 2 \end{pmatrix} \in M_2(\mathbb{R})$.

Solution. Step 1. For a 2×2 matrix, $p_{\mathbf{A}}(x) = x^2 - (\operatorname{tr}\mathbf{A})x + \det\mathbf{A}$ (the examples after Definition 6.10.1). Here $\operatorname{tr}\mathbf{A} = 3$ and $\det\mathbf{A} = 2 - 6 = -4$, so

$$p_{\mathbf{A}}(x) = x^2 - 3x - 4 = (x - 4)(x + 1).$$

By Theorem 8.2.1, the eigenvalues are 4 and -1.

Step 2. For $\lambda = 4$,

$$\mathbf{A} - 4\mathbf{I} = \begin{pmatrix} -3 & 2 \\ 3 & -2 \end{pmatrix}.$$

The second row is -1 times the first, so the system reduces to $-3x + 2y = 0$, with solutions $(x, y) = t(2, 3)$. Hence $E_4(\mathbf{A}) = \operatorname{span}((2, 3))$. For $\lambda = -1$,

$$\mathbf{A} + \mathbf{I} = \begin{pmatrix} 2 & 2 \\ 3 & 3 \end{pmatrix},$$

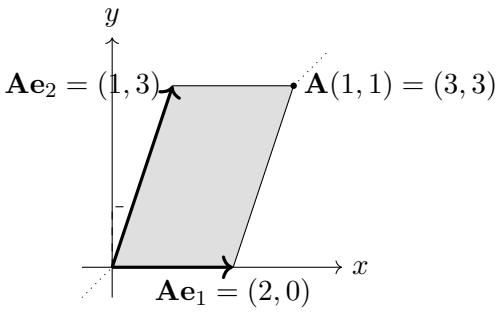
which reduces to $x + y = 0$, so $E_{-1}(\mathbf{A}) = \operatorname{span}((1, -1))$.

Check. $\mathbf{A}(2,3) = (2{+}6, 6{+}6) = (8,12) = 4\,(2,3)$ and $\mathbf{A}(1,-1) = (1{-}2, 3{-}2) = (-1,1) = -(1,-1)$. In the basis $((2,3),(1,-1))$, the operator $T_{\mathbf{A}}$ has matrix $\operatorname{diag}(4,-1)$, by the computation at the start of this section.

In Step 2, the matrix $\mathbf{A} - \lambda\mathbf{I}$ **must** be singular; if elimination produces only the trivial solution, then λ was not a root of $p_{\mathbf{A}}$, and Step 1 contains an error. This is a built-in check.

Triangular matrices. If $\mathbf{A}$ is upper or lower triangular, then $p_{\mathbf{A}}(x) = (x - a_{11}) \cdots (x - a_{nn})$ (the examples after Definition 6.10.1), so the eigenvalues of a triangular matrix are its diagonal entries. For $\begin{pmatrix} 2 & 1 \\ 0 & 3 \end{pmatrix}$ they are 2 and 3, with eigenvectors $\mathbf{e}_1$ and $(1,1)$, found in the previous section.

You can watch eigenvectors in the widget below. It shows the unit square and its image under $\mathbf{A} = \begin{pmatrix} 2 & 1 \\ 0 & 3 \end{pmatrix}$. The image $\mathbf{A}\mathbf{e}_1$ lies on the x-axis, which says that $\mathbf{e}_1$ is an eigenvector. The far corner of the image parallelogram is $\mathbf{A}(1,1) = \mathbf{A}\mathbf{e}_1 + \mathbf{A}\mathbf{e}_2 = (3,3)$, and it lies on the diagonal line through $(1,1)$: so $(1,1)$ is an eigenvector too, for the eigenvalue 3. Drag $\mathbf{A}\mathbf{e}_2$ to $(1,2)$, which changes the matrix to $\begin{pmatrix} 2 & 1 \\ 0 & 2 \end{pmatrix}$. Now the far corner $(3,2)$ leaves the diagonal, and only the x-axis is still mapped into itself. The next section explains what was lost.



The unit square (dashed) and its image under $\mathbf{A} = \begin{pmatrix} 2 & 1 \\ 0 & 3 \end{pmatrix}$. The image of $\mathbf{e}_1$ stays on the x-axis (eigenvalue 2), and the image of $(1,1)$ stays on the dotted diagonal (eigenvalue 3). The image of $\mathbf{e}_2$ leaves the y-axis, so $\mathbf{e}_2$ is not an eigenvector.

The set of all eigenvalues is used so often that it gets a symbol.

Definition 8.2.3 — Spectrum

Let $T \in \mathcal{L}(V)$. The **spectrum** of T is the set $\operatorname{spec}(T) \subseteq F$ of all eigenvalues of T. For $\mathbf{A} \in M_n(F)$, $\operatorname{spec}(\mathbf{A}) := \operatorname{spec}(T_{\mathbf{A}})$.

For instance $\operatorname{spec}\begin{pmatrix} 1 & 2 \\ 3 & 2 \end{pmatrix} = \{4, -1\}$, $\operatorname{spec}(\mathrm{id}_V) = \{1\}$ for $V \neq \{\mathbf{0}\}$, and the spectrum of a projection is contained in $\{0,1\}$. By Theorem 8.2.1, if $\dim V = n \geq 1$, then $\operatorname{spec}(T)$ is the set of roots of p_T in F, and it has at most n elements. It may be empty: the characteristic polynomial of the rotation $\mathbf{R} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$ is $x^2 + 1$, which has no real root, so $\operatorname{spec}(\mathbf{R}) = \emptyset$ over $\mathbb{R}$. This matches Example (A Rotation Has No Invariant Lines): no invariant lines, no eigenvectors.

Infinite dimension. Without a characteristic polynomial, we go back to the definition, and anything can happen.

- **Differentiation of smooth functions.** Let V be the space of infinitely differentiable functions $\mathbb{R} \to \mathbb{R}$ (a subspace of $\mathbb{R}^{\mathbb{R}}$, by the argument of Example (Differentiable Functions) applied to all derivatives), and $Df = f'$. Here we take three facts from calculus as known: $e^{\lambda x}$ is smooth with derivative $\lambda e^{\lambda x}$; the product rule; and a function on $\mathbb{R}$ with derivative 0 everywhere is constant. For **every** $\lambda \in \mathbb{R}$, the function $f(x) = e^{\lambda x}$ is non-zero and satisfies $Df = \lambda f$. So $\operatorname{spec}(D) = \mathbb{R}$, an infinite set. In fact $E_\lambda(D) = \operatorname{span}(e^{\lambda x})$: if $f' = \lambda f$, then by the product rule $g(x) = e^{-\lambda x} f(x)$ has $g' = e^{-\lambda x}(f' - \lambda f) = 0$, so g is a constant c and $f = ce^{\lambda x}$.
- **The right shift.** Let $R(s_0, s_1, s_2, \dots) = (0, s_0, s_1, \dots)$ on $F^{\mathbb{N}}$ (Example (The Shift Maps on Sequences)). If $R\mathbf{s} = \lambda\mathbf{s}$, compare entries: $0 = \lambda s_0$, and $s_k = \lambda s_{k+1}$ for all $k \geq 0$. If $\lambda = 0$, the second equation gives $s_k = 0$ for all k. If $\lambda \neq 0$, the first gives $s_0 = 0$, and then $s_{k+1} = \lambda^{-1} s_k$ gives $s_1 = 0$, $s_2 = 0$, and so on by induction. Either way $\mathbf{s} = \mathbf{0}$. So $\operatorname{spec}(R) = \emptyset$, over **every** field.

Warning. **In infinite dimension, "not invertible" does not produce an eigenvalue.** The step (b) $\Leftrightarrow$ (c) of Theorem 8.2.1 used finite dimension. The right shift R is injective but not surjective (Example (The Shifts: Injective but Not Surjective, and Conversely)), so $R - 0 \cdot \mathrm{id}$ is not invertible, yet 0 is not an eigenvalue of R: nothing non-zero is sent to $\mathbf{0}$.

8.2.3 Distinct eigenvalues give independent eigenvectors

In Example (Eigenvalues and Eigenspaces of a 2×2 Matrix) the eigenvectors $(2, 3)$ and $(1, -1)$ for the eigenvalues 4 and -1 formed a basis. That is no accident. Eigenvectors for different eigenvalues can never be linearly dependent.

Theorem 8.2.2 — Distinct Eigenvalues Give Independent Eigenvectors

Let $T \in \mathcal{L}(V)$, let $\lambda_1, \dots, \lambda_k \in F$ be **distinct** eigenvalues of T, and for each i let $\mathbf{v}_i$ be an eigenvector of T for λ_i. Then $(\mathbf{v}_1, \dots, \mathbf{v}_k)$ is linearly independent.

Idea. Try two vectors first. From $a\mathbf{v}_1 + b\mathbf{v}_2 = \mathbf{0}$, we want to kill one term, and the operator $T - \lambda_2 \mathrm{id}_V$ does exactly that: it sends $\mathbf{v}_2$ to $\mathbf{0}$ and $\mathbf{v}_1$ to $(\lambda_1 - \lambda_2)\mathbf{v}_1$. So $a(\lambda_1 - \lambda_2)\mathbf{v}_1 = \mathbf{0}$, and since $\lambda_1 \neq \lambda_2$ and $\mathbf{v}_1 \neq \mathbf{0}$, $a = 0$; then $b = 0$. In general, applying $T - \lambda_j \mathrm{id}_V$ to a dependence kills the j-th vector and rescales the others by non-zero factors, producing a **shorter** dependence. So a shortest dependence cannot exist. The Linear Dependence Lemma lets us pick that shortest one cleanly.

Proof. Suppose, for a contradiction, that $(\mathbf{v}_1, \dots, \mathbf{v}_k)$ is linearly dependent. By Theorem 1.4.1 (1), there is an index j with $\mathbf{v}_j \in \operatorname{span}(\mathbf{v}_1, \dots, \mathbf{v}_{j-1})$; choose the **smallest** such j. Since $\mathbf{v}_1 \neq \mathbf{0}$, $j \geq 2$. The list $(\mathbf{v}_1, \dots, \mathbf{v}_{j-1})$ is linearly independent: otherwise Theorem 1.4.1 (1), applied to it, would give a smaller index with the same property.

Write

$$\mathbf{v}_j = a_1\mathbf{v}_1 + \cdots + a_{j-1}\mathbf{v}_{j-1} \qquad (a_i \in F).$$

Apply $T - \lambda_j \operatorname{id}_V$ to both sides. Since $(T - \lambda_j \operatorname{id}_V)\mathbf{v}_i = (\lambda_i - \lambda_j)\mathbf{v}_i$ for each i, linearity gives

$$\mathbf{0} = a_1(\lambda_1 - \lambda_j)\mathbf{v}_1 + \cdots + a_{j-1}(\lambda_{j-1} - \lambda_j)\mathbf{v}_{j-1}.$$

By independence of $(\mathbf{v}_1, \ldots, \mathbf{v}_{j-1})$, every coefficient $a_i(\lambda_i - \lambda_j)$ is 0. The eigenvalues are distinct, so $\lambda_i - \lambda_j \neq 0$ for $i < j$, and hence $a_i = 0$ for all $i < j$. Then $\mathbf{v}_j = \mathbf{0}$, which contradicts the fact that an eigenvector is non-zero. This proves that $(\mathbf{v}_1, \ldots, \mathbf{v}_k)$ is linearly independent.

■

The theorem works in any vector space, finite-dimensional or not. For instance, for distinct real numbers $\lambda_1, \ldots, \lambda_k$, the functions $e^{\lambda_1 x}, \ldots, e^{\lambda_k x}$ are eigenvectors of differentiation for distinct eigenvalues, so they are linearly independent, with no computation at all. Two consequences follow at once, and the second is the first half of a promise made in Chapter 1, §7: eigenspaces sit inside V as a direct sum.

Corollary 8.2.3 — Eigenspaces Form a Direct Sum

Let $T \in \mathcal{L}(V)$ and let $\lambda_1, \ldots, \lambda_k \in F$ be distinct. Then the sum $E_{\lambda_1}(T) + \cdots + E_{\lambda_k}(T)$ is direct. If V is finite-dimensional, then

$$\dim E_{\lambda_1}(T) + \cdots + \dim E_{\lambda_k}(T) \leq \dim V,$$

and T has at most $\dim V$ distinct eigenvalues.

Proof. By Theorem 1.7.5 ((b) ⇒ (a)), it suffices to show: if $\mathbf{u}_1 + \cdots + \mathbf{u}_k = \mathbf{0}$ with $\mathbf{u}_i \in E_{\lambda_i}(T)$, then every $\mathbf{u}_i = \mathbf{0}$. Suppose not, and let S be the non-empty set of indices i with $\mathbf{u}_i \neq \mathbf{0}$. For $i \in S$, $\mathbf{u}_i$ is an eigenvector of T for λ_i, and these eigenvalues are distinct. By Theorem 8.2.2, the list $(\mathbf{u}_i)_{i \in S}$ is linearly independent. But $\sum_{i \in S} 1 \cdot \mathbf{u}_i = \sum_{i=1}^{k} \mathbf{u}_i = \mathbf{0}$ is a relation with all coefficients $1 \neq 0$, a contradiction. So the sum is direct.

If V is finite-dimensional, Theorem 1.7.5 ((a) ⇒ (e)) gives $\dim(E_{\lambda_1}(T) \oplus \cdots \oplus E_{\lambda_k}(T)) = \sum_i \dim E_{\lambda_i}(T)$, and this is at most $\dim V$ by Theorem 1.6.7. If the λ_i are eigenvalues, each $\dim E_{\lambda_i}(T) \geq 1$, so $k \leq \dim V$.

■

The corollary gives a second, polynomial-free proof that an operator on an n-dimensional space has at most n eigenvalues. Section 4 shows that T has a diagonal matrix exactly when the inequality is an equality.

8.2.4 Existence over the complex numbers

We have seen operators without eigenvalues: the rotation of $\mathbb{R}^2$, and the right shift. The rotation fails because $\mathbb{R}$ is missing the roots of $x^2 + 1$; the shift fails because its space is infinite-dimensional. Remove both obstacles and eigenvalues always exist.

Theorem 8.2.4 — Complex Operators Have Eigenvalues

Let V be a finite-dimensional vector space over $\mathbb{C}$ with $V \neq \{\mathbf{0}\}$, and let $T \in \mathcal{L}(V)$. Then T has an eigenvalue. The same holds for every $\mathbf{A} \in M_n(\mathbb{C})$ with $n \geq 1$.

Proof. Let $n = \dim V \geq 1$. By Theorem 6.10.2 and Definition 6.10.2, $p_T \in \mathbb{C}[x]$ is monic of degree $n \geq 1$, so it is not constant. By the Fundamental Theorem of Algebra (Theorem 5.5.1), $p_T(\lambda) = 0$ for some $\lambda \in \mathbb{C}$. By Theorem 8.2.1 ((e) $\Rightarrow$ (a)), λ is an eigenvalue of T. For $\mathbf{A} \in M_n(\mathbb{C})$, apply this to $T_{\mathbf{A}}$. ∎

Alternatively, determinants can be avoided altogether, and the proof then shows where the eigenvector comes from. By Theorem 5.7.2, there is a non-zero $p \in \mathbb{C}[x]$ with $p(T) = 0$. It is not a non-zero constant c, since $c \operatorname{id}_V \neq 0$ on $V \neq \{\mathbf{0}\}$. By Corollary 5.5.5, $p = c(x - z_1) \cdots (x - z_m)$ with $c \neq 0$ and $m \geq 1$, so by Theorem 5.7.1 (a) and (b),

$$0 = p(T) = c\,(T - z_1 \operatorname{id}_V)(T - z_2 \operatorname{id}_V) \cdots (T - z_m \operatorname{id}_V).$$

Since $c \neq 0$, multiplying by c^{-1} shows that the composite $(T - z_1 \operatorname{id}_V) \cdots (T - z_m \operatorname{id}_V)$ is the zero operator, which is not injective on $V \neq \{\mathbf{0}\}$. A composition of injective maps is injective (Theorem 0.4.3 (a), applied $m - 1$ times), so at least one factor $T - z_j \operatorname{id}_V$ is not injective, and z_j is an eigenvalue by Theorem 8.2.1 ((b) $\Rightarrow$ (a)).

Both routes use the Fundamental Theorem of Algebra, and both need all three hypotheses. Over $\mathbb{R}$ the rotation has no eigenvalue. In infinite dimension the right shift on $\mathbb{C}^{\mathbb{N}}$ has none, and indeed no non-zero polynomial annihilates it: for $p = a_0 + a_1 x + \cdots + a_N x^N \neq 0$, the sequence $p(R)(1, 0, 0, \dots) = (a_0, a_1, \dots, a_N, 0, \dots)$ is not zero. On $V = \{\mathbf{0}\}$ there is nothing to be an eigenvector. This theorem pays off the promise made in Chapter 5, and it is the base step of every structure theorem over $\mathbb{C}$ in this book: find one eigenvector, then look at what is left.

Quick check. Does every operator on $\mathbb{C}^3$ have an invariant line? Does every operator on $\mathbb{R}^2$?

Solution. Every operator on $\mathbb{C}^3$ has one: by Theorem 8.2.4 it has an eigenvector $\mathbf{v}$, and $\operatorname{span}(\mathbf{v})$ is invariant by Proposition 8.1.2. Not every operator on $\mathbb{R}^2$: the rotation by a right angle has no invariant line (Example (A Rotation Has No Invariant Lines)).

8.2.5 Real matrices and complex eigenvalues

A real matrix may have no real eigenvalues, but it is also a complex matrix, and as such it has eigenvalues by Theorem 8.2.4. This is the situation Chapter 1, §9 prepared for. Let $\mathbf{A} \in M_n(\mathbb{R})$. The complexification of $\mathbb{R}^n$ is $\mathbb{C}^n$: the pair $(\mathbf{x}, \mathbf{y})$ is the vector $\mathbf{x} + i\mathbf{y}$ (Example (The Complexification of $\mathbb{R}^n$ Is $\mathbb{C}^n$)). The real operator $T_{\mathbf{A}}$ extends to the complexification by the only rule compatible with complex scalars,

$$\mathbf{x} + i\mathbf{y} \;\mapsto\; \mathbf{A}\mathbf{x} + i\mathbf{A}\mathbf{y} = \mathbf{A}(\mathbf{x} + i\mathbf{y}),$$

which is just $T_{\mathbf{A}}$ for $\mathbf{A}$ regarded as a matrix in $M_n(\mathbb{C})$. By Theorem 1.9.3, the real standard basis is also a complex basis of $\mathbb{C}^n$, and in it the extended operator still has matrix $\mathbf{A}$; in particular

it has the same characteristic polynomial $p_{\mathbf{A}} \in \mathbb{R}[x] \subseteq \mathbb{C}[x]$. So the **complex eigenvalues** of a real matrix are the roots of $p_{\mathbf{A}}$ in $\mathbb{C}$, with eigenvectors in $\mathbb{C}^n$, and the real eigenvalues are among them. The complex ones cannot appear alone.

Theorem 8.2.5 — Complex Eigenvalues of Real Matrices Come in Conjugate Pairs

Let $\mathbf{A} \in M_n(\mathbb{R})$, regarded as an element of $M_n(\mathbb{C})$. If $\lambda \in \mathbb{C}$ is an eigenvalue of $\mathbf{A}$ with eigenvector $\mathbf{v} \in \mathbb{C}^n$, then $\overline{\lambda}$ is an eigenvalue of $\mathbf{A}$ with eigenvector $\overline{\mathbf{v}}$, the vector of conjugated entries. Moreover:

(a) $\operatorname{mult}_{\lambda}(p_{\mathbf{A}}) = \operatorname{mult}_{\overline{\lambda}}(p_{\mathbf{A}})$;
(b) if $\lambda \notin \mathbb{R}$, then $(\mathbf{v}, \overline{\mathbf{v}})$ is linearly independent over $\mathbb{C}$.

Proof. Let $\mathbf{A}\mathbf{v} = \lambda\mathbf{v}$ with $\mathbf{v} = (v_1, \dots, v_n) \neq \mathbf{0}$. For each k, the k-th entry of $\mathbf{A}\mathbf{v}$ is $\sum_j a_{kj} v_j$ (Definition 0.9.9). By Theorem 0.6.2 (a) and (b), and since $\overline{a_{kj}} = a_{kj}$ for the real entries of $\mathbf{A}$,

$$\overline{\textstyle\sum_j a_{kj} v_j} = \sum_j a_{kj} \overline{v_j}, \qquad \overline{\lambda v_k} = \overline{\lambda}\,\overline{v_k}.$$

Conjugating the equation $\mathbf{A}\mathbf{v} = \lambda\mathbf{v}$ entry by entry therefore gives $\mathbf{A}\overline{\mathbf{v}} = \overline{\lambda}\,\overline{\mathbf{v}}$. Since $\overline{\overline{v_k}} = v_k$, $\overline{\mathbf{v}} = \mathbf{0}$ would force $\mathbf{v} = \mathbf{0}$; so $\overline{\mathbf{v}} \neq \mathbf{0}$, and $\overline{\mathbf{v}}$ is an eigenvector for $\overline{\lambda}$.

(a) The entries of $x\mathbf{I} - \mathbf{A}$ lie in $\mathbb{R}[x]$, so its determinant $p_{\mathbf{A}}$ lies in $\mathbb{R}[x]$ (Definition 6.10.1). By Theorem 5.5.6, $\operatorname{mult}_{\overline{\lambda}}(p_{\mathbf{A}}) = \operatorname{mult}_{\lambda}(p_{\mathbf{A}})$.
(b) If $\lambda \notin \mathbb{R}$, then $\overline{\lambda} \neq \lambda$, so $\mathbf{v}$ and $\overline{\mathbf{v}}$ are eigenvectors for distinct eigenvalues, and they are independent by Theorem 8.2.2.

■

For the rotation $\mathbf{R} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$, the vector $(1, -i)$ satisfies $\mathbf{R}(1,-i) = (i, 1) = i\,(1,-i)$, so i is an eigenvalue. Conjugating, $\mathbf{R}(1, i) = (-i, 1) = -i\,(1, i)$. Over $\mathbb{C}$, the two eigenvectors form a basis of $\mathbb{C}^2$, and the rotation has a diagonal matrix $\operatorname{diag}(i, -i)$ in it, although no real basis diagonalizes it. So the field matters for eigenvalues, and it will matter for diagonalization.

Example. (A Real Matrix with Non-Real Eigenvalues)

Find the eigenvalues of $\mathbf{A} = \begin{pmatrix} 3 & -2 \\ 4 & -1 \end{pmatrix}$ over $\mathbb{C}$, with an eigenvector for each.

Solution. Here $\operatorname{tr}\mathbf{A} = 2$ and $\det\mathbf{A} = -3 + 8 = 5$, so $p_{\mathbf{A}}(x) = x^2 - 2x + 5 = (x-1)^2 + 4$. Over $\mathbb{R}$ this has no root, so $\operatorname{spec}(\mathbf{A}) = \emptyset$ over $\mathbb{R}$. Over $\mathbb{C}$, $(x-1)^2 = -4$ gives the roots $1 + 2i$ and $1 - 2i$.

For $\lambda = 1 + 2i$,

$$\mathbf{A} - \lambda\mathbf{I} = \begin{pmatrix} 2 - 2i & -2 \\ 4 & -2 - 2i \end{pmatrix}.$$

The first row gives $(2 - 2i)x = 2y$, that is, $y = (1 - i)x$; take $\mathbf{v} = (1, 1 - i)$. Check the second row: $4 \cdot 1 + (-2 - 2i)(1 - i) = 4 + (-2 + 2i - 2i + 2i^2) = 4 - 4 = 0$. So $\mathbf{v}$ is an

eigenvector for $1+2i$. By Theorem 8.2.5, $\overline{\mathbf{v}} = (1, 1+i)$ is an eigenvector for $1-2i$, with no further computation.

8.2.6 The invertible matrix theorem grows

Chapter 2 listed eight conditions equivalent to invertibility (Theorem 2.4.4), and Chapter 6 added the determinant (Theorem 6.5.3). Eigenvalues give one more: a matrix is singular exactly when it kills a non-zero vector, which is to say, when it stretches some non-zero vector by the factor 0.

Theorem 8.2.6 — Invertible Matrix Theorem, with Eigenvalues

Let $\mathbf{A} \in M_n(F)$ with $n \geq 1$. The following are equivalent, and each is equivalent to each of the conditions of Theorem 6.5.3 and Theorem 2.4.4.

(a) $\mathbf{A}$ is invertible.

(b) 0 is **not** an eigenvalue of $\mathbf{A}$, that is, $0 \notin \operatorname{spec}(\mathbf{A})$.

Likewise, an operator T on a finite-dimensional space $V \neq \{\mathbf{0}\}$ is invertible if and only if $0 \notin \operatorname{spec}(T)$.

Proof. By Definition 8.2.2, $E_0(\mathbf{A}) = \ker(T_\mathbf{A} - 0\ \mathrm{id}) = \ker T_\mathbf{A}$. So $0 \notin \operatorname{spec}(\mathbf{A})$ if and only if $\ker T_\mathbf{A} = \{\mathbf{0}\}$, if and only if $T_\mathbf{A}$ is injective (Theorem 3.2.3), if and only if $\mathbf{A}$ is invertible (Theorem 6.5.3, (a) $\Leftrightarrow$ (b)). For an operator, $E_0(T) = \ker T$, and Theorem 3.5.7 ((a) $\Leftrightarrow$ (c)) finishes the same way. ■

For example, $\operatorname{spec}\begin{pmatrix} 1 & 2 \\ 3 & 2 \end{pmatrix} = \{4, -1\}$ does not contain 0, so that matrix is invertible, while $\begin{pmatrix} 1 & 2 \\ 2 & 4 \end{pmatrix}$ has the eigenvalue 0 and is singular.

Eigenvalues are easy to compute for one matrix, and it is tempting to assume they behave well under the operations we use on matrices. Two such assumptions are false.

Warning. **Eigenvalues do not add or multiply.** Let $\mathbf{A} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$ and $\mathbf{B} = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix}$. Both are triangular with zero diagonal, so $\operatorname{spec}(\mathbf{A}) = \operatorname{spec}(\mathbf{B}) = \{0\}$. But $\mathbf{A} + \mathbf{B} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$ has $p(x) = x^2 - 1$ and eigenvalues ± 1, which are not sums of eigenvalues of $\mathbf{A}$ and $\mathbf{B}$; and $\mathbf{AB} = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}$ has the eigenvalue 1, which is not a product of them.

Warning. **Row operations change eigenvalues.** Elimination preserves the solution set of $\mathbf{Ax} = \mathbf{0}$ (Theorem 2.2.2), not the solution sets of $\mathbf{Ax} = \lambda\mathbf{x}$. For $\mathbf{A} = \begin{pmatrix} 1 & 2 \\ 3 & 2 \end{pmatrix}$, with eigenvalues 4 and -1, subtracting 3 times row 1 from row 2 gives the triangular matrix $\begin{pmatrix} 1 & 2 \\ 0 & -4 \end{pmatrix}$, whose eigenvalues are 1 and -4. So never row reduce $\mathbf{A}$ to find its

eigenvalues; row reduce $\mathbf{A} - \lambda\mathbf{I}$ to find eigenvectors, once λ is known.

8.2.7 Exercises

8.2.7.1 A. Check your understanding

Exercise A1.

(a) Define eigenvalue, eigenvector and eigenspace of an operator $T \in \mathcal{L}(V)$.

(b) True or false: $\mathbf{0}$ is an eigenvector of every operator. Justify your answer.

(c) True or false: if 0 is an eigenvalue of $\mathbf{A} \in M_n(F)$, then $\mathbf{A}$ is not invertible. Justify your answer.

(d) State four conditions equivalent to "λ is an eigenvalue of T" for an operator on a finite-dimensional space $V \neq \{\mathbf{0}\}$.

(e) True or false: every operator on $\mathbb{R}^2$ has an eigenvalue. Justify your answer.

(f) True or false: the eigenvalues of $\mathbf{A}$ are the diagonal entries of a row echelon form of $\mathbf{A}$. Justify your answer.

Solution.

(a) $\lambda \in F$ is an eigenvalue of T if $T\mathbf{v} = \lambda\mathbf{v}$ for some **non-zero** $\mathbf{v} \in V$; each such non-zero $\mathbf{v}$ is an eigenvector for λ (Definition 8.2.1). The eigenspace is $E_\lambda(T) = \ker(T - \lambda\,\mathrm{id}_V)$ (Definition 8.2.2).

(b) False. Eigenvectors are non-zero by definition. (The equation $T\mathbf{0} = \lambda\mathbf{0}$ holds for every λ, which is why $\mathbf{0}$ is excluded.)

(c) True, by Theorem 8.2.6.

(d) By Theorem 8.2.1: $T - \lambda\,\mathrm{id}_V$ is not injective; $T - \lambda\,\mathrm{id}_V$ is not invertible; $\det(\lambda\,\mathrm{id}_V - T) = 0$; $p_T(\lambda) = 0$.

(e) False. The rotation $R(x, y) = (-y, x)$ has $p_R = x^2 + 1$, with no real root, so it has no real eigenvalue.

(f) False. Row operations change eigenvalues: $\begin{pmatrix} 1 & 2 \\ 3 & 2 \end{pmatrix}$ has eigenvalues $4, -1$, but the echelon form $\begin{pmatrix} 1 & 2 \\ 0 & -4 \end{pmatrix}$ has diagonal entries $1, -4$.

8.2.7.2 B. Practice

Exercise B1: Computing eigenvalues and eigenspaces.

Find the eigenvalues and a basis of each eigenspace of the following real matrices.

(a) $\mathbf{A} = \begin{pmatrix} 5 & 4 \\ -2 & -1 \end{pmatrix}$.

(b) $\mathbf{B} = \begin{pmatrix} 2 & 0 & 1 \\ -1 & 3 & 1 \\ 2 & -2 & 1 \end{pmatrix}$.

Hence write down a basis of $\mathbb{R}^2$ consisting of eigenvectors of $\mathbf{A}$, and a basis of $\mathbb{R}^3$ consisting of eigenvectors of $\mathbf{B}$.

Solution.

(a) $\operatorname{tr}\mathbf{A} = 4$ and $\det\mathbf{A} = -5 + 8 = 3$, so $p_{\mathbf{A}}(x) = x^2 - 4x + 3 = (x-1)(x-3)$, and $\operatorname{spec}(\mathbf{A}) = \{1, 3\}$ by Theorem 8.2.1. For $\lambda = 1$, $\mathbf{A} - \mathbf{I} = \begin{pmatrix} 4 & 4 \\ -2 & -2 \end{pmatrix}$ reduces to $x + y = 0$, so $E_1(\mathbf{A}) = \operatorname{span}((1,-1))$. For $\lambda = 3$, $\mathbf{A} - 3\mathbf{I} = \begin{pmatrix} 2 & 4 \\ -2 & -4 \end{pmatrix}$ reduces to $x + 2y = 0$, so $E_3(\mathbf{A}) = \operatorname{span}((2,-1))$. Check: $\mathbf{A}(1,-1) = (1,-1)$ and $\mathbf{A}(2,-1) = (6,-3) = 3(2,-1)$.

(b) Expanding $\det(x\mathbf{I} - \mathbf{B})$ along the first row,

$$\begin{aligned} p_{\mathbf{B}}(x) &= \det\begin{pmatrix} x-2 & 0 & -1 \\ 1 & x-3 & -1 \\ -2 & 2 & x-1 \end{pmatrix} \\ &= (x-2)\big[(x-3)(x-1)+2\big] + (-1)\big[1\cdot 2 - (x-3)(-2)\big]. \end{aligned}$$

The first bracket is $x^2 - 4x + 5$ and the second is $2x - 4 = 2(x-2)$, so

$$\begin{aligned} p_{\mathbf{B}}(x) &= (x-2)(x^2 - 4x + 5) - 2(x-2) \\ &= (x-2)(x^2 - 4x + 3) = (x-1)(x-2)(x-3). \end{aligned}$$

So $\operatorname{spec}(\mathbf{B}) = \{1, 2, 3\}$. Solving $(\mathbf{B} - \lambda\mathbf{I})\mathbf{x} = \mathbf{0}$:

- $\lambda = 1$: $\mathbf{B} - \mathbf{I} = \begin{pmatrix} 1 & 0 & 1 \\ -1 & 2 & 1 \\ 2 & -2 & 0 \end{pmatrix}$. The first row gives $z = -x$, the third gives $y = x$, and the second is then $-x + 2x - x = 0$. So $E_1(\mathbf{B}) = \operatorname{span}((1,1,-1))$.
- $\lambda = 2$: $\mathbf{B} - 2\mathbf{I} = \begin{pmatrix} 0 & 0 & 1 \\ -1 & 1 & 1 \\ 2 & -2 & -1 \end{pmatrix}$. The first row gives $z = 0$, and then the second gives $y = x$. So $E_2(\mathbf{B}) = \operatorname{span}((1,1,0))$.
- $\lambda = 3$: $\mathbf{B} - 3\mathbf{I} = \begin{pmatrix} -1 & 0 & 1 \\ -1 & 0 & 1 \\ 2 & -2 & -2 \end{pmatrix}$. The first row gives $z = x$, and the third gives $2x - 2y - 2x = 0$, so $y = 0$. So $E_3(\mathbf{B}) = \operatorname{span}((1,0,1))$.

Check: $\mathbf{B}(1,1,-1) = (1,1,-1)$, $\mathbf{B}(1,1,0) = (2,2,0)$, $\mathbf{B}(1,0,1) = (3,0,3)$.

Hence: the eigenvalues of $\mathbf{A}$ are distinct, so by Theorem 8.2.2 the eigenvectors $((1,-1),(2,-1))$ are independent, and two independent vectors in $\mathbb{R}^2$ form a basis (Theorem 1.6.4). In the same way $((1,1,-1),(1,1,0),(1,0,1))$ is a basis of $\mathbb{R}^3$ consisting of eigenvectors of $\mathbf{B}$.

Exercise B2: The transpose map.

Let F be a field of characteristic not 2, and let $\tau\colon M_2(F) \to M_2(F)$, $\tau(\mathbf{X}) = \mathbf{X}^\top$.

(a) Show that every eigenvalue λ of τ satisfies $\lambda^2 = 1$.

(b) Find $\operatorname{spec}(\tau)$, and describe $E_1(\tau)$ and $E_{-1}(\tau)$ with a basis of each.

Solution.

(a) Let $\tau(\mathbf{X}) = \lambda\mathbf{X}$ with $\mathbf{X} \neq 0$. Since $(\mathbf{X}^\top)^\top = \mathbf{X}$ (Theorem 0.9.5), $\mathbf{X} = \tau(\tau(\mathbf{X})) = \tau(\lambda\mathbf{X}) = \lambda\tau(\mathbf{X}) = \lambda^2\mathbf{X}$. So $(\lambda^2 - 1)\mathbf{X} = 0$ with $\mathbf{X} \neq 0$, and $\lambda^2 = 1$ by Theorem 1.1.9.

(b) From $\lambda^2 - 1 = (\lambda - 1)(\lambda + 1) = 0$, the only candidates are 1 and -1, which are different because the characteristic is not 2. $E_1(\tau) = \{\mathbf{X} : \mathbf{X}^\top = \mathbf{X}\}$ is the space of symmetric matrices. Writing $\mathbf{X} = \begin{pmatrix} a & b \\ c & d \end{pmatrix}$, the condition is $b = c$, so $E_1(\tau) = \operatorname{span}(\mathbf{E}_{11}, \mathbf{E}_{22}, \mathbf{E}_{12} + \mathbf{E}_{21})$, and these three matrices are independent (compare entries). $E_{-1}(\tau) = \{\mathbf{X} : \mathbf{X}^\top = -\mathbf{X}\}$ is the space of skew-symmetric matrices. The condition $\mathbf{X}^\top = -\mathbf{X}$ says $a = -a$, $d = -d$ and $c = -b$; since $2 \neq 0$, $a = d = 0$, so $E_{-1}(\tau) = \operatorname{span}(\mathbf{E}_{12} - \mathbf{E}_{21})$. Both eigenspaces are non-zero, so $\operatorname{spec}(\tau) = \{1, -1\}$. This agrees with Theorem 3.10.5: $\tau^2 = \mathrm{id}$, and $M_2(F) = E_1(\tau) \oplus E_{-1}(\tau)$, with dimensions $3 + 1 = 4$.

Exercise B3: Eigenvalues of powers and inverses.

Let $T \in \mathcal{L}(V)$ and let $\mathbf{v}$ be an eigenvector of T for λ.

(a) Prove that $\mathbf{v}$ is an eigenvector of T^2 for λ^2, and more generally of $p(T)$ for $p(\lambda)$, for every $p \in F[x]$.

(b) Suppose T is invertible. Prove that $\lambda \neq 0$ and that $\mathbf{v}$ is an eigenvector of T^{-1} for λ^{-1}.

(c) Show that the converse of the first statement in (a) fails: give $T \in \mathcal{L}(\mathbb{R}^2)$ such that -1 is an eigenvalue of T^2 but T has no eigenvalue.

Solution.

(a) $T^2\mathbf{v} = T(T\mathbf{v}) = T(\lambda\mathbf{v}) = \lambda T\mathbf{v} = \lambda^2\mathbf{v}$, and $\mathbf{v} \neq \mathbf{0}$. By induction on k, $T^k\mathbf{v} = \lambda^k\mathbf{v}$: if $T^k\mathbf{v} = \lambda^k\mathbf{v}$, then $T^{k+1}\mathbf{v} = T(\lambda^k\mathbf{v}) = \lambda^{k+1}\mathbf{v}$. For $p = \sum_k a_k x^k$, Definition 3.4.2 gives $p(T)\mathbf{v} = \sum_k a_k T^k\mathbf{v} = \sum_k a_k\lambda^k\mathbf{v} = p(\lambda)\mathbf{v}$.

(b) An invertible operator is injective, so $\ker T = \{\mathbf{0}\}$ and $T\mathbf{v} \neq \mathbf{0}$; as $T\mathbf{v} = \lambda\mathbf{v}$, $\lambda \neq 0$ by Theorem 1.1.9. Applying T^{-1} to $T\mathbf{v} = \lambda\mathbf{v}$ gives $\mathbf{v} = \lambda T^{-1}\mathbf{v}$, so $T^{-1}\mathbf{v} = \lambda^{-1}\mathbf{v}$.

(c) Take the rotation $R(x, y) = (-y, x)$. It has no real eigenvalue (Example (A Rotation Has No Invariant Lines)). But $R^2(x, y) = R(-y, x) = (-x, -y)$, so $R^2 = -\mathrm{id}$, and every non-zero vector is an eigenvector of R^2 for -1. Part (a) would need a real λ with $\lambda^2 = -1$, and there is none.

8.2.7.3 C. Going deeper

Exercise C1: Every vector an eigenvector.

Let V be a vector space over F and $T \in \mathcal{L}(V)$. Suppose every non-zero vector of V is an eigenvector of T. Prove that $T = c\,\mathrm{id}_V$ for some $c \in F$.

Hint: compare the eigenvalues of $\mathbf{v}$, $\mathbf{w}$ *and* $\mathbf{v} + \mathbf{w}$.

Solution. If $V = \{\mathbf{0}\}$, then $T = 0 = 1 \cdot \mathrm{id}_V$. Otherwise, for each $\mathbf{v} \neq \mathbf{0}$ let $\lambda_{\mathbf{v}}$ be its eigenvalue, which is unique by the well-definedness remark after Definition 8.2.1. We show that $\lambda_{\mathbf{v}} = \lambda_{\mathbf{w}}$ for all non-zero $\mathbf{v}, \mathbf{w}$.

Case 1: $(\mathbf{v}, \mathbf{w})$ *is linearly dependent.* Then $\mathbf{w} = a\mathbf{v}$ for some $a \neq 0$, and $T\mathbf{w} = aT\mathbf{v} = \lambda_{\mathbf{v}}(a\mathbf{v}) = \lambda_{\mathbf{v}}\mathbf{w}$. By uniqueness of the eigenvalue of $\mathbf{w}$, $\lambda_{\mathbf{w}} = \lambda_{\mathbf{v}}$.

Case 2: $(\mathbf{v}, \mathbf{w})$ *is linearly independent.* Then $\mathbf{v} + \mathbf{w} \neq \mathbf{0}$, and

$$\lambda_{\mathbf{v}+\mathbf{w}}\mathbf{v} + \lambda_{\mathbf{v}+\mathbf{w}}\mathbf{w} = T(\mathbf{v} + \mathbf{w}) = T\mathbf{v} + T\mathbf{w} = \lambda_{\mathbf{v}}\mathbf{v} + \lambda_{\mathbf{w}}\mathbf{w}.$$

So $(\lambda_{\mathbf{v}+\mathbf{w}} - \lambda_{\mathbf{v}})\mathbf{v} + (\lambda_{\mathbf{v}+\mathbf{w}} - \lambda_{\mathbf{w}})\mathbf{w} = \mathbf{0}$, and by independence $\lambda_{\mathbf{v}} = \lambda_{\mathbf{v}+\mathbf{w}} = \lambda_{\mathbf{w}}$.

Fix $\mathbf{v}_0 \neq \mathbf{0}$ and put $c = \lambda_{\mathbf{v}_0}$. Then $T\mathbf{v} = c\mathbf{v}$ for every $\mathbf{v} \neq \mathbf{0}$, and also for $\mathbf{v} = \mathbf{0}$. Hence $T = c\,\mathrm{id}_V$.

Exercise C2: Nilpotent operators.

An operator $T \in \mathcal{L}(V)$ is **nilpotent** if $T^k = 0$ for some integer $k \geq 1$.

(a) Let $V \neq \{\mathbf{0}\}$ and T nilpotent. Prove that $\mathrm{spec}(T) = \{0\}$. (No finite dimension is needed.)

(b) Let $\mathbf{A} \in M_n(\mathbb{C})$, $n \geq 1$, be nilpotent. Deduce that $p_{\mathbf{A}}(x) = x^n$.

(c) Let $\mathbf{A} \in M_n(F)$, $n \geq 1$, be nilpotent. Prove that $\mathbf{I} + \mathbf{A}$ is invertible.

Solution.

(a) Let $T\mathbf{v} = \lambda\mathbf{v}$ with $\mathbf{v} \neq \mathbf{0}$. By Exercise (B3: Eigenvalues of powers and inverses) (a), $\mathbf{0} = T^k\mathbf{v} = \lambda^k\mathbf{v}$, so $\lambda^k = 0$ by Theorem 1.1.9, and hence $\lambda = 0$ (a product of non-zero elements of a field is non-zero, Theorem 0.7.1). So $\mathrm{spec}(T) \subseteq \{0\}$. Conversely, $T^k = 0$ is not injective on $V \neq \{\mathbf{0}\}$; if T were injective, so would be the composite T^k (Theorem 0.4.3). So $\ker T \neq \{\mathbf{0}\}$, and $0 \in \mathrm{spec}(T)$.

(b) By Corollary 5.5.5 and Theorem 6.10.2, $p_{\mathbf{A}} = (x - z_1)\cdots(x - z_n)$ for some $z_i \in \mathbb{C}$. Each z_i is a root of $p_{\mathbf{A}}$, hence an eigenvalue of $\mathbf{A}$ by Theorem 8.2.1, hence $z_i = 0$ by (a). So $p_{\mathbf{A}} = x^n$.

(c) By Theorem 8.2.6, it suffices to show $0 \notin \mathrm{spec}(\mathbf{I} + \mathbf{A})$. Suppose $(\mathbf{I} + \mathbf{A})\mathbf{v} = \mathbf{0}$ with $\mathbf{v} \neq \mathbf{0}$. Then $\mathbf{A}\mathbf{v} = -\mathbf{v}$, so $-1 \in \mathrm{spec}(\mathbf{A})$. By (a), $\mathrm{spec}(\mathbf{A}) = \{0\}$, but $-1 \neq 0$ in every field. This contradiction shows that $\mathbf{I} + \mathbf{A}$ is invertible.

Exercise C3: Real matrices of odd size.

(a) Prove that every $\mathbf{A} \in M_n(\mathbb{R})$ with n odd has a real eigenvalue.

(b) Deduce that every operator on a real vector space of dimension 3 has an invariant line.

(c) Show that (a) fails for $n = 4$: find $\mathbf{A} \in M_4(\mathbb{R})$ with no real eigenvalue.

Solution.

(a) By Theorem 6.10.2, $p_{\mathbf{A}} \in \mathbb{R}[x]$ is monic of degree n, which is odd. By Corollary 5.5.9, $p_{\mathbf{A}}(\lambda) = 0$ for some $\lambda \in \mathbb{R}$, and λ is an eigenvalue of $\mathbf{A}$ by Theorem 8.2.1.

(b) Let $\dim V = 3$ over $\mathbb{R}$ and $T \in \mathcal{L}(V)$. Choose a basis $\mathcal{B}$. By (a), the real matrix $[T]_{\mathcal{B}}$ has a real eigenvalue λ, which is a root of $p_{[T]_{\mathcal{B}}} = p_T$ (Theorem 8.2.1, Definition 6.10.2). So λ is an eigenvalue of T, again by Theorem 8.2.1, and T has an eigenvector $\mathbf{v}$ for it. By Proposition 8.1.2, $\operatorname{span}(\mathbf{v})$ is invariant.

(c) Let $\mathbf{R} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$ and $\mathbf{A} = \mathbf{R} \oplus \mathbf{R} \in M_4(\mathbb{R})$. Then $x\mathbf{I}_4 - \mathbf{A} = (x\mathbf{I}_2 - \mathbf{R}) \oplus (x\mathbf{I}_2 - \mathbf{R})$ is block diagonal, so by the block triangular determinant over $\mathbb{R}[x]$ (the remark after Theorem 6.8.4), $p_{\mathbf{A}} = p_{\mathbf{R}}^2 = (x^2+1)^2$. For real λ, $(\lambda^2+1)^2 \geq 1 > 0$, so $p_{\mathbf{A}}$ has no real root, and $\mathbf{A}$ has no real eigenvalue. The argument of (a) needs odd degree.

8.3 Algebraic and Geometric Multiplicity

An eigenvalue can be counted in two ways. It is a root of the characteristic polynomial, and a root has a multiplicity. It also has an eigenspace, and a subspace has a dimension. The two numbers need not agree, and the gap between them is exactly what can stop an operator from having a diagonal matrix. This section defines both counts, proves that the dimension never exceeds the root multiplicity, and shows that the root multiplicities package the trace and the determinant. The next section turns the comparison into a test for diagonalizability.

8.3.1 Two ways to count an eigenvalue

Compare two matrices over any field F:

$$2\mathbf{I}_2 = \begin{pmatrix} 2 & 0 \\ 0 & 2 \end{pmatrix}, \qquad \mathbf{J} = \begin{pmatrix} 2 & 1 \\ 0 & 2 \end{pmatrix}.$$

Both are triangular with diagonal $2, 2$, so both have characteristic polynomial $(x-2)^2$ and spectrum $\{2\}$. By the only measure we have so far, the eigenvalue data agree. Yet the eigenvectors are very different. For $2\mathbf{I}_2$, every non-zero vector is an eigenvector and $E_2 = F^2$. For $\mathbf{J}$, the matrix $\mathbf{J} - 2\mathbf{I} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$ kills exactly the multiples of $\mathbf{e}_1$, so $E_2(\mathbf{J}) = \operatorname{span}(\mathbf{e}_1)$ is a line. The root 2 "counts twice" in both characteristic polynomials, but it supplies two independent eigenvectors for $2\mathbf{I}_2$ and only one for $\mathbf{J}$. Both numbers deserve names.

The algebraic multiplicity counts an eigenvalue as a root; the geometric multiplicity counts the independent eigenvectors it supplies.

Definition 8.3.1 — Algebraic Multiplicity

Let V be a finite-dimensional vector space over F with $\dim V \geq 1$, let $T \in \mathcal{L}(V)$ and $\lambda \in F$. The **algebraic multiplicity** of λ for T is

$$a_T(\lambda) := \operatorname{mult}_\lambda(p_T),$$

the multiplicity of λ as a root of the characteristic polynomial (Definition 5.4.1). For $\mathbf{A} \in M_n(F)$, $a_{\mathbf{A}}(\lambda) := \operatorname{mult}_\lambda(p_{\mathbf{A}})$.

Definition 8.3.2 — Geometric Multiplicity

Let V be a finite-dimensional vector space over F, $T \in \mathcal{L}(V)$ and $\lambda \in F$. The **geometric multiplicity** of λ for T is

$$g_T(\lambda) \coloneqq \dim E_\lambda(T) = \dim \ker(T - \lambda \operatorname{id}_V).$$

For $\mathbf{A} \in M_n(F)$, $g_{\mathbf{A}}(\lambda) \coloneqq \dim E_\lambda(\mathbf{A}) = n - \operatorname{rank}(\mathbf{A} - \lambda \mathbf{I}_n)$.

When T or $\mathbf{A}$ is clear from context we write simply $a(\lambda)$ and $g(\lambda)$.

In words: $a_T(\lambda)$ is the **largest** m such that $(x-\lambda)^m$ divides p_T. It is a statement about a polynomial and can be computed by factoring. $g_T(\lambda)$ is the dimension of the subspace of solutions of $T\mathbf{v} = \lambda\mathbf{v}$, including $\mathbf{0}$. It is the largest number of **linearly independent** eigenvectors for λ, not the number of eigenvectors, which is infinite over an infinite field. For matrices the second formula comes from Theorem 2.5.7 applied to $\mathbf{A} - \lambda\mathbf{I}_n$, and it is the one we compute with: find the rank of $\mathbf{A} - \lambda\mathbf{I}$ by elimination and subtract from n.

Well-definedness. Both numbers are defined for every $\lambda \in F$, eigenvalue or not. By Theorem 8.2.1, λ is an eigenvalue if and only if $p_T(\lambda) = 0$, if and only if $a_T(\lambda) \geq 1$; and by Definition 8.2.1, if and only if $E_\lambda(T) \neq \{\mathbf{0}\}$, that is, $g_T(\lambda) \geq 1$. So for a scalar that is not an eigenvalue both multiplicities are 0, and for an eigenvalue both are at least 1. Neither depends on a basis: p_T does not (Definition 6.10.2), and $E_\lambda(T)$ is defined without one. If $\mathcal{B}$ is a basis of V, then $a_T(\lambda) = a_{[T]_\mathcal{B}}(\lambda)$ because $p_T = p_{[T]_\mathcal{B}}$, and $g_T(\lambda) = g_{[T]_\mathcal{B}}(\lambda)$ because the coordinate map is an isomorphism from $\ker(T - \lambda \operatorname{id}_V)$ onto $\operatorname{nul}([T]_\mathcal{B} - \lambda\mathbf{I})$ (Theorem 3.6.5 (a) and Corollary 3.6.3).

Examples.

- **The hook.** For $2\mathbf{I}_2$: $a(2) = 2$ and $g(2) = 2 - \operatorname{rank} 0 = 2$. For $\mathbf{J}$: $a(2) = 2$ and $g(2) = 2 - \operatorname{rank}\begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} = 1$.
- **A 1×1 matrix.** For $\mathbf{A} = (c)$, $p_{\mathbf{A}} = x - c$, so $a(c) = 1$, and $\mathbf{A} - c\mathbf{I} = (0)$ has rank 0, so $g(c) = 1$. This degenerate case already shows the pattern of the theorem below: the two counts can only differ when there is room, a repeated root.
- **Differentiation.** On $V = \mathbb{R}[x]_{\leq n}$, the matrix of D in the basis $(1, x, \ldots, x^n)$ is strictly upper triangular, so $p_D = x^{n+1}$ and $a_D(0) = n + 1$. But $E_0(D)$ is the line of constant polynomials (the examples after Definition 8.2.2), so $g_D(0) = 1$. The gap can be as large as n.
- **A matrix from Chapter 6.** For $\mathbf{A} = \begin{pmatrix} 2 & 0 & 1 \\ 1 & 3 & 1 \\ 1 & 0 & 2 \end{pmatrix}$, Example (A 3×3 Characteristic Polynomial) found $p_{\mathbf{A}} = (x-1)(x-3)^2$, so $a(1) = 1$ and $a(3) = 2$. The matrix $\mathbf{A} - 3\mathbf{I} = \begin{pmatrix} -1 & 0 & 1 \\ 1 & 0 & 1 \\ 1 & 0 & -1 \end{pmatrix}$ has a zero column, and its first two rows are independent while the third is minus the first, so its rank is 2 and $g(3) = 3 - 2 = 1$. Similarly $\mathbf{A} - \mathbf{I} = \begin{pmatrix} 1 & 0 & 1 \\ 1 & 2 & 1 \\ 1 & 0 & 1 \end{pmatrix}$ has third row equal to the first and first two rows independent, so its rank is 2 and $g(1) = 1$.

Minimal change. Take the triangular matrices

$$\mathbf{B} = \begin{pmatrix} 2 & 0 & 1 \\ 0 & 2 & 0 \\ 0 & 0 & 1 \end{pmatrix}, \qquad \mathbf{B}' = \begin{pmatrix} 2 & 1 & 1 \\ 0 & 2 & 0 \\ 0 & 0 & 1 \end{pmatrix},$$

which differ in one entry. Both have $p = (x-2)^2(x-1)$, so $a(2) = 2$ for both: the algebraic multiplicity does not notice the change. But $\mathbf{B} - 2\mathbf{I}$ has non-zero rows $(0,0,1)$ and $(0,0,-1)$, rank 1, so $g_{\mathbf{B}}(2) = 2$; while $\mathbf{B}' - 2\mathbf{I}$ has rows $(0,1,1)$ and $(0,0,-1)$, rank 2, so $g_{\mathbf{B}'}(2) = 1$. One off-diagonal entry, invisible to p, removed an eigenvector.

Why these definitions. The algebraic multiplicity is the natural count for a polynomial: with it, the roots of p_T add up to $\deg p_T = \dim V$ whenever p_T splits (Theorem 5.4.3), and the trace and determinant come out right (Theorem 8.3.3 below). The geometric multiplicity is the natural count for eigenvectors: it is the number of basis vectors we can take from $E_\lambda(T)$ when we try to build a basis of eigenvectors. The names record where each number lives, in algebra (a polynomial) or in geometry (a subspace).

Warning. **The geometric multiplicity is not read off from p_T.** Two operators with the same characteristic polynomial can have different geometric multiplicities: $2\mathbf{I}_2$ and $\mathbf{J}$ above, or $\mathbf{B}$ and $\mathbf{B}'$. To find $g(\lambda)$ you must compute $\operatorname{rank}(\mathbf{A} - \lambda\mathbf{I})$. Also, $g(\lambda)$ is **not** "how many eigenvectors" λ has: over $\mathbb{R}$, $E_\lambda \neq \{\mathbf{0}\}$ always contains infinitely many eigenvectors.

Quick check. Find $a(0)$ and $g(0)$ for $\mathbf{N} = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} \in M_3(F)$.

Solution. $\mathbf{N}$ is triangular with zero diagonal, so $p_{\mathbf{N}} = x^3$ and $a(0) = 3$. The rank of $\mathbf{N} - 0\mathbf{I} = \mathbf{N}$ is 1, so $g(0) = 3 - 1 = 2$, with $E_0(\mathbf{N}) = \operatorname{span}(\mathbf{e}_1, \mathbf{e}_3)$.

8.3.2 The geometric multiplicity never exceeds the algebraic

In every example so far, $g(\lambda) \le a(\lambda)$. That is always the case.

Theorem 8.3.1 — Geometric Multiplicity Is at Most Algebraic Multiplicity

Let V be a finite-dimensional vector space over F with $\dim V = n \ge 1$, let $T \in \mathcal{L}(V)$, and let $\lambda \in F$ be an eigenvalue of T. Then

$$1 \le g_T(\lambda) \le a_T(\lambda).$$

Idea. Start from the smallest subspace in sight, $E_\lambda(T)$. Take a basis of it and extend it to a basis of V. In that basis, the first g columns of the matrix are $\lambda\mathbf{e}_1, \dots, \lambda\mathbf{e}_g$, so the matrix is block upper triangular with top-left block $\lambda\mathbf{I}_g$. The block triangular determinant then factors $(x-\lambda)^g$ out of p_T, and a root with a factor $(x-\lambda)^g$ has multiplicity at least g. The inequality can be strict because the other block may contribute further

factors $x - \lambda$, as it does for $\mathbf{J}$.

Proof. Since λ is an eigenvalue, $E_\lambda(T) \neq \{\mathbf{0}\}$, so $g = g_T(\lambda) \geq 1$. Let $(\mathbf{v}_1, \ldots, \mathbf{v}_g)$ be a basis of $E_\lambda(T)$. By Theorem 1.6.5, it extends to a basis $\mathcal{B} = (\mathbf{v}_1, \ldots, \mathbf{v}_g, \mathbf{w}_1, \ldots, \mathbf{w}_{n-g})$ of V.

Case $g = n$. Then $T\mathbf{v}_i = \lambda \mathbf{v}_i$ for every basis vector, so $[T]_\mathcal{B} = \lambda \mathbf{I}_n$ by Definition 3.6.1, and $p_T = (x - \lambda)^n$ by the triangular case of Definition 6.10.1. Hence $a_T(\lambda) = n = g$.

Case $g < n$. For $i \leq g$, $T\mathbf{v}_i = \lambda \mathbf{v}_i$, so column i of $[T]_\mathcal{B}$ is $\lambda \mathbf{e}_i$. Hence

$$[T]_\mathcal{B} = \begin{pmatrix} \lambda \mathbf{I}_g & \mathbf{B} \\ 0 & \mathbf{D} \end{pmatrix}, \qquad x\mathbf{I}_n - [T]_\mathcal{B} = \begin{pmatrix} (x-\lambda)\mathbf{I}_g & -\mathbf{B} \\ 0 & x\mathbf{I}_{n-g} - \mathbf{D} \end{pmatrix},$$

for some $\mathbf{B} \in M_{g \times (n-g)}(F)$ and $\mathbf{D} \in M_{n-g}(F)$. The second matrix is block upper triangular over $F[x]$ with square diagonal blocks. By Theorem 6.8.4, which holds over the commutative ring $F[x]$ (the remark after it), and Definition 6.10.2,

$$p_T = \det\big((x-\lambda)\mathbf{I}_g\big)\, \det(x\mathbf{I}_{n-g} - \mathbf{D}) = (x-\lambda)^g\, p_\mathbf{D},$$

where $\det((x-\lambda)\mathbf{I}_g) = (x-\lambda)^g$ because the matrix is diagonal. So $(x-\lambda)^g \mid p_T$. By Definition 5.4.1, $a_T(\lambda)$, the **largest** m with $(x-\lambda)^m \mid p_T$, satisfies $a_T(\lambda) \geq g$. This proves the theorem. ∎

The inequality is strict exactly when λ is also a root of $p_\mathbf{D}$, the characteristic polynomial of the "rest" of the operator. For $\mathbf{J}$, with $\mathcal{B} = (\mathbf{e}_1, \mathbf{e}_2)$, the block $\mathbf{D}$ is (2), and $p_\mathbf{D} = x - 2$ contributes the second factor.

A useful consequence: if $a(\lambda) = 1$, then $g(\lambda) = 1$. A **simple** root of p_T always has a one-dimensional eigenspace, and so the only eigenvalues whose eigenspaces need checking are the repeated ones.

Both multiplicities are properties of the operator, not of the basis, so they cannot distinguish similar matrices. That makes them tools for proving that two matrices are **not** similar.

Proposition 8.3.2 — Similar Matrices Have the Same Multiplicities

Let $\mathbf{A}, \mathbf{B} \in M_n(F)$ with $\mathbf{A} \sim \mathbf{B}$, and let $\lambda \in F$. Then $a_\mathbf{A}(\lambda) = a_\mathbf{B}(\lambda)$ and $g_\mathbf{A}(\lambda) = g_\mathbf{B}(\lambda)$.

Proof. Let $\mathbf{B} = \mathbf{P}^{-1}\mathbf{A}\mathbf{P}$. By Theorem 6.10.3, $p_\mathbf{A} = p_\mathbf{B}$, so the algebraic multiplicities agree. Also $\mathbf{B} - \lambda\mathbf{I} = \mathbf{P}^{-1}\mathbf{A}\mathbf{P} - \lambda\mathbf{P}^{-1}\mathbf{P} = \mathbf{P}^{-1}(\mathbf{A} - \lambda\mathbf{I})\mathbf{P}$, so $\mathbf{B} - \lambda\mathbf{I} \sim \mathbf{A} - \lambda\mathbf{I}$, and these have the same rank by Proposition 3.7.6 (a). Hence $g_\mathbf{B}(\lambda) = n - \operatorname{rank}(\mathbf{B} - \lambda\mathbf{I}) = n - \operatorname{rank}(\mathbf{A} - \lambda\mathbf{I}) = g_\mathbf{A}(\lambda)$. ∎

For example, $2\mathbf{I}_2$ and $\mathbf{J}$ have the same characteristic polynomial but $g(2) = 2$ versus $g(2) = 1$, so they are not similar. The same test shows $\mathbf{B} \not\sim \mathbf{B}'$ in the minimal change above.

Warning. **A repeated eigenvalue does not force a shortage of eigenvectors, and equal eigenvalues do not force similarity.** The identity $\mathbf{I}_2$ has the repeated eigenvalue 1, yet $g(1) = a(1) = 2$ and its matrix is as simple as possible. In the other direction, $\mathbf{I}_2$ and $\begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$ have the same eigenvalues with the same algebraic multiplicities, and they are not similar. Even agreement of **both** multiplicities for every eigenvalue does not force similarity; Exercise (C2: Multiplicities do not determine similarity) gives two 4×4 matrices showing this.

8.3.3 Multiplicities, trace and determinant

By Theorem 5.4.3, the algebraic multiplicities of the eigenvalues of T add up to at most $\deg p_T = \dim V$, with equality exactly when p_T splits over F. Over $\mathbb{C}$ this always happens (Corollary 5.5.5). When it does, p_T is determined by the eigenvalues and their algebraic multiplicities,

$$p_T = (x - \lambda_1)^{a(\lambda_1)} \cdots (x - \lambda_k)^{a(\lambda_k)},$$

and two of its coefficients are familiar: by Theorem 6.10.2, the coefficient of x^{n-1} is $-\operatorname{tr} T$ and the constant term is $(-1)^n \det T$. Comparing the two descriptions expresses trace and determinant through eigenvalues.

Theorem 8.3.3 — Trace and Determinant from Eigenvalues

Let V be a finite-dimensional vector space over F with $\dim V = n \geq 1$, and let $T \in \mathcal{L}(V)$. Suppose p_T splits over F, and let $\lambda_1, \ldots, \lambda_k$ be the distinct eigenvalues of T. Then

$$a(\lambda_1) + \cdots + a(\lambda_k) = n, \qquad \operatorname{tr} T = \sum_{i=1}^{k} a(\lambda_i)\, \lambda_i, \qquad \det T = \prod_{i=1}^{k} \lambda_i^{a(\lambda_i)}.$$

In words: listing each eigenvalue as often as its algebraic multiplicity, the trace is the sum of the list and the determinant is its product. In particular this holds for every operator on a non-zero finite-dimensional complex space, and for every $\mathbf{A} \in M_n(\mathbb{C})$.

Idea. Rather than expanding a product of linear factors by hand, notice that the product is itself a characteristic polynomial: that of the diagonal matrix with the eigenvalues on its diagonal. Chapter 6 already knows the x^{n-1} coefficient and the constant term of any characteristic polynomial, so we read them off twice and compare.

Proof. Since p_T splits and is monic of degree n (Theorem 6.10.2), Definition 5.4.2 gives $p_T = (x - c_1) \cdots (x - c_n)$ for some $c_1, \ldots, c_n \in F$. For $c, \lambda \in F$, the polynomial $x - c$ has $\operatorname{mult}_\lambda(x - c) = 1$ if $c = \lambda$ and 0 otherwise, since λ is a root of $x - c$ only when $c = \lambda$ (Theorem 5.1.3). So by Theorem 5.4.2, $\operatorname{mult}_\lambda(p_T) = \sum_j \operatorname{mult}_\lambda(x - c_j)$ is the number of indices j with $c_j = \lambda$. In particular the values occurring among $c_1, \ldots, c_n$ are exactly the roots of p_T in F, which are $\lambda_1, \ldots, \lambda_k$ by Theorem 8.2.1, and λ_i occurs exactly $a(\lambda_i)$ times. Counting the n factors gives $\sum_i a(\lambda_i) = n$, and

$$c_1 + \cdots + c_n = \sum_i a(\lambda_i)\lambda_i, \qquad c_1 \cdots c_n = \prod_i \lambda_i^{a(\lambda_i)}.$$

Let $\mathbf{C} = \operatorname{diag}(c_1, \ldots, c_n)$. It is triangular, so $p_{\mathbf{C}} = (x - c_1) \cdots (x - c_n) = p_T$ (the examples

after Definition 6.10.1). Apply Theorem 6.10.2 to both $\mathbf{C}$ and T: the coefficient of x^{n-1} in this one polynomial is $-\operatorname{tr}\mathbf{C} = -(c_1 + \cdots + c_n)$ and also $-\operatorname{tr}T$; the constant term is $(-1)^n \det\mathbf{C} = (-1)^n c_1 \cdots c_n$ (Theorem 6.4.6) and also $(-1)^n \det T$. Hence $\operatorname{tr}T = c_1 + \cdots + c_n$ and $\det T = c_1 \cdots c_n$, which are the displayed formulas. The complex case follows from Corollary 5.5.5.

■

Examples.

- For $\mathbf{A} = \begin{pmatrix} 2 & 0 & 1 \\ 1 & 3 & 1 \\ 1 & 0 & 2 \end{pmatrix}$, with $a(1) = 1$ and $a(3) = 2$: $\operatorname{tr}\mathbf{A} = 2 + 3 + 2 = 7 = 1 + 3 + 3$, and $\det\mathbf{A} = 9 = 1 \cdot 3 \cdot 3$.
- For the real matrix $\begin{pmatrix} 3 & -2 \\ 4 & -1 \end{pmatrix}$ of Example (A Real Matrix with Non-Real Eigenvalues), p does not split over $\mathbb{R}$, but it splits over $\mathbb{C}$ with roots $1 \pm 2i$. The theorem over $\mathbb{C}$ gives $(1 + 2i) + (1 - 2i) = 2 = \operatorname{tr}\mathbf{A}$ and $(1 + 2i)(1 - 2i) = 1 + 4 = 5 = \det\mathbf{A}$. The trace and determinant are real, while the eigenvalues are not.
- For a 2×2 matrix whose characteristic polynomial splits, the theorem says the eigenvalues λ, μ (listed with multiplicity) satisfy $\lambda + \mu = \operatorname{tr}\mathbf{A}$ and $\lambda\mu = \det\mathbf{A}$. This is a quick way to guess eigenvalues: for $\begin{pmatrix} 1 & 2 \\ 3 & 2 \end{pmatrix}$, we want two numbers with sum 3 and product -4, namely 4 and -1.

Without splitting, the theorem says nothing. If p_T does not split, the eigenvalues in F, counted with algebraic multiplicity, do not account for all of p_T, and summing or multiplying them gives no information. For $\mathbf{A} = \begin{pmatrix} 3 & -2 \\ 4 & -1 \end{pmatrix}$ over $\mathbb{R}$ there are no eigenvalues: the multiplicities add up to $0 \neq 2$, the empty sum 0 is not $\operatorname{tr}\mathbf{A} = 2$, and the empty product 1 is not $\det\mathbf{A} = 5$. For the real rotation $\begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$, with trace 0 and determinant 1, the empty sum and product happen to give the right values, but only by coincidence. For real matrices the remedy is to pass to $\mathbb{C}$, where $p_{\mathbf{A}}$ always splits, as in the second example above.

8.3.4 Exercises

8.3.4.1 A. Check your understanding

Exercise A1.

(a) Define the algebraic and the geometric multiplicity of $\lambda \in F$ for $\mathbf{A} \in M_n(F)$.

(b) State the inequality between them for an eigenvalue λ, and name the tool its proof uses.

(c) True or false: if $a(\lambda) = 1$, then $g(\lambda) = 1$. Justify your answer.

(d) True or false: for every $\mathbf{A} \in M_n(\mathbb{C})$, the geometric multiplicities of the eigenvalues add up to n. Justify your answer.

(e) True or false: if $\mathbf{A}, \mathbf{B} \in M_n(F)$ have the same characteristic polynomial, then $g_{\mathbf{A}}(\lambda) = g_{\mathbf{B}}(\lambda)$ for every λ. Justify your answer.

(f) For $\mathbf{A} \in M_3(\mathbb{C})$ with eigenvalues 2 (algebraic multiplicity 2) and -1, what are

tr $\mathbf{A}$ and det $\mathbf{A}$?

Solution.

(a) $a_{\mathbf{A}}(\lambda) = \text{mult}_\lambda(p_{\mathbf{A}})$, the largest m with $(x-\lambda)^m \mid p_{\mathbf{A}}$; $g_{\mathbf{A}}(\lambda) = \dim E_\lambda(\mathbf{A}) = n - \text{rank}(\mathbf{A} - \lambda\mathbf{I})$ (Definition 8.3.1, Definition 8.3.2).

(b) $1 \le g(\lambda) \le a(\lambda)$ (Theorem 8.3.1). The proof extends a basis of E_λ to a basis of the space and uses the block triangular determinant (Theorem 6.8.4) over $F[x]$.

(c) True. An eigenvalue has $g(\lambda) \ge 1$, and $g(\lambda) \le a(\lambda) = 1$.

(d) False. For $\mathbf{J} = \begin{pmatrix} 2 & 1 \\ 0 & 2 \end{pmatrix}$, the only eigenvalue is 2, with $g(2) = 1 \neq 2$. (The **algebraic** multiplicities do add up to n over $\mathbb{C}$.)

(e) False. $2\mathbf{I}_2$ and $\mathbf{J}$ both have $p = (x-2)^2$, but $g(2) = 2$ and $g(2) = 1$.

(f) By Theorem 8.3.3, listing eigenvalues with algebraic multiplicity as $2, 2, -1$: tr $\mathbf{A} = 3$ and det $\mathbf{A} = -4$.

8.3.4.2 B. Practice

Exercise B1: Computing multiplicities.

For each real matrix, find every eigenvalue together with its algebraic and geometric multiplicity.

(a) $\mathbf{A}_1 = \begin{pmatrix} 4 & -1 \\ 1 & 2 \end{pmatrix}$.

(b) $\mathbf{A}_2 = \begin{pmatrix} 2 & 1 & 1 \\ 0 & 1 & -1 \\ -1 & -1 & 1 \end{pmatrix}$.

(c) $\mathbf{A}_3 = \begin{pmatrix} 2 & 1 & 1 \\ -1 & 0 & -1 \\ 1 & 1 & 2 \end{pmatrix}$, given that $p_{\mathbf{A}_3} = p_{\mathbf{A}_2}$.

(d) The matrix of the operator $S(q)(x) = q(x+1)$ on $\mathbb{R}[x]_{\le 2}$, in the basis $(1, x, x^2)$.

Solution.

(a) tr $\mathbf{A}_1 = 6$, det $\mathbf{A}_1 = 8 + 1 = 9$, so $p = x^2 - 6x + 9 = (x-3)^2$: the only eigenvalue is 3, with $a(3) = 2$. $\mathbf{A}_1 - 3\mathbf{I} = \begin{pmatrix} 1 & -1 \\ 1 & -1 \end{pmatrix}$ has rank 1, so $g(3) = 1$.

(b) Expand $\det(x\mathbf{I} - \mathbf{A}_2)$ along the first column:

$$\det \begin{pmatrix} x-2 & -1 & -1 \\ 0 & x-1 & 1 \\ 1 & 1 & x-1 \end{pmatrix} = (x-2)\big[(x-1)^2 - 1\big] + 1 \cdot \det \begin{pmatrix} -1 & -1 \\ x-1 & 1 \end{pmatrix}.$$

The first bracket is $x^2 - 2x = x(x-2)$ and the last determinant is $-1 + (x-1) = x-2$, so $p_{\mathbf{A}_2} = (x-2)(x^2 - 2x + 1) = (x-1)^2(x-2)$. Thus $a(1) = 2$ and $a(2) = 1$. By

Theorem 8.3.1, $g(2) = 1$. For $\lambda = 1$,

$$\mathbf{A}_2 - \mathbf{I} = \begin{pmatrix} 1 & 1 & 1 \\ 0 & 0 & -1 \\ -1 & -1 & 0 \end{pmatrix}.$$

Row 3 is $-$(row 1) $-$ (row 2), and rows 1 and 2 are independent, so the rank is 2 and $g(1) = 1$.

(c) Here $a(1) = 2$ and $a(2) = 1$, as for $\mathbf{A}_2$, so $g(2) = 1$. Now

$$\mathbf{A}_3 - \mathbf{I} = \begin{pmatrix} 1 & 1 & 1 \\ -1 & -1 & -1 \\ 1 & 1 & 1 \end{pmatrix}$$

has all rows multiples of $(1, 1, 1)$, so its rank is 1 and $g(1) = 2$. By Proposition 8.3.2, $\mathbf{A}_2$ and $\mathbf{A}_3$ are not similar, although they have the same characteristic polynomial.

(d) $S(1) = 1$, $S(x) = 1 + x$, $S(x^2) = 1 + 2x + x^2$, so the matrix is $\begin{pmatrix} 1 & 1 & 1 \\ 0 & 1 & 2 \\ 0 & 0 & 1 \end{pmatrix}$ (as in Example (Characteristic Polynomials of Two Operators)). It is triangular, so $p = (x-1)^3$ and $a(1) = 3$. The matrix minus $\mathbf{I}$ is $\begin{pmatrix} 0 & 1 & 1 \\ 0 & 0 & 2 \\ 0 & 0 & 0 \end{pmatrix}$, of rank 2, so $g(1) = 1$: the only polynomials with $q(x+1) = q(x)$ in $\mathbb{R}[x]_{\leq 2}$ are the constants.

Exercise B2: A parameter that merges eigenvalues.

For $t \in \mathbb{R}$, let $\mathbf{A}_t = \begin{pmatrix} t & 1 \\ -1 & 3 \end{pmatrix}$. Find all t for which $\mathbf{A}_t$ has a real eigenvalue λ with $g(\lambda) < a(\lambda)$.

Solution. $\operatorname{tr} \mathbf{A}_t = t + 3$ and $\det \mathbf{A}_t = 3t + 1$, so $p(x) = x^2 - (t+3)x + (3t+1)$. For a 2×2 matrix, $g(\lambda) < a(\lambda)$ is possible only if $a(\lambda) = 2$, because $a(\lambda) = 1$ forces $g(\lambda) = 1$ (Theorem 8.3.1). So p must have a repeated real root, which happens exactly when its discriminant vanishes:

$$(t+3)^2 - 4(3t+1) = t^2 - 6t + 5 = (t-1)(t-5) = 0.$$

If $t = 1$, then $p = x^2 - 4x + 4 = (x-2)^2$ and $\mathbf{A}_1 - 2\mathbf{I} = \begin{pmatrix} -1 & 1 \\ -1 & 1 \end{pmatrix}$, of rank 1, so $g(2) = 1 < 2 = a(2)$. If $t = 5$, then $p = (x-4)^2$ and $\mathbf{A}_5 - 4\mathbf{I} = \begin{pmatrix} 1 & 1 \\ -1 & -1 \end{pmatrix}$, of rank 1, so $g(4) = 1 < 2$. Hence the answer is $t \in \{1, 5\}$. (In both cases $g = a$ was impossible anyway: $g(\lambda) = 2$ would mean $\mathbf{A}_t - \lambda\mathbf{I} = 0$, but the off-diagonal entries of $\mathbf{A}_t$ are non-zero.)

Exercise B3: Eigenvalues from trace and determinant.

(a) Let $\mathbf{A} \in M_3(\mathbb{R})$ have the eigenvalue $1 + i$ (as a complex matrix) and $\det \mathbf{A} = 6$. Find all eigenvalues of $\mathbf{A}$ over $\mathbb{C}$, and $\operatorname{tr} \mathbf{A}$.

(b) Let $\mathbf{B} \in M_2(\mathbb{R})$ with $\operatorname{tr}\mathbf{B} = 6$ and $\det\mathbf{B} = 9$. Show that $\operatorname{spec}(\mathbf{B}) = \{3\}$ with $a(3) = 2$. Give one such $\mathbf{B}$ with $g(3) = 2$ and one with $g(3) = 1$.

Solution.

(a) By Theorem 8.2.5, $1 - i$ is also an eigenvalue. By Corollary 5.5.5, $p_{\mathbf{A}}$ splits over $\mathbb{C}$ into three linear factors, and two of them are $x - (1 + i)$ and $x - (1 - i)$; let μ be the third root. By Theorem 8.3.3, $6 = \det\mathbf{A} = (1 + i)(1 - i)\mu = 2\mu$, so $\mu = 3$. Hence the eigenvalues are $1 + i, 1 - i, 3$, and $\operatorname{tr}\mathbf{A} = (1 + i) + (1 - i) + 3 = 5$.

(b) By Theorem 6.10.2, $p_{\mathbf{B}} = x^2 - 6x + 9 = (x - 3)^2$. So $\operatorname{spec}(\mathbf{B}) = \{3\}$ and $a(3) = 2$. For $\mathbf{B} = 3\mathbf{I}_2$, $g(3) = 2$. For $\mathbf{B} = \begin{pmatrix} 4 & -1 \\ 1 & 2 \end{pmatrix}$ of Exercise (B1: Computing multiplicities) (a), $\operatorname{tr}\mathbf{B} = 6$, $\det\mathbf{B} = 9$ and $g(3) = 1$.

8.3.4.3 C. Going deeper

Exercise C1: Nilpotent matrices.

Let $\mathbf{A} \in M_n(\mathbb{C})$, $n \geq 1$, be nilpotent ($\mathbf{A}^k = 0$ for some $k \geq 1$).

(a) Prove that $a(0) = n$ and $g(0) = n - \operatorname{rank}\mathbf{A}$.

(b) Deduce that $g(0) = a(0)$ if and only if $\mathbf{A} = 0$.

(c) For $\mathbf{N} = \begin{pmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \end{pmatrix}$, check that $\mathbf{N}^4 = 0$ and compute $g(0)$. How large can $a(0) - g(0)$ be for a nilpotent $n \times n$ matrix?

Solution.

(a) By Exercise (C2: Nilpotent operators) (b), $p_{\mathbf{A}} = x^n$, so $a(0) = \operatorname{mult}_0(x^n) = n$. By Definition 8.3.2, $g(0) = n - \operatorname{rank}(\mathbf{A} - 0\mathbf{I}) = n - \operatorname{rank}\mathbf{A}$.

(b) By (a), $g(0) = a(0)$ if and only if $n - \operatorname{rank}\mathbf{A} = n$, that is, $\operatorname{rank}\mathbf{A} = 0$, that is, $\mathbf{A} = 0$ (a matrix of rank 0 has no non-zero column).

(c) $\mathbf{N}\mathbf{e}_1 = \mathbf{0}$ and $\mathbf{N}\mathbf{e}_j = \mathbf{e}_{j-1}$ for $j \geq 2$. So $\mathbf{N}^j\mathbf{e}_i = \mathbf{0}$ once $j \geq i$, and $\mathbf{N}^4\mathbf{e}_i = \mathbf{0}$ for $i \leq 4$; hence $\mathbf{N}^4 = 0$. The columns of $\mathbf{N}$ are $\mathbf{0}, \mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3$, so $\operatorname{rank}\mathbf{N} = 3$ and $g(0) = 1$, while $a(0) = 4$. In general, a nilpotent $\mathbf{A}$ has $0 \in \operatorname{spec}(\mathbf{A})$ (Exercise (C2: Nilpotent operators) (a)), so $g(0) \geq 1$ and $a(0) - g(0) \leq n - 1$; the $n \times n$ analogue of $\mathbf{N}$, with ones just above the diagonal, has rank $n - 1$ and attains $a(0) - g(0) = n - 1$.

Exercise C2: Multiplicities do not determine similarity.

Let

$$\mathbf{M}_1 = \begin{pmatrix} 1 & 1 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 1 \end{pmatrix}, \qquad \mathbf{M}_2 = \begin{pmatrix} 1 & 1 & 0 & 0 \\ 0 & 1 & 1 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} \in M_4(\mathbb{R}).$$

(a) Show that $\mathbf{M}_1$ and $\mathbf{M}_2$ have the same eigenvalues with the same algebraic **and** geometric multiplicities.

(b) Compute $\operatorname{rank}(\mathbf{M}_1 - \mathbf{I})^2$ and $\operatorname{rank}(\mathbf{M}_2 - \mathbf{I})^2$. Deduce that $\mathbf{M}_1 \not\sim \mathbf{M}_2$.

(c) Construct a matrix $\mathbf{M} \in M_4(\mathbb{R})$ with $\operatorname{spec}(\mathbf{M}) = \{2, 5\}$, $a(2) = 3$, $g(2) = 1$, and $a(5) = g(5) = 1$.

Hint: for (b), if $\mathbf{B} = \mathbf{P}^{-1}\mathbf{A}\mathbf{P}$, *relate* $(\mathbf{B} - \mathbf{I})^2$ *to* $(\mathbf{A} - \mathbf{I})^2$.

Solution.

(a) Both matrices are upper triangular with diagonal $1, 1, 1, 1$, so both have $p = (x - 1)^4$, spectrum $\{1\}$ and $a(1) = 4$. The matrix $\mathbf{M}_1 - \mathbf{I}$ has columns $\mathbf{0}, \mathbf{e}_1, \mathbf{0}, \mathbf{e}_3$, of rank 2; $\mathbf{M}_2 - \mathbf{I}$ has columns $\mathbf{0}, \mathbf{e}_1, \mathbf{e}_2, \mathbf{0}$, also of rank 2. So $g(1) = 4 - 2 = 2$ for both.

(b) Let $\mathbf{N}_1 = \mathbf{M}_1 - \mathbf{I}$, so $\mathbf{N}_1\mathbf{e}_2 = \mathbf{e}_1$, $\mathbf{N}_1\mathbf{e}_4 = \mathbf{e}_3$ and $\mathbf{N}_1\mathbf{e}_1 = \mathbf{N}_1\mathbf{e}_3 = \mathbf{0}$. Then $\mathbf{N}_1^2$ kills every $\mathbf{e}_j$, so $\mathbf{N}_1^2 = 0$ and $\operatorname{rank}\mathbf{N}_1^2 = 0$. Let $\mathbf{N}_2 = \mathbf{M}_2 - \mathbf{I}$, so $\mathbf{N}_2\mathbf{e}_2 = \mathbf{e}_1$, $\mathbf{N}_2\mathbf{e}_3 = \mathbf{e}_2$, and $\mathbf{N}_2\mathbf{e}_1 = \mathbf{N}_2\mathbf{e}_4 = \mathbf{0}$. Then $\mathbf{N}_2^2\mathbf{e}_3 = \mathbf{e}_1 \neq \mathbf{0}$ and $\mathbf{N}_2^2$ kills $\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_4$, so $\mathbf{N}_2^2 = \mathbf{E}_{13}$ has rank 1.
Suppose $\mathbf{M}_2 = \mathbf{P}^{-1}\mathbf{M}_1\mathbf{P}$. With $p(x) = (x - 1)^2$, Proposition 3.7.6 (c) gives $(\mathbf{M}_2 - \mathbf{I})^2 = \mathbf{P}^{-1}(\mathbf{M}_1 - \mathbf{I})^2\mathbf{P}$, and then (a) of the same proposition gives equal ranks, $1 = 0$. This contradiction shows $\mathbf{M}_1 \not\sim \mathbf{M}_2$. So eigenvalues together with both multiplicities do not determine a matrix up to similarity; Chapter 9 finds invariants that do.

(c) Take

$$\mathbf{M} = \begin{pmatrix} 2 & 1 & 0 & 0 \\ 0 & 2 & 1 & 0 \\ 0 & 0 & 2 & 0 \\ 0 & 0 & 0 & 5 \end{pmatrix}.$$

It is triangular, so $p_{\mathbf{M}} = (x - 2)^3(x - 5)$, $a(2) = 3$ and $a(5) = 1$, hence $g(5) = 1$ by Theorem 8.3.1. The matrix $\mathbf{M} - 2\mathbf{I}$ has columns $\mathbf{0}, \mathbf{e}_1, \mathbf{e}_2, 3\mathbf{e}_4$, which has rank 3, so $g(2) = 4 - 3 = 1$.

8.4 Diagonalization

We can now answer the question of Chapter 3 in the best case. An operator has a diagonal matrix in some basis exactly when there are enough eigenvectors to form a basis, and the previous two sections give precise ways to count "enough": by dimensions of eigenspaces, or by comparing geometric with algebraic multiplicities. This section proves that these tests agree, shows how to find the diagonalizing basis for a concrete matrix, and uses it to compute powers. The payoff is a closed formula for the Fibonacci numbers. We also meet the operators for which the method fails, and see that the field is part of the answer.

8.4.1 Diagonalizable operators

Chapter 3 introduced similarity to compare the matrices of one operator in different bases (Theorem 3.7.4), and asked for the simplest representative. Section 2 unwound the wish "$[T]_{\mathcal{B}}$

is diagonal" and found that it says exactly that every vector of $\mathcal{B}$ is an eigenvector. Diagonal matrices are the matrices we can compute with most easily: they add, multiply, power and invert entry by entry. So the operators that admit such a basis deserve a name.

An operator is diagonalizable when some basis consists of vectors that the operator only stretches.

Definition 8.4.1 — Diagonalizable

Let V be a finite-dimensional vector space over F. An operator $T \in \mathcal{L}(V)$ is **diagonalizable** if there **exists** a basis $\mathcal{B}$ of V such that $[T]_{\mathcal{B}}$ is a diagonal matrix.

A matrix $\mathbf{A} \in M_n(F)$ is **diagonalizable over** F if it is similar to a diagonal matrix: there **exist** an **invertible** $\mathbf{P} \in M_n(F)$ and a diagonal $\mathbf{D} \in M_n(F)$ with $\mathbf{P}^{-1}\mathbf{A}\mathbf{P} = \mathbf{D}$, equivalently $\mathbf{A} = \mathbf{P}\mathbf{D}\mathbf{P}^{-1}$.

In words: for an operator, we are free to choose **any** basis, and we ask whether **one** of them makes the matrix diagonal; most bases will not. For a matrix, the change-of-basis matrix $\mathbf{P}$ and the diagonal entries of $\mathbf{D}$ must both have entries **in** F. The two notions match: $\mathbf{A}$ is diagonalizable over F if and only if $T_{\mathbf{A}} \in \mathcal{L}(F^n)$ is diagonalizable, by Theorem 3.7.4 (c), because the matrices of $T_{\mathbf{A}}$ in the bases of F^n are exactly the matrices similar to $\mathbf{A}$. Likewise, T is diagonalizable if and only if $[T]_{\mathcal{C}}$ is diagonalizable for one, equivalently every, basis $\mathcal{C}$ of V, by Theorem 3.7.4 (a) and (b).

Examples.

- **Diagonal matrices** are diagonalizable, with $\mathbf{P} = \mathbf{I}$. So is every scalar operator $c\,\mathrm{id}_V$, whose matrix is $c\mathbf{I}$ in every basis.
- **The degenerate cases.** Every 1×1 matrix is diagonal. On $V = \{\mathbf{0}\}$, the empty basis gives the empty matrix, which counts as diagonal. These cases are harmless, but they remind us that diagonalizability is a question about repeated eigenvalues and missing eigenvectors, which need room to occur.
- $\mathbf{A}$ 2×2 **matrix.** In Example (Eigenvalues and Eigenspaces of a 2×2 Matrix), $\mathbf{A} = \begin{pmatrix} 1 & 2 \\ 3 & 2 \end{pmatrix}$ has eigenvectors $(2, 3)$ for 4 and $(1, -1)$ for -1. They form a basis of $\mathbb{R}^2$, so $\mathbf{A}$ is diagonalizable, with $\mathbf{P} = \begin{pmatrix} 2 & 1 \\ 3 & -1 \end{pmatrix}$ and $\mathbf{D} = \mathrm{diag}(4, -1)$; we check this below.
- **Projections and involutions.** A projection $\mathbf{P}$ satisfies $V = \operatorname{im}\mathbf{P} \oplus \ker\mathbf{P}$ with $\mathbf{P}$ the identity on $\operatorname{im}\mathbf{P}$ and zero on $\ker\mathbf{P}$ (Theorem 3.10.1). A basis of $\operatorname{im}\mathbf{P}$ followed by a basis of $\ker\mathbf{P}$ gives $[\mathbf{P}] = \mathrm{diag}(1, \ldots, 1, 0, \ldots, 0)$. In characteristic not 2, an involution splits $V = E_+ \oplus E_-$ (Theorem 3.10.5), and gives $\mathrm{diag}(1, \ldots, 1, -1, \ldots, -1)$ in the same way.

Non-example by minimal change. Change the $(1, 2)$-entry of $\mathbf{I}_2$ from 0 to 1, giving $\mathbf{J} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$ over any field F. It is still triangular with the single eigenvalue 1, and still invertible. What fails is the existence of a basis of eigenvectors: $E_1(\mathbf{J}) = \ker \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} = \mathrm{span}(\mathbf{e}_1)$ is a line, so every eigenvector of $\mathbf{J}$ is a multiple of $\mathbf{e}_1$, and no two eigenvectors are independent. By the unwinding in Section 2, no basis makes $[T_{\mathbf{J}}]$ diagonal. (Directly: if $\mathbf{P}^{-1}\mathbf{J}\mathbf{P} = \mathbf{D}$ were diagonal, its diagonal entries would be eigenvalues of $\mathbf{J}$, so $\mathbf{D} = \mathbf{I}$, and then $\mathbf{J} = \mathbf{P}\mathbf{I}\mathbf{P}^{-1} = \mathbf{I}$, which is false.)

Why this definition. We ask for similarity to a diagonal matrix, not equality, because the

basis is ours to choose; a matrix like $\begin{pmatrix} 1 & 2 \\ 3 & 2 \end{pmatrix}$ has nothing diagonal about it until the right basis is found. We insist that $\mathbf{P}$ and $\mathbf{D}$ have entries in F, because otherwise the word would not depend on the field and would hide a real phenomenon: the rotation $\mathbf{R} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$ has no real eigenvector, so it is not diagonalizable over $\mathbb{R}$, while over $\mathbb{C}$ it becomes $\operatorname{diag}(i, -i)$ (Section 2). The name says what the definition promises: the operator can be **made** diagonal.

Warning. **Diagonalizability depends on the field, and even on its characteristic.** The rotation $\mathbf{R}$ is diagonalizable over $\mathbb{C}$ but not over $\mathbb{R}$. A subtler case: $\mathbf{S} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$ is diagonalizable over $\mathbb{Q}$, with eigenvectors $(1, 1)$ for 1 and $(1, -1)$ for -1. Over $\mathbb{F}_2$ the same matrix has $p_{\mathbf{S}} = x^2 - 1 = (x - 1)^2$, since $-1 = 1$, and $\mathbf{S} - \mathbf{I} = \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix}$ has rank 1, so its only eigenvectors are the multiples of $(1, 1)$, and $\mathbf{S}$ is **not** diagonalizable over $\mathbb{F}_2$. Always say over which field.

8.4.2 The Diagonalization Theorem

How do we decide whether a basis of eigenvectors exists without searching for one? Eigenvectors for different eigenvalues are automatically independent (Theorem 8.2.2), so the only question is whether each eigenspace supplies enough of them. The theorem below lists five equivalent ways to say "enough".

Theorem 8.4.1 — Diagonalization Theorem

Let V be a finite-dimensional vector space over F with $\dim V = n \geq 1$, let $T \in \mathcal{L}(V)$, and let $\lambda_1, \ldots, \lambda_k$ be the distinct eigenvalues of T (possibly $k = 0$). The following are equivalent:

(a) T is diagonalizable;
(b) V has a basis consisting of eigenvectors of T;
(c) $V = E_{\lambda_1}(T) \oplus \cdots \oplus E_{\lambda_k}(T)$;
(d) $\dim E_{\lambda_1}(T) + \cdots + \dim E_{\lambda_k}(T) = n$;
(e) p_T splits over F, and $g_T(\lambda_i) = a_T(\lambda_i)$ for every $i = 1, \ldots, k$.

In that case, if $\mathcal{B}$ is a basis of eigenvectors, then $[T]_{\mathcal{B}}$ is diagonal, its diagonal entries are the eigenvalues of the corresponding basis vectors, and each λ_i appears on the diagonal exactly $a_T(\lambda_i) = g_T(\lambda_i)$ times.

(For $k = 0$ the sum in (c) is $\{\mathbf{0}\}$ and the sum in (d) is 0; all five conditions are then false, since $n \geq 1$.)

Idea. **Plan:** prove (a) $\Rightarrow$ (b) $\Rightarrow$ (c) $\Rightarrow$ (d) $\Rightarrow$ (e) $\Rightarrow$ (b) $\Rightarrow$ (a).

① (a) $\Leftrightarrow$ (b) is the unwinding of columns from Section 2. ② From a basis of eigenvectors, the eigenspaces add up to V, and Corollary 8.2.3 makes the sum direct. ③ Dimensions add in a direct sum. ④ (d) $\Rightarrow$ (e) is a sandwich: $n = \sum g \leq \sum a \leq n$, so every inequality is an equality. ⑤ (e) $\Rightarrow$ (b) runs the sandwich backwards and glues bases of

the eigenspaces together.

The hard work was done in Sections 2 and 3; this proof only assembles it.

Proof.

(a) $\Leftrightarrow$ (b). Let $\mathcal{B} = (\mathbf{v}_1, \ldots, \mathbf{v}_n)$ be a basis of V. By Definition 3.6.1, column j of $[T]_{\mathcal{B}}$ is $[T\mathbf{v}_j]_{\mathcal{B}}$, and this column is $d_j\mathbf{e}_j$ if and only if $T\mathbf{v}_j = d_j\mathbf{v}_j$. Hence $[T]_{\mathcal{B}} = \operatorname{diag}(d_1, \ldots, d_n)$ if and only if $T\mathbf{v}_j = d_j\mathbf{v}_j$ for every j. Since basis vectors are non-zero, this says that every $\mathbf{v}_j$ is an eigenvector of T, for the eigenvalue d_j. So a basis makes $[T]_{\mathcal{B}}$ diagonal exactly when it consists of eigenvectors, which also proves the final statement about the diagonal entries, apart from the count.

(b) $\Rightarrow$ (c). Let $\mathcal{B}$ be a basis of eigenvectors. Each vector of $\mathcal{B}$ lies in $E_{\lambda_i}(T)$ for some i, so $\mathcal{B} \subseteq E_{\lambda_1}(T) + \cdots + E_{\lambda_k}(T)$. This sum is a subspace (Theorem 1.7.1) containing a spanning list of V, so it equals V. By Corollary 8.2.3 the sum is direct.

(c) $\Rightarrow$ (d). By Theorem 1.7.5 ((a) $\Rightarrow$ (e)), $n = \dim V = \sum_i \dim E_{\lambda_i}(T)$.

(d) $\Rightarrow$ (e). By Theorem 8.3.1, $g_T(\lambda_i) \leq a_T(\lambda_i)$ for each i. The eigenvalues are exactly the roots of p_T in F (Theorem 8.2.1), so by Theorem 5.4.3, $\sum_i a_T(\lambda_i) \leq \deg p_T = n$ (Theorem 6.10.2). With (d),

$$n = \sum_{i=1}^{k} g_T(\lambda_i) \leq \sum_{i=1}^{k} a_T(\lambda_i) \leq n.$$

Hence both inequalities are equalities. The second equality, $\sum_i a_T(\lambda_i) = \deg p_T$, means that p_T splits over F (Theorem 5.4.3). The first says $\sum_i \big(a_T(\lambda_i) - g_T(\lambda_i)\big) = 0$, a sum of non-negative integers, so every term is 0 and $g_T(\lambda_i) = a_T(\lambda_i)$ for each i.

(e) $\Rightarrow$ (b). Since p_T splits, Theorem 5.4.3 gives $\sum_i a_T(\lambda_i) = n$, and so $\sum_i g_T(\lambda_i) = n$ by (e). For each i let $\mathcal{B}_i$ be a basis of $E_{\lambda_i}(T)$, of length $g_T(\lambda_i)$, and let $\mathcal{B}$ be the list $\mathcal{B}_1, \ldots, \mathcal{B}_k$. The sum $W = E_{\lambda_1}(T) + \cdots + E_{\lambda_k}(T)$ is direct (Corollary 8.2.3), so by Theorem 1.7.5 ((a) $\Rightarrow$ (d)), $\mathcal{B}$ is a basis of W, and $\dim W = n = \dim V$. By Theorem 1.6.8, $W = V$. So $\mathcal{B}$ is a basis of V, and its vectors are eigenvectors, being non-zero vectors of eigenspaces.

Finally, suppose $\mathcal{B}$ is a basis of eigenvectors, and let m_i be the number of its vectors with eigenvalue λ_i. By (a) $\Leftrightarrow$ (b), $[T]_{\mathcal{B}}$ is diagonal with λ_i appearing m_i times, so $p_T = \prod_i (x - \lambda_i)^{m_i}$ (the triangular case after Definition 6.10.1). Since the λ_i are distinct, $(x - \lambda_i)^{m_i}$ divides p_T and the remaining factors do not vanish at λ_i, so $m_i = a_T(\lambda_i)$ by Lemma 5.4.1; and $a_T(\lambda_i) = g_T(\lambda_i)$ by (e). This proves the theorem.

■

This is the theorem promised in Chapter 1, §7: **an operator is diagonalizable exactly when its eigenspaces split V as a direct sum**, and then T acts on the i-th piece as the scalar λ_i. In the language of Theorem 8.1.5, the pieces are invariant, the blocks are $\lambda_i \mathbf{I}_{g(\lambda_i)}$, and the matrix is block diagonal with scalar blocks.

Condition (e) is the practical test. It separates two different ways to fail, and they have different remedies. If p_T does not split, the field is too small, and enlarging it (from $\mathbb{R}$ to $\mathbb{C}$) may help. If p_T splits but some $g(\lambda) < a(\lambda)$, there are genuinely too few eigenvectors, and no change of field helps; Chapter 9 explains what the best matrix is then.

The easiest case of (e) needs no rank computation at all.

Corollary 8.4.2 — Distinct Eigenvalues Imply Diagonalizable

Let V be a finite-dimensional vector space over F with $\dim V = n \geq 1$, and let $T \in \mathcal{L}(V)$ have n distinct eigenvalues. Then T is diagonalizable. The same holds for $\mathbf{A} \in M_n(F)$ with n distinct eigenvalues in F.

Proof. Let $\lambda_1, \dots, \lambda_n$ be the eigenvalues. Each λ_i is an eigenvalue, so $E_{\lambda_i}(T) \neq \{\mathbf{0}\}$ (Definition 8.2.2) and $\dim E_{\lambda_i}(T) \geq 1$, so $\sum_i \dim E_{\lambda_i}(T) \geq n$, and by Corollary 8.2.3 the sum is at most n. Hence it equals n, and T is diagonalizable by Theorem 8.4.1 ((d) $\Rightarrow$ (a)).

■

So a matrix whose characteristic polynomial has n distinct roots in F is diagonalizable over F; for example $\begin{pmatrix} 2 & 1 \\ 0 & 3 \end{pmatrix}$ is, because its eigenvalues 2 and 3 are distinct. This is the generic situation, but it is only a sufficient condition.

Warning. **The converse fails: diagonalizable matrices may have repeated eigenvalues.** $\mathbf{I}_n$ is diagonal, and its only eigenvalue is 1. Less trivially, the matrix of Example (Diagonalizing a 3×3 Matrix with a Repeated Eigenvalue) below has eigenvalues $1, 1, 3$ and is diagonalizable. A repeated eigenvalue is a reason to **check** $g(\lambda) = a(\lambda)$, not a verdict.

Quick check. Which of $\begin{pmatrix} 3 & 1 \\ 0 & 5 \end{pmatrix}$, $\begin{pmatrix} 3 & 1 \\ 0 & 3 \end{pmatrix}$, $\begin{pmatrix} 3 & 0 \\ 0 & 3 \end{pmatrix}$ are diagonalizable over $\mathbb{R}$?

Solution. The first has distinct eigenvalues $3, 5$, so it is diagonalizable by Corollary 8.4.2. The second has $a(3) = 2$ but $\operatorname{rank} \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} = 1$, so $g(3) = 1 < a(3)$, and it is not diagonalizable by Theorem 8.4.1 (e). The third is already diagonal.

8.4.3 Computing P and D

For a matrix $\mathbf{A} \in M_n(F)$, a basis of eigenvectors turns into the matrices $\mathbf{P}$ and $\mathbf{D}$ of Definition 8.4.1 directly. Let $(\mathbf{v}_1, \dots, \mathbf{v}_n)$ be a basis of F^n with $\mathbf{A}\mathbf{v}_j = d_j \mathbf{v}_j$, let $\mathbf{P}$ be the matrix with **columns** $\mathbf{v}_1, \dots, \mathbf{v}_n$, and $\mathbf{D} = \operatorname{diag}(d_1, \dots, d_n)$. By the column view of matrix multiplication (Theorem 0.9.2), column j of $\mathbf{AP}$ is $\mathbf{A}\mathbf{v}_j = d_j \mathbf{v}_j$, and column j of $\mathbf{PD}$ is $\mathbf{P}(d_j \mathbf{e}_j) = d_j \mathbf{v}_j$. So

$$\mathbf{AP} = \mathbf{PD}.$$

The columns of $\mathbf{P}$ form a basis, so $\mathbf{P}$ is invertible (Theorem 2.4.4), and multiplying on the left by $\mathbf{P}^{-1}$ gives $\mathbf{P}^{-1}\mathbf{AP} = \mathbf{D}$. The **order** matters in one way only: the j-th column of $\mathbf{P}$ must be an eigenvector for the j-th diagonal entry of $\mathbf{D}$. Reordering the eigenvectors reorders the diagonal of $\mathbf{D}$ in the same way, and any order works.

For $\mathbf{A} = \begin{pmatrix} 1 & 2 \\ 3 & 2 \end{pmatrix}$, with $\mathbf{P} = \begin{pmatrix} 2 & 1 \\ 3 & -1 \end{pmatrix}$ and $\mathbf{D} = \operatorname{diag}(4, -1)$: $\mathbf{AP} = \begin{pmatrix} 8 & -1 \\ 12 & 1 \end{pmatrix}$ and $\mathbf{PD} =$

$\begin{pmatrix} 8 & -1 \\ 12 & 1 \end{pmatrix}$. Checking $\mathbf{AP} = \mathbf{PD}$ avoids computing $\mathbf{P}^{-1}$, and together with $\det \mathbf{P} = -5 \neq 0$ it proves $\mathbf{P}^{-1}\mathbf{AP} = \mathbf{D}$.

The full procedure, then: compute $p_{\mathbf{A}}$ and its roots; if it does not split over F, stop (not diagonalizable over F); for each eigenvalue compute a basis of $E_\lambda(\mathbf{A})$; if some $g(\lambda) < a(\lambda)$, stop; otherwise put the basis vectors as columns of $\mathbf{P}$.

Example. (Diagonalizing a 3×3 Matrix with a Repeated Eigenvalue)

Let

$$\mathbf{A} = \begin{pmatrix} 3 & 2 & -2 \\ -2 & -1 & 2 \\ -2 & -2 & 3 \end{pmatrix} \in M_3(\mathbb{R}).$$

Decide whether $\mathbf{A}$ is diagonalizable over $\mathbb{R}$. If it is, find an invertible $\mathbf{P}$ and a diagonal $\mathbf{D}$ with $\mathbf{P}^{-1}\mathbf{AP} = \mathbf{D}$.

Solution. Characteristic polynomial. Expanding along the first row (Theorem 6.6.1 over $\mathbb{R}[x]$),

$$\begin{aligned} p_{\mathbf{A}}(x) &= \det \begin{pmatrix} x-3 & -2 & 2 \\ 2 & x+1 & -2 \\ 2 & 2 & x-3 \end{pmatrix} \\ &= (x-3)\big[(x+1)(x-3)+4\big] + 2\big[2(x-3)+4\big] \\ &\quad + 2\big[4-2(x+1)\big]. \end{aligned}$$

The brackets are $x^2 - 2x + 1 = (x-1)^2$, $2(x-1)$ and $-2(x-1)$, so the last two terms cancel and

$$p_{\mathbf{A}}(x) = (x-1)^2(x-3).$$

It splits over $\mathbb{R}$, with $a(1) = 2$ and $a(3) = 1$. As a check, $\operatorname{tr}\mathbf{A} = 5 = 1 + 1 + 3$ (Theorem 8.3.3).

Eigenspace for 1.

$$\mathbf{A} - \mathbf{I} = \begin{pmatrix} 2 & 2 & -2 \\ -2 & -2 & 2 \\ -2 & -2 & 2 \end{pmatrix}.$$

Every row is a multiple of $(1, 1, -1)$, so the rank is 1 and $g(1) = 3 - 1 = 2 = a(1)$. The system reduces to $x + y - z = 0$; with the free variables y and z, a basis of $E_1(\mathbf{A})$ is $(-1, 1, 0)$, $(1, 0, 1)$ (Theorem 2.5.4).

Eigenspace for 3. Here $g(3) = 1 = a(3)$ by Theorem 8.3.1, so condition (e) of Theorem 8.4.1 holds and $\mathbf{A}$ is diagonalizable. To find the eigenvector,

$$\mathbf{A} - 3\mathbf{I} = \begin{pmatrix} 0 & 2 & -2 \\ -2 & -4 & 2 \\ -2 & -2 & 0 \end{pmatrix}.$$

Row 1 gives $y = z$, and row 3 gives $x = -y$; row 2 then reads $2y - 4y + 2y = 0$. So $E_3(\mathbf{A}) = \operatorname{span}((1, -1, -1))$.

The matrices. Put the eigenvectors as columns, in the order of the eigenvalues we want

on the diagonal:

$$\mathbf{P} = \begin{pmatrix} -1 & 1 & 1 \\ 1 & 0 & -1 \\ 0 & 1 & -1 \end{pmatrix}, \qquad \mathbf{D} = \operatorname{diag}(1, 1, 3).$$

Check. The columns of $\mathbf{AP}$ are $\mathbf{A}(-1,1,0) = (-1,1,0)$, $\mathbf{A}(1,0,1) = (1,0,1)$ and $\mathbf{A}(1,-1,-1) = (3,-3,-3)$, which are the columns of $\mathbf{PD}$. Expanding along the first column, $\det \mathbf{P} = -1 \cdot (0+1) - 1 \cdot (-1-1) = 1 \neq 0$, so $\mathbf{P}$ is invertible, and in fact

$$\mathbf{P}^{-1} = \begin{pmatrix} 1 & 2 & -1 \\ 1 & 1 & 0 \\ 1 & 1 & -1 \end{pmatrix},$$

as multiplying out $\mathbf{P}\mathbf{P}^{-1} = \mathbf{I}$ confirms. Hence $\mathbf{P}^{-1}\mathbf{A}\mathbf{P} = \mathbf{D}$.

Had we listed the eigenvectors in the order $(1,-1,-1), (-1,1,0), (1,0,1)$, we would get $\mathbf{D} = \operatorname{diag}(3,1,1)$ instead. Both are correct.

8.4.4 Powers and polynomials

Why diagonalize? Because powers of diagonal matrices are free: $\operatorname{diag}(d_1,\dots,d_n)^k = \operatorname{diag}(d_1^k,\dots,d_n^k)$. Similarity carries this over.

Theorem 8.4.3 — Powers and Polynomials of a Diagonalizable Matrix

Let $\mathbf{A} = \mathbf{P}\mathbf{D}\mathbf{P}^{-1}$ with $\mathbf{P} \in M_n(F)$ invertible and $\mathbf{D} = \operatorname{diag}(d_1,\dots,d_n)$. Then for every $k \in \mathbb{N}$ and every $p \in F[x]$,

$$\mathbf{A}^k = \mathbf{P}\,\operatorname{diag}(d_1^k,\dots,d_n^k)\,\mathbf{P}^{-1}, \qquad p(\mathbf{A}) = \mathbf{P}\,\operatorname{diag}\big(p(d_1),\dots,p(d_n)\big)\,\mathbf{P}^{-1}.$$

If moreover every $d_i \neq 0$, then $\mathbf{A}$ is invertible and $\mathbf{A}^{-1} = \mathbf{P}\,\operatorname{diag}(d_1^{-1},\dots,d_n^{-1})\,\mathbf{P}^{-1}$.

Proof. Since $\mathbf{D} = \mathbf{P}^{-1}\mathbf{A}\mathbf{P}$, Proposition 3.7.6 (c) gives $p(\mathbf{D}) = \mathbf{P}^{-1}p(\mathbf{A})\mathbf{P}$, so $p(\mathbf{A}) = \mathbf{P}\,p(\mathbf{D})\,\mathbf{P}^{-1}$. A diagonal matrix is the direct sum $(d_1) \oplus \cdots \oplus (d_n)$ of 1×1 blocks, so by Theorem 7.1.4 (b), extended to n blocks by induction on the number of blocks, $p(\mathbf{D}) = (p(d_1)) \oplus \cdots \oplus (p(d_n)) = \operatorname{diag}(p(d_1),\dots,p(d_n))$. Taking $p = x^k$ gives the formula for $\mathbf{A}^k$. If every $d_i \neq 0$, put $\mathbf{B} = \mathbf{P}\,\operatorname{diag}(d_1^{-1},\dots,d_n^{-1})\,\mathbf{P}^{-1}$; then $\mathbf{A}\mathbf{B} = \mathbf{P}\mathbf{D}\mathbf{P}^{-1}\mathbf{P}\,\operatorname{diag}(d_i^{-1})\,\mathbf{P}^{-1} = \mathbf{P}\,\operatorname{diag}(d_i d_i^{-1})\,\mathbf{P}^{-1} = \mathbf{P}\mathbf{P}^{-1} = \mathbf{I}$, and $\mathbf{B} = \mathbf{A}^{-1}$ by Theorem 2.4.5. ∎

In words: to apply a polynomial to a diagonalizable matrix, apply it to the eigenvalues and change basis back. The work is done once, when $\mathbf{P}$ is found; every power after that costs a single product of three matrices. For Example (Diagonalizing a 3×3 Matrix with a Repeated Eigenvalue),

$$\mathbf{A}^k = \mathbf{P}\,\operatorname{diag}(1,1,3^k)\,\mathbf{P}^{-1} = \begin{pmatrix} 3^k & 3^k-1 & 1-3^k \\ 1-3^k & 2-3^k & 3^k-1 \\ 1-3^k & 1-3^k & 3^k \end{pmatrix},$$

which is $\mathbf{I}$ for $k = 0$ and $\mathbf{A}$ for $k = 1$, as it must be.

The most famous application is to a recurrence. A linear recurrence of order two becomes a first-order recurrence for vectors, whose solution is a matrix power.

Example. (A Closed Formula for the Fibonacci Numbers)

The Fibonacci numbers are defined by $F_0 = 0$, $F_1 = 1$ and $F_{k+2} = F_{k+1} + F_k$ for $k \geq 0$. (Here F_k is a number, not a field; we work over $\mathbb{R}$.) Find a formula for F_k by diagonalizing a 2×2 matrix.

Solution. A vector recurrence. Put $\mathbf{x}_k = (F_{k+1}, F_k) \in \mathbb{R}^2$. The recurrence says

$$\mathbf{x}_{k+1} = \begin{pmatrix} F_{k+2} \\ F_{k+1} \end{pmatrix} = \begin{pmatrix} F_{k+1} + F_k \\ F_{k+1} \end{pmatrix} = \mathbf{A}\mathbf{x}_k, \qquad \mathbf{A} = \begin{pmatrix} 1 & 1 \\ 1 & 0 \end{pmatrix}.$$

By induction on k, $\mathbf{x}_k = \mathbf{A}^k \mathbf{x}_0$ with $\mathbf{x}_0 = (1, 0)$.

Eigenvalues. $\operatorname{tr} \mathbf{A} = 1$ and $\det \mathbf{A} = -1$, so $p_{\mathbf{A}}(x) = x^2 - x - 1$, with the two real roots

$$\varphi = \frac{1 + \sqrt{5}}{2}, \qquad \psi = \frac{1 - \sqrt{5}}{2}.$$

They are distinct, so $\mathbf{A}$ is diagonalizable over $\mathbb{R}$ (Corollary 8.4.2). Each root satisfies $\lambda^2 = \lambda + 1$, and we will use $\varphi + \psi = 1$, $\varphi\psi = -1$ and $\varphi - \psi = \sqrt{5}$.

Eigenvectors. For a root λ, the vector $(\lambda, 1)$ is an eigenvector: $\mathbf{A}(\lambda, 1) = (\lambda + 1, \lambda) = (\lambda^2, \lambda) = \lambda(\lambda, 1)$. So

$$\mathbf{P} = \begin{pmatrix} \varphi & \psi \\ 1 & 1 \end{pmatrix}, \qquad \mathbf{D} = \operatorname{diag}(\varphi, \psi), \qquad \mathbf{P}^{-1} = \frac{1}{\sqrt{5}} \begin{pmatrix} 1 & -\psi \\ -1 & \varphi \end{pmatrix},$$

where $\det \mathbf{P} = \varphi - \psi = \sqrt{5} \neq 0$ and $\mathbf{P}^{-1}$ comes from Theorem 0.9.8.

The power. By Theorem 8.4.3, $\mathbf{x}_k = \mathbf{P}\mathbf{D}^k\mathbf{P}^{-1}\mathbf{x}_0$. Working from the right:

$$\begin{aligned} \mathbf{P}^{-1}\mathbf{x}_0 &= \frac{1}{\sqrt{5}} \begin{pmatrix} 1 \\ -1 \end{pmatrix}, \\ \mathbf{D}^k\mathbf{P}^{-1}\mathbf{x}_0 &= \frac{1}{\sqrt{5}} \begin{pmatrix} \varphi^k \\ -\psi^k \end{pmatrix}, \\ \mathbf{P}\mathbf{D}^k\mathbf{P}^{-1}\mathbf{x}_0 &= \frac{1}{\sqrt{5}} \begin{pmatrix} \varphi^{k+1} - \psi^{k+1} \\ \varphi^k - \psi^k \end{pmatrix}. \end{aligned}$$

The second entry of $\mathbf{x}_k$ is F_k, so

$$F_k = \frac{\varphi^k - \psi^k}{\sqrt{5}} = \frac{1}{\sqrt{5}} \left[\left(\frac{1 + \sqrt{5}}{2} \right)^k - \left(\frac{1 - \sqrt{5}}{2} \right)^k \right].$$

Check. $k = 0$: 0. $k = 1$: $(\varphi - \psi)/\sqrt{5} = 1$. $k = 2$: $(\varphi^2 - \psi^2)/\sqrt{5} = (\varphi - \psi)(\varphi + \psi)/\sqrt{5} = 1$. And the right side satisfies the recurrence, because $\varphi^{k+2} = \varphi^{k+1} + \varphi^k$ (multiply $\varphi^2 = \varphi + 1$ by φ^k), and likewise for ψ.

Since $|\psi| < 1$, the term $\psi^k/\sqrt{5}$ has absolute value less than $1/2$, so F_k is the integer nearest to $\varphi^k/\sqrt{5}$; the Fibonacci numbers grow like powers of $\varphi \approx 1.618$, the larger eigenvalue.

The irrational numbers in the formula are forced. Over $\mathbb{Q}$, the polynomial $x^2 - x - 1$ has no root (by Theorem 5.3.6, the only candidates are ± 1, and neither works), so $\mathbf{A}$ has no eigenvalue in $\mathbb{Q}$ and is **not** diagonalizable over $\mathbb{Q}$, although all its entries and powers are integers. Chapter 6 met the same numbers as determinants of tridiagonal matrices (Example (Fibonacci Numbers as Determinants)); here the recurrence is solved rather than just recognized. Section 11 of this chapter treats general linear recurrences and Markov chains the same way.

8.4.5 When diagonalization fails

Two examples collect the ways Theorem 8.4.1 (e) can fail.

Too few eigenvectors. $\mathbf{J} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$ is not diagonalizable over **any** field, because $p_{\mathbf{J}} = (x-1)^2$ splits but $g(1) = 1 < 2 = a(1)$. Enlarging the field changes nothing: the rank of $\mathbf{J} - \mathbf{I}$ is 1 over every field. Its powers are still easy, $\mathbf{J}^k = \begin{pmatrix} 1 & k \\ 0 & 1 \end{pmatrix}$ by induction, but they are not of the form $\mathbf{P}\,\mathrm{diag}(1,1)\,\mathbf{P}^{-1} = \mathbf{I}$; the entry k, growing linearly rather than like a power, is the footprint of the missing eigenvector. Chapter 9 shows that such blocks are the only additional ingredient.

Too small a field. The rotation $\mathbf{R} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$ has $p_{\mathbf{R}} = x^2 + 1$, which does not split over $\mathbb{R}$, so $\mathbf{R}$ is not diagonalizable over $\mathbb{R}$. Over $\mathbb{C}$ it has the distinct eigenvalues $\pm i$ with eigenvectors $(1, -i)$ and $(1, i)$, so with $\mathbf{P} = \begin{pmatrix} 1 & 1 \\ -i & i \end{pmatrix}$,

$$\mathbf{P}^{-1}\mathbf{R}\mathbf{P} = \begin{pmatrix} i & 0 \\ 0 & -i \end{pmatrix}.$$

Then $\mathbf{R}^k = \mathbf{P}\,\mathrm{diag}(i^k, (-i)^k)\,\mathbf{P}^{-1}$, and since $i^4 = 1$, $\mathbf{R}^4 = \mathbf{I}$: four quarter-turns make a full turn, as they should.

When a matrix depends on a parameter, the same test decides diagonalizability for every value at once.

Example. (Diagonalizability with a Parameter)

For which $t \in \mathbb{R}$ is $\mathbf{A}_t = \begin{pmatrix} 2 & t & 0 \\ 0 & 2 & 0 \\ 0 & 0 & 3 \end{pmatrix}$ diagonalizable over $\mathbb{R}$?

Solution. The matrix is upper triangular, so $p_{\mathbf{A}_t}(x) = (x-2)^2(x-3)$ for every t, by Theorem 6.4.6. This splits, with $a(2) = 2$ and $a(3) = 1$. Since $1 \le g(3) \le a(3) = 1$ by Theorem 8.3.1, only $\lambda = 2$ needs checking. Here

$$\mathbf{A}_t - 2\mathbf{I} = \begin{pmatrix} 0 & t & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix},$$

whose rank is 1 if $t = 0$ and 2 if $t \neq 0$. By rank–nullity for matrices (Theorem 2.5.7), $g(2) = 3 - \operatorname{rank}(\mathbf{A}_t - 2\mathbf{I})$ is 2 when $t = 0$ and 1 when $t \neq 0$. By Theorem 8.4.1 (e), $\mathbf{A}_t$ is diagonalizable exactly when $t = 0$.

Notice what did not change: the eigenvalues and their algebraic multiplicities are the same for every t. Only the geometric multiplicity, a rank, detects the difference.

8.4.6 Exercises

8.4.6.1 A. Check your understanding

Exercise A1.

(a) Define what it means for $\mathbf{A} \in M_n(F)$ to be diagonalizable over F.

(b) State the Diagonalization Theorem, with at least four equivalent conditions.

(c) True or false: a diagonalizable $n \times n$ matrix has n distinct eigenvalues. Justify your answer.

(d) True or false: every invertible matrix is diagonalizable. Justify your answer.

(e) True or false: every diagonalizable matrix is invertible. Justify your answer.

(f) If $\mathbf{P}^{-1}\mathbf{A}\mathbf{P} = \mathbf{D}$ is diagonal, what are the columns of $\mathbf{P}$, and how are they matched with the diagonal of $\mathbf{D}$?

Solution.

(a) There are an invertible $\mathbf{P} \in M_n(F)$ and a diagonal $\mathbf{D} \in M_n(F)$ with $\mathbf{P}^{-1}\mathbf{A}\mathbf{P} = \mathbf{D}$ (Definition 8.4.1).

(b) See Theorem 8.4.1: for $T \in \mathcal{L}(V)$, $\dim V = n \geq 1$, with distinct eigenvalues $\lambda_1, \ldots, \lambda_k$, the following are equivalent: T is diagonalizable; V has a basis of eigenvectors; $V = \bigoplus_i E_{\lambda_i}(T)$; $\sum_i \dim E_{\lambda_i}(T) = n$; p_T splits and $g(\lambda_i) = a(\lambda_i)$ for all i.

(c) False. $\mathbf{I}_n$ is diagonal, with the single eigenvalue 1.

(d) False. $\begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$ has determinant 1 but is not diagonalizable.

(e) False. The zero matrix is diagonal and not invertible.

(f) The columns of $\mathbf{P}$ form a basis of eigenvectors of $\mathbf{A}$, and column j is an eigenvector for the j-th diagonal entry of $\mathbf{D}$, since $\mathbf{A}\mathbf{P} = \mathbf{P}\mathbf{D}$.

8.4.6.2 B. Practice

Exercise B1: Diagonalize or show impossible.

For each real matrix, either find an invertible $\mathbf{P}$ and a diagonal $\mathbf{D}$ with $\mathbf{P}^{-1}\mathbf{A}\mathbf{P} = \mathbf{D}$, or show that none exist.

(a) $\mathbf{A}_1 = \begin{pmatrix} 0 & 1 \\ -6 & 5 \end{pmatrix}$.

(b) $\mathbf{A}_2 = \begin{pmatrix} 1 & 1 & 1 \\ 2 & 0 & 1 \\ -3 & 3 & 2 \end{pmatrix}$.

(c) $\mathbf{A}_3 = \begin{pmatrix} -1 & 2 & -2 \\ -2 & 3 & -2 \\ 2 & -2 & 3 \end{pmatrix}$.

Solution.

(a) $\operatorname{tr}\mathbf{A}_1 = 5$, $\det\mathbf{A}_1 = 6$, so $p = x^2 - 5x + 6 = (x-2)(x-3)$. The eigenvalues are distinct, so $\mathbf{A}_1$ is diagonalizable (Corollary 8.4.2). $\mathbf{A}_1 - 2\mathbf{I} = \begin{pmatrix} -2 & 1 \\ -6 & 3 \end{pmatrix}$ gives $y = 2x$, eigenvector $(1,2)$; $\mathbf{A}_1 - 3\mathbf{I} = \begin{pmatrix} -3 & 1 \\ -6 & 2 \end{pmatrix}$ gives $y = 3x$, eigenvector $(1,3)$. So

$$\mathbf{P} = \begin{pmatrix} 1 & 1 \\ 2 & 3 \end{pmatrix}, \quad \mathbf{D} = \operatorname{diag}(2,3), \quad \mathbf{P}^{-1} = \begin{pmatrix} 3 & -1 \\ -2 & 1 \end{pmatrix},$$

and indeed $\mathbf{A}_1\mathbf{P} = \begin{pmatrix} 2 & 3 \\ 4 & 9 \end{pmatrix} = \mathbf{P}\mathbf{D}$.

(b) Expanding along the first row,

$$\begin{aligned} p(x) &= \det \begin{pmatrix} x-1 & -1 & -1 \\ -2 & x & -1 \\ 3 & -3 & x-2 \end{pmatrix} \\ &= (x-1)\big[x(x-2) - 3\big] + \big[-2(x-2) + 3\big] - \big[6 - 3x\big]. \end{aligned}$$

The first bracket is $(x-3)(x+1)$, and the last two terms add up to $-2x+7-6+3x = x+1$. So $p(x) = (x+1)\big[(x-1)(x-3)+1\big] = (x+1)(x-2)^2$, and $a(2) = 2$. Now

$$\mathbf{A}_2 - 2\mathbf{I} = \begin{pmatrix} -1 & 1 & 1 \\ 2 & -2 & 1 \\ -3 & 3 & 0 \end{pmatrix}.$$

Row 3 equals row 1 minus row 2, and rows 1 and 2 are not proportional, so the rank is 2 and $g(2) = 1 < 2 = a(2)$. By Theorem 8.4.1 (e), $\mathbf{A}_2$ is **not** diagonalizable, over $\mathbb{R}$ or over $\mathbb{C}$.

(c) Expanding along the first row,

$$\begin{aligned} p(x) &= \det \begin{pmatrix} x+1 & -2 & 2 \\ 2 & x-3 & 2 \\ -2 & 2 & x-3 \end{pmatrix} \\ &= (x+1)\big[(x-3)^2 - 4\big] + 2\big[2(x-3) + 4\big] \\ &\quad + 2\big[4 + 2(x-3)\big]. \end{aligned}$$

The first bracket is $(x-5)(x-1)$ and the other two are $2(x-1)$ each, so $p(x) = (x-1)\big[(x+1)(x-5)+8\big] = (x-1)(x^2-4x+3) = (x-1)^2(x-3)$. For $\lambda = 1$, $\mathbf{A}_3 - \mathbf{I} = \begin{pmatrix} -2 & 2 & -2 \\ -2 & 2 & -2 \\ 2 & -2 & 2 \end{pmatrix}$ has rank 1, so $g(1) = 2 = a(1)$, and E_1 is the plane $x - y + z = 0$, with basis $(1,1,0), (-1,0,1)$. Also $g(3) = 1 = a(3)$, so $\mathbf{A}_3$ is

diagonalizable. From $\mathbf{A}_3 - 3\mathbf{I} = \begin{pmatrix} -4 & 2 & -2 \\ -2 & 0 & -2 \\ 2 & -2 & 0 \end{pmatrix}$, row 3 gives $y = x$ and row 2 gives $z = -x$, so $E_3 = \operatorname{span}((1,1,-1))$. Hence

$$\mathbf{P} = \begin{pmatrix} 1 & -1 & 1 \\ 1 & 0 & 1 \\ 0 & 1 & -1 \end{pmatrix}, \qquad \mathbf{D} = \operatorname{diag}(1,1,3).$$

Check: $\mathbf{A}_3(1,1,0) = (1,1,0)$, $\mathbf{A}_3(-1,0,1) = (-1,0,1)$, $\mathbf{A}_3(1,1,-1) = (3,3,-3)$, so $\mathbf{A}_3\mathbf{P} = \mathbf{P}\mathbf{D}$; and $\det \mathbf{P} = 1(0-1) + 1(-1-0) + 1(1-0) = -1 \neq 0$.

Exercise B2: A tenth power.

Let $\mathbf{A} = \begin{pmatrix} 1 & 2 \\ 2 & 1 \end{pmatrix} \in M_2(\mathbb{R})$.

(a) Diagonalize $\mathbf{A}$.

(b) Hence find a formula for $\mathbf{A}^k$, $k \in \mathbb{N}$, and compute $\mathbf{A}^{10}$.

Solution.

(a) $\operatorname{tr} \mathbf{A} = 2$, $\det \mathbf{A} = -3$, so $p = x^2 - 2x - 3 = (x-3)(x+1)$. $\mathbf{A} - 3\mathbf{I} = \begin{pmatrix} -2 & 2 \\ 2 & -2 \end{pmatrix}$ gives the eigenvector $(1,1)$, and $\mathbf{A} + \mathbf{I} = \begin{pmatrix} 2 & 2 \\ 2 & 2 \end{pmatrix}$ gives $(1,-1)$. So $\mathbf{P} = \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}$, $\mathbf{D} = \operatorname{diag}(3,-1)$, and $\mathbf{P}^{-1} = \frac{1}{2}\begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}$ by Theorem 0.9.8.

(b) By Theorem 8.4.3,

$$\mathbf{A}^k = \frac{1}{2}\begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}\begin{pmatrix} 3^k & 0 \\ 0 & (-1)^k \end{pmatrix}\begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix} = \frac{1}{2}\begin{pmatrix} 3^k + (-1)^k & 3^k - (-1)^k \\ 3^k - (-1)^k & 3^k + (-1)^k \end{pmatrix}.$$

For $k = 1$ this gives $\frac{1}{2}\begin{pmatrix} 2 & 4 \\ 4 & 2 \end{pmatrix} = \mathbf{A}$. With $3^{10} = 59049$ and $(-1)^{10} = 1$,

$$\mathbf{A}^{10} = \begin{pmatrix} 29525 & 29524 \\ 29524 & 29525 \end{pmatrix}.$$

Exercise B3: A matrix with a parameter.

For $t \in \mathbb{R}$, let $\mathbf{A}_t = \begin{pmatrix} 1 & 1 & 0 \\ 0 & t & 0 \\ 0 & 0 & 2 \end{pmatrix}$. Determine all t for which $\mathbf{A}_t$ is diagonalizable over $\mathbb{R}$. Justify your answer.

Solution. $\mathbf{A}_t$ is upper triangular, so $p(x) = (x-1)(x-t)(x-2)$, which splits over $\mathbb{R}$.

Case $t \notin \{1,2\}$. The eigenvalues $1, t, 2$ are distinct, so $\mathbf{A}_t$ is diagonalizable (Corollary 8.4.2).

Case $t = 1$. Then $a(1) = 2$, and $\mathbf{A}_1 - \mathbf{I} = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix}$ has rank 2, so $g(1) = 1 < 2$. Not diagonalizable.

Case $t = 2$. Then $a(2) = 2$, and $\mathbf{A}_2 - 2\mathbf{I} = \begin{pmatrix} -1 & 1 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}$ has rank 1, so $g(2) = 2 = a(2)$; also $g(1) = a(1) = 1$. Diagonalizable, with eigenvectors $\mathbf{e}_1$ for 1 and $(1, 1, 0), \mathbf{e}_3$ for 2.

Hence $\mathbf{A}_t$ is diagonalizable over $\mathbb{R}$ if and only if $t \neq 1$. In both exceptional cases a diagonal entry is repeated, but only for $t = 1$ is an eigenvector lost: the entry 1 in position $(1, 2)$ couples $\mathbf{e}_1$ and $\mathbf{e}_2$, and it matters only when their diagonal entries agree.

8.4.6.3 C. Going deeper

Exercise C1: Matrices with $\mathbf{A}^k = \mathbf{I}$.

Let $\mathbf{A} \in M_n(\mathbb{C})$, $n \geq 1$, and $k \geq 1$.

(a) Prove that if $\mathbf{A}^k = \mathbf{I}$, then every eigenvalue λ of $\mathbf{A}$ satisfies $\lambda^k = 1$.

(b) Prove that if $\mathbf{A}$ is diagonalizable and every eigenvalue satisfies $\lambda^k = 1$, then $\mathbf{A}^k = \mathbf{I}$.

(c) Show that the hypothesis "diagonalizable" in (b) cannot be dropped.

Solution.

(a) Let $\mathbf{Av} = \lambda\mathbf{v}$ with $\mathbf{v} \neq \mathbf{0}$. By Exercise (B3: Eigenvalues of powers and inverses) (a), $\mathbf{v} = \mathbf{Iv} = \mathbf{A}^k\mathbf{v} = \lambda^k\mathbf{v}$, so $(\lambda^k - 1)\mathbf{v} = \mathbf{0}$ and $\lambda^k = 1$ by Theorem 1.1.9.

(b) Write $\mathbf{A} = \mathbf{PDP}^{-1}$ with $\mathbf{D} = \operatorname{diag}(d_1, \ldots, d_n)$ (Definition 8.4.1). The d_i are eigenvalues of $\mathbf{A}$: $\mathbf{D}$ and $\mathbf{A}$ are similar, so $p_{\mathbf{D}} = p_{\mathbf{A}}$ (Theorem 6.10.3), and each d_i is a root of $p_{\mathbf{D}} = \prod_j (x - d_j)$. So $d_i^k = 1$ for all i, and by Theorem 8.4.3, $\mathbf{A}^k = \mathbf{P} \operatorname{diag}(d_1^k, \ldots, d_n^k)\, \mathbf{P}^{-1} = \mathbf{PIP}^{-1} = \mathbf{I}$.

(c) Let $\mathbf{J} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$. Its only eigenvalue is 1, and $1^k = 1$. But $\mathbf{J}^k = \begin{pmatrix} 1 & k \\ 0 & 1 \end{pmatrix}$ by induction ($\mathbf{J}^{k+1} = \mathbf{J}^k\mathbf{J}$), which is not $\mathbf{I}$ since $k \neq 0$ in $\mathbb{C}$. (Section 8 proves the converse of (b) in a strong form: over $\mathbb{C}$, $\mathbf{A}^k = \mathbf{I}$ forces $\mathbf{A}$ to be diagonalizable.)

Exercise C2: Polynomials of diagonalizable matrices.

(a) Prove that if $\mathbf{A} \in M_n(F)$ is diagonalizable over F, then so is $p(\mathbf{A})$ for every $p \in F[x]$, and that every eigenvalue of $p(\mathbf{A})$ has the form $p(\lambda)$ with $\lambda \in \operatorname{spec}(\mathbf{A})$.

(b) Show that the converse of the first statement fails: find a non-diagonalizable $\mathbf{A}$ and a polynomial p with $p(\mathbf{A})$ diagonalizable.

Solution.

(a) Let $\mathbf{A} = \mathbf{PDP}^{-1}$, $\mathbf{D} = \operatorname{diag}(d_1, \ldots, d_n)$. By Theorem 8.4.3, $p(\mathbf{A}) = \mathbf{P} \operatorname{diag}(p(d_1), \ldots, p(d_n))\, \mathbf{P}^{-1}$, so $p(\mathbf{A})$ is similar to a diagonal matrix, that is, diagonalizable. By Theorem 6.10.3,

$p_{p(\mathbf{A})} = \prod_i (x - p(d_i))$, so by Theorem 8.2.1 every eigenvalue of $p(\mathbf{A})$ is some $p(d_i)$. As in Exercise (C1: Matrices with $\mathbf{A}^k = \mathbf{I}$) (b), each d_i is an eigenvalue of $\mathbf{A}$.

(b) Let $\mathbf{A} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$ and $p = x^2$. Then $\mathbf{A}$ is not diagonalizable: $p_{\mathbf{A}} = x^2$ gives $a(0) = 2$, while $\operatorname{rank} \mathbf{A} = 1$ gives $g(0) = 1$ (Theorem 8.4.1 (e)). But $p(\mathbf{A}) = \mathbf{A}^2 = 0$ is diagonal.

Exercise C3: The transpose map on $M_n(F)$.

Let $n \geq 1$ and $\tau \colon M_n(F) \to M_n(F)$, $\tau(\mathbf{X}) = \mathbf{X}^\top$.

(a) Suppose the characteristic of F is not 2. Prove that τ is diagonalizable, and find $\dim E_1(\tau)$ and $\dim E_{-1}(\tau)$.

(b) Under the same hypothesis, deduce p_τ, $\operatorname{tr} \tau$ and $\det \tau$.

(c) Now let $F = \mathbb{F}_2$ and $n \geq 2$. Prove that τ is **not** diagonalizable.

Hint: for the dimensions, use the matrices $\mathbf{E}_{ij} + \mathbf{E}_{ji}$ and $\mathbf{E}_{ij} - \mathbf{E}_{ji}$.

Solution.

(a) Since $(\mathbf{X}^\top)^\top = \mathbf{X}$ (Theorem 0.9.5), $\tau^2 = \mathrm{id}$. By Theorem 3.10.5, $M_n(F) = E_+ \oplus E_-$, where $E_+ = E_1(\tau)$ is the space of symmetric matrices and $E_- = E_{-1}(\tau)$ the space of skew-symmetric matrices.
A symmetric $\mathbf{X} = (x_{ij})$ is determined by its entries on and above the diagonal, and $\mathbf{X} = \sum_i x_{ii}\mathbf{E}_{ii} + \sum_{i<j} x_{ij}(\mathbf{E}_{ij} + \mathbf{E}_{ji})$. These $n + \binom{n}{2}$ matrices are symmetric and independent, since their non-zero entries sit in disjoint positions. So $\dim E_1(\tau) = n(n+1)/2$. A skew-symmetric $\mathbf{X}$ has $x_{ii} = -x_{ii}$, so $2x_{ii} = 0$ and $x_{ii} = 0$ (as $2 \neq 0$); and $\mathbf{X} = \sum_{i<j} x_{ij}(\mathbf{E}_{ij} - \mathbf{E}_{ji})$, with these $\binom{n}{2}$ matrices independent for the same reason. So $\dim E_{-1}(\tau) = n(n-1)/2$.
The eigenvalues of τ lie among ± 1 (as in Exercise (B2: The transpose map)), and $n(n+1)/2 + n(n-1)/2 = n^2 = \dim M_n(F)$. If $n \geq 2$, both eigenspaces are non-zero, and the dimensions of the eigenspaces add up to n^2; if $n = 1$, $\tau = \mathrm{id}$ and $E_1(\tau)$ is everything. Either way Theorem 8.4.1 ((d) $\Rightarrow$ (a)) shows that τ is diagonalizable.

(b) In a basis of eigenvectors, $[\tau] = \operatorname{diag}(1, \ldots, 1, -1, \ldots, -1)$ with $n(n+1)/2$ ones and $n(n-1)/2$ entries -1 (Theorem 8.4.1). This matrix is triangular, so

$$\begin{aligned} p_\tau &= (x-1)^{n(n+1)/2}(x+1)^{n(n-1)/2}, \\ \operatorname{tr} \tau &= \frac{n(n+1)}{2} - \frac{n(n-1)}{2} = n, \\ \det \tau &= (-1)^{n(n-1)/2}. \end{aligned}$$

As a check on the trace: in the basis $(\mathbf{E}_{ij})$, $\tau(\mathbf{E}_{ij}) = \mathbf{E}_{ji}$, so the diagonal entry of $[\tau]$ at $\mathbf{E}_{ij}$ is 1 if $i = j$ and 0 otherwise, and the trace is n.

(c) Over $\mathbb{F}_2$, $-1 = 1$. If $\tau(\mathbf{X}) = \lambda \mathbf{X}$ with $\mathbf{X} \neq 0$, then as in Exercise (B2: The transpose map) (a), $\lambda^2 = 1$, so $(\lambda - 1)^2 = \lambda^2 - 2\lambda + 1 = \lambda^2 + 1 = 0$ and $\lambda = 1$. So $\operatorname{spec}(\tau) = \{1\}$ and $E_1(\tau)$ is the space of symmetric matrices. The spanning argument in (a) did not divide by 2, so $\dim E_1(\tau) = n(n+1)/2$. For $n \geq 2$, $n(n+1)/2 < n^2$, so condition (d) of Theorem 8.4.1 fails, and τ is not diagonalizable.

> For instance, $\mathbf{E}_{12}$ is not a sum of eigenvectors.

8.5 The Minimal Polynomial

Section 4 decided diagonalizability by counting eigenvectors, one eigenspace at a time. There is a second source of information about an operator, which Chapter 5 set up: the polynomials that kill it. On a finite-dimensional space they form an ideal of $F[x]$, and that ideal has a single monic generator. This section gives the generator its name, the minimal polynomial, and shows that its roots are exactly the eigenvalues. We learn two ways to compute it and check that similar matrices share it. The next section compares it with the characteristic polynomial, and Section 8 reads diagonalizability off its factorization.

8.5.1 The polynomial that divides all the others

Chapter 5 turned every polynomial identity satisfied by an operator into a statement about one ideal. For $T \in \mathcal{L}(V)$, the set

$$I_T = \{p \in F[x] : p(T) = 0\}$$

is an ideal of $F[x]$ (Theorem 5.7.3 (a)). If V is finite-dimensional, it contains a non-zero polynomial (Theorem 5.7.3 (c)). Then it consists of the multiples of a unique monic polynomial (Theorem 5.7.3 (b)).

Look at what this says for one operator. A projection P with $P \neq 0, \mathrm{id}_V$ satisfies $P^2 = P$, so $x^2 - x$ kills it. So do $x^3 - x^2$, $(x^2 - x)(x + 5)$ and $x^{10} - x^9$, and a short calculation shows each one is a multiple of $x^2 - x$. This is no accident. Every annihilating polynomial of P is a multiple of $x^2 - x$, which Chapter 5 found to be the monic generator of I_P. One polynomial controls the whole list, and whenever something in mathematics is unique we give it a name.

The minimal polynomial of T is the one monic polynomial that kills T and divides every other polynomial that kills T.

Definition 8.5.1 — Minimal Polynomial

Let V be a **finite-dimensional** vector space over F and $T \in \mathcal{L}(V)$. The **minimal polynomial** of T is **the** unique **monic** polynomial $m_T \in F[x]$ with

$$I_T = \{p \in F[x] : p(T) = 0\} = \langle m_T \rangle.$$

Equivalently, m_T is the monic polynomial of **least degree** with $m_T(T) = 0$.

For $\mathbf{A} \in M_n(F)$, the minimal polynomial is $m_{\mathbf{A}} := m_{T_{\mathbf{A}}}$: the monic polynomial of least degree with $m_{\mathbf{A}}(\mathbf{A}) = 0$.

In words: we look at **all** polynomials p with $p(T) = 0$, where $p(T)$ replaces x^k by T^k and the constant term c by $c\,\mathrm{id}_V$ (Definition 3.4.2). They are exactly the multiples of one polynomial m_T. Among the generators of this ideal, which differ by non-zero constant factors, we pick **the monic** one. The second sentence of the definition gives the same polynomial described by size: it is the monic polynomial of **least degree** that kills T.

Well-definedness. Three things need checking, and Chapter 5 did all three. *Existence:* $I_T \neq \{0\}$ because V is finite-dimensional (Theorem 5.7.3 (c)). *Uniqueness:* a non-zero ideal of $F[x]$ has exactly one monic generator (Theorem 5.2.2). *The two descriptions agree:* the same theorem says that the monic generator is the unique monic polynomial of least degree in the ideal. For a matrix, $p(T_{\mathbf{A}}) = 0$ if and only if $p(\mathbf{A}) = 0$, because $[p(T_{\mathbf{A}})]_{\mathcal{E}} = p(\mathbf{A})$ in the standard basis $\mathcal{E}$ (Corollary 3.6.3). So $I_{T_{\mathbf{A}}} = \{p : p(\mathbf{A}) = 0\}$, and the matrix version is the operator version for $T_{\mathbf{A}}$.

The name records the second description: m_T is the annihilating polynomial of minimal degree. The first description is the one we use in proofs, because it hands us a divisibility for free.

Theorem 8.5.1 — Annihilating Polynomials Are Multiples of the Minimal Polynomial

Let V be finite-dimensional and $T \in \mathcal{L}(V)$. For every $p \in F[x]$,

$$p(T) = 0 \iff m_T \mid p.$$

In particular, a non-zero polynomial that annihilates T has degree at least $\deg m_T$. If $V \neq \{\mathbf{0}\}$, then $\deg m_T \geq 1$.

Proof. By Definition 8.5.1, $p(T) = 0$ means $p \in \langle m_T \rangle$, that is, $p = q\, m_T$ for some $q \in F[x]$, that is, $m_T \mid p$. If $p \neq 0$ and $m_T \mid p$, then $\deg m_T \leq \deg p$ by Proposition 5.1.2 (c). Finally, the only monic polynomial of degree 0 is the constant 1, and $1(T) = \mathrm{id}_V \neq 0$ when $V \neq \{\mathbf{0}\}$; so $m_T \neq 1$ and $\deg m_T \geq 1$.

■

This is the move we will use again and again: **a polynomial relation becomes a divisibility.** If we learn that $T^3 = T$, we do not need to know anything else about T to conclude that $m_T \mid x^3 - x = x(x-1)(x+1)$. That leaves only finitely many candidates for m_T. To list candidates like these we need to know the monic divisors of a factored polynomial, and unique factorization describes them exactly.

Lemma 8.5.2 — Monic Divisors of a Factored Polynomial

Let $f = p_1^{e_1} \cdots p_k^{e_k} \in F[x]$, where $k \geq 1$, $p_1, \ldots, p_k$ are **distinct** monic irreducible polynomials and $e_i \geq 1$. Then the monic divisors of f are exactly the polynomials

$$p_1^{f_1} \cdots p_k^{f_k} \qquad \text{with } 0 \leq f_i \leq e_i \text{ for each } i.$$

Idea. One direction is a product: the missing factors form the cofactor. For the other, factor a monic divisor d into irreducibles, multiply that factorization by one of the cofactor, and compare the result with the factorization of f. Uniqueness says the two lists of irreducibles agree, so the irreducibles in d are among the p_i, and none can occur more often in d than in f.

Proof. Each such product divides f, with cofactor $p_1^{e_1-f_1} \cdots p_k^{e_k-f_k}$. Conversely, let d be monic with $f = dh$. If $d = 1$, take every $f_i = 0$. Otherwise d is non-constant, and by Theorem 5.3.5 (a) it is a product $q_1 \cdots q_s$ of monic irreducibles; the constant in front is

the leading coefficient of d, which is 1. The cofactor h is non-zero (as $f \neq 0$), so it is either a non-zero constant c or, by the same theorem, $c\,r_1 \cdots r_t$ with r_j monic irreducible. Multiplying, $f = c\,q_1 \cdots q_s\,r_1 \cdots r_t$ (with no r's in the first case) is a factorization of f into a constant and monic irreducibles. By Theorem 5.3.5 (b), after renumbering it is the factorization $f = 1 \cdot p_1^{e_1} \cdots p_k^{e_k}$, in which p_i occurs exactly e_i times. So each q_j is one of the p_i, and p_i occurs at most e_i times among $q_1, \ldots, q_s$. Hence $d = p_1^{f_1} \cdots p_k^{f_k}$ with $0 \leq f_i \leq e_i$.

■

Examples. Each computation follows the same plan: find one annihilating polynomial, list its monic divisors with Lemma 8.5.2, and discard those that do not annihilate.

- **A diagonal matrix with a repeated entry.** Let $\mathbf{A} = \operatorname{diag}(1, 1, 2)$. Diagonal matrices multiply entry by entry, so

$$(\mathbf{A} - \mathbf{I})(\mathbf{A} - 2\mathbf{I}) = \operatorname{diag}(0, 0, 1)\ \operatorname{diag}(-1, -1, 0) = 0.$$

  By Theorem 8.5.1, $m_{\mathbf{A}}$ is a monic divisor of $(x-1)(x-2)$: one of 1, $x-1$, $x-2$, $(x-1)(x-2)$. None of the first three annihilates $\mathbf{A}$, since $\mathbf{I}$, $\mathbf{A} - \mathbf{I} = \operatorname{diag}(0, 0, 1)$ and $\mathbf{A} - 2\mathbf{I} = \operatorname{diag}(-1, -1, 0)$ are non-zero. So $m_{\mathbf{A}} = (x-1)(x-2)$. The repeated diagonal entry 1 appears only **once** in $m_{\mathbf{A}}$, while the characteristic polynomial is $p_{\mathbf{A}} = (x-1)^2(x-2)$.
- **A matrix with too few eigenvectors.** Let $\mathbf{J} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$ over any field. Then $\mathbf{J} - \mathbf{I} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} \neq 0$, and $(\mathbf{J} - \mathbf{I})^2 = 0$. So $m_{\mathbf{J}}$ is a monic divisor of $(x-1)^2$, namely 1, $x-1$ or $(x-1)^2$, and the first two do not annihilate $\mathbf{J}$. Hence $m_{\mathbf{J}} = (x-1)^2$, which equals $p_{\mathbf{J}}$.
- **Projections.** Chapter 5 found, by this plan, that a projection P with $P \neq 0$ and $P \neq \mathrm{id}_V$ has $m_P = x^2 - x$ (the examples after Theorem 5.7.3).
- **Differentiation.** Let D be differentiation on $\mathbb{R}[x]_{\leq n}$. Then $D^{n+1} = 0$ and $D^n \neq 0$ (Example (Differentiation Is Nilpotent)). By Lemma 8.5.2, the monic divisors of x^{n+1} are the powers x^j with $0 \leq j \leq n+1$. For $j \leq n$, $D^j \neq 0$, since $D^n = D^{n-j}D^j$ would otherwise be 0. Hence $m_D = x^{n+1}$, of degree $n+1 = \dim \mathbb{R}[x]_{\leq n}$.
- **Degenerate cases.** On $V \neq \{\mathbf{0}\}$, the identity has $m = x - 1$ and the zero operator has $m = x$: each is killed by a polynomial of degree 1, which is the least possible degree. More generally $m_{c\,\mathrm{id}_V} = x - c$, and every 1×1 matrix (c) has $m = x - c$. On $V = \{\mathbf{0}\}$, even the constant 1 annihilates, so $m_T = 1$. This last case is the reason for the hypothesis $V \neq \{\mathbf{0}\}$ in Theorem 8.5.1.

Non-example by minimal change. For $\mathbf{J}$ above, take $q = x - 1$ instead of $(x-1)^2$. It is still monic, it has the least degree a minimal polynomial can have on a non-zero space, and its only root is the eigenvalue 1 of $\mathbf{J}$. What fails is the clause $q(\mathbf{J}) = 0$: $q(\mathbf{J}) = \mathbf{J} - \mathbf{I} \neq 0$. In the other direction, $(x-1)^3$ is monic and does annihilate $\mathbf{J}$, but it fails the clause $I_{\mathbf{J}} = \langle q \rangle$: the annihilating polynomial $(x-1)^2$ is not a multiple of $(x-1)^3$.

Quick check. Find the minimal polynomial of $2\mathbf{I}_3$ and of $\mathbf{N} = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{pmatrix} \in M_3(F)$.

Solution. $2\mathbf{I}_3 - 2\mathbf{I}_3 = 0$, so $m_{2\mathbf{I}_3}$ divides $x-2$; it is not 1, since $\mathbf{I}_3 \neq 0$. Hence $m_{2\mathbf{I}_3} = x-2$. For $\mathbf{N}$: $\mathbf{N}\mathbf{e}_1 = \mathbf{0}$, $\mathbf{N}\mathbf{e}_2 = \mathbf{e}_1$, $\mathbf{N}\mathbf{e}_3 = \mathbf{e}_2$, so $\mathbf{N}^2\mathbf{e}_3 = \mathbf{e}_1 \neq \mathbf{0}$ and $\mathbf{N}^3$ kills $\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3$. Thus

$\mathbf{N}^3 = 0 \neq \mathbf{N}^2$. By Lemma 8.5.2, $m_{\mathbf{N}} \in \{1, x, x^2, x^3\}$, and only x^3 annihilates $\mathbf{N}$ (the others give $\mathbf{I}_3, \mathbf{N}, \mathbf{N}^2 \neq 0$). So $m_{\mathbf{N}} = x^3$.

Why this definition. Each clause has a job.

- *Monic.* The polynomials m and $5m$ generate the same ideal, so "a generator" is determined only up to a non-zero constant. Insisting on leading coefficient 1 picks one, and makes statements like "$m_{\mathbf{A}} = (x-1)(x-2)$" meaningful.
- *Generator, not only least degree.* The two descriptions give the same polynomial. Stating the definition through the ideal puts Theorem 8.5.1 in front of us, and divisibility is the property we use.
- *Finite dimension.* Without it, I_T can be $\{0\}$, and then there is nothing to name. For multiplication by x on $F[x]$, $p(S)(1) = p$, so $p(S) \neq 0$ for every $p \neq 0$ (the remark after Theorem 5.7.2). The same happens for the right shift on $F^{\mathbb{N}}$.

Warning. **The minimal polynomial is not the characteristic polynomial.** For $\mathbf{I}_2$, $m = x - 1$ while $p = (x-1)^2$; for $\operatorname{diag}(1, 1, 2)$ above, $m = (x-1)(x-2)$ while $p = (x-1)^2(x-2)$. The two can differ in their exponents, and m can have smaller degree than the size of the matrix. How they are related is the subject of the next section. Its main theorem is one that Chapter 6 warned against "proving" by substituting $x = \mathbf{A}$ into $\det(x\mathbf{I} - \mathbf{A})$; that shortcut is not a proof and must not be used here either.

8.5.2 The roots are the eigenvalues

The minimal polynomial is defined by an ideal, and eigenvalues by vectors. They are closely linked.

Theorem 8.5.3 — Roots of the Minimal Polynomial

Let V be finite-dimensional, $T \in \mathcal{L}(V)$ and $\lambda \in F$. Then $m_T(\lambda) = 0$ if and only if λ is an eigenvalue of T. Consequently, if $\dim V \geq 1$, then m_T and p_T have the same roots in F.

Idea. ($\Leftarrow$) is a one-liner: apply $m_T(T) = 0$ to an eigenvector $\mathbf{v}$. Since T scales $\mathbf{v}$ by λ, every polynomial in T scales $\mathbf{v}$ by the value of the polynomial at λ. For ($\Rightarrow$), a root gives a factor: $m_T = (x - \lambda)q$. The cofactor q has smaller degree, so by minimality it does **not** kill T, and some vector $\mathbf{w}$ survives it. Then $q(T)\mathbf{w}$ is non-zero and is killed by $T - \lambda\,\mathrm{id}_V$. The eigenvector is manufactured by the part of m_T we removed.

Proof. ($\Leftarrow$) Let $\mathbf{v} \neq \mathbf{0}$ with $T\mathbf{v} = \lambda\mathbf{v}$. By Exercise (B3: Eigenvalues of powers and inverses) (a), $p(T)\mathbf{v} = p(\lambda)\mathbf{v}$ for every $p \in F[x]$. With $p = m_T$,

$$\mathbf{0} = m_T(T)\mathbf{v} = m_T(\lambda)\mathbf{v}.$$

Since $\mathbf{v} \neq \mathbf{0}$, Theorem 1.1.9 gives $m_T(\lambda) = 0$.

($\Rightarrow$) Suppose $m_T(\lambda) = 0$. By Theorem 5.1.3 (b), $m_T = (x - \lambda)q$ for some $q \in F[x]$, and q is monic with $\deg q = \deg m_T - 1$ by Theorem 0.8.3. By Theorem 8.5.1, a non-zero polynomial of degree less than $\deg m_T$ does not annihilate T; so $q(T) \neq 0$, and there is

$\mathbf{w} \in V$ with $\mathbf{v} := q(T)\mathbf{w} \neq \mathbf{0}$. By Theorem 5.7.1 (b),

$$(T - \lambda\,\mathrm{id}_V)\mathbf{v} = (T - \lambda\,\mathrm{id}_V)\,q(T)\mathbf{w} = m_T(T)\mathbf{w} = \mathbf{0}.$$

So $T\mathbf{v} = \lambda\mathbf{v}$ with $\mathbf{v} \neq \mathbf{0}$, and λ is an eigenvalue of T.

If $\dim V \geq 1$, the eigenvalues of T are exactly the roots of p_T in F (Theorem 8.2.1, (a) $\Leftrightarrow$ (e)), so m_T and p_T have the same roots in F. This proves the theorem.

■

So the minimal polynomial knows the spectrum, just as the characteristic polynomial does, although the multiplicities of the roots may differ. The examples bear this out. $\mathrm{diag}(1,1,2)$ has spectrum $\{1,2\}$, the roots of $(x-1)(x-2)$. $\mathbf{J}$ has spectrum $\{1\}$, the root of $(x-1)^2$. The rotation R of $\mathbb{R}^2$ by a right angle has $m_R = x^2+1$ (the check after Theorem 5.7.3), with no real root, and indeed $\mathrm{spec}(R) = \emptyset$ over $\mathbb{R}$. Its minimal polynomial has no linear factor at all.

Two consequences are worth stating.

- **Invertibility.** Taking $\lambda = 0$: for $V \neq \{\mathbf{0}\}$, T is invertible if and only if $m_T(0) \neq 0$. Indeed $m_T(0) = 0$ if and only if $0 \in \mathrm{spec}(T)$, if and only if $T = T - 0\,\mathrm{id}_V$ is not invertible (Theorem 8.2.1, (a) $\Leftrightarrow$ (c) with $\lambda = 0$; for matrices this is Theorem 8.2.6). Chapter 5 proved the same statement without eigenvalues (Exercise (C1: Inverses are polynomials) (c)).
- **Over $\mathbb{C}$.** If $F = \mathbb{C}$ and $V \neq \{\mathbf{0}\}$, then m_T splits (Corollary 5.5.5), and its roots are the distinct eigenvalues $\lambda_1, \dots, \lambda_k$. So

  $$m_T = (x-\lambda_1)^{s_1} \cdots (x-\lambda_k)^{s_k} \qquad \text{with every } s_i \geq 1.$$

  Only the exponents remain to be found.

8.5.3 Computing the minimal polynomial

There are two practical methods. The first needs nothing but elimination. The second uses the eigenvalues, when we know them, to cut the search down to a few candidates.

Method 1: the first dependence among powers. The proof of Theorem 5.7.2 searched for a dependence among $\mathrm{id}_V, T, T^2, \dots$. The **first** dependence that appears gives m_T exactly.

Proposition 8.5.4 — The First Dependence Among the Powers

Let V be finite-dimensional and $T \in \mathcal{L}(V)$. Let $d \geq 0$ be the **least** integer such that the list $(\mathrm{id}_V, T, \dots, T^d)$ in $\mathcal{L}(V)$ is linearly dependent. Then there are unique $c_0, \dots, c_{d-1} \in F$ with

$$T^d = c_0\,\mathrm{id}_V + c_1 T + \cdots + c_{d-1}T^{d-1},$$

and $m_T = x^d - c_{d-1}x^{d-1} - \cdots - c_1 x - c_0$. In particular $\deg m_T = d$. The same holds for $\mathbf{A} \in M_n(F)$, with powers of $\mathbf{A}$ in $M_n(F)$.

Proof. Such a d exists: with $n = \dim V$, the space $\mathcal{L}(V)$ has dimension n^2 (Theorem 3.6.4), so the list $(\mathrm{id}_V, T, \dots, T^{n^2})$, of length n^2+1, is linearly dependent (Theorem 1.6.3 (a)). By minimality of d, the list $(\mathrm{id}_V, \dots, T^{d-1})$ is independent (for $d = 0$ it is empty). By Lemma 1.5.3, since appending T^d makes it dependent, $T^d \in \mathrm{span}(\mathrm{id}_V, \dots, T^{d-1})$. The coefficients are unique by Theorem 1.4.3.

Let $q = x^d - c_{d-1}x^{d-1} - \cdots - c_0$. It is monic, and $q(T) = 0$ by the displayed relation. Let $p \neq 0$ with $\deg p < d$. Then $p(T) = \sum_{k<d} a_k T^k$ with the a_k not all zero, and this is not 0 because $(\mathrm{id}_V, \dots, T^{d-1})$ is independent. So no non-zero polynomial of degree less than d annihilates T, and q is the monic annihilating polynomial of least degree. By Definition 8.5.1, $q = m_T$.

■

Example. (The Minimal Polynomial from the First Dependence)

Find the minimal polynomial of

$$\mathbf{A} = \begin{pmatrix} 3 & 2 & -2 \\ -2 & -1 & 2 \\ -2 & -2 & 3 \end{pmatrix} \in M_3(\mathbb{R}),$$

the matrix of Example (Diagonalizing a 3×3 Matrix with a Repeated Eigenvalue), without using its eigenvalues.

Solution. Degree 1. $\mathbf{A}$ is not a scalar multiple of $\mathbf{I}_3$, since its $(1,2)$-entry is non-zero. So $(\mathbf{I}_3, \mathbf{A})$ is independent.

Degree 2. Multiplying out,

$$\mathbf{A}^2 = \begin{pmatrix} 9 & 8 & -8 \\ -8 & -7 & 8 \\ -8 & -8 & 9 \end{pmatrix}.$$

We look for a, b with $\mathbf{A}^2 = a\mathbf{A} + b\mathbf{I}_3$. The $(1,2)$-entries give $8 = 2a$, so $a = 4$. The $(1,1)$-entries give $9 = 3a + b$, so $b = -3$. Now check every entry of $4\mathbf{A} - 3\mathbf{I}_3$:

$$4\mathbf{A} - 3\mathbf{I}_3 = \begin{pmatrix} 12-3 & 8 & -8 \\ -8 & -4-3 & 8 \\ -8 & -8 & 12-3 \end{pmatrix} = \begin{pmatrix} 9 & 8 & -8 \\ -8 & -7 & 8 \\ -8 & -8 & 9 \end{pmatrix} = \mathbf{A}^2.$$

So $(\mathbf{I}_3, \mathbf{A}, \mathbf{A}^2)$ is dependent, and $d = 2$. By Proposition 8.5.4,

$$m_{\mathbf{A}} = x^2 - 4x + 3 = (x-1)(x-3).$$

This fits Theorem 8.5.3: Example (Diagonalizing a 3×3 Matrix with a Repeated Eigenvalue) found the eigenvalues 1 and 3, and $p_{\mathbf{A}} = (x-1)^2(x-3)$. Once again the repeated eigenvalue 1 appears only once in $m_{\mathbf{A}}$. Section 8 explains that this is exactly why $\mathbf{A}$ was diagonalizable.

Method 2: eigenvalues and trial exponents. Suppose p_T splits, $p_T = (x-\lambda_1)^{a_1} \cdots (x-\lambda_k)^{a_k}$ with distinct λ_i. By Theorem 8.5.3, every $x - \lambda_i$ divides m_T. If we find **any** annihilating polynomial of the form $q = (x-\lambda_1)^{t_1} \cdots (x-\lambda_k)^{t_k}$, then $m_T \mid q$. By Lemma 8.5.2, $m_T =$

$(x-\lambda_1)^{s_1}\cdots(x-\lambda_k)^{s_k}$ with $1 \le s_i \le t_i$, so only finitely many candidates remain, and we test them from the smallest degree up. The next section proves that $q = p_T$ always annihilates T, so the search always succeeds with $t_i \le a_i$. Here we verify that directly.

Example. (The Minimal Polynomial from the Eigenvalues)

Let $\mathbf{A} = \begin{pmatrix} 2 & 0 & 1 \\ 1 & 3 & 1 \\ 1 & 0 & 2 \end{pmatrix} \in M_3(\mathbb{R})$, with $p_{\mathbf{A}} = (x-1)(x-3)^2$ (Example (A 3×3 Characteristic Polynomial)). Find $m_{\mathbf{A}}$.

Solution. By Theorem 8.5.3, both $x-1$ and $x-3$ divide $m_{\mathbf{A}}$, so the candidate of least degree is $(x-1)(x-3)$. With

$$\mathbf{A}-\mathbf{I} = \begin{pmatrix} 1 & 0 & 1 \\ 1 & 2 & 1 \\ 1 & 0 & 1 \end{pmatrix}, \qquad \mathbf{A}-3\mathbf{I} = \begin{pmatrix} -1 & 0 & 1 \\ 1 & 0 & 1 \\ 1 & 0 & -1 \end{pmatrix},$$

the product is

$$(\mathbf{A}-\mathbf{I})(\mathbf{A}-3\mathbf{I}) = \begin{pmatrix} 0 & 0 & 0 \\ 2 & 0 & 2 \\ 0 & 0 & 0 \end{pmatrix} \neq 0.$$

So $m_{\mathbf{A}} \neq (x-1)(x-3)$. Raise one exponent and try $(x-1)(x-3)^2$ (had this failed, the other candidate of degree 3, namely $(x-1)^2(x-3)$, would come next). Polynomials in $\mathbf{A}$ commute (Theorem 5.7.1 (c)), so we can multiply the matrix just found by $\mathbf{A}-3\mathbf{I}$ on the right:

$$(\mathbf{A}-\mathbf{I})(\mathbf{A}-3\mathbf{I})^2 = \begin{pmatrix} 0 & 0 & 0 \\ 2 & 0 & 2 \\ 0 & 0 & 0 \end{pmatrix}\begin{pmatrix} -1 & 0 & 1 \\ 1 & 0 & 1 \\ 1 & 0 & -1 \end{pmatrix} = \begin{pmatrix} 0 & 0 & 0 \\ -2+2 & 0 & 2-2 \\ 0 & 0 & 0 \end{pmatrix} = 0.$$

So $m_{\mathbf{A}} \mid (x-1)(x-3)^2$, and by Lemma 8.5.2, $m_{\mathbf{A}} = (x-1)^s(x-3)^t$ with $1 \le s \le 1$ and $1 \le t \le 2$. The case $t = 1$ was excluded, so

$$m_{\mathbf{A}} = (x-1)(x-3)^2 = p_{\mathbf{A}}.$$

In Section 3 we found $g(3) = 1 < 2 = a(3)$ for this matrix. The exponent 2 of $x-3$ in $m_{\mathbf{A}}$ is the polynomial trace of the same shortage of eigenvectors.

The product in Method 2 need not be multiplied out completely: to rule out a candidate it is enough to find **one** non-zero entry, and to confirm one, the factored form usually makes the zero visible.

8.5.4 Similar matrices and block diagonal matrices

The minimal polynomial belongs to the operator, not to a basis. That is what makes it an invariant of similarity.

Theorem 8.5.5 — Similar Matrices Have the Same Minimal Polynomial

Let V be finite-dimensional with a basis $\mathcal{B}$, and let $T \in \mathcal{L}(V)$. Then $m_T = m_{[T]_\mathcal{B}}$. If $\mathbf{A}, \mathbf{B} \in M_n(F)$ are similar, then $m_\mathbf{A} = m_\mathbf{B}$.

Proof. By Corollary 3.6.3, $[p(T)]_\mathcal{B} = p([T]_\mathcal{B})$ for every $p \in F[x]$. An operator is zero exactly when its matrix is zero (Theorem 3.6.4), so $p(T) = 0$ if and only if $p([T]_\mathcal{B}) = 0$. Thus T and $[T]_\mathcal{B}$ have the same ideal of annihilating polynomials, and hence the same monic generator. If $\mathbf{B} = \mathbf{P}^{-1}\mathbf{A}\mathbf{P}$, then $p(\mathbf{B}) = \mathbf{P}^{-1}p(\mathbf{A})\mathbf{P}$ by Proposition 3.7.6 (c), so again $p(\mathbf{A}) = 0$ if and only if $p(\mathbf{B}) = 0$, and $m_\mathbf{A} = m_\mathbf{B}$. ■

The theorem gives a quick non-similarity test. For instance $\mathbf{I}_2$ and $\mathbf{J} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$ have the same characteristic polynomial, but $m_{\mathbf{I}_2} = x - 1 \neq (x-1)^2 = m_\mathbf{J}$, so they are not similar.

Chapter 7 showed that a block diagonal matrix computes polynomials blockwise: $p(\mathbf{A} \oplus \mathbf{B}) = p(\mathbf{A}) \oplus p(\mathbf{B})$ (Theorem 7.1.4 (b)). So a polynomial kills $\mathbf{A} \oplus \mathbf{B}$ exactly when it kills both blocks. In the language of ideals, the answer is the least common multiple.

Proposition 8.5.6 — Minimal Polynomial of a Block Diagonal Matrix

Let $\mathbf{A} \in M_k(F)$ and $\mathbf{B} \in M_l(F)$ with $k, l \geq 1$. Then $m_{\mathbf{A}\oplus\mathbf{B}} = \operatorname{lcm}(m_\mathbf{A}, m_\mathbf{B})$.

Proof. Let $p \in F[x]$. By Theorem 7.1.4 (b), $p(\mathbf{A} \oplus \mathbf{B}) = p(\mathbf{A}) \oplus p(\mathbf{B})$, which is zero if and only if $p(\mathbf{A}) = 0$ and $p(\mathbf{B}) = 0$. By Theorem 8.5.1, this holds if and only if $p \in \langle m_\mathbf{A} \rangle \cap \langle m_\mathbf{B} \rangle$. So $I_{\mathbf{A}\oplus\mathbf{B}} = \langle m_\mathbf{A} \rangle \cap \langle m_\mathbf{B} \rangle$. This ideal contains $m_{\mathbf{A}\oplus\mathbf{B}} \neq 0$, and by Definition 5.2.4 its monic generator is $\operatorname{lcm}(m_\mathbf{A}, m_\mathbf{B})$. By Definition 8.5.1 its monic generator is also $m_{\mathbf{A}\oplus\mathbf{B}}$, and the monic generator is unique (Theorem 5.2.2). ■

For example, $\operatorname{diag}(1,1,2) = \mathbf{I}_2 \oplus (2)$ has $m = \operatorname{lcm}(x-1, x-2) = (x-1)(x-2)$, as computed above. And $\mathbf{J} \oplus (1)$ has $m = \operatorname{lcm}\left((x-1)^2, x-1\right) = (x-1)^2$: a block can contribute a factor that the other block already contains, and then the factor is not repeated. This is the difference from the characteristic polynomial, which multiplies: $p_{\mathbf{A}\oplus\mathbf{B}} = p_\mathbf{A}\, p_\mathbf{B}$.

Warning. **Equal minimal polynomials do not make matrices similar.** $\operatorname{diag}(1,1,2)$ and $\operatorname{diag}(1,2,2)$ both have minimal polynomial $(x-1)(x-2)$, by Proposition 8.5.6. But their characteristic polynomials $(x-1)^2(x-2)$ and $(x-1)(x-2)^2$ differ, so they are not similar (Theorem 6.10.3).

Remark. Even the minimal and characteristic polynomials **together** do not decide similarity. With $\mathbf{J} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$, the matrices $\mathbf{J} \oplus \mathbf{J}$ and $\mathbf{J} \oplus \mathbf{I}_2$ in $M_4(F)$ both have characteristic polynomial $(x-1)^4$ and, by Proposition 8.5.6, minimal polynomial $(x-1)^2$, as $\operatorname{lcm}\left((x-1)^2, (x-1)^2\right)$ and $\operatorname{lcm}\left((x-1)^2, x-1\right)$ are both $(x-1)^2$. Yet $(\mathbf{J} \oplus \mathbf{J}) - \mathbf{I}_4$

has rank 2 and $(\mathbf{J} \oplus \mathbf{I}_2) - \mathbf{I}_4$ has rank 1; if $\mathbf{B} = \mathbf{P}^{-1}\mathbf{A}\mathbf{P}$, then $\mathbf{B} - \mathbf{I} = \mathbf{P}^{-1}(\mathbf{A} - \mathbf{I})\mathbf{P}$, so these ranks would have to agree (Proposition 3.7.6 (a)), and the two matrices are not similar. The invariant that does decide similarity is the subject of Chapter 9.

8.5.5 Exercises

8.5.5.1 A. Check your understanding

Exercise A1.

(a) Define the minimal polynomial of an operator T on a finite-dimensional space, and give its two equivalent descriptions.

(b) True or false: $m_{\mathbf{A}} = p_{\mathbf{A}}$ for every $\mathbf{A} \in M_n(F)$. Justify your answer.

(c) State the relation between the roots of m_T and the eigenvalues of T.

(d) Let $\mathbf{A} \neq 0$ satisfy $\mathbf{A}^3 = 0$. Which polynomials can $m_{\mathbf{A}}$ be?

(e) True or false: if $m_{\mathbf{A}} = m_{\mathbf{B}}$, then $\mathbf{A} \sim \mathbf{B}$. Justify your answer.

(f) Explain why multiplication by x on $F[x]$ has no minimal polynomial.

Solution.

(a) m_T is the unique monic polynomial with $\{p : p(T) = 0\} = \langle m_T \rangle$; equivalently, the monic polynomial of least degree with $m_T(T) = 0$ (Definition 8.5.1).

(b) False. For $\mathbf{I}_2$, $m = x - 1$ and $p = (x-1)^2$.

(c) They coincide: $m_T(\lambda) = 0$ if and only if λ is an eigenvalue of T (Theorem 8.5.3).

(d) By Theorem 8.5.1, $m_{\mathbf{A}} \mid x^3$, so $m_{\mathbf{A}} \in \{1, x, x^2, x^3\}$ by Lemma 8.5.2. It is not 1 (as $\mathbf{I} \neq 0$) and not x (as $\mathbf{A} \neq 0$). So $m_{\mathbf{A}} = x^2$ or $m_{\mathbf{A}} = x^3$, and both occur: $\begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$ and the matrix $\mathbf{N}$ of the Quick check.

(e) False. $\operatorname{diag}(1, 1, 2)$ and $\operatorname{diag}(1, 2, 2)$ have the same minimal polynomial but different characteristic polynomials.

(f) For $S(f) = xf$, we have $p(S)(1) = p$, so $p(S) \neq 0$ for all $p \neq 0$. The ideal I_S is $\{0\}$ and has no monic generator. The space $F[x]$ is infinite-dimensional, so the definition does not apply.

8.5.5.2 B. Practice

Exercise B1: Computing minimal polynomials.

Find the minimal polynomial of each real matrix.

(a) $\mathbf{A}_1 = \begin{pmatrix} 4 & -1 \\ 1 & 2 \end{pmatrix}$.

(b) $\mathbf{A}_2 = \begin{pmatrix} 1 & 1 & 1 \\ 1 & 1 & 1 \\ 1 & 1 & 1 \end{pmatrix}$.

(c) $\mathbf{A}_3 = \begin{pmatrix} 2 & 1 & 1 \\ 0 & 1 & -1 \\ -1 & -1 & 1 \end{pmatrix}$, given that $p_{\mathbf{A}_3} = (x-1)^2(x-2)$.

(d) $\mathbf{A}_4 = \begin{pmatrix} 2 & 1 & 1 \\ -1 & 0 & -1 \\ 1 & 1 & 2 \end{pmatrix}$, given that $p_{\mathbf{A}_4} = (x-1)^2(x-2)$.

Hence decide whether $\mathbf{A}_3$ and $\mathbf{A}_4$ are similar.

Solution.

(a) $\mathbf{A}_1$ is not scalar, so $\deg m_{\mathbf{A}_1} \geq 2$. Here $\operatorname{tr}\mathbf{A}_1 = 6$ and $\det\mathbf{A}_1 = 9$, and $\mathbf{A}_1^2 = \begin{pmatrix} 15 & -6 \\ 6 & 3 \end{pmatrix} = 6\mathbf{A}_1 - 9\mathbf{I}_2$, as one checks entry by entry. By Proposition 8.5.4, $m_{\mathbf{A}_1} = x^2 - 6x + 9 = (x-3)^2$.

(b) $\mathbf{A}_2$ is not scalar. Every entry of $\mathbf{A}_2^2$ is $1+1+1 = 3$, so $\mathbf{A}_2^2 = 3\mathbf{A}_2$. By Proposition 8.5.4, $m_{\mathbf{A}_2} = x^2 - 3x = x(x-3)$.

(c) By Theorem 8.5.3, $(x-1)(x-2) \mid m_{\mathbf{A}_3}$. First candidate:

$$(\mathbf{A}_3 - \mathbf{I})(\mathbf{A}_3 - 2\mathbf{I}) = \begin{pmatrix} 1 & 1 & 1 \\ 0 & 0 & -1 \\ -1 & -1 & 0 \end{pmatrix}\begin{pmatrix} 0 & 1 & 1 \\ 0 & -1 & -1 \\ -1 & -1 & -1 \end{pmatrix} = \begin{pmatrix} -1 & -1 & -1 \\ 1 & 1 & 1 \\ 0 & 0 & 0 \end{pmatrix} \neq 0.$$

Next candidate: multiplying this on the left by $\mathbf{A}_3 - \mathbf{I}$, the rows of the result are $(1,1,1)\mathbf{M}$, $(0,0,-1)\mathbf{M}$ and $(-1,-1,0)\mathbf{M}$, where $\mathbf{M}$ is the matrix just found. Since the rows of $\mathbf{M}$ sum to zero and its third row is zero, all three products are $\mathbf{0}$. So $(\mathbf{A}_3 - \mathbf{I})^2(\mathbf{A}_3 - 2\mathbf{I}) = 0$, and by Lemma 8.5.2, $m_{\mathbf{A}_3} = (x-1)^2(x-2)$.

(d) Again $(x-1)(x-2) \mid m_{\mathbf{A}_4}$, and

$$(\mathbf{A}_4 - \mathbf{I})(\mathbf{A}_4 - 2\mathbf{I}) = \begin{pmatrix} 1 & 1 & 1 \\ -1 & -1 & -1 \\ 1 & 1 & 1 \end{pmatrix}\begin{pmatrix} 0 & 1 & 1 \\ -1 & -2 & -1 \\ 1 & 1 & 0 \end{pmatrix} = 0,$$

since each column of the second matrix has entries summing to 0 and each row of the first is a multiple of $(1,1,1)$. So $m_{\mathbf{A}_4} = (x-1)(x-2)$.

Hence $m_{\mathbf{A}_3} \neq m_{\mathbf{A}_4}$, and by Theorem 8.5.5 $\mathbf{A}_3$ and $\mathbf{A}_4$ are **not** similar, although their characteristic polynomials agree. (This matches Exercise (B1: Computing multiplicities), where the same two matrices appear as $\mathbf{A}_2$ and $\mathbf{A}_3$, with $g(1) = 1$ for the first and $g(1) = 2$ for the second.)

Exercise B2: Operators with $T^2 = T$.

Let $V \neq \{\mathbf{0}\}$ be finite-dimensional and $T \in \mathcal{L}(V)$ with $T^2 = T$.

(a) Show that $m_T \in \{x,\ x-1,\ x(x-1)\}$.

(b) Show that $m_T = x$ exactly when $T = 0$, and $m_T = x - 1$ exactly when $T = \mathrm{id}_V$.

(c) What is m_T on $V = \{\mathbf{0}\}$?

Solution.

(a) $x^2 - x = x(x-1)$ annihilates T, so $m_T \mid x(x-1)$ by Theorem 8.5.1. By Lemma 8.5.2, the monic divisors are $1, x, x-1, x(x-1)$. Since $V \neq \{\mathbf{0}\}$, $\deg m_T \geq 1$, so $m_T \neq 1$.

(b) If $m_T = x$, then $T = m_T(T) = 0$. Conversely, if $T = 0$, then x annihilates T, so $m_T \mid x$, and $m_T = x$ by (a). Likewise $m_T = x - 1$ if and only if $T - \mathrm{id}_V = 0$. In all other cases $m_T = x(x-1)$.

(c) On $V = \{\mathbf{0}\}$, $1(T) = \mathrm{id}_V = 0$, so $m_T = 1$.

Exercise B3: Companion matrices.

Let $n \geq 2$, $p = x^n + a_{n-1}x^{n-1} + \cdots + a_1 x + a_0 \in F[x]$, and let $\mathbf{C} = \mathbf{C}(p)$ be its companion matrix (Exercise (C1: Companion matrices)).

(a) Show that $\mathbf{C}\mathbf{e}_k = \mathbf{e}_{k+1}$ for $1 \leq k \leq n-1$, so $\mathbf{C}^k\mathbf{e}_1 = \mathbf{e}_{k+1}$ for $0 \leq k \leq n-1$.

(b) Deduce that no non-zero polynomial of degree less than n annihilates $\mathbf{C}$.

(c) Show that $p(\mathbf{C})\mathbf{e}_1 = \mathbf{0}$, and hence $p(\mathbf{C})\mathbf{e}_{k+1} = \mathbf{0}$ for all $k \leq n-1$.

(d) Deduce that $m_{\mathbf{C}} = p = p_{\mathbf{C}}$.

Solution.

(a) Column k of $\mathbf{C}$, for $k \leq n-1$, has a single 1 in row $k+1$, so $\mathbf{C}\mathbf{e}_k = \mathbf{e}_{k+1}$. By induction on k, $\mathbf{C}^k\mathbf{e}_1 = \mathbf{C}(\mathbf{C}^{k-1}\mathbf{e}_1) = \mathbf{C}\mathbf{e}_k = \mathbf{e}_{k+1}$.

(b) Let $q = \sum_{k=0}^{d} b_k x^k \neq 0$ with $d \leq n-1$. By (a), $q(\mathbf{C})\mathbf{e}_1 = \sum_k b_k \mathbf{C}^k\mathbf{e}_1 = \sum_k b_k \mathbf{e}_{k+1}$, which is not $\mathbf{0}$ because some $b_k \neq 0$. So $q(\mathbf{C}) \neq 0$.

(c) By (a), $\mathbf{C}^n\mathbf{e}_1 = \mathbf{C}\mathbf{e}_n$, the last column $(-a_0, \ldots, -a_{n-1}) = -\sum_{k=0}^{n-1} a_k \mathbf{e}_{k+1}$. Hence

$$p(\mathbf{C})\mathbf{e}_1 = \mathbf{C}^n\mathbf{e}_1 + \sum_{k=0}^{n-1} a_k \mathbf{C}^k\mathbf{e}_1 = -\sum_k a_k \mathbf{e}_{k+1} + \sum_k a_k \mathbf{e}_{k+1} = \mathbf{0}.$$

For $k \leq n-1$, polynomials in $\mathbf{C}$ commute (Theorem 5.7.1 (c)), so $p(\mathbf{C})\mathbf{e}_{k+1} = p(\mathbf{C})\mathbf{C}^k\mathbf{e}_1 = \mathbf{C}^k p(\mathbf{C})\mathbf{e}_1 = \mathbf{0}$.

(d) By (c), $p(\mathbf{C})$ kills the standard basis, so $p(\mathbf{C}) = 0$ and $m_{\mathbf{C}} \mid p$. By (b), $\deg m_{\mathbf{C}} \geq n = \deg p$. Two monic polynomials, one dividing the other, with $\deg m_{\mathbf{C}} \geq \deg p$, are equal (Proposition 5.1.2 (c), (d)). So $m_{\mathbf{C}} = p$, and $p = p_{\mathbf{C}}$ by Exercise (C1: Companion matrices) (b). Every monic polynomial of degree $n \geq 2$ is therefore the minimal polynomial of some $n \times n$ matrix.

8.5.5.3 C. Going deeper

Exercise C1: Cyclic vectors.

Let $\dim V = n \geq 1$ and $T \in \mathcal{L}(V)$. A vector $\mathbf{v}$ is a **cyclic vector** for T if $(\mathbf{v}, T\mathbf{v}, \ldots, T^{n-1}\mathbf{v})$ is a basis of V.

(a) Prove that if T has a cyclic vector, then $\deg m_T \geq n$.

(b) Suppose $\mathbf{v}$ is cyclic and $T^n\mathbf{v} = -(a_0\mathbf{v} + a_1T\mathbf{v} + \cdots + a_{n-1}T^{n-1}\mathbf{v})$. Show that the matrix of T in the basis $(\mathbf{v}, \dots, T^{n-1}\mathbf{v})$ is the companion matrix of $p = x^n + a_{n-1}x^{n-1} + \cdots + a_0$ (for $n \geq 2$), and deduce $m_T = p_T = p$.

(c) Find a cyclic vector for $\mathbf{J} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$, and show that $\mathbf{I}_2$ has none.

(The converse of (a), that $\deg m_T = n$ forces a cyclic vector, is proved in Chapter 9.)

Solution.

(a) Let $q = \sum_{k=0}^{d} b_k x^k \neq 0$ with $d \leq n-1$. Then $q(T)\mathbf{v} = \sum_k b_k T^k\mathbf{v} \neq \mathbf{0}$, because the vectors $T^k\mathbf{v}$, $k \leq n-1$, are independent and some $b_k \neq 0$. So $q(T) \neq 0$, and by Theorem 8.5.1, $\deg m_T \geq n$.

(b) Let $\mathcal{B} = (\mathbf{v}, T\mathbf{v}, \dots, T^{n-1}\mathbf{v})$. For $k \leq n-2$, $T(T^k\mathbf{v}) = T^{k+1}\mathbf{v}$, the $(k+2)$-th basis vector, so column $k+1$ of $[T]_{\mathcal{B}}$ is $\mathbf{e}_{k+2}$. The last column is $[T^n\mathbf{v}]_{\mathcal{B}} = (-a_0, \dots, -a_{n-1})$. This is $\mathbf{C}(p)$. By Theorem 8.5.5 and Exercise (B3: Companion matrices) (d), $m_T = m_{\mathbf{C}(p)} = p$. By Definition 6.10.2 and Exercise (C1: Companion matrices) (b), $p_T = p_{\mathbf{C}(p)} = p$. (For $n = 1$, $T\mathbf{v} = -a_0\mathbf{v}$ and $T = -a_0\,\mathrm{id}_V$, so $m_T = p_T = x + a_0$ directly.)

(c) $\mathbf{J}\mathbf{e}_2 = (1, 1)$, and $(\mathbf{e}_2, (1, 1))$ is independent, so $\mathbf{e}_2$ is cyclic. For $\mathbf{I}_2$, every $\mathbf{v}$ has $\mathbf{I}_2\mathbf{v} = \mathbf{v}$, so $(\mathbf{v}, \mathbf{I}_2\mathbf{v})$ is dependent. This matches (a): $\deg m_{\mathbf{I}_2} = 1 < 2$.

Exercise C2: Minimal polynomials of the pieces.

Let V be finite-dimensional, $T \in \mathcal{L}(V)$, and U a T-invariant subspace, with restriction $T|_U$ and induced operator $\bar{T}$ on V/U (Definition 8.1.2).

(a) Prove that $p(T|_U) = p(T)|_U$ and $p(\bar{T})(\mathbf{v} + U) = p(T)\mathbf{v} + U$ for every $p \in F[x]$.

(b) Deduce that $m_{T|_U} \mid m_T$ and $m_{\bar{T}} \mid m_T$.

(c) Prove that $m_T \mid m_{T|_U}\, m_{\bar{T}}$.

(d) For $\mathbf{J} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$ and $U = \mathrm{span}(\mathbf{e}_1)$, compute all three minimal polynomials, and show that m_T need not equal $\mathrm{lcm}(m_{T|_U}, m_{\bar{T}})$.

Hint: for (c), apply $m_{\bar{T}}(T)$ to $\mathbf{v}$ and ask where the result lies.

Solution.

(a) First, $(T|_U)^k = T^k|_U$ by induction on k: for $\mathbf{u} \in U$, $(T|_U)^{k+1}\mathbf{u} = T|_U\big((T|_U)^k\mathbf{u}\big) = T(T^k\mathbf{u}) = T^{k+1}\mathbf{u}$. Taking linear combinations, $p(T|_U)\mathbf{u} = p(T)\mathbf{u}$. For the quotient, $\bar{T}^k(\mathbf{v} + U) = T^k\mathbf{v} + U$ by the same induction, using Definition 8.1.2 (b) at each step, and $p(\bar{T})(\mathbf{v}+U) = \sum_k c_k(T^k\mathbf{v}+U) = p(T)\mathbf{v}+U$ by the coset operations (Theorem 3.9.4).

(b) By (a), $m_T(T|_U) = m_T(T)|_U = 0$ and $m_T(\bar{T})(\mathbf{v} + U) = \mathbf{0} + U$ for all $\mathbf{v}$. By Theorem 8.5.1, applied to $T|_U \in \mathcal{L}(U)$ and to $\bar{T} \in \mathcal{L}(V/U)$, both finite-dimensional, $m_{T|_U} \mid m_T$ and $m_{\bar{T}} \mid m_T$.

(c) Let $\mathbf{v} \in V$. By (a), $m_{\bar{T}}(T)\mathbf{v} + U = m_{\bar{T}}(\bar{T})(\mathbf{v} + U) = \mathbf{0} + U$, so $\mathbf{u} \coloneqq m_{\bar{T}}(T)\mathbf{v} \in U$. By (a) again, $m_{T|_U}(T)\mathbf{u} = m_{T|_U}(T|_U)\mathbf{u} = \mathbf{0}$. Hence $(m_{T|_U}\, m_{\bar{T}})(T)\mathbf{v} = m_{T|_U}(T)\, m_{\bar{T}}(T)\mathbf{v} = \mathbf{0}$ (Theorem 5.7.1 (b)). As $\mathbf{v}$ was arbitrary, $m_{T|_U} m_{\bar{T}}$ anni-

hilates T, and $m_T \mid m_{T|_U} m_{\bar{T}}$ by Theorem 8.5.1.

(d) $\mathbf{J}\mathbf{e}_1 = \mathbf{e}_1$, so $T|_U = \mathrm{id}_U$ and $m_{T|_U} = x - 1$. The quotient F^2/U has basis $\mathbf{e}_2 + U$, and $\bar{T}(\mathbf{e}_2 + U) = (1,1) + U = \mathbf{e}_2 + U$, so $\bar{T} = \mathrm{id}$ and $m_{\bar{T}} = x - 1$. But $m_{\mathbf{J}} = (x-1)^2$, computed earlier. So $m_{\mathbf{J}} = m_{T|_U} m_{\bar{T}}$, while $\mathrm{lcm}(m_{T|_U}, m_{\bar{T}}) = x - 1 \neq m_{\mathbf{J}}$. Compare Proposition 8.5.6: when U has an invariant complement the lcm is right, but in general it is not.

8.6 The Cayley–Hamilton Theorem

An operator on an n-dimensional space now carries two monic polynomials. The characteristic polynomial p_T comes from determinants and has degree exactly n. The minimal polynomial m_T comes from the ideal of polynomials that kill T, and the previous section showed that it has the same roots as p_T. Chapter 6 stated, without proof, the fact that ties the two together: every square matrix satisfies its own characteristic polynomial. Chapter 6 also warned against a one-line fake proof of that statement. This section gives a real proof, built on the adjugate identity of Chapter 6 read over $F[x]$. It then draws the consequences: m_T divides p_T, inverses are polynomials, and high powers of a matrix reduce to low ones.

8.6.1 The statement, and a proof that is not one

Chapter 5 proved that every operator on an n-dimensional space is killed by some non-zero polynomial of degree at most n^2 (Theorem 5.7.2). The bound came from counting: $\mathcal{L}(V)$ has dimension n^2. Counting cannot do better, yet in every example so far a polynomial of degree at most n sufficed. The characteristic polynomial always has degree n, and it is the natural candidate.

Theorem 8.6.1 — Cayley–Hamilton Theorem

Let $n \geq 1$ and $\mathbf{A} \in M_n(F)$. Then

$$p_{\mathbf{A}}(\mathbf{A}) = 0.$$

Likewise, if V is a finite-dimensional vector space over F with $\dim V \geq 1$ and $T \in \mathcal{L}(V)$, then $p_T(T) = 0$.

Here $p_{\mathbf{A}}(\mathbf{A})$ means what it always means (Definition 0.9.14): if $p_{\mathbf{A}} = x^n + c_{n-1}x^{n-1} + \cdots + c_1 x + c_0$, then

$$p_{\mathbf{A}}(\mathbf{A}) = \mathbf{A}^n + c_{n-1}\mathbf{A}^{n-1} + \cdots + c_1\mathbf{A} + c_0\mathbf{I}_n,$$

an $n \times n$ matrix, with the constant term becoming $c_0\mathbf{I}_n$.

For $n = 2$ the theorem can be checked by hand. With $\mathbf{A} = \begin{pmatrix} a & b \\ c & d \end{pmatrix}$, $p_{\mathbf{A}} = x^2 - (\operatorname{tr}\mathbf{A})x + \det\mathbf{A}$, and Exercise (C2: Nilpotent 2×2 matrices) (b) multiplied out

$$\mathbf{A}^2 - (a+d)\mathbf{A} + (ad - bc)\mathbf{I}_2 = 0.$$

For $n = 3$, the same brute force already involves cubic expressions in nine entries, and for general

n it is hopeless. We need an argument. There is a tempting one, and we name it before it can do any harm.

Warning. **The fake proof of Cayley–Hamilton, again.** "Since $p_{\mathbf{A}}(x) = \det(x\mathbf{I}-\mathbf{A})$, substitute $x = \mathbf{A}$ to get $p_{\mathbf{A}}(\mathbf{A}) = \det(\mathbf{A}\mathbf{I}-\mathbf{A}) = \det 0 = 0$." Chapter 6 (the warning at the end of its §10) explained why this is not a proof. The left side $p_{\mathbf{A}}(\mathbf{A})$ is a **matrix**, while $\det(\cdots)$ is a **scalar**, so the equation compares objects of different kinds. And substituting $\mathbf{A}$ for x **inside the entries** of $x\mathbf{I}-\mathbf{A}$ is not what substituting into a polynomial means: the entry $x-a_{11}$ would have to become the matrix $\mathbf{A}-a_{11}\mathbf{I}$, and the determinant of a matrix whose entries are matrices is undefined. The same "argument" applied to $q(x) = \operatorname{tr}(x\mathbf{I}-\mathbf{A}) = nx - \operatorname{tr}\mathbf{A}$ would prove $q(\mathbf{A}) = 0$, which is false for $\mathbf{A} = \operatorname{diag}(1,0)$: there $q(\mathbf{A}) = 2\mathbf{A}-\mathbf{I} = \operatorname{diag}(1,-1)$. Any correct proof must keep x a polynomial variable until the very end, and only then put a matrix in its place.

8.6.2 A proof through the adjugate

The adjugate identity of Chapter 6 says $\mathbf{M}\operatorname{adj}\mathbf{M} = (\det\mathbf{M})\,\mathbf{I}$ for every square matrix $\mathbf{M}$, and the remark after Theorem 6.6.2 notes that its proof works over any commutative ring. Over $F[x]$, with $\mathbf{M} = x\mathbf{I}-\mathbf{A}$, it reads

$$(x\mathbf{I}-\mathbf{A})\operatorname{adj}(x\mathbf{I}-\mathbf{A}) = p_{\mathbf{A}}(x)\,\mathbf{I}. \tag{1}$$

This is an identity between matrices of **polynomials**, and it contains $p_{\mathbf{A}}$ on the right. The proof extracts $p_{\mathbf{A}}(\mathbf{A})$ from it legally.

Idea. Try $n = 2$ first. By Exercise (C3: An adjugate over $F[x]$) (b) (done there over $\mathbb{R}$, but the computation works over any field), $\operatorname{adj}(x\mathbf{I}-\mathbf{A}) = x\mathbf{I} - \operatorname{adj}\mathbf{A}$, a polynomial in x with **matrix coefficients** $\mathbf{B}_1 = \mathbf{I}$ and $\mathbf{B}_0 = -\operatorname{adj}\mathbf{A}$. Expanding the left side of (1),

$$(x\mathbf{I}-\mathbf{A})(x\mathbf{I}-\operatorname{adj}\mathbf{A}) = x^2\,\mathbf{I} - x\,(\mathbf{A}+\operatorname{adj}\mathbf{A}) + \mathbf{A}\operatorname{adj}\mathbf{A}.$$

Comparing the coefficients of x^2, x and 1 with those of $\big(x^2 - (\operatorname{tr}\mathbf{A})x + \det\mathbf{A}\big)\mathbf{I}$ gives three matrix equations:

$$\mathbf{I} = \mathbf{I}, \qquad -(\mathbf{A}+\operatorname{adj}\mathbf{A}) = -(\operatorname{tr}\mathbf{A})\,\mathbf{I}, \qquad \mathbf{A}\operatorname{adj}\mathbf{A} = (\det\mathbf{A})\,\mathbf{I}.$$

Now multiply the first by $\mathbf{A}^2$, the second by $\mathbf{A}$, the third by $\mathbf{I}$, and add. The right sides add up to $\mathbf{A}^2 - (\operatorname{tr}\mathbf{A})\mathbf{A} + (\det\mathbf{A})\mathbf{I} = p_{\mathbf{A}}(\mathbf{A})$. The left sides add up to $\mathbf{A}^2 - \mathbf{A}^2 - \mathbf{A}\operatorname{adj}\mathbf{A} + \mathbf{A}\operatorname{adj}\mathbf{A}$, in which every term cancels against its neighbor. So $p_{\mathbf{A}}(\mathbf{A}) = 0$. This is the whole proof; for general n there are $n+1$ equations and the cancellation is a telescoping sum. The variable x is never replaced by a matrix: we compare coefficients first, and only then multiply the resulting **matrix** equations by powers of $\mathbf{A}$.

Proof. Let $p_{\mathbf{A}} = c_n x^n + c_{n-1}x^{n-1} + \cdots + c_1 x + c_0$ with $c_n = 1$ (Theorem 6.10.2).

Step 1: the adjugate as a polynomial with matrix coefficients. If $n = 1$, then $\operatorname{adj}(x\mathbf{I}-\mathbf{A}) = (1)$ by Definition 6.6.2. If $n \geq 2$, each entry of $\operatorname{adj}(x\mathbf{I}-\mathbf{A})$ is a cofactor $\pm\det\mathbf{N}$, where $\mathbf{N}$ is an $(n-1)\times(n-1)$ submatrix of $x\mathbf{I}-\mathbf{A}$ (Definition 6.6.2, Definition 6.6.1). Every entry of $\mathbf{N}$ lies in $F[x]_{\leq 1}$. A product of $n-1$ such polynomials lies in $F[x]_{\leq n-1}$ (Theorem 0.8.3, the zero polynomial being harmless), and so does a sum of such products (Theorem 0.8.2); in particular the Leibniz sum $\det\mathbf{N}$ does (Definition 6.4.1). In both cases every entry of $\operatorname{adj}(x\mathbf{I}-\mathbf{A})$ lies in $F[x]_{\leq n-1}$. For

$0 \le k \le n-1$, let $\mathbf{B}_k \in M_n(F)$ be the matrix whose (i,j)-entry is the coefficient of x^k in the (i,j)-entry of $\operatorname{adj}(x\mathbf{I}-\mathbf{A})$. Then, entry by entry,

$$\operatorname{adj}(x\mathbf{I}-\mathbf{A}) = \sum_{k=0}^{n-1} x^k \mathbf{B}_k.$$

Put $\mathbf{B}_{-1} = \mathbf{B}_n = 0$ for convenience.

Step 2: compare coefficients. By (1), which holds by Theorem 6.6.2 over the commutative ring $F[x]$ (the remark after it), the (i,j)-entries of both sides of (1) agree. On the left, by Definition 0.9.9,

$$\sum_{l=1}^{n} (x\delta_{il} - a_{il}) \sum_{k=0}^{n-1} (\mathbf{B}_k)_{lj}\, x^k = \sum_{k=0}^{n-1} (\mathbf{B}_k)_{ij}\, x^{k+1} - \sum_{k=0}^{n-1} (\mathbf{A}\mathbf{B}_k)_{ij}\, x^k,$$

where $\delta_{il} = 1$ if $i = l$ and 0 otherwise. So for $0 \le k \le n$, the coefficient of x^k is $(\mathbf{B}_{k-1})_{ij} - (\mathbf{A}\mathbf{B}_k)_{ij}$. On the right the (i,j)-entry is $p_{\mathbf{A}}\,\delta_{ij}$, whose coefficient of x^k is $c_k\delta_{ij}$. Two polynomials are equal exactly when their coefficients are equal (Definition 0.8.1). Since this holds for every (i,j),

$$\mathbf{B}_{k-1} - \mathbf{A}\mathbf{B}_k = c_k\,\mathbf{I} \qquad (0 \le k \le n). \tag{2}$$

Step 3: telescope. Multiply equation (2) for k on the left by $\mathbf{A}^k$, and add the $n+1$ equations. On the right we get $\sum_{k=0}^{n} c_k \mathbf{A}^k = p_{\mathbf{A}}(\mathbf{A})$ by Definition 0.9.14. On the left, writing $\mathbf{S}_k = \mathbf{A}^k\mathbf{B}_{k-1}$ for $0 \le k \le n+1$,

$$\sum_{k=0}^{n} \left(\mathbf{A}^k\mathbf{B}_{k-1} - \mathbf{A}^{k+1}\mathbf{B}_k\right) = \sum_{k=0}^{n} (\mathbf{S}_k - \mathbf{S}_{k+1}) = \mathbf{S}_0 - \mathbf{S}_{n+1} = \mathbf{B}_{-1} - \mathbf{A}^{n+1}\mathbf{B}_n = 0,$$

since $\mathbf{B}_{-1} = \mathbf{B}_n = 0$. Hence $p_{\mathbf{A}}(\mathbf{A}) = 0$.

The operator version. Let $\mathcal{B}$ be a basis of V and $\mathbf{A} = [T]_{\mathcal{B}}$. By Definition 6.10.2, $p_T = p_{\mathbf{A}}$. By Corollary 3.6.3, $[p_T(T)]_{\mathcal{B}} = p_T(\mathbf{A}) = p_{\mathbf{A}}(\mathbf{A}) = 0$, so $p_T(T) = 0$ (Theorem 3.6.4). This proves the theorem.

■

Compare with the fake proof. There, $\mathbf{A}$ was pushed into the entries of $x\mathbf{I}-\mathbf{A}$. Here, (1) is first unpacked into the $n+1$ matrix equations (2), which contain no x at all, and $\mathbf{A}$ enters only when we multiply those equations by $\mathbf{A}^k$. Every multiplication is on the **left**, so no commutativity of matrices was used; the only commutativity used is inside $F[x]$, in the adjugate identity.

Nothing in the proof divides. The determinant, the adjugate identity, coefficient comparison and matrix multiplication all make sense over a commutative ring, and Exercise (C1: Cayley–Hamilton over a commutative ring) asks you to check that the theorem holds, with the same proof, for matrices with entries in a commutative ring such as $\mathbb{Z}$ or $\mathbb{R}[t]$.

The proof also produced more than it was asked for. Equation (2) with $k = n$ says $\mathbf{B}_{n-1} = \mathbf{I}$, and the others say $\mathbf{B}_{k-1} = \mathbf{A}\mathbf{B}_k + c_k\mathbf{I}$. Working down from $\mathbf{B}_{n-1}$, every $\mathbf{B}_k$ is a polynomial in $\mathbf{A}$; Exercise (C2: The adjugate is a polynomial in the matrix) turns this into a formula for $\operatorname{adj}\mathbf{A}$.

8.6.3 Consequences

The first consequence is the promised comparison of the two polynomials.

Corollary 8.6.2 — The Minimal Polynomial Divides the Characteristic Polynomial

Let V be finite-dimensional with $\dim V = n \geq 1$, and let $T \in \mathcal{L}(V)$.

(a) $m_T \mid p_T$; in particular $1 \leq \deg m_T \leq n$.

(b) If p_T splits over F, say $p_T = (x-\lambda_1)^{a_1} \cdots (x-\lambda_k)^{a_k}$ with distinct λ_i, then

$$m_T = (x-\lambda_1)^{s_1} \cdots (x-\lambda_k)^{s_k} \qquad \text{with } 1 \leq s_i \leq a_i = a_T(\lambda_i).$$

The same holds for $\mathbf{A} \in M_n(F)$ with $m_{\mathbf{A}}$ and $p_{\mathbf{A}}$. In particular, over $\mathbb{C}$, (b) applies to every $\mathbf{A} \in M_n(\mathbb{C})$.

Proof.

(a) By Theorem 8.6.1, $p_T(T) = 0$, so $m_T \mid p_T$ by Theorem 8.5.1. Since p_T is monic of degree n (Theorem 6.10.2), $\deg m_T \leq n$ by Proposition 5.1.2 (c), and $\deg m_T \geq 1$ by Theorem 8.5.1, as $V \neq \{\mathbf{0}\}$.

(b) A polynomial $x-\lambda$ of degree 1 is irreducible: if $x-\lambda = gh$, then $\deg g + \deg h = 1$ (Theorem 0.8.3), so one factor is constant. The $x-\lambda_i$ are distinct and monic. By (a) and Lemma 8.5.2, $m_T = \prod_i (x-\lambda_i)^{s_i}$ with $0 \leq s_i \leq a_i$. Each λ_i is a root of p_T, hence an eigenvalue (Theorem 8.2.1), hence a root of m_T (Theorem 8.5.3), so $s_i \geq 1$. Finally $a_i = \operatorname{mult}_{\lambda_i}(p_T) = a_T(\lambda_i)$ by Lemma 5.4.1, since the other factors do not vanish at λ_i. The matrix case is the operator $T_{\mathbf{A}}$, and over $\mathbb{C}$ every $p_{\mathbf{A}}$ splits (Corollary 5.5.5).

■

This pays off a promise from Chapter 5: the bound n^2 of Theorem 5.7.2 improves to n, and p_T is an explicit annihilating polynomial of degree exactly n. It also makes Method 2 of the previous section a finite search that always succeeds. For a matrix with $p_{\mathbf{A}} = (x-2)^2(x-3)$, the corollary leaves exactly two candidates, $(x-2)(x-3)$ and $(x-2)^2(x-3)$, and one matrix product decides between them.

Warning. **Cayley–Hamilton gives an annihilating polynomial, not the minimal one.** From $p_{\mathbf{A}}(\mathbf{A}) = 0$ we may **not** conclude $m_{\mathbf{A}} = p_{\mathbf{A}}$; only $m_{\mathbf{A}} \mid p_{\mathbf{A}}$. For $\mathbf{A} = \operatorname{diag}(1,1,2)$, $p_{\mathbf{A}} = (x-1)^2(x-2)$ kills $\mathbf{A}$, and so does the proper divisor $(x-1)(x-2) = m_{\mathbf{A}}$. Nor may we conclude that every divisor of $p_{\mathbf{A}}$ with the right roots kills $\mathbf{A}$: for $\mathbf{J} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$, $x-1$ has the right root and does not.

The second consequence expresses inverses through powers.

Corollary 8.6.3 — The Inverse Is a Polynomial in the Matrix

Let $n \geq 1$, $\mathbf{A} \in M_n(F)$, and $p_{\mathbf{A}} = x^n + c_{n-1}x^{n-1} + \cdots + c_1 x + c_0$. Then $c_0 = (-1)^n \det \mathbf{A}$. If $\mathbf{A}$ is invertible, then $c_0 \neq 0$ and

$$\mathbf{A}^{-1} = -\frac{1}{c_0}\left(\mathbf{A}^{n-1} + c_{n-1}\mathbf{A}^{n-2} + \cdots + c_2\mathbf{A} + c_1\mathbf{I}\right).$$

(For $n = 1$ the bracket is $\mathbf{I}$ alone, and the formula reads $\mathbf{A}^{-1} = -c_0^{-1}\mathbf{I}$.) The same holds for an invertible operator T on a space of dimension $n \geq 1$, with id_V in place of $\mathbf{I}$.

Proof. By Theorem 6.10.2, $c_0 = (-1)^n \det \mathbf{A}$, which is non-zero when $\mathbf{A}$ is invertible (Theorem 6.5.3). By Theorem 8.6.1,

$$\mathbf{A}\left(\mathbf{A}^{n-1} + c_{n-1}\mathbf{A}^{n-2} + \cdots + c_1\mathbf{I}\right) = \mathbf{A}^n + c_{n-1}\mathbf{A}^{n-1} + \cdots + c_1\mathbf{A} = -c_0\mathbf{I}.$$

Multiplying by $-c_0^{-1}$, the matrix in parentheses times $-c_0^{-1}$ is a right inverse of $\mathbf{A}$, hence the inverse by Theorem 2.4.5. For an operator, apply this to $[T]_{\mathcal{B}}$ and use Corollary 3.6.3.

■

So inverting an $n \times n$ matrix never requires more than its first $n-1$ powers and the coefficients of $p_{\mathbf{A}}$. The theorem also reduces **every** power of $\mathbf{A}$ to the first $n-1$. Divide x^N by $p_{\mathbf{A}}$ (Theorem 5.1.1): $x^N = q\,p_{\mathbf{A}} + r$ with $\deg r < n$. Then by Theorem 5.7.1 and Theorem 8.6.1,

$$\mathbf{A}^N = q(\mathbf{A})\,p_{\mathbf{A}}(\mathbf{A}) + r(\mathbf{A}) = r(\mathbf{A}).$$

When $p_{\mathbf{A}}$ has n distinct roots $\lambda_1, \ldots, \lambda_n$, the remainder can be found without long division. Substituting $x = \lambda_i$ in $x^N = q\,p_{\mathbf{A}} + r$ gives $r(\lambda_i) = \lambda_i^N$ for each i, and these n conditions determine $r \in F[x]_{\leq n-1}$ by Lagrange interpolation (Theorem 5.6.1). This substitution is legal: λ_i is a **scalar** plugged into an identity of polynomials.

Example. (Cayley–Hamilton for a 3×3 Matrix)

Let

$$\mathbf{A} = \begin{pmatrix} 1 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 0 & 1 \end{pmatrix} \in M_3(\mathbb{Q}).$$

Compute $p_{\mathbf{A}}$ and verify $p_{\mathbf{A}}(\mathbf{A}) = 0$. Then use it to find $\mathbf{A}^{-1}$ and $\mathbf{A}^5$, and write down the matrices $\mathbf{B}_k$ of the proof.

Solution. Characteristic polynomial. Expand $\det(x\mathbf{I} - \mathbf{A})$ along the first row (Theorem 6.6.1 over $\mathbb{Q}[x]$):

$$\begin{aligned} p_{\mathbf{A}} &= \det \begin{pmatrix} x-1 & -1 & 0 \\ 0 & x & -1 \\ -1 & 0 & x-1 \end{pmatrix} \\ &= (x-1)\det \begin{pmatrix} x & -1 \\ 0 & x-1 \end{pmatrix} + (-1)(-1)^{1+2} \det \begin{pmatrix} 0 & -1 \\ -1 & x-1 \end{pmatrix}. \end{aligned}$$

The two minors are $x(x-1)$ and -1, so $p_{\mathbf{A}} = x(x-1)^2 - 1 = x^3 - 2x^2 + x - 1$. As a check, $\operatorname{tr}\mathbf{A} = 2$ matches the coefficient -2 of x^2, and $c_0 = -1 = (-1)^3 \det \mathbf{A}$ says $\det \mathbf{A} = 1$.

Verification. Multiplying out,

$$\mathbf{A}^2 = \begin{pmatrix} 1 & 1 & 1 \\ 1 & 0 & 1 \\ 2 & 1 & 1 \end{pmatrix}, \qquad \mathbf{A}^3 = \mathbf{A}\,\mathbf{A}^2 = \begin{pmatrix} 2 & 1 & 2 \\ 2 & 1 & 1 \\ 3 & 2 & 2 \end{pmatrix}.$$

Then $\mathbf{A}^3 - 2\mathbf{A}^2 + \mathbf{A} - \mathbf{I}$ has first row $(2-2+1-1,\ 1-2+1,\ 2-2+0) = (0,0,0)$, second row $(2-2+0,\ 1-0+0-1,\ 1-2+1) = (0,0,0)$, and third row $(3-4+1,\ 2-2+0,\ 2-2+1-1) = (0,0,0)$. So $p_{\mathbf{A}}(\mathbf{A}) = 0$, as the theorem predicts.

Inverse. Here $c_0 = -1$, $c_1 = 1$, $c_2 = -2$. By Corollary 8.6.3,

$$\mathbf{A}^{-1} = \mathbf{A}^2 - 2\mathbf{A} + \mathbf{I} = \begin{pmatrix} 0 & -1 & 1 \\ 1 & 1 & -1 \\ 0 & 1 & 0 \end{pmatrix}.$$

Check: the first row of $\mathbf{A}\,\mathbf{A}^{-1}$ is $(0+1,\ -1+1,\ 1-1) = (1,0,0)$, and the other rows work the same way. The entries are integers, as they must be for an integer matrix of determinant 1 (Corollary 6.6.5).

Fifth power. The relation $\mathbf{A}^3 = 2\mathbf{A}^2 - \mathbf{A} + \mathbf{I}$ lets us lower degrees step by step:

$$\mathbf{A}^4 = 2\mathbf{A}^3 - \mathbf{A}^2 + \mathbf{A} = 2(2\mathbf{A}^2 - \mathbf{A} + \mathbf{I}) - \mathbf{A}^2 + \mathbf{A} = 3\mathbf{A}^2 - \mathbf{A} + 2\mathbf{I},$$

$$\mathbf{A}^5 = 3\mathbf{A}^3 - \mathbf{A}^2 + 2\mathbf{A} = 3(2\mathbf{A}^2 - \mathbf{A} + \mathbf{I}) - \mathbf{A}^2 + 2\mathbf{A} = 5\mathbf{A}^2 - \mathbf{A} + 3\mathbf{I}.$$

(Equivalently, $x^5 = (x^2 + 2x + 3)\,p_{\mathbf{A}} + (5x^2 - x + 3)$.) Hence

$$\mathbf{A}^5 = 5\begin{pmatrix} 1 & 1 & 1 \\ 1 & 0 & 1 \\ 2 & 1 & 1 \end{pmatrix} - \begin{pmatrix} 1 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 0 & 1 \end{pmatrix} + 3\mathbf{I} = \begin{pmatrix} 7 & 4 & 5 \\ 5 & 3 & 4 \\ 9 & 5 & 7 \end{pmatrix}.$$

The matrices of the proof. By (2), $\mathbf{B}_2 = \mathbf{I}$, $\mathbf{B}_1 = \mathbf{A}\mathbf{B}_2 + c_2\mathbf{I} = \mathbf{A} - 2\mathbf{I}$ and $\mathbf{B}_0 = \mathbf{A}\mathbf{B}_1 + c_1\mathbf{I} = \mathbf{A}^2 - 2\mathbf{A} + \mathbf{I}$. So

$$\begin{aligned} \operatorname{adj}(x\mathbf{I} - \mathbf{A}) &= x^2\mathbf{I} + x(\mathbf{A} - 2\mathbf{I}) + (\mathbf{A}^2 - 2\mathbf{A} + \mathbf{I}) \\ &= \begin{pmatrix} x^2 - x & x - 1 & 1 \\ 1 & x^2 - 2x + 1 & x - 1 \\ x & 1 & x^2 - x \end{pmatrix}, \end{aligned}$$

which one can confirm entry by entry from cofactors of $x\mathbf{I} - \mathbf{A}$; for instance the $(1,3)$-entry is the cofactor $C_{31} = \det\begin{pmatrix} -1 & 0 \\ x & -1 \end{pmatrix} = 1$. The last equation of (2), $-\mathbf{A}\mathbf{B}_0 = c_0\mathbf{I} = -\mathbf{I}$, is the statement $\mathbf{A}^{-1} = \mathbf{B}_0$ found above.

Quick check. Let $\mathbf{A} \in M_2(\mathbb{R})$ with $\operatorname{tr}\mathbf{A} = 5$ and $\det\mathbf{A} = 6$. Write $\mathbf{A}^2$ and $\mathbf{A}^3$ as combinations of $\mathbf{A}$ and $\mathbf{I}$, and write $\mathbf{A}^{-1}$ the same way.

Solution. $p_{\mathbf{A}} = x^2 - 5x + 6$, so by Theorem 8.6.1 $\mathbf{A}^2 = 5\mathbf{A} - 6\mathbf{I}$. Then $\mathbf{A}^3 = 5\mathbf{A}^2 - 6\mathbf{A} = 5(5\mathbf{A} - 6\mathbf{I}) - 6\mathbf{A} = 19\mathbf{A} - 30\mathbf{I}$. By Corollary 8.6.3 with $c_0 = 6$ and $c_1 = -5$, $\mathbf{A}^{-1} = -\frac{1}{6}(\mathbf{A} - 5\mathbf{I}) = \frac{1}{6}(5\mathbf{I} - \mathbf{A})$.

Alternatively. When p_T splits, there is a second proof that avoids determinants of polynomial

matrices entirely. The next section shows that such an operator has an upper triangular matrix, and a triangular matrix reveals directly why the product $(T-\lambda_1 \mathrm{id}_V)\cdots(T-\lambda_n \mathrm{id}_V)$ is zero. That proof is set out as an exercise there. The adjugate proof has the advantage of working over every field at once, with no splitting hypothesis.

8.6.4 Exercises

8.6.4.1 A. Check your understanding

Exercise A1.

(a) State the Cayley–Hamilton Theorem for $\mathbf{A} \in M_n(F)$.

(b) True or false: $\deg m_{\mathbf{A}} \leq n$ for every $\mathbf{A} \in M_n(F)$, $n \geq 1$. Justify your answer.

(c) In one sentence, why is "$p_{\mathbf{A}}(\mathbf{A}) = \det(\mathbf{AI} - \mathbf{A}) = 0$" not a proof?

(d) Suppose $p_{\mathbf{A}} = (x-1)^2(x+2)$. Which polynomials can $m_{\mathbf{A}}$ be?

(e) True or false: if $p_{\mathbf{A}}(\mathbf{A}) = 0$, then $p_{\mathbf{A}}$ is the minimal polynomial of $\mathbf{A}$. Justify your answer.

(f) How do you write $\mathbf{A}^{-1}$ as a polynomial in $\mathbf{A}$ when $\mathbf{A}$ is invertible?

Solution.

(a) If $n \geq 1$ and $\mathbf{A} \in M_n(F)$, then $p_{\mathbf{A}}(\mathbf{A}) = 0$ (Theorem 8.6.1).

(b) True. By Corollary 8.6.2, $m_{\mathbf{A}} \mid p_{\mathbf{A}}$, and $\deg p_{\mathbf{A}} = n$.

(c) It substitutes a matrix into the entries of $x\mathbf{I} - \mathbf{A}$ and then equates the matrix $p_{\mathbf{A}}(\mathbf{A})$ with the scalar $\det 0$, neither of which is legitimate.

(d) By Corollary 8.6.2 (b), $m_{\mathbf{A}} = (x-1)^s(x+2)^t$ with $1 \leq s \leq 2$ and $t = 1$: so $(x-1)(x+2)$ or $(x-1)^2(x+2)$. Both occur, for $\mathrm{diag}(1,1,-2)$ and for $\begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix} \oplus (-2)$ (Proposition 8.5.6).

(e) False. $p_{\mathbf{I}_2} = (x-1)^2$ kills $\mathbf{I}_2$, but $m_{\mathbf{I}_2} = x - 1$.

(f) If $p_{\mathbf{A}} = x^n + c_{n-1}x^{n-1} + \cdots + c_0$, then $c_0 = (-1)^n \det \mathbf{A} \neq 0$ and $\mathbf{A}^{-1} = -c_0^{-1}(\mathbf{A}^{n-1} + c_{n-1}\mathbf{A}^{n-2} + \cdots + c_1\mathbf{I})$ (Corollary 8.6.3).

8.6.4.2 B. Practice

Exercise B1: Inverse and a hundredth power.

Let $\mathbf{A} = \begin{pmatrix} 3 & -2 \\ 1 & 0 \end{pmatrix} \in M_2(\mathbb{R})$.

(a) Find $p_{\mathbf{A}}$, and use the Cayley–Hamilton Theorem to compute $\mathbf{A}^{-1}$.

(b) Hence find $\mathbf{A}^{100}$ as a combination $a\mathbf{A} + b\mathbf{I}$, and write it as a matrix.

Solution.

(a) $\operatorname{tr} \mathbf{A} = 3$ and $\det \mathbf{A} = 2$, so $p_{\mathbf{A}} = x^2 - 3x + 2 = (x-1)(x-2)$. By Theorem 8.6.1,

$\mathbf{A}^2 - 3\mathbf{A} + 2\mathbf{I} = 0$, that is, $\mathbf{A}(3\mathbf{I} - \mathbf{A}) = 2\mathbf{I}$. By Corollary 8.6.3,

$$\mathbf{A}^{-1} = \tfrac{1}{2}(3\mathbf{I} - \mathbf{A}) = \begin{pmatrix} 0 & 1 \\ -\tfrac{1}{2} & \tfrac{3}{2} \end{pmatrix}.$$

Check: $\mathbf{A}\,\mathbf{A}^{-1} = \begin{pmatrix} 0+1 & 3-3 \\ 0 & 1 \end{pmatrix} = \mathbf{I}$.

(b) By Theorem 5.1.1, $x^{100} = q\,p_{\mathbf{A}} + (ax + b)$ for some q and scalars a, b. Substituting the roots $x = 1$ and $x = 2$ of $p_{\mathbf{A}}$ gives $1 = a + b$ and $2^{100} = 2a + b$. So $a = 2^{100} - 1$ and $b = 2 - 2^{100}$. By Theorem 8.6.1, $\mathbf{A}^{100} = q(\mathbf{A})p_{\mathbf{A}}(\mathbf{A}) + a\mathbf{A} + b\mathbf{I} = a\mathbf{A} + b\mathbf{I}$, that is,

$$\mathbf{A}^{100} = (2^{100} - 1)\mathbf{A} + (2 - 2^{100})\mathbf{I} = \begin{pmatrix} 2^{101} - 1 & 2 - 2^{101} \\ 2^{100} - 1 & 2 - 2^{100} \end{pmatrix}.$$

For $k = 1$ in place of 100, the same recipe gives $a = 1$, $b = 0$, and returns $\mathbf{A}$, as it should.

Exercise B2: Trace zero in size two.

(a) Let $\mathbf{A} \in M_2(F)$ with $\operatorname{tr}\mathbf{A} = 0$. Prove that $\mathbf{A}^2 = -(\det\mathbf{A})\,\mathbf{I}$.

(b) Deduce that for all $\mathbf{X}, \mathbf{Y} \in M_2(F)$, the matrix $(\mathbf{XY} - \mathbf{YX})^2$ is a scalar multiple of $\mathbf{I}$.

(c) Show that the converse of (a) fails: give $\mathbf{A} \in M_2(\mathbb{R})$ with $\mathbf{A}^2$ scalar and $\operatorname{tr}\mathbf{A} \neq 0$.

Solution.

(a) By Theorem 8.6.1, $\mathbf{A}^2 - (\operatorname{tr}\mathbf{A})\mathbf{A} + (\det\mathbf{A})\mathbf{I} = 0$. With $\operatorname{tr}\mathbf{A} = 0$, this is $\mathbf{A}^2 = -(\det\mathbf{A})\mathbf{I}$.

(b) By Theorem 3.10.3 applied to $T_{\mathbf{X}}, T_{\mathbf{Y}}$, or directly by $\operatorname{tr}(\mathbf{XY}) = \operatorname{tr}(\mathbf{YX})$, we have $\operatorname{tr}(\mathbf{XY} - \mathbf{YX}) = 0$. By (a), $(\mathbf{XY} - \mathbf{YX})^2 = -\det(\mathbf{XY} - \mathbf{YX})\,\mathbf{I}$.

(c) $\mathbf{A} = \mathbf{I}_2$ has $\mathbf{A}^2 = \mathbf{I}_2$ and $\operatorname{tr}\mathbf{A} = 2 \neq 0$.

Exercise B3: Minimal polynomial from one product.

Each of the real matrices

$$\mathbf{M}_1 = \begin{pmatrix} 2 & 1 & 0 \\ 0 & 2 & 0 \\ -1 & 1 & 3 \end{pmatrix}, \qquad \mathbf{M}_2 = \begin{pmatrix} 2 & 0 & 0 \\ 0 & 2 & 0 \\ -1 & 0 & 3 \end{pmatrix}$$

has characteristic polynomial $(x-2)^2(x-3)$. Find $m_{\mathbf{M}_1}$ and $m_{\mathbf{M}_2}$. Are $\mathbf{M}_1$ and $\mathbf{M}_2$ similar?

Solution. By Corollary 8.6.2 (b), each minimal polynomial is $(x-2)(x-3)$ or $(x-2)^2(x-3)$, and only the first needs testing.

For $\mathbf{M}_1$: $\mathbf{M}_1 - 2\mathbf{I} = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 0 \\ -1 & 1 & 1 \end{pmatrix}$ and $\mathbf{M}_1 - 3\mathbf{I} = \begin{pmatrix} -1 & 1 & 0 \\ 0 & -1 & 0 \\ -1 & 1 & 0 \end{pmatrix}$. The first row of the product $(\mathbf{M}_1 - 2\mathbf{I})(\mathbf{M}_1 - 3\mathbf{I})$ is row 2 of $\mathbf{M}_1 - 3\mathbf{I}$, namely $(0, -1, 0) \neq \mathbf{0}$. So

$m_{\mathbf{M}_1} = (x-2)^2(x-3)$.

For $\mathbf{M}_2$: $\mathbf{M}_2 - 2\mathbf{I} = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ -1 & 0 & 1 \end{pmatrix}$ and $\mathbf{M}_2 - 3\mathbf{I} = \begin{pmatrix} -1 & 0 & 0 \\ 0 & -1 & 0 \\ -1 & 0 & 0 \end{pmatrix}$. The only non-zero row of the product is $-(\text{row } 1) + (\text{row } 3)$ of $\mathbf{M}_2 - 3\mathbf{I}$, which is $(1,0,0) + (-1,0,0) = \mathbf{0}$. So the product is 0, and $m_{\mathbf{M}_2} = (x-2)(x-3)$.

The minimal polynomials differ, so $\mathbf{M}_1 \not\sim \mathbf{M}_2$ by Theorem 8.5.5.

8.6.4.3 C. Going deeper

Exercise C1: Cayley–Hamilton over a commutative ring.

Let R be a commutative ring (the remark in Chapter 6, §4), and suppose, as for $F[x]$, that the polynomials in x with coefficients in R form a commutative ring $R[x]$ in which two polynomials are equal exactly when all their coefficients are equal. For $\mathbf{A} \in M_n(R)$, define $p_{\mathbf{A}} = \det(x\mathbf{I} - \mathbf{A}) \in R[x]$.

(a) Go through the proof of Theorem 8.6.1 and name, for each step, the fact it uses. Explain why each fact holds over R and $R[x]$, and conclude that $p_{\mathbf{A}}(\mathbf{A}) = 0$ for every $\mathbf{A} \in M_n(R)$.

(b) Let $R = \mathbb{R}[t]$ and $\mathbf{A} = \begin{pmatrix} t & 1 \\ t^2 & 0 \end{pmatrix}$. Compute $p_{\mathbf{A}}$ and verify $p_{\mathbf{A}}(\mathbf{A}) = 0$ directly.

(c) Let $\mathbf{A} \in M_n(\mathbb{Z})$ with $\det \mathbf{A} = \pm 1$. Using (a) with $R = \mathbb{Z}$, show that $\mathbf{A}^{-1}$ has integer entries.

Solution.

(a) *The shape of $p_{\mathbf{A}}$.* In the Leibniz sum for $\det(x\mathbf{I} - \mathbf{A})$, the identity permutation contributes $(x - a_{11}) \cdots (x - a_{nn})$, of degree n with leading coefficient 1, and every other term omits at least two diagonal entries, so it has degree at most $n - 2$. Hence $p_{\mathbf{A}} = x^n + c_{n-1}x^{n-1} + \cdots + c_0$ with $c_k \in R$, which is what the proof uses in place of Theorem 6.10.2; only sums and products of entries appear. *Step 1* uses the Leibniz formula over $R[x]$ (which only multiplies and adds entries) and the degree bounds for sums and products, which hold because the degree of a product of polynomials is at most the sum of the degrees; no inverse is needed for the upper bound. *Step 2* uses the adjugate identity over the commutative ring $R[x]$, which holds by the remark after Theorem 6.6.2, and coefficient comparison in $R[x]$, which is the assumption on $R[x]$. *Step 3* uses only associativity and distributivity of matrix multiplication over R and a telescoping sum. No step divides, so each works verbatim over R, and $p_{\mathbf{A}}(\mathbf{A}) = 0$.

(b) $x\mathbf{I} - \mathbf{A} = \begin{pmatrix} x - t & -1 \\ -t^2 & x \end{pmatrix}$, so $p_{\mathbf{A}} = x(x-t) - t^2 = x^2 - tx - t^2$. Then

$$\mathbf{A}^2 = \begin{pmatrix} t^2 + t^2 & t \\ t^3 & t^2 \end{pmatrix}, \qquad \mathbf{A}^2 - t\mathbf{A} - t^2\mathbf{I} = \begin{pmatrix} 2t^2 - t^2 - t^2 & t - t \\ t^3 - t^3 & t^2 - 0 - t^2 \end{pmatrix} = 0.$$

(c) The Leibniz formula for $\det(x\mathbf{I} - \mathbf{A})$ only adds and multiplies integers and x, so the coefficients c_k of $p_{\mathbf{A}}$ are integers. Regarding $\mathbf{A}$ as a rational matrix, Theorem 6.10.2 gives $c_0 = (-1)^n \det \mathbf{A} = \pm 1$. By (a), $\mathbf{A}(\mathbf{A}^{n-1} + c_{n-1}\mathbf{A}^{n-2} + \cdots + c_1\mathbf{I}) = -c_0\mathbf{I}$.

Since $c_0^2 = 1$, multiplying by $-c_0$ gives $\mathbf{A}\,\mathbf{B} = \mathbf{I}$ with $\mathbf{B} = -c_0(\mathbf{A}^{n-1} + \cdots + c_1\mathbf{I}) \in M_n(\mathbb{Z})$. Regarding $\mathbf{A}$ and $\mathbf{B}$ as rational matrices, Theorem 2.4.5 gives $\mathbf{B} = \mathbf{A}^{-1}$, which therefore has integer entries. (This reproves part of Corollary 6.6.5.)

Exercise C2: The adjugate is a polynomial in the matrix.

Let $n \geq 2$, $\mathbf{A} \in M_n(F)$, $p_{\mathbf{A}} = x^n + c_{n-1}x^{n-1} + \cdots + c_0$, and let $\mathbf{B}_0, \ldots, \mathbf{B}_{n-1}$ be as in the proof of Theorem 8.6.1.

(a) Using equation (2) of the proof, show that $\mathbf{B}_0 = \mathbf{A}^{n-1} + c_{n-1}\mathbf{A}^{n-2} + \cdots + c_2\mathbf{A} + c_1\mathbf{I}$.

(b) Show that the constant matrix $\mathbf{B}_0$ equals $\operatorname{adj}(-\mathbf{A})$, and that $\operatorname{adj}(-\mathbf{A}) = (-1)^{n-1}\operatorname{adj}\mathbf{A}$.

(c) Deduce that for **every** $\mathbf{A} \in M_n(F)$, invertible or not,

$$\operatorname{adj}\mathbf{A} = (-1)^{n-1}\bigl(\mathbf{A}^{n-1} + c_{n-1}\mathbf{A}^{n-2} + \cdots + c_2\mathbf{A} + c_1\mathbf{I}\bigr).$$

(d) Check (c) for $\mathbf{S} = \begin{pmatrix} 1 & 2 & 3 \\ 2 & 4 & 6 \\ 1 & 0 & 1 \end{pmatrix}$, whose adjugate Chapter 6 computed (the warning after Corollary 6.6.3), given that $p_{\mathbf{S}} = x^3 - 6x^2 + 2x$.

Solution.

(a) Equation (2) with $k = n$ gives $\mathbf{B}_{n-1} = c_n\mathbf{I} = \mathbf{I}$, and for $1 \leq k \leq n-1$ it gives $\mathbf{B}_{k-1} = \mathbf{A}\mathbf{B}_k + c_k\mathbf{I}$. By downward induction on k, $\mathbf{B}_{k-1} = \mathbf{A}^{n-k} + c_{n-1}\mathbf{A}^{n-k-1} + \cdots + c_k\mathbf{I}$: this holds for $k = n$, and if it holds for k, then $\mathbf{B}_{k-2} = \mathbf{A}\mathbf{B}_{k-1} + c_{k-1}\mathbf{I} = \mathbf{A}^{n-k+1} + c_{n-1}\mathbf{A}^{n-k} + \cdots + c_k\mathbf{A} + c_{k-1}\mathbf{I}$. The case $k = 1$ is the claim.

(b) Each entry of $\operatorname{adj}(x\mathbf{I} - \mathbf{A})$ is a cofactor $\pm\det\mathbf{N}$ of $x\mathbf{I} - \mathbf{A}$, and its constant coefficient is its value at 0. By Lemma 7.3.7, $(\det\mathbf{N})(0) = \det\mathbf{N}(0)$, and $\mathbf{N}(0)$ is the corresponding submatrix of $-\mathbf{A}$. So the matrix of constant coefficients, $\mathbf{B}_0$, is $\operatorname{adj}(-\mathbf{A})$. Each cofactor of $-\mathbf{A}$ is $\pm$ the determinant of an $(n-1)\times(n-1)$ submatrix of $-\mathbf{A}$, which is -1 times the corresponding submatrix of $\mathbf{A}$. Multiplying each of the $n-1$ rows by -1 multiplies the determinant by $(-1)^{n-1}$ (Theorem 6.5.1). Hence $\operatorname{adj}(-\mathbf{A}) = (-1)^{n-1}\operatorname{adj}\mathbf{A}$.

(c) By (a) and (b), $(-1)^{n-1}\operatorname{adj}\mathbf{A} = \mathbf{B}_0 = \mathbf{A}^{n-1} + c_{n-1}\mathbf{A}^{n-2} + \cdots + c_1\mathbf{I}$; multiply by $(-1)^{n-1}$. Nothing assumed $\det\mathbf{A} \neq 0$.

(d) Here $n = 3$, $c_2 = -6$, $c_1 = 2$, so the formula predicts $\operatorname{adj}\mathbf{S} = \mathbf{S}^2 - 6\mathbf{S} + 2\mathbf{I}$. Now

$$\mathbf{S}^2 = \begin{pmatrix} 8 & 10 & 18 \\ 16 & 20 & 36 \\ 2 & 2 & 4 \end{pmatrix},$$

$$\mathbf{S}^2 - 6\mathbf{S} + 2\mathbf{I} = \begin{pmatrix} 8-6+2 & 10-12 & 18-18 \\ 16-12 & 20-24+2 & 36-36 \\ 2-6 & 2 & 4-6+2 \end{pmatrix}$$

$$= \begin{pmatrix} 4 & -2 & 0 \\ 4 & -2 & 0 \\ -4 & 2 & 0 \end{pmatrix},$$

which is the adjugate found in Chapter 6.

Exercise C3: Nilpotent matrices of size n.

Let F be any field, $n \geq 1$, and $\mathbf{A} \in M_n(F)$ with $\mathbf{A}^k = 0$ for some $k \geq 1$.

(a) Prove that $m_{\mathbf{A}} = x^s$ for some s with $1 \leq s \leq n$.

(b) Deduce that $\mathbf{A}^n = 0$.

(c) Give a 3×3 example with $\mathbf{A}^2 \neq 0$, and explain why no 3×3 matrix has $\mathbf{A}^3 \neq 0 = \mathbf{A}^4$.

Solution.

(a) x^k annihilates $\mathbf{A}$, so $m_{\mathbf{A}} \mid x^k$ (Theorem 8.5.1). The polynomial x is monic and irreducible (degree 1), so by Lemma 8.5.2, $m_{\mathbf{A}} = x^s$ with $0 \leq s \leq k$. By Corollary 8.6.2 (a), $1 \leq s = \deg m_{\mathbf{A}} \leq n$.

(b) $x^n = x^{n-s}\, x^s$, so $m_{\mathbf{A}} \mid x^n$ and $\mathbf{A}^n = 0$ by Theorem 8.5.1.

(c) The matrix $\mathbf{N}$ of the Quick check in Section 5 has $\mathbf{N}^2 \neq 0 = \mathbf{N}^3$. If $\mathbf{A} \in M_3(F)$ satisfies $\mathbf{A}^4 = 0$, then $\mathbf{A}$ is nilpotent and $\mathbf{A}^3 = 0$ by (b), so $\mathbf{A}^3 \neq 0 = \mathbf{A}^4$ is impossible. Note that no splitting or complex numbers were needed; compare Exercise (C2: Nilpotent operators), which worked over $\mathbb{C}$.

8.7 Triangularization

Section 4 found two ways for diagonalization to fail. The field can be too small, as for a rotation of $\mathbb{R}^2$. Or there can be too few eigenvectors, as for $\begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$, and no change of field helps. In the second case we should ask for less. The next simplest shape after a diagonal matrix is an upper triangular one, and triangular matrices are almost as good for computation: their eigenvalues, trace and determinant are visible on the diagonal. This section proves that an operator has a triangular matrix exactly when its characteristic polynomial splits, so every complex matrix is similar to a triangular one. The proof is the induction on dimension that Section 1 promised: take one eigenvector, pass to the quotient, and repeat.

8.7.1 Triangular matrices and chains of invariant subspaces

As in Section 2, start with the wish and unwind it. Let $\mathcal{B} = (\mathbf{v}_1, \ldots, \mathbf{v}_n)$ be a basis of V and $T \in \mathcal{L}(V)$. Column j of $[T]_{\mathcal{B}}$ holds the coordinates of $T\mathbf{v}_j$ (Definition 3.6.1). The matrix is upper triangular when every entry below the diagonal is 0 (Definition 0.9.5), that is, when $T\mathbf{v}_j$ is a combination of $\mathbf{v}_1, \ldots, \mathbf{v}_j$ only. So the first basis vector must be sent to a multiple of itself, the second into the plane of the first two, and so on. In the language of Section 1, each of the growing spans must be invariant. Chapter 3 proved this as an exercise (Exercise (C1: Upper triangular matrices and invariant subspaces)), where the word *invariant* was introduced just for that problem; here it is again, with one more piece of information about the diagonal.

Theorem 8.7.1 — Triangular Matrices and Chains of Invariant Subspaces

Let V be finite-dimensional with basis $\mathcal{B} = (\mathbf{v}_1, \dots, \mathbf{v}_n)$, let $T \in \mathcal{L}(V)$, and put $U_0 = \{\mathbf{0}\}$ and $U_k = \operatorname{span}(\mathbf{v}_1, \dots, \mathbf{v}_k)$ for $1 \le k \le n$. The following are equivalent:

(a) $[T]_{\mathcal{B}}$ is upper triangular;
(b) $T\mathbf{v}_k \in U_k$ for every $k = 1, \dots, n$;
(c) each U_k is T-invariant.

In that case, if $d_1, \dots, d_n$ are the diagonal entries of $[T]_{\mathcal{B}}$, then $(T - d_k \operatorname{id}_V)(U_k) \subseteq U_{k-1}$ for every k.

Proof. Write $[T]_{\mathcal{B}} = (a_{ij})$, so that $T\mathbf{v}_j = \sum_i a_{ij}\mathbf{v}_i$ with unique coefficients (Definition 3.6.1, Theorem 1.5.1).

(a) $\Leftrightarrow$ (b). If $a_{ij} = 0$ for $i > j$, then $T\mathbf{v}_j = \sum_{i \le j} a_{ij}\mathbf{v}_i \in U_j$. Conversely, if $T\mathbf{v}_j \in U_j$, it has a representation using only $\mathbf{v}_1, \dots, \mathbf{v}_j$; by uniqueness, $a_{ij} = 0$ for $i > j$.
(b) $\Rightarrow$ (c). For $j \le k$, $T\mathbf{v}_j \in U_j \subseteq U_k$, so U_k is invariant by Lemma 8.1.1.
(c) $\Rightarrow$ (b). $\mathbf{v}_k \in U_k$, so $T\mathbf{v}_k \in U_k$ by invariance.

Finally, suppose (a) holds and let $\mathbf{u} = \sum_{j \le k} b_j \mathbf{v}_j \in U_k$. For $j < k$, $(T - d_k \operatorname{id}_V)\mathbf{v}_j = T\mathbf{v}_j - d_k\mathbf{v}_j \in U_j \subseteq U_{k-1}$. For $j = k$, $(T - d_k \operatorname{id}_V)\mathbf{v}_k = \sum_{i \le k} a_{ik}\mathbf{v}_i - a_{kk}\mathbf{v}_k = \sum_{i<k} a_{ik}\mathbf{v}_i \in U_{k-1}$, since $d_k = a_{kk}$. By linearity, $(T - d_k \operatorname{id}_V)\mathbf{u} \in U_{k-1}$.

■

A chain $U_1 \subset U_2 \subset \cdots \subset U_n = V$ of subspaces with $\dim U_k = k$ is often called a **flag**, after the picture of a point on a line in a plane in space. The theorem says: an upper triangular matrix is the same thing as a flag of invariant subspaces, together with a basis adapted to it. The last statement says what the diagonal entry d_k measures. Modulo the smaller space U_{k-1}, the operator T acts on the new basis vector $\mathbf{v}_k$ as multiplication by d_k.

The operators for which such a basis exists deserve a name.

Definition 8.7.1 — Triangularizable

Let V be a finite-dimensional vector space over F. An operator $T \in \mathcal{L}(V)$ is **triangularizable over** F if there **exists** a basis $\mathcal{B}$ of V such that $[T]_{\mathcal{B}}$ is upper triangular. A matrix $\mathbf{A} \in M_n(F)$ is **triangularizable over** F if there **exist** an **invertible** $\mathbf{P} \in M_n(F)$ and an upper triangular $\mathbf{U} \in M_n(F)$ with $\mathbf{P}^{-1}\mathbf{A}\mathbf{P} = \mathbf{U}$.

As for diagonalizability, $\mathbf{A}$ is triangularizable over F exactly when $T_{\mathbf{A}}$ is, by Theorem 3.7.4.

Examples.

- **Diagonalizable operators** are triangularizable, since a diagonal matrix is upper triangular. So are all operators on a space of dimension 1, and the zero and identity operators.
- **Differentiation.** For D on $\mathbb{R}[x]_{\le n}$ in the basis $(1, x, \dots, x^n)$, the matrix is upper triangu-

lar with zero diagonal: $D(x^k) = kx^{k-1} \in \operatorname{span}(1, \dots, x^k)$. The flag is $\mathbb{R}[x]_{\le 0} \subset \mathbb{R}[x]_{\le 1} \subset \cdots \subset \mathbb{R}[x]_{\le n}$, a chain of invariant subspaces we met in Section 1. D is not diagonalizable (its only eigenvectors are the constants), but it is triangularizable.

- **Too few eigenvectors.** $\mathbf{J} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$ is already triangular, with flag $\operatorname{span}(\mathbf{e}_1) \subset F^2$.

Non-example by minimal change. Reverse the basis for D on $\mathbb{R}[x]_{\le 2}$: take $(x^2, x, 1)$. The spans are $\operatorname{span}(x^2) \subset \operatorname{span}(x^2, x) \subset \mathbb{R}[x]_{\le 2}$, still a chain of subspaces of dimensions $1, 2, 3$. What fails is invariance of the first one: $D(x^2) = 2x \notin \operatorname{span}(x^2)$. Accordingly, the matrix in this basis is

$$\begin{pmatrix} 0 & 0 & 0 \\ 2 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix},$$

which is lower triangular, not upper. Being triangularizable is a property of T; being triangular is a property of T **and** a basis.

A triangularizable operator on $V \neq \{\mathbf{0}\}$ must have an invariant line $U_1 = \operatorname{span}(\mathbf{v}_1)$, hence an eigenvector (Proposition 8.1.2). So the rotation R of $\mathbb{R}^2$ by a right angle, which has no invariant line (Example (A Rotation Has No Invariant Lines)), is **not** triangularizable over $\mathbb{R}$. An eigenvector to start the flag is exactly what is needed, and the next theorem shows that it is also enough, provided eigenvectors keep existing at every stage.

> *Quick check.* Is $\begin{pmatrix} 2 & 0 \\ 1 & 2 \end{pmatrix} \in M_2(\mathbb{R})$ triangularizable over $\mathbb{R}$? If so, find a basis in which its matrix is upper triangular.

> *Solution.* Yes. We need a first basis vector that is an eigenvector. The matrix sends $\mathbf{e}_2$ to $(0, 2) = 2\mathbf{e}_2$, so start with $\mathbf{e}_2$, and complete with $\mathbf{e}_1$. In the basis $(\mathbf{e}_2, \mathbf{e}_1)$, the image of $\mathbf{e}_2$ is $2\mathbf{e}_2$ and the image of $\mathbf{e}_1$ is $(2, 1) = \mathbf{e}_2 + 2\mathbf{e}_1$, so the matrix is $\begin{pmatrix} 2 & 1 \\ 0 & 2 \end{pmatrix}$, which is upper triangular. (The standard basis gives a lower triangular matrix: $\operatorname{span}(\mathbf{e}_1)$ is not invariant.)

8.7.2 The Triangularization Theorem

If T has a triangular matrix, its characteristic polynomial is a product of linear factors, one for each diagonal entry. The converse is the real content: splitting of p_T is enough to build the flag.

Theorem 8.7.2 — Triangularization Theorem

Let V be a finite-dimensional vector space over F with $\dim V = n \ge 1$, and let $T \in \mathcal{L}(V)$. Then T is triangularizable over F if and only if p_T splits over F. The same holds for $\mathbf{A} \in M_n(F)$ and $p_{\mathbf{A}}$.

> *Idea.* Take one eigenvector, extend, recurse. Since p_T splits, it has a root in F, so T has an eigenvector $\mathbf{v}_1$. Put $U = \operatorname{span}(\mathbf{v}_1)$ and extend $\mathbf{v}_1$ to a basis. By Theorem 8.1.3 the matrix looks like
>
> $$\begin{pmatrix} \lambda & * \\ 0 & [\bar{T}] \end{pmatrix},$$

where $\bar{T}$ is the induced operator on the smaller space V/U. The first column is already right. If $[\bar{T}]$ could be made triangular, the whole matrix would be. Now $\bar{T}$ lives on a space of dimension $n-1$, and $p_T = (x-\lambda)\,p_{\bar{T}}$, so $p_{\bar{T}}$ splits too: this is the induction on dimension. The only technical point is that a basis of V/U lifts to vectors that, together with $\mathbf{v}_1$, form a basis of V.

Proof. ($\Rightarrow$) Let $[T]_{\mathcal{B}}$ be upper triangular with diagonal entries $d_1, \dots, d_n$. The matrix $x\mathbf{I}_n - [T]_{\mathcal{B}}$ is upper triangular with diagonal entries $x - d_i$, and Theorem 6.4.6 holds over $F[x]$ (the remark at the end of Chapter 6, §4). So $p_T = (x-d_1)\cdots(x-d_n)$ by Definition 6.10.2, which splits (Definition 5.4.2).

($\Leftarrow$) We prove, by induction on $n \geq 1$, that every operator on an n-dimensional space whose characteristic polynomial splits is triangularizable. For $n = 1$, every 1×1 matrix is upper triangular.

Let $n \geq 2$, and assume the statement for spaces of dimension $n-1$. Since p_T is monic of degree n (Theorem 6.10.2) and splits, $p_T = (x-c_1)(x-c_2)\cdots(x-c_n)$ with $c_i \in F$. As $p_T(c_1) = 0$, Theorem 8.2.1 gives an eigenvector $\mathbf{v}_1$ with $T\mathbf{v}_1 = c_1\mathbf{v}_1$. Let $U = \operatorname{span}(\mathbf{v}_1)$. It is T-invariant (Proposition 8.1.2), $\dim U = 1$, and $U \neq V$ since $n \geq 2$. Let $\bar{T}$ be the induced operator on V/U (Definition 8.1.2), a space of dimension $n - 1 \geq 1$ (Theorem 3.9.5).

$p_{\bar{T}}$ splits. The restriction $T|_U$ is $c_1\,\mathrm{id}_U$, whose matrix in the basis $(\mathbf{v}_1)$ is (c_1), so $p_{T|_U} = x - c_1$. By Theorem 8.1.3 (b),

$$(x-c_1)(x-c_2)\cdots(x-c_n) = p_T = (x-c_1)\,p_{\bar{T}}.$$

Canceling the non-zero factor $x - c_1$ (Corollary 0.8.4 (2)) gives $p_{\bar{T}} = (x-c_2)\cdots(x-c_n)$, which splits.

Apply the induction hypothesis. There is a basis $\bar{\mathcal{C}} = (\mathbf{w}_2 + U, \dots, \mathbf{w}_n + U)$ of V/U with $[\bar{T}]_{\bar{\mathcal{C}}}$ upper triangular, for some $\mathbf{w}_2, \dots, \mathbf{w}_n \in V$.

Lift the basis. Let $\mathcal{B} = (\mathbf{v}_1, \mathbf{w}_2, \dots, \mathbf{w}_n)$. Suppose $a\mathbf{v}_1 + b_2\mathbf{w}_2 + \cdots + b_n\mathbf{w}_n = \mathbf{0}$. Passing to cosets, and using $\mathbf{v}_1 \in U$, gives $b_2(\mathbf{w}_2+U) + \cdots + b_n(\mathbf{w}_n+U) = \mathbf{0}+U$ (Theorem 3.9.4). Since $\bar{\mathcal{C}}$ is a basis, all $b_i = 0$. Then $a\mathbf{v}_1 = \mathbf{0}$ with $\mathbf{v}_1 \neq \mathbf{0}$, so $a = 0$ (Theorem 1.1.9). Thus $\mathcal{B}$ is a linearly independent list of n vectors in V, hence a basis (Theorem 1.6.4).

The matrix. $\mathcal{B}$ extends the basis $(\mathbf{v}_1)$ of U, and the cosets of the added vectors form $\bar{\mathcal{C}}$. By Theorem 8.1.3 (b),

$$[T]_{\mathcal{B}} = \begin{pmatrix} c_1 & * \\ 0 & [\bar{T}]_{\bar{\mathcal{C}}} \end{pmatrix},$$

where the 0 is a column of $n-1$ zeros. The block $[\bar{T}]_{\bar{\mathcal{C}}}$ is upper triangular, so $[T]_{\mathcal{B}}$ is upper triangular. This completes the induction.

For $\mathbf{A} \in M_n(F)$, apply the result to $T_{\mathbf{A}}$, using Theorem 3.7.4.

■

The proof is an algorithm, and its output is a flag. The first invariant subspace is the eigenline U; the k-th is spanned by $\mathbf{v}_1$ and the lifts $\mathbf{w}_2, \dots, \mathbf{w}_k$ of the first $k-1$ vectors of the flag for $\bar{T}$. The eigenvalue found at each stage is the next diagonal entry.

Over the complex numbers the hypothesis is automatic.

Corollary 8.7.3 — Complex Operators Are Triangularizable

Every operator on a finite-dimensional complex vector space $V \neq \{\mathbf{0}\}$ is triangularizable over $\mathbb{C}$. Every $\mathbf{A} \in M_n(\mathbb{C})$, $n \geq 1$, is similar to an upper triangular matrix in $M_n(\mathbb{C})$.

Proof. By Theorem 6.10.2, p_T is non-zero, and by Corollary 5.5.5 (a) it splits over $\mathbb{C}$. Apply Theorem 8.7.2.

■

So over $\mathbb{C}$ the question of Chapter 3 always has at least this answer: a basis exists in which the matrix has zeros below the diagonal. A real matrix can always be triangularized as a complex matrix, but perhaps only with complex entries.

Warning. **Triangularizing may require leaving the field, and the triangular form is far from unique.** The rotation $\mathbf{R} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$ has $p_{\mathbf{R}} = x^2 + 1$, which does not split over $\mathbb{R}$, so no **real** invertible $\mathbf{P}$ makes $\mathbf{P}^{-1}\mathbf{R}\mathbf{P}$ triangular; over $\mathbb{C}$ it becomes $\operatorname{diag}(i, -i)$. And a triangularizable matrix has many triangular forms. $\begin{pmatrix} 1 & 1 \\ 0 & 2 \end{pmatrix}$ and $\begin{pmatrix} 2 & 0 \\ 0 & 1 \end{pmatrix}$ are both triangular forms of the same operator (the first has distinct eigenvalues $1, 2$, so it is diagonalizable, and similar to the second). The off-diagonal entries change with the flag and the basis, and even the order of the diagonal entries is not fixed. Only the diagonal entries, as a list with repetitions, are determined, as the next theorem shows.

8.7.3 What the diagonal records

A diagonalization displays the eigenvalues. A triangularization does too, with their algebraic multiplicities.

Theorem 8.7.4 — The Diagonal of a Triangular Form

Let V be finite-dimensional with $\dim V = n \geq 1$, $T \in \mathcal{L}(V)$, and let $\mathcal{B}$ be a basis with $[T]_{\mathcal{B}}$ upper triangular, with diagonal entries $d_1, \ldots, d_n$. Then:

(a) $p_T = (x - d_1)(x - d_2) \cdots (x - d_n)$;

(b) $\operatorname{spec}(T) = \{d_1, \ldots, d_n\}$, and each eigenvalue λ occurs among $d_1, \ldots, d_n$ exactly $a_T(\lambda)$ times;

(c) $\operatorname{tr} T = d_1 + \cdots + d_n$ and $\det T = d_1 \cdots d_n$.

In particular, any two triangular forms of T have the same diagonal entries, up to order.

Proof.

(a) was shown in the proof of Theorem 8.7.2, ($\Rightarrow$).

(b) By Theorem 8.2.1, the eigenvalues are the roots of p_T in F, and λ is a root of $\prod_i (x - d_i)$ exactly when $\prod_i (\lambda - d_i) = 0$, that is, when $\lambda = d_i$ for some i (Theorem 0.7.1). By Theorem 5.4.2, $a_T(\lambda) = \operatorname{mult}_\lambda(p_T) = \sum_i \operatorname{mult}_\lambda(x - d_i)$. Each term is 1 if $d_i = \lambda$ and 0 otherwise, by Theorem 5.1.3 (b), since $x - d_i$ is not divisible by $(x - \lambda)^2$ for degree reasons. So the sum counts the indices with $d_i = \lambda$.

(c) By Definition 3.10.2, $\operatorname{tr} T = \operatorname{tr}[T]_{\mathcal{B}} = \sum_i d_i$. By Definition 6.5.1 and Theorem 6.4.6, $\det T = \det[T]_{\mathcal{B}} = \prod_i d_i$.

The final statement follows from (b): the number of times λ occurs on the diagonal is $a_T(\lambda)$, which does not depend on the basis.

■

Part (c) recovers Theorem 8.3.3. In Section 3 it came from comparing coefficients of p_T; here it is read off a matrix. For instance, a complex 3×3 matrix with $p_{\mathbf{A}} = (x-1)^2(x+4)$ is similar to a triangular matrix with diagonal $1, 1, -4$ in some order, so $\operatorname{tr} \mathbf{A} = -2$ and $\det \mathbf{A} = -4$, however complicated $\mathbf{A}$ looks.

The theorem does **not** say that a triangular form with **distinct** diagonal entries is itself diagonal: $\begin{pmatrix} 1 & 1 \\ 0 & 2 \end{pmatrix}$ is a counterexample. What does follow is that T is then diagonalizable (Corollary 8.4.2), so some **other** basis makes its matrix diagonal. And an operator with repeated diagonal entries may or may not be diagonalizable: compare $\mathbf{I}_2$ with $\mathbf{J}$.

8.7.4 Triangularizing a matrix in practice

For a matrix $\mathbf{A} \in M_n(F)$ whose characteristic polynomial splits, the proof of Theorem 8.7.2 becomes a procedure.

1. Find an eigenvalue λ_1 and an eigenvector $\mathbf{v}_1$.
2. Extend $\mathbf{v}_1$ to a basis $(\mathbf{v}_1, \mathbf{w}_2, \dots, \mathbf{w}_n)$ of F^n, choosing the $\mathbf{w}_i$ as simple as possible, for example standard basis vectors.
3. Compute the matrix of the induced operator on $F^n/\operatorname{span}(\mathbf{v}_1)$ in the basis $(\mathbf{w}_2 + U, \dots, \mathbf{w}_n + U)$. Its entries are the coordinates of $\mathbf{A}\mathbf{w}_j$ along $\mathbf{w}_2, \dots, \mathbf{w}_n$, ignoring the $\mathbf{v}_1$-coordinate.
4. Triangularize this $(n-1) \times (n-1)$ matrix in the same way, and lift each coset back to its representative.

Example. (Triangularizing a Matrix with a Single Eigenvector Line)

Let

$$\mathbf{A} = \begin{pmatrix} 2 & 0 & 1 \\ 0 & 2 & 1 \\ 1 & -1 & 2 \end{pmatrix} \in M_3(\mathbb{R}).$$

Show that $\mathbf{A}$ is not diagonalizable but is triangularizable over $\mathbb{R}$, and find an invertible $\mathbf{P}$ with $\mathbf{P}^{-1}\mathbf{A}\mathbf{P}$ upper triangular.

Solution. The characteristic polynomial. Expanding along the first row (Theorem 6.6.1

over $\mathbb{R}[x]$),

$$p_{\mathbf{A}} = \det \begin{pmatrix} x-2 & 0 & -1 \\ 0 & x-2 & -1 \\ -1 & 1 & x-2 \end{pmatrix} = (x-2)\big[(x-2)^2+1\big] + (-1)\det \begin{pmatrix} 0 & x-2 \\ -1 & 1 \end{pmatrix}.$$

The last determinant is $0\cdot 1-(x-2)(-1) = x-2$, so $p_{\mathbf{A}} = (x-2)\big[(x-2)^2+1-1\big] = (x-2)^3$. It splits, so $\mathbf{A}$ is triangularizable by Theorem 8.7.2.

Eigenvectors. $\mathbf{A} - 2\mathbf{I} = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 1 \\ 1 & -1 & 0 \end{pmatrix}$ has rank 2, so $g(2) = 1 < 3 = a(2)$, and $\mathbf{A}$ is not diagonalizable (Theorem 8.4.1 (e)). The system gives $z = 0$ and $x = y$, so $E_2(\mathbf{A}) = \operatorname{span}(\mathbf{v}_1)$ with $\mathbf{v}_1 = (1,1,0)$: all eigenvectors lie on one line.

Step 1. Let $U = \operatorname{span}(\mathbf{v}_1)$, and extend to the basis $(\mathbf{v}_1, \mathbf{e}_2, \mathbf{e}_3)$ of $\mathbb{R}^3$ (the matrix with these columns has determinant 1).

Step 2: the induced operator. Express the images of $\mathbf{e}_2$ and $\mathbf{e}_3$ in the basis:

$$\mathbf{A}\mathbf{e}_2 = (0,2,-1) = 0\,\mathbf{v}_1 + 2\mathbf{e}_2 - \mathbf{e}_3, \qquad \mathbf{A}\mathbf{e}_3 = (1,1,2) = 1\,\mathbf{v}_1 + 0\,\mathbf{e}_2 + 2\mathbf{e}_3.$$

Dropping the $\mathbf{v}_1$-coordinates, the induced operator $\bar{\mathbf{A}}$ on $\mathbb{R}^3/U$ has, in the basis $(\mathbf{e}_2 + U, \mathbf{e}_3 + U)$, the matrix

$$[\bar{\mathbf{A}}] = \begin{pmatrix} 2 & 0 \\ -1 & 2 \end{pmatrix},$$

with $p_{\bar{\mathbf{A}}} = (x-2)^2$, as the proof predicts.

Step 3: triangularize $\bar{\mathbf{A}}$. Its second column says $\bar{\mathbf{A}}(\mathbf{e}_3 + U) = 2(\mathbf{e}_3 + U)$, so $\mathbf{e}_3 + U$ is an eigenvector. In the basis $(\mathbf{e}_3 + U, \mathbf{e}_2 + U)$, $\bar{\mathbf{A}}(\mathbf{e}_2 + U) = -(\mathbf{e}_3 + U) + 2(\mathbf{e}_2 + U)$, and the matrix becomes $\begin{pmatrix} 2 & -1 \\ 0 & 2 \end{pmatrix}$.

Step 4: lift. The basis $\mathcal{B} = (\mathbf{v}_1, \mathbf{e}_3, \mathbf{e}_2)$ of $\mathbb{R}^3$ gives

$$\mathbf{P} = \begin{pmatrix} 1 & 0 & 0 \\ 1 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix}, \qquad \mathbf{P}^{-1}\mathbf{A}\mathbf{P} = \begin{pmatrix} 2 & 1 & 0 \\ 0 & 2 & -1 \\ 0 & 0 & 2 \end{pmatrix}.$$

Check. $\mathbf{A}\mathbf{v}_1 = (2,2,0) = 2\mathbf{v}_1$; $\mathbf{A}\mathbf{e}_3 = (1,1,2) = \mathbf{v}_1 + 2\mathbf{e}_3$; $\mathbf{A}\mathbf{e}_2 = (0,2,-1) = -\mathbf{e}_3 + 2\mathbf{e}_2$. These are the columns $(2,0,0)$, $(1,2,0)$, $(0,-1,2)$ of the triangular matrix, read in the basis $\mathcal{B}$. Also $\det \mathbf{P} = -1 \neq 0$.

The flag is $\operatorname{span}((1,1,0)) \subset \{(a,a,b) : a,b \in \mathbb{R}\} \subset \mathbb{R}^3$. One can check the plane directly: $\mathbf{A}(a,a,b) = (2a+b,\ 2a+b,\ 2b)$ lies in it again. The diagonal is $2,2,2$, as Theorem 8.7.4 requires.

Different choices in Step 2 give different triangular matrices, with the same diagonal. Chapter 9 shows how to choose the basis so that the entries above the diagonal are as simple as possible (the Jordan form). Chapter 11 shows that over $\mathbb{C}$ with an inner product, the basis can even be chosen orthonormal (Schur's theorem).

8.7.5 Exercises

8.7.5.1 A. Check your understanding

Exercise A1.

(a) Define what it means for $\mathbf{A} \in M_n(F)$ to be triangularizable over F.

(b) State the Triangularization Theorem.

(c) For a basis $(\mathbf{v}_1, \ldots, \mathbf{v}_n)$, which subspaces must be invariant for $[T]_{\mathcal{B}}$ to be upper triangular?

(d) True or false: every $\mathbf{A} \in M_n(\mathbb{R})$ is triangularizable over $\mathbb{R}$. Justify your answer.

(e) True or false: every triangularizable matrix is diagonalizable. Justify your answer.

(f) Let $\mathbf{A} \in M_4(\mathbb{C})$ have $p_{\mathbf{A}} = (x-3)^3(x+1)$. What are the diagonal entries of any upper triangular matrix similar to $\mathbf{A}$, and what are $\operatorname{tr}\mathbf{A}$ and $\det\mathbf{A}$?

Solution.

(a) There are an invertible $\mathbf{P} \in M_n(F)$ and an upper triangular $\mathbf{U} \in M_n(F)$ with $\mathbf{P}^{-1}\mathbf{A}\mathbf{P} = \mathbf{U}$ (Definition 8.7.1).

(b) An operator on a space of dimension $n \geq 1$ over F is triangularizable over F if and only if its characteristic polynomial splits over F (Theorem 8.7.2).

(c) All the spans $\operatorname{span}(\mathbf{v}_1, \ldots, \mathbf{v}_k)$, $1 \leq k \leq n$ (Theorem 8.7.1).

(d) False. The rotation $\begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$ has $p = x^2 + 1$, which does not split over $\mathbb{R}$.

(e) False. $\begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$ is triangular but not diagonalizable.

(f) By Theorem 8.7.4, the diagonal is $3, 3, 3, -1$ in some order, so $\operatorname{tr}\mathbf{A} = 8$ and $\det\mathbf{A} = -27$.

8.7.5.2 B. Practice

Exercise B1: Triangularizing matrices.

For each real matrix, find an invertible $\mathbf{P}$ such that $\mathbf{P}^{-1}\mathbf{A}\mathbf{P}$ is upper triangular, and write down $\mathbf{P}^{-1}\mathbf{A}\mathbf{P}$.

(a) $\mathbf{A} = \begin{pmatrix} 3 & 1 \\ -1 & 1 \end{pmatrix}$.

(b) $\mathbf{A} = \begin{pmatrix} 2 & 0 & 1 \\ 1 & 3 & 1 \\ 1 & 0 & 2 \end{pmatrix}$, with $p_{\mathbf{A}} = (x-1)(x-3)^2$ (Example (A 3×3 Characteristic Polynomial)).

Solution.

(a) $\operatorname{tr}\mathbf{A} = 4$, $\det\mathbf{A} = 4$, so $p_{\mathbf{A}} = (x-2)^2$, which splits. $\mathbf{A} - 2\mathbf{I} = \begin{pmatrix} 1 & 1 \\ -1 & -1 \end{pmatrix}$ gives

the eigenvector $\mathbf{v}_1 = (1, -1)$. Extend with $\mathbf{e}_2$: $\mathbf{A}\mathbf{e}_2 = (1, 1) = \mathbf{v}_1 + 2\mathbf{e}_2$. So with

$$\mathbf{P} = \begin{pmatrix} 1 & 0 \\ -1 & 1 \end{pmatrix}, \qquad \mathbf{P}^{-1}\mathbf{A}\mathbf{P} = \begin{pmatrix} 2 & 1 \\ 0 & 2 \end{pmatrix}.$$

(In size 2, one eigenvector already fixes the flag.)

(b) $\mathbf{A}\mathbf{e}_2 = (0, 3, 0) = 3\mathbf{e}_2$, so $\mathbf{v}_1 = \mathbf{e}_2$ is an eigenvector for 3. Let $U = \operatorname{span}(\mathbf{e}_2)$ and extend to $(\mathbf{e}_2, \mathbf{e}_1, \mathbf{e}_3)$. Then $\mathbf{A}\mathbf{e}_1 = (2, 1, 1) = \mathbf{e}_2 + 2\mathbf{e}_1 + \mathbf{e}_3$ and $\mathbf{A}\mathbf{e}_3 = (1, 1, 2) = \mathbf{e}_2 + \mathbf{e}_1 + 2\mathbf{e}_3$, so the induced operator has matrix $\begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix}$ in the basis $(\mathbf{e}_1 + U, \mathbf{e}_3 + U)$. Its characteristic polynomial is $x^2 - 4x + 3 = (x - 3)(x - 1)$, with eigenvectors $(1, 1)$ for 3 and $(1, -1)$ for 1, that is, $\mathbf{e}_1 + \mathbf{e}_3 + U$ and $\mathbf{e}_1 - \mathbf{e}_3 + U$. Lifting gives the basis $(\mathbf{e}_2,\ \mathbf{e}_1 + \mathbf{e}_3,\ \mathbf{e}_1 - \mathbf{e}_3)$. Now

$$\begin{aligned} \mathbf{A}(\mathbf{e}_1 + \mathbf{e}_3) &= (3, 2, 3) = 2\mathbf{e}_2 + 3(\mathbf{e}_1 + \mathbf{e}_3), \\ \mathbf{A}(\mathbf{e}_1 - \mathbf{e}_3) &= (1, 0, -1) = \mathbf{e}_1 - \mathbf{e}_3, \end{aligned}$$

so

$$\mathbf{P} = \begin{pmatrix} 0 & 1 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & -1 \end{pmatrix}, \qquad \mathbf{P}^{-1}\mathbf{A}\mathbf{P} = \begin{pmatrix} 3 & 2 & 0 \\ 0 & 3 & 0 \\ 0 & 0 & 1 \end{pmatrix},$$

with $\det \mathbf{P} = 2 \neq 0$ (expand along the second row). The diagonal $3, 3, 1$ agrees with $p_{\mathbf{A}}$.

Exercise B2: Nilpotent matrices are strictly triangular.

Let $\mathbf{A} \in M_n(\mathbb{C})$, $n \geq 1$, with $\mathbf{A}^k = 0$ for some $k \geq 1$. Prove that $\mathbf{A}$ is similar to a **strictly** upper triangular matrix, that is, an upper triangular matrix with zero diagonal.

Solution. By Corollary 8.7.3, $\mathbf{P}^{-1}\mathbf{A}\mathbf{P} = \mathbf{U}$ is upper triangular for some invertible $\mathbf{P}$. By Theorem 8.7.4 (b), each diagonal entry of $\mathbf{U}$ is an eigenvalue of $\mathbf{A}$. By Exercise (C2: Nilpotent operators) (a), the only eigenvalue of a nilpotent operator on a non-zero space is 0. So every diagonal entry of $\mathbf{U}$ is 0, and $\mathbf{U}$ is strictly upper triangular. (The statement holds over every field, with a different proof: use the chain $\ker \mathbf{A} \subseteq \ker \mathbf{A}^2 \subseteq \cdots \subseteq \ker \mathbf{A}^k = F^n$ to build the basis.)

Exercise B3: Eigenvalues of powers from a triangular form.

Let $\mathbf{A} \in M_n(\mathbb{C})$, $n \geq 1$, and let $\mathbf{P}^{-1}\mathbf{A}\mathbf{P} = \mathbf{U}$ be upper triangular with diagonal entries $d_1, \ldots, d_n$.

(a) Show that the product of two upper triangular matrices is upper triangular, with diagonal entries the products of the corresponding diagonal entries.

(b) Deduce that $p_{\mathbf{A}^k} = (x - d_1^k) \cdots (x - d_n^k)$ and $\operatorname{tr}(\mathbf{A}^k) = d_1^k + \cdots + d_n^k$ for every $k \geq 1$.

(c) Suppose $p_{\mathbf{A}} = (x - 1)(x + 1)(x - 2)$. Find $p_{\mathbf{A}^2}$, $\operatorname{tr} \mathbf{A}^2$ and $\det \mathbf{A}^2$.

Solution.

(a) Let $\mathbf{U}, \mathbf{U}'$ be upper triangular. The (i, j)-entry of $\mathbf{U}\mathbf{U}'$ is $\sum_l u_{il} u'_{lj}$. A term can

be non-zero only if $u_{il} \neq 0$ and $u'_{lj} \neq 0$, which forces $i \leq l \leq j$. So the entry is 0 when $i > j$, and for $i = j$ only $l = i$ survives, giving $u_{ii}u'_{ii}$.

(b) $\mathbf{P}^{-1}\mathbf{A}^k\mathbf{P} = (\mathbf{P}^{-1}\mathbf{A}\mathbf{P})^k = \mathbf{U}^k$, by induction on k. By (a) and induction, $\mathbf{U}^k$ is upper triangular with diagonal entries d_i^k. By Theorem 8.7.4 (a) and (c), applied to $T_{\mathbf{A}^k}$ in the basis given by the columns of $\mathbf{P}$, $p_{\mathbf{A}^k} = \prod_i (x - d_i^k)$ and $\operatorname{tr} \mathbf{A}^k = \sum_i d_i^k$.

(c) By Theorem 8.7.4, the diagonal of $\mathbf{U}$ is $1, -1, 2$ in some order. By (b), $p_{\mathbf{A}^2} = (x-1)(x-1)(x-4) = (x-1)^2(x-4)$, $\operatorname{tr} \mathbf{A}^2 = 1+1+4 = 6$, and $\det \mathbf{A}^2 = 1 \cdot 1 \cdot 4 = 4$. The last agrees with $\det \mathbf{A}^2 = (\det \mathbf{A})^2 = (-2)^2$.

8.7.5.3 C. Going deeper

Exercise C1: A second proof of Cayley–Hamilton.

Let V be finite-dimensional with $\dim V = n \geq 1$, and let $T \in \mathcal{L}(V)$ have a basis $\mathcal{B} = (\mathbf{v}_1, \ldots, \mathbf{v}_n)$ with $[T]_{\mathcal{B}}$ upper triangular, with diagonal entries $d_1, \ldots, d_n$. Let $U_0 = \{\mathbf{0}\}$ and $U_k = \operatorname{span}(\mathbf{v}_1, \ldots, \mathbf{v}_k)$.

(a) Let $S_k = (T - d_1 \operatorname{id}_V)(T - d_2 \operatorname{id}_V) \cdots (T - d_k \operatorname{id}_V)$. Prove by induction on k that $S_k(U_k) = \{\mathbf{0}\}$ for $1 \leq k \leq n$.

(b) Deduce that $p_T(T) = 0$, without using the adjugate.

(c) Deduce the Cayley–Hamilton Theorem for every $\mathbf{A} \in M_n(\mathbb{C})$, and then for every $\mathbf{A} \in M_n(\mathbb{R})$.

(d) Why does this argument, on its own, not prove the theorem for $\mathbf{A} \in M_2(\mathbb{F}_2)$ with $p_{\mathbf{A}} = x^2 + x + 1$?

Hint: for (a), use the last statement of Theorem 8.7.1.

Solution.

(a) By Theorem 8.7.1, each U_k is invariant and $(T - d_k \operatorname{id}_V)(U_k) \subseteq U_{k-1}$. For $k = 1$, $S_1(U_1) = (T - d_1 \operatorname{id}_V)(U_1) \subseteq U_0 = \{\mathbf{0}\}$. Suppose $S_{k-1}(U_{k-1}) = \{\mathbf{0}\}$ for some $k \geq 2$. Since $S_k = S_{k-1}(T - d_k \operatorname{id}_V)$, for $\mathbf{u} \in U_k$ we get $S_k\mathbf{u} = S_{k-1}\big((T - d_k \operatorname{id}_V)\mathbf{u}\big) \in S_{k-1}(U_{k-1}) = \{\mathbf{0}\}$.

(b) By Theorem 8.7.4 (a), $p_T = \prod_{i=1}^n (x - d_i)$, so $p_T(T) = S_n$ by Theorem 5.7.1 (b). By (a), S_n kills $U_n = V$, so $p_T(T) = 0$.

(c) Let $\mathbf{A} \in M_n(\mathbb{C})$. By Corollary 8.7.3, $T_{\mathbf{A}}$ has a basis in which its matrix is upper triangular, and (b) gives $p_{\mathbf{A}}(T_{\mathbf{A}}) = 0$, so $p_{\mathbf{A}}(\mathbf{A}) = 0$ by Corollary 3.6.3. For $\mathbf{A} \in M_n(\mathbb{R})$, regard $\mathbf{A}$ as an element of $M_n(\mathbb{C})$. The Leibniz formula gives the same polynomial $p_{\mathbf{A}}$ with real coefficients, and $p_{\mathbf{A}}(\mathbf{A})$ is computed from the same entries by the same sums and products; it is 0 by the complex case.

(d) Over $\mathbb{F}_2$, $x^2 + x + 1$ has no root (its values at 0 and 1 are both 1), so it does not split, and the matrix is not triangularizable over $\mathbb{F}_2$ by Theorem 8.7.2. To run the argument we would need a larger field containing $\mathbb{F}_2$ in which the polynomial splits, and we have not constructed one. The adjugate proof of Theorem 8.6.1 needs no such field. (For instance $\mathbf{A} = \begin{pmatrix} 0 & 1 \\ 1 & 1 \end{pmatrix}$ has this characteristic polynomial, and indeed $\mathbf{A}^2 + \mathbf{A} + \mathbf{I} = 0$ over $\mathbb{F}_2$.)

Exercise C2: Real operators have small invariant subspaces.

Let $\mathbf{A} \in M_n(\mathbb{R})$, $n \geq 1$, regarded also as a complex matrix.

(a) Let $\lambda = a+bi$ $(a, b \in \mathbb{R})$ be a complex eigenvalue of $\mathbf{A}$ with eigenvector $\mathbf{z} = \mathbf{x}+i\mathbf{y}$, where $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$. Show that $\mathbf{Ax} = a\mathbf{x} - b\mathbf{y}$ and $\mathbf{Ay} = b\mathbf{x} + a\mathbf{y}$.

(b) Deduce that $\operatorname{span}(\mathbf{x}, \mathbf{y}) \subseteq \mathbb{R}^n$ is $\mathbf{A}$-invariant, and has dimension 1 or 2.

(c) Deduce that every operator on a real vector space V with $1 \leq \dim V < \infty$ has an invariant subspace of dimension 1 or 2.

(d) For $\mathbf{C} = \begin{pmatrix} 0 & 0 & 2 \\ 1 & 0 & -1 \\ 0 & 1 & 2 \end{pmatrix}$, check that $\mathbf{z} = (0, -2, 1) + i(-2, 1, 0)$ is an eigenvector for i, and find the invariant plane of (b).

Solution.

(a) The eigenvalue exists by Theorem 8.2.4. Since $\mathbf{A}$ has real entries, $\mathbf{Az} = \mathbf{Ax}+i\mathbf{Ay}$ with $\mathbf{Ax}, \mathbf{Ay} \in \mathbb{R}^n$. On the other hand, $\lambda\mathbf{z} = (a+bi)(\mathbf{x}+i\mathbf{y}) = (a\mathbf{x}-b\mathbf{y})+i(b\mathbf{x}+a\mathbf{y})$. A vector of $\mathbb{C}^n$ determines its real and imaginary parts entry by entry, so $\mathbf{Ax} = a\mathbf{x} - b\mathbf{y}$ and $\mathbf{Ay} = b\mathbf{x} + a\mathbf{y}$.

(b) By (a), $\mathbf{Ax}$ and $\mathbf{Ay}$ lie in $W = \operatorname{span}(\mathbf{x}, \mathbf{y})$, so W is invariant by Lemma 8.1.1. Since $\mathbf{z} \neq \mathbf{0}$, at least one of $\mathbf{x}, \mathbf{y}$ is non-zero, so $\dim W \geq 1$, and $\dim W \leq 2$ since W is spanned by two vectors.

(c) Choose a basis $\mathcal{B}$ of V, let $\mathbf{A} = [T]_{\mathcal{B}} \in M_n(\mathbb{R})$, and let W be as in (b). Let $\Phi\colon V \to \mathbb{R}^n$ be the coordinate isomorphism $\mathbf{v} \mapsto [\mathbf{v}]_{\mathcal{B}}$ (Corollary 3.5.5). Then $\Phi^{-1}(W)$ is a subspace of the same dimension as W, and for $\mathbf{v} \in \Phi^{-1}(W)$, $\Phi(T\mathbf{v}) = \mathbf{A}\Phi(\mathbf{v}) \in W$ (Theorem 3.6.1), so $T\mathbf{v} \in \Phi^{-1}(W)$.

(d) With $\mathbf{x} = (0, -2, 1)$ and $\mathbf{y} = (-2, 1, 0)$: $\mathbf{Cx} = (2, -1, 0) = -\mathbf{y}$ and $\mathbf{Cy} = (0, -2, 1) = \mathbf{x}$. So $\mathbf{Cz} = \mathbf{Cx} + i\mathbf{Cy} = -\mathbf{y} + i\mathbf{x} = i(\mathbf{x} + i\mathbf{y}) = i\mathbf{z}$, and $\mathbf{z}$ is an eigenvector for i (here $a = 0$, $b = 1$, matching (a)). The invariant plane is $\operatorname{span}((0, -2, 1), (-2, 1, 0))$, which is the plane $x + 2y + 4z = 0$. Over $\mathbb{R}$, $\mathbf{C}$ also has the eigenvalue 2 with eigenvector $(1, 0, 1)$, an invariant line.

Exercise C3: Traces of powers detect nilpotency.

Let $\mathbf{C} \in M_n(\mathbb{C})$, $n \geq 1$, with $\operatorname{tr}(\mathbf{C}^k) = 0$ for $k = 1, \ldots, n$. The goal is to prove that $\mathbf{C}^n = 0$.

(a) Let $d_1, \ldots, d_n$ be the diagonal entries of a triangular form of $\mathbf{C}$. Show that $d_1^k + \cdots + d_n^k = 0$ for $k = 1, \ldots, n$.

(b) Suppose some $d_i \neq 0$. Let $\mu_1, \ldots, \mu_r$ $(r \geq 1)$ be the distinct non-zero values among the d_i, and let $m_j \geq 1$ be the number of indices i with $d_i = \mu_j$. Show that $\sum_{j=1}^{r} m_j \mu_j^k = 0$ for $k = 1, \ldots, r$.

(c) Show that the $r \times r$ matrix with (k, j)-entry μ_j^k is invertible, and derive a contradiction from (b).

(d) Conclude that every $d_i = 0$, that $p_{\mathbf{C}} = x^n$, and that $\mathbf{C}^n = 0$.

(e) Show that the statement fails over $\mathbb{F}_2$.

Hint: for (c), factor the matrix as a transposed Vandermonde matrix times a diagonal matrix.

Solution.

(a) By Corollary 8.7.3 a triangular form exists, and by Exercise (B3: Eigenvalues of powers from a triangular form) (b), $\operatorname{tr} \mathbf{C}^k = \sum_i d_i^k$, which is 0 by hypothesis.

(b) Indices with $d_i = 0$ contribute nothing to $\sum_i d_i^k$ for $k \geq 1$. Grouping the other indices by their value, $\sum_i d_i^k = \sum_j m_j \mu_j^k$. Since $r \leq n$, (a) applies for $k = 1, \ldots, r$.

(c) Let $\mathbf{M}$ be the matrix with (k, j)-entry μ_j^k. The Vandermonde matrix $\mathbf{V} = \mathbf{V}(\mu_1, \ldots, \mu_r)$ has (j, k)-entry μ_j^{k-1}, so $\mathbf{V}^\top$ has (k, j)-entry μ_j^{k-1}, and multiplying column j by μ_j gives $\mathbf{M} = \mathbf{V}^\top \operatorname{diag}(\mu_1, \ldots, \mu_r)$. Since the μ_j are distinct, $\mathbf{V}$ is invertible (Corollary 6.8.2), hence so is $\mathbf{V}^\top$ (Theorem 6.4.5); since the μ_j are non-zero, the diagonal matrix is invertible. So $\mathbf{M}$ is invertible. By (b), $\mathbf{M}(m_1, \ldots, m_r) = \mathbf{0}$, so $(m_1, \ldots, m_r) = \mathbf{0}$ in $\mathbb{C}^r$. But each m_j is a positive integer, which is non-zero in $\mathbb{C}$. This contradiction shows that no d_i is non-zero.

(d) By (c), all $d_i = 0$, so $p_{\mathbf{C}} = x^n$ by Theorem 8.7.4 (a). By Theorem 8.6.1, $\mathbf{C}^n = p_{\mathbf{C}}(\mathbf{C}) = 0$.

(e) Over $\mathbb{F}_2$, $\mathbf{C} = \mathbf{I}_2$ has $\operatorname{tr} \mathbf{C}^k = \operatorname{tr} \mathbf{I}_2 = 1 + 1 = 0$ for every k, but $\mathbf{C}^k = \mathbf{I}_2 \neq 0$. The step that fails is (c): the positive integer $m_1 = 2$ is 0 in $\mathbb{F}_2$. Compare Exercise (C2: When $\mathbf{A}$ commutes with $[\mathbf{A}, \mathbf{B}]$), where in characteristic 0 the same conclusion was reached for a commutator by a route that avoids eigenvalues.

8.8 Primary Decomposition

Chapter 5 ended with a lemma about any polynomial that kills an operator: if it factors into coprime pieces, the space splits into the kernels of the pieces. The previous sections produced the best polynomial to feed it, the minimal polynomial, which factors into powers of distinct irreducibles. This section runs the lemma on that factorization. The result, the primary decomposition, cuts V into invariant pieces, one for each irreducible factor of m_T, and on each piece the operator has a minimal polynomial that is a single prime power. Two answers follow at once. An operator is diagonalizable exactly when its minimal polynomial is a product of distinct linear factors. And every complex matrix with $\mathbf{A}^k = \mathbf{I}$ is diagonalizable, a promise from Section 4. Finally, when m_T splits, the pieces are the spaces on which Chapter 9 builds the Jordan form.

8.8.1 Splitting the space along the minimal polynomial

Here is the question. Diagonalization splits V into eigenspaces, and it can fail. What splitting survives for **every** operator? The minimal polynomial suggests one. By Theorem 5.3.5, if $V \neq \{\mathbf{0}\}$, then m_T (monic, of degree at least 1 by Theorem 8.5.1) factors as

$$m_T = p_1^{e_1} p_2^{e_2} \cdots p_k^{e_k},$$

with $p_1, \dots, p_k$ **distinct** monic irreducible polynomials and exponents $e_i \geq 1$. Powers of distinct irreducibles have no common factor, so the kernel splitting lemma of Chapter 5, in its form with k factors (Exercise (C2: Splitting with k coprime factors)), applies to them. It gives a direct sum. The new information is what happens on the pieces.

The primary decomposition splits V into one invariant piece for each irreducible factor of m_T, and on that piece the operator is killed by exactly that factor's power.

Theorem 8.8.1 — Primary Decomposition Theorem

Let $V \neq \{\mathbf{0}\}$ be a finite-dimensional vector space over F, let $T \in \mathcal{L}(V)$, and let $m_T = p_1^{e_1} \cdots p_k^{e_k}$, where $p_1, \dots, p_k$ are distinct monic irreducible polynomials and $e_i \geq 1$. Put

$$V_i := \ker p_i(T)^{e_i} \qquad (i = 1, \dots, k).$$

Then:

(a) $V = V_1 \oplus V_2 \oplus \cdots \oplus V_k$;
(b) each V_i is T-invariant and non-zero;
(c) the restriction $T|_{V_i}$ has minimal polynomial $m_{T|_{V_i}} = p_i^{e_i}$;
(d) for each i there is $h_i \in F[x]$ such that $h_i(T)$ is the projection of V onto V_i along $\bigoplus_{j \neq i} V_j$.

In words: (a) every vector is **uniquely** a sum of pieces, one from each V_i. (b) T maps each piece into itself, so T is determined by the k restrictions, and in a basis made of bases of the V_i its matrix is block diagonal (Theorem 8.1.5). (c) Nothing is wasted: on V_i the operator is killed by $p_i^{e_i}$, and by no proper divisor of it. (d) The pieces can be computed with polynomials in T alone. The word *primary* refers to the prime powers $p_i^{e_i}$.

Idea. ① The splitting is Chapter 5's lemma: distinct irreducible powers are pairwise coprime, and their product m_T kills T. ② Invariance holds for every kernel of a polynomial in T. ③ For (c), each restriction is killed by $p_i^{e_i}$, so its minimal polynomial is some $p_i^{f_i}$ with $f_i \leq e_i$. Conversely, the product of these minimal polynomials kills T piece by piece, hence on all of V, so it is a multiple of m_T. A degree count then forces $f_i = e_i$.

Proof. Coprime. Let $i \neq j$ and $d = \gcd(p_i^{e_i}, p_j^{e_j})$, which is monic. By Lemma 8.5.2, $d = p_i^f$ and $d = p_j^g$ for some $f, g \geq 0$. By the uniqueness in Theorem 5.3.5, and since $p_i \neq p_j$, this forces $f = g = 0$, so $d = 1$.

(a) and (d). If $k = 1$, then $V_1 = \ker m_T(T) = V$ and $h_1 = 1$ works. If $k \geq 2$, apply Exercise (C2: Splitting with k coprime factors) (d) to the pairwise coprime polynomials $p_1^{e_1}, \dots, p_k^{e_k}$, whose product m_T annihilates T. It gives $V = V_1 \oplus \cdots \oplus V_k$, with the projections given by polynomials $h_i(T)$.

(b) Each V_i is the kernel of a polynomial in T, so it is T-invariant by Theorem 5.7.4 (b). That $V_i \neq \{\mathbf{0}\}$ will follow from (c): the minimal polynomial of an operator on the zero space is 1, and $p_i^{e_i} \neq 1$.

(c) Let $q_i = m_{T|_{V_i}}$. By Exercise (C2: Minimal polynomials of the pieces) (a), $p_i^{e_i}(T|_{V_i}) = p_i^{e_i}(T)|_{V_i} = 0$, so $q_i \mid p_i^{e_i}$ (Theorem 8.5.1), and $q_i = p_i^{f_i}$ with $0 \leq f_i \leq e_i$ by Lemma 8.5.2. Put $q = q_1 \cdots q_k$. For $\mathbf{v}_i \in V_i$, polynomials in T commute (Theo-

rem 5.7.1 (c)), so

$$q(T)\mathbf{v}_i = \Big(\prod_{j\neq i} q_j\Big)(T)\; q_i(T)\mathbf{v}_i = \Big(\prod_{j\neq i} q_j\Big)(T)\; q_i(T|_{V_i})\mathbf{v}_i = \mathbf{0},$$

using Exercise (C2: Minimal polynomials of the pieces) (a) again. By (a), every $\mathbf{v} \in V$ is a sum of such $\mathbf{v}_i$, so $q(T) = 0$, and $m_T \mid q$ by Theorem 8.5.1. Comparing degrees (Proposition 5.1.2 (c), Theorem 0.8.3),

$$\sum_{i=1}^{k} e_i \deg p_i = \deg m_T \leq \deg q = \sum_{i=1}^{k} f_i \deg p_i.$$

Since $f_i \leq e_i$ and $\deg p_i \geq 1$ for every i, each term on the right is at most the matching term on the left, so equality holds term by term, and $f_i = e_i$. Hence $m_{T|_{V_i}} = p_i^{e_i}$. This proves the theorem.

■

The theorem reduces the study of T to the study of operators whose minimal polynomial is a power of **one** irreducible. For a matrix, choose a basis of each V_i and put them together: $\mathbf{A}$ is similar to a block diagonal matrix $\mathbf{A}_1 \oplus \cdots \oplus \mathbf{A}_k$ with $m_{\mathbf{A}_i} = p_i^{e_i}$, and then $m_{\mathbf{A}} = \operatorname{lcm}(m_{\mathbf{A}_1}, \ldots, m_{\mathbf{A}_k})$ by Proposition 8.5.6, applied $k-1$ times, consistent with (c).

Example. (A Primary Decomposition with an Irreducible Quadratic)

Let $\mathbf{C} = \begin{pmatrix} 0 & 0 & 2 \\ 1 & 0 & -1 \\ 0 & 1 & 2 \end{pmatrix} \in M_3(\mathbb{R})$. Chapter 5 showed that its minimal polynomial is $m_{\mathbf{C}} = (x-2)(x^2+1)$ (Exercise (B2: An annihilating polynomial by elimination)). Find the primary decomposition of $\mathbb{R}^3$, the projections as polynomials in $\mathbf{C}$, and the matrix of $\mathbf{C}$ in an adapted basis.

Solution. The factorization. $x-2$ is irreducible (degree 1), and x^2+1 is irreducible over $\mathbb{R}$ because it has no real root (Theorem 5.3.1 (b)). So $k = 2$, $p_1 = x-2$, $p_2 = x^2+1$, $e_1 = e_2 = 1$.

The pieces. $V_1 = \ker(\mathbf{C} - 2\mathbf{I})$: the matrix $\mathbf{C} - 2\mathbf{I} = \begin{pmatrix} -2 & 0 & 2 \\ 1 & -2 & -1 \\ 0 & 1 & 0 \end{pmatrix}$ gives $y = 0$ and $x = z$, so $V_1 = \operatorname{span}((1,0,1))$. For $V_2 = \ker(\mathbf{C}^2 + \mathbf{I})$, multiply out:

$$\mathbf{C}^2 = \begin{pmatrix} 0 & 2 & 4 \\ 0 & -1 & 0 \\ 1 & 2 & 3 \end{pmatrix}, \qquad \mathbf{C}^2 + \mathbf{I} = \begin{pmatrix} 1 & 2 & 4 \\ 0 & 0 & 0 \\ 1 & 2 & 4 \end{pmatrix}.$$

So V_2 is the plane $x + 2y + 4z = 0$, with basis $(-2,1,0)$, $(-4,0,1)$. As the theorem predicts, $\dim V_1 + \dim V_2 = 3$, and $(1,0,1) \notin V_2$ since $1+0+4 \neq 0$.

The projections. Bézout's identity for p_1, p_2: since $x^2+1 = (x+2)(x-2)+5$,

$$\tfrac{1}{5}(x^2+1) - \tfrac{1}{5}(x+2)(x-2) = 1.$$

Following Theorem 5.7.5 (c) with $p = x - 2$, $q = x^2 + 1$, $a = -\frac{1}{5}(x + 2)$ and $b = \frac{1}{5}$, the projection onto V_1 along V_2 is $h_1(\mathbf{C}) = b(\mathbf{C})q(\mathbf{C}) = \frac{1}{5}(\mathbf{C}^2 + \mathbf{I})$, and the projection onto V_2 along V_1 is $h_2(\mathbf{C}) = \mathbf{I} - h_1(\mathbf{C})$. Concretely,

$$h_1(\mathbf{C}) \begin{pmatrix} x \\ y \\ z \end{pmatrix} = \frac{x + 2y + 4z}{5} \begin{pmatrix} 1 \\ 0 \\ 1 \end{pmatrix},$$

which lies in V_1, is $\mathbf{0}$ on V_2, and fixes $(1, 0, 1)$.

The adapted basis. $\mathbf{C}(1, 0, 1) = (2, 0, 2)$. On V_2, $\mathbf{C}(-2, 1, 0) = (0, -2, 1) = -2(-2, 1, 0) + (-4, 0, 1)$ and $\mathbf{C}(-4, 0, 1) = (2, -5, 2) = -5(-2, 1, 0) + 2(-4, 0, 1)$. So in the basis $\big((1, 0, 1), (-2, 1, 0), (-4, 0, 1)\big)$,

$$[\mathbf{C}] = (2) \oplus \begin{pmatrix} -2 & -5 \\ 1 & 2 \end{pmatrix}.$$

The second block has trace 0 and determinant $-4+5 = 1$, so its characteristic polynomial is $x^2 + 1$; it is not a scalar matrix, so its minimal polynomial is also $x^2 + 1$, as (c) says. Over $\mathbb{R}$, no further splitting of V_2 is possible, since $\mathbf{C}$ has no eigenvector in V_2. Over $\mathbb{C}$, the factor $x^2 + 1 = (x - i)(x + i)$ splits, and so does the plane.

Warning. **The pieces are kernels of the powers $p_i^{e_i}$, not of the p_i.** Replacing $\ker p_i(T)^{e_i}$ by $\ker p_i(T)$ can lose most of the space. For $\mathbf{J} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$, $m_{\mathbf{J}} = (x - 1)^2$, and the primary decomposition has the single piece $\ker(\mathbf{J} - \mathbf{I})^2 = F^2$; but $\ker(\mathbf{J} - \mathbf{I}) = \operatorname{span}(\mathbf{e}_1)$ is only a line. The sum of the kernels $\ker p_i(T)$ is still direct, but it equals V only when every $e_i = 1$, which is the subject of the next subsection.

Quick check. Let $T \in \mathcal{L}(V)$, $V \neq \{\mathbf{0}\}$ finite-dimensional over $\mathbb{Q}$, satisfy $T^3 = T^2$ but $T^2 \neq T$. Which polynomials can m_T be? What are the pieces of the primary decomposition?

Solution. $x^3 - x^2 = x^2(x - 1)$ annihilates T, so by Lemma 8.5.2 $m_T = x^a(x - 1)^b$ with $a \leq 2$, $b \leq 1$, not both 0. Since $x(x-1)$ does not annihilate T, and neither do its divisors x and $x - 1$ (they would give $T = 0$ or $T = \mathrm{id}_V$, both satisfying $T^2 = T$), we need $a = 2$. So $m_T = x^2$ or $m_T = x^2(x - 1)$. In the first case the only piece is $\ker T^2 = V$; in the second, $V = \ker T^2 \oplus \ker(T - \mathrm{id}_V)$.

8.8.2 Diagonalizability and the minimal polynomial

When every p_i is linear and every $e_i = 1$, the pieces are kernels of $T - \lambda_i \mathrm{id}_V$, that is, eigenspaces. That is exactly diagonalizability, and it gives the criterion Chapter 5 promised.

Theorem 8.8.2 — Diagonalizability via the Minimal Polynomial

Let V be a finite-dimensional vector space over F with $\dim V \geq 1$, and let $T \in \mathcal{L}(V)$. The following are equivalent:

(a) T is diagonalizable;

(b) $m_T = (x-\lambda_1)(x-\lambda_2)\cdots(x-\lambda_k)$ for some **distinct** $\lambda_1, \ldots, \lambda_k \in F$, that is, m_T splits over F with no repeated root;

(c) some polynomial $(x-\mu_1)\cdots(x-\mu_r)$ with **distinct** $\mu_1, \ldots, \mu_r \in F$ annihilates T.

In that case $\lambda_1, \ldots, \lambda_k$ are the distinct eigenvalues of T. The same holds for $\mathbf{A} \in M_n(F)$.

Idea.

(a) $\Rightarrow$ (b): the polynomial $\prod_i (x-\lambda_i)$ over the distinct eigenvalues kills each vector of an eigenbasis, hence kills T; and m_T must contain every factor $x-\lambda_i$, because its roots are the eigenvalues. (b) $\Rightarrow$ (c) is free. (c) $\Rightarrow$ (a): m_T divides a product of distinct linear factors, so it is one, and the primary decomposition with every $e_i = 1$ splits V into eigenspaces.

Proof.

(a) $\Rightarrow$ (b). Let $\lambda_1, \ldots, \lambda_k$ be the distinct eigenvalues of T, let $\mathcal{B}$ be a basis of eigenvectors (Theorem 8.4.1 (b)), and put $q = (x-\lambda_1)\cdots(x-\lambda_k)$. For $\mathbf{v} \in \mathcal{B}$ with eigenvalue λ_j, Exercise (B3: Eigenvalues of powers and inverses) (a) gives $q(T)\mathbf{v} = q(\lambda_j)\mathbf{v} = \mathbf{0}$, as $x-\lambda_j$ is a factor of q. So $q(T)$ and the zero operator agree on a basis, and $q(T) = 0$ by the uniqueness in Theorem 3.1.5. Hence $m_T \mid q$, and by Lemma 8.5.2 m_T is a product of some of the factors $x-\lambda_i$. Each λ_i is a root of m_T by Theorem 8.5.3, so no factor is missing, and $m_T = q$.

(b) $\Rightarrow$ (c). Take $q = m_T$.

(c) $\Rightarrow$ (a). Let $q = (x-\mu_1)\cdots(x-\mu_r)$ with distinct μ_j annihilate T. Each factor $x-\mu_j$ is monic irreducible, being of degree 1 (Theorem 0.8.3: a factorization would leave one factor constant). By Theorem 8.5.1 and Lemma 8.5.2, $m_T = (x-\lambda_1)\cdots(x-\lambda_k)$ for some distinct λ_i among the μ_j, and $k \geq 1$ since $V \neq \{\mathbf{0}\}$. By Theorem 8.5.3, $\lambda_1, \ldots, \lambda_k$ are exactly the eigenvalues of T. Apply Theorem 8.8.1 with $p_i = x-\lambda_i$ and $e_i = 1$:

$$V = \ker(T - \lambda_1 \operatorname{id}_V) \oplus \cdots \oplus \ker(T - \lambda_k \operatorname{id}_V) = E_{\lambda_1}(T) \oplus \cdots \oplus E_{\lambda_k}(T).$$

This is condition (c) of Theorem 8.4.1, so T is diagonalizable. The statement for matrices follows by applying this to $T_{\mathbf{A}}$, since $m_{\mathbf{A}} = m_{T_{\mathbf{A}}}$.

■

This is the promise of Chapter 5 kept: **diagonalizable means the minimal polynomial splits with distinct roots.** The criterion is often the fastest test, because it needs no eigenvectors, only one polynomial identity. Chapter 5 also supplied a way to detect repeated factors without finding roots: if $\gcd(m_T, m_T') = 1$, then no irreducible factor of m_T is repeated (Corollary 5.4.6 (a)). So T is diagonalizable as soon as m_T splits and is coprime to its derivative.

Condition (c) is especially useful because it does not require knowing m_T at all.

- **Projections.** If $P^2 = P$, then $x(x-1)$ annihilates P, and $0 \neq 1$ in every field. So every projection on a finite-dimensional space is diagonalizable, over every field.
- **Involutions.** If $T^2 = \operatorname{id}_V$ and the characteristic of F is not 2, then $(x-1)(x+1)$ annihilates T, and $1 \neq -1$ because $2 \neq 0$. So T is diagonalizable. In characteristic 2 this

fails: over $\mathbb{F}_2$, $\mathbf{J} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$ has $\mathbf{J}^2 = \begin{pmatrix} 1 & 2 \\ 0 & 1 \end{pmatrix} = \mathbf{I}$, but $m_{\mathbf{J}} = (x-1)^2$.

- **Too few eigenvectors.** $\mathbf{J}$ over any field has $m_{\mathbf{J}} = (x-1)^2$, with a repeated root, so it is not diagonalizable, confirming Section 4 without any rank computation. Likewise the matrix of Example (The Minimal Polynomial from the Eigenvalues), with $m = (x-1)(x-3)^2$, is not diagonalizable, while that of Example (The Minimal Polynomial from the First Dependence), with $m = (x-1)(x-3)$, is.

The most striking use settles the question left open in Section 4 (Exercise (C1: Matrices with $\mathbf{A}^k = \mathbf{I}$)).

Example. (Complex Matrices of Finite Order Are Diagonalizable)

Let $\mathbf{A} \in M_n(\mathbb{C})$, $n \geq 1$, satisfy $\mathbf{A}^k = \mathbf{I}$ for some $k \geq 1$. Show that $\mathbf{A}$ is diagonalizable, with eigenvalues among the k-th roots of unity. Show that both "over $\mathbb{C}$" and "characteristic 0" matter.

Solution. Diagonalizable. The polynomial $q = x^k - 1$ annihilates $\mathbf{A}$. By Corollary 5.5.5, $q = (x-\zeta_1)\cdots(x-\zeta_k)$ for some $\zeta_j \in \mathbb{C}$. The ζ_j are distinct: if c were a multiple root, then $q(c) = 0$ and $q'(c) = kc^{k-1} = 0$ by Theorem 5.4.5 (a). But $q(c) = 0$ means $c^k = 1$, so $c \neq 0$; and $k \neq 0$ in $\mathbb{C}$; so $kc^{k-1} \neq 0$, a contradiction. By Theorem 8.8.2 ((c) $\Rightarrow$ (a)), $\mathbf{A}$ is diagonalizable. Its eigenvalues are roots of $m_{\mathbf{A}}$, which divides q, so each eigenvalue λ satisfies $\lambda^k = 1$. (Explicitly, the ζ_j are $e^{2\pi ij/k}$, $j = 0, \ldots, k-1$.)

Over $\mathbb{R}$ it fails. The rotation $\mathbf{R} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$ has $\mathbf{R}^4 = \mathbf{I}$ but is not diagonalizable over $\mathbb{R}$, since $m_{\mathbf{R}} = x^2 + 1$ does not split. The step that breaks is the splitting of $x^4 - 1 = (x-1)(x+1)(x^2+1)$.

In characteristic p it fails. Over $\mathbb{F}_p$, $\mathbf{J} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$ has $\mathbf{J}^p = \begin{pmatrix} 1 & p \\ 0 & 1 \end{pmatrix} = \mathbf{I}$ (the powers of $\mathbf{J}$ computed in Section 4), but $m_{\mathbf{J}} = (x-1)^2$. The step that breaks is distinctness: the derivative of $x^p - 1$ is $px^{p-1} = 0$ in $\mathbb{F}_p$, and indeed 1 is a multiple root of $x^p - 1$.

8.8.3 Restrictions and polynomials of diagonalizable operators

The criterion in terms of a single annihilating polynomial passes easily to smaller spaces.

Corollary 8.8.3 — Restrictions of Diagonalizable Operators

Let V be finite-dimensional, $T \in \mathcal{L}(V)$ diagonalizable, and U a T-invariant subspace. Then $T|_U$ is diagonalizable. Moreover $U = \bigoplus_{\lambda \in \operatorname{spec}(T)} \big(U \cap E_\lambda(T)\big)$.

Proof. If $U = \{\mathbf{0}\}$, the empty basis gives the empty (diagonal) matrix, and both statements are trivial. Let $U \neq \{\mathbf{0}\}$. By Theorem 8.8.2 ((a) $\Rightarrow$ (b)), $m_T = (x-\lambda_1)\cdots(x-\lambda_k)$ with distinct λ_i, the eigenvalues of T. By Exercise (C2: Minimal polynomials of the pieces) (a), $m_T(T|_U) = m_T(T)|_U = 0$, so m_T is a product of distinct linear factors

annihilating $T|_U$. By Theorem 8.8.2 ((c) $\Rightarrow$ (a)), $T|_U$ is diagonalizable.

For the decomposition, Theorem 8.4.1 (c) applied to $T|_U$ gives $U = \bigoplus_\mu E_\mu(T|_U)$, over the eigenvalues μ of $T|_U$. An eigenvector of $T|_U$ is an eigenvector of T lying in U, so $E_\mu(T|_U) = U \cap E_\mu(T)$, and every such μ is in $\operatorname{spec}(T)$. For $\lambda \in \operatorname{spec}(T)$ that is not an eigenvalue of $T|_U$, $U \cap E_\lambda(T) = \{\mathbf{0}\}$, and adding zero summands does not change a direct sum.

■

The second statement says that an invariant subspace of a diagonalizable operator is spanned by the eigenvectors it contains. It will be the key step in Section 9, where two commuting diagonalizable operators are diagonalized by a single basis.

Diagonalizability is also preserved by polynomials: if T is diagonalizable and $p \in F[x]$, then every eigenvector of T for λ is an eigenvector of $p(T)$ for $p(\lambda)$ (Exercise (B3: Eigenvalues of powers and inverses) (a)), so a basis of eigenvectors of T is also one for $p(T)$. This is the operator form of Exercise (C2: Polynomials of diagonalizable matrices). The converse fails, as that exercise shows.

8.8.4 When the minimal polynomial splits: a first look at Chapter 9

Suppose p_T splits, $p_T = (x-\lambda_1)^{a_1}\cdots(x-\lambda_k)^{a_k}$ with distinct λ_i; this always happens over $\mathbb{C}$. By Corollary 8.6.2, $m_T = (x-\lambda_1)^{s_1}\cdots(x-\lambda_k)^{s_k}$ with $1 \le s_i \le a_i$, and the primary decomposition reads

$$V = \ker(T-\lambda_1 \operatorname{id}_V)^{s_1} \oplus \cdots \oplus \ker(T-\lambda_k \operatorname{id}_V)^{s_k}.$$

On the i-th piece, $T|_{V_i} = \lambda_i \operatorname{id}_{V_i} + N_i$, where $N_i = (T-\lambda_i \operatorname{id}_V)|_{V_i}$ satisfies $N_i^{s_i} = 0$, because $V_i = \ker(T-\lambda_i \operatorname{id}_V)^{s_i}$. So every operator whose characteristic polynomial splits is, piece by piece, a scalar plus a nilpotent operator. Chapter 9 calls the pieces **generalized eigenspaces** and finds the best basis for each nilpotent part, which leads to the Jordan form. Here we record only their dimensions.

Corollary 8.8.4 — Dimensions of the Primary Components

Let V be finite-dimensional with $\dim V \ge 1$, $T \in \mathcal{L}(V)$, and suppose p_T splits over F, with distinct eigenvalues $\lambda_1, \dots, \lambda_k$ and $m_T = \prod_i (x-\lambda_i)^{s_i}$. Let $V_i = \ker(T-\lambda_i \operatorname{id}_V)^{s_i}$. Then

$$p_{T|_{V_i}} = (x-\lambda_i)^{\dim V_i} \qquad \text{and} \qquad \dim V_i = a_T(\lambda_i).$$

Moreover $E_{\lambda_i}(T) \subseteq V_i$, with equality if and only if $s_i = 1$.

Idea. The decomposition makes p_T the product of the characteristic polynomials of the restrictions. Each of those factors is a monic divisor of p_T, and its roots are the eigenvalues of the restriction, which the minimal polynomial $(x-\lambda_i)^{s_i}$ pins down to the single value λ_i. So the i-th factor is $(x-\lambda_i)^{\dim V_i}$, and multiplying the factors back together identifies $\dim V_i$ as the multiplicity of λ_i in p_T.

Proof. By Theorem 8.8.1, $V = V_1 \oplus \cdots \oplus V_k$ with each V_i invariant, non-zero, and $m_{T|_{V_i}} = (x - \lambda_i)^{s_i}$. By Theorem 8.1.5, $p_T = p_{T|_{V_1}} \cdots p_{T|_{V_k}}$. So each $p_{T|_{V_i}}$ is a monic divisor of p_T, and by Lemma 8.5.2 it is a product of powers of the $x - \lambda_j$. Its roots are the eigenvalues of $T|_{V_i}$ (Theorem 8.2.1), which are the roots of $m_{T|_{V_i}} = (x - \lambda_i)^{s_i}$ (Theorem 8.5.3), that is, only λ_i. So $p_{T|_{V_i}} = (x - \lambda_i)^{d_i}$, with $d_i = \deg p_{T|_{V_i}} = \dim V_i$ (Theorem 6.10.2). Then $p_T = \prod_i (x - \lambda_i)^{d_i}$, and since the λ_i are distinct, Lemma 5.4.1 gives $a_T(\lambda_i) = d_i$.

If $T\mathbf{v} = \lambda_i \mathbf{v}$, then $(T - \lambda_i \operatorname{id}_V)^{s_i}\mathbf{v} = \mathbf{0}$ since $s_i \geq 1$, so $E_{\lambda_i}(T) \subseteq V_i$. If $s_i = 1$, the two spaces are equal by definition. Conversely, if $E_{\lambda_i}(T) = V_i$, then $x - \lambda_i$ annihilates $T|_{V_i}$, so $m_{T|_{V_i}} = (x - \lambda_i)^{s_i}$ divides $x - \lambda_i$, and $s_i = 1$.

■

So, when p_T splits, the dimension of the i-th piece is the algebraic multiplicity $a(\lambda_i)$, and inside it the eigenspace has dimension $g(\lambda_i)$. The operator is diagonalizable exactly when all these pieces are eigenspaces, which ties together the three criteria of this chapter: $g(\lambda_i) = a(\lambda_i)$ for all i (Section 4), every $s_i = 1$ (this section), and every piece $\ker(T - \lambda_i \operatorname{id}_V)^{s_i}$ equal to $\ker(T - \lambda_i \operatorname{id}_V)$.

Warning. **A single eigenvalue gives a single piece, whatever the operator looks like.** If $p_T = (x - \lambda)^n$, then the primary decomposition is $V = \ker(T - \lambda \operatorname{id}_V)^s$, all of V, and says nothing new. For instance $2\mathbf{I}_3$, $\begin{pmatrix} 2 & 1 \\ 0 & 2 \end{pmatrix} \oplus (2)$ and the matrix $\mathbf{A}$ of Example (Triangularizing a Matrix with a Single Eigenvector Line) all have $p = (x-2)^3$ and a primary decomposition with one piece, yet they are pairwise non-similar: their minimal polynomials are $x - 2$, $(x-2)^2$ (Proposition 8.5.6) and $(x-2)^3$, the last because $(\mathbf{A} - 2\mathbf{I})^2 = \begin{pmatrix} 1 & -1 & 0 \\ 1 & -1 & 0 \\ 0 & 0 & 0 \end{pmatrix} \neq 0$, and equal minimal polynomials are necessary for similarity (Theorem 8.5.5). Distinguishing operators within one piece is the work of Chapter 9.

8.8.5 Exercises

8.8.5.1 A. Check your understanding

Exercise A1.

(a) State the Primary Decomposition Theorem.

(b) State the criterion for diagonalizability in terms of the minimal polynomial.

(c) True or false: if $m_{\mathbf{A}} = x(x-1)(x+1)$ over $\mathbb{Q}$, then $\mathbf{A}$ is diagonalizable over $\mathbb{Q}$. Justify your answer.

(d) True or false: if $\mathbf{A} \in M_n(\mathbb{R})$ and $\mathbf{A}^k = \mathbf{I}$ for some $k \geq 1$, then $\mathbf{A}$ is diagonalizable over $\mathbb{R}$. Justify your answer.

(e) Let $m_T = (x-2)^2(x+1)$. What are the summands of the primary decomposition, and is T diagonalizable?

(f) True or false: the restriction of a diagonalizable operator to an invariant subspace is diagonalizable. Justify your answer.

Solution.

(a) If $V \neq \{\mathbf{0}\}$ is finite-dimensional and $m_T = p_1^{e_1} \cdots p_k^{e_k}$ with distinct monic irreducible p_i, then $V = \bigoplus_i \ker p_i(T)^{e_i}$; the summands are invariant and non-zero, T restricted to the i-th has minimal polynomial $p_i^{e_i}$, and the projections are polynomials in T (Theorem 8.8.1).

(b) T is diagonalizable if and only if m_T is a product of distinct monic linear factors over F (Theorem 8.8.2).

(c) True: $m_{\mathbf{A}}$ splits over $\mathbb{Q}$ with distinct roots $0, 1, -1$.

(d) False. The rotation by a right angle satisfies $\mathbf{R}^4 = \mathbf{I}$ but has no real eigenvalue (Example (Complex Matrices of Finite Order Are Diagonalizable)).

(e) $\ker(T-2\,\mathrm{id}_V)^2$ and $\ker(T+\mathrm{id}_V)$. T is not diagonalizable, since m_T has the repeated root 2.

(f) True, by Corollary 8.8.3.

8.8.5.2 B. Practice

Exercise B1: Diagonalizable or not?.

Determine whether each matrix is diagonalizable over the given field. Justify your answer.

(a) $\mathbf{A}_1 = \begin{pmatrix} 2 & 1 & 1 \\ -1 & 0 & -1 \\ 1 & 1 & 2 \end{pmatrix}$ over $\mathbb{R}$ (see Exercise (B1: Computing minimal polynomials)).

(b) $\mathbf{M}_1 = \begin{pmatrix} 2 & 1 & 0 \\ 0 & 2 & 0 \\ -1 & 1 & 3 \end{pmatrix}$ over $\mathbb{R}$ (see Exercise (B3: Minimal polynomial from one product)).

(c) Any $\mathbf{A} \in M_5(\mathbb{Q})$ with $\mathbf{A}^3 = 4\mathbf{A}$.

(d) Any $\mathbf{A} \in M_2(\mathbb{R})$ with $\mathbf{A}^2 + \mathbf{I} = 0$, over $\mathbb{R}$ and over $\mathbb{C}$.

Solution.

(a) By Exercise (B1: Computing minimal polynomials) (d), $m_{\mathbf{A}_1} = (x-1)(x-2)$, which has distinct linear factors. Diagonalizable, by Theorem 8.8.2.

(b) By Exercise (B3: Minimal polynomial from one product), $m_{\mathbf{M}_1} = (x-2)^2(x-3)$, with a repeated root. Not diagonalizable.

(c) $x^3 - 4x = x(x-2)(x+2)$ annihilates $\mathbf{A}$, and $0, 2, -2$ are distinct in $\mathbb{Q}$. Diagonalizable, by condition (c) of Theorem 8.8.2.

(d) $m_{\mathbf{A}} \mid x^2+1$. Over $\mathbb{R}$, x^2+1 has no root, so it is irreducible (Theorem 5.3.1), and $m_{\mathbf{A}} = x^2+1$ (it is not 1 since $\mathbf{A}$ acts on $\mathbb{R}^2 \neq \{\mathbf{0}\}$). It does not split over $\mathbb{R}$, so $\mathbf{A}$ is not diagonalizable over $\mathbb{R}$. Over $\mathbb{C}$, $x^2+1 = (x-i)(x+i)$ with $i \neq -i$, so condition (c) holds and $\mathbf{A}$ is diagonalizable over $\mathbb{C}$.

Exercise B2: Decomposing $\mathbb{R}^3$.

Let $\mathbf{A} = \begin{pmatrix} 2 & 1 & 1 \\ 0 & 1 & -1 \\ -1 & -1 & 1 \end{pmatrix} \in M_3(\mathbb{R})$, which has $m_{\mathbf{A}} = (x-1)^2(x-2)$ (Exercise (B1: Computing minimal polynomials) (c)).

(a) Find bases of $V_1 = \ker(\mathbf{A}-\mathbf{I})^2$ and $V_2 = \ker(\mathbf{A}-2\mathbf{I})$, and check that $\mathbb{R}^3 = V_1 \oplus V_2$.

(b) Compare V_1 with $E_1(\mathbf{A})$.

(c) Using $(x-1)^2 - x(x-2) = 1$, write the two projections as polynomials in $\mathbf{A}$, and compute them.

(d) Write the matrix of $T_{\mathbf{A}}$ in the basis formed by your bases of V_1 and V_2.

Solution.

(a) $(\mathbf{A}-\mathbf{I})^2 = \begin{pmatrix} 1 & 1 & 1 \\ 0 & 0 & -1 \\ -1 & -1 & 0 \end{pmatrix}^2 = \begin{pmatrix} 0 & 0 & 0 \\ 1 & 1 & 0 \\ -1 & -1 & 0 \end{pmatrix}$, whose kernel is $x+y=0$, with basis $(-1,1,0)$, $(0,0,1)$. $\mathbf{A}-2\mathbf{I} = \begin{pmatrix} 0 & 1 & 1 \\ 0 & -1 & -1 \\ -1 & -1 & -1 \end{pmatrix}$ gives $y+z=0$ and $x = -y-z = 0$, so $V_2 = \operatorname{span}((0,-1,1))$. The three vectors form a basis of $\mathbb{R}^3$: the matrix with these columns has determinant $-1\cdot(0\cdot 1 - 1\cdot(-1)) - 0 + 0 = -1 \neq 0$, expanding along the first row. So $\mathbb{R}^3 = V_1 \oplus V_2$, as Theorem 8.8.1 guarantees.

(b) $\mathbf{A}-\mathbf{I}$ has rank 2 (its third row is minus the sum of the first two, and the first two are independent), so $E_1(\mathbf{A})$ is a line, $\operatorname{span}((-1,1,0))$, strictly inside the plane V_1. This matches Corollary 8.8.4: $\dim V_1 = a(1) = 2$, $g(1) = 1$, $s_1 = 2$.

(c) With $p = (x-1)^2$, $q = x-2$, $a = 1$, $b = -x$ in Theorem 5.7.5 (c), the projection onto V_1 along V_2 is $b(\mathbf{A})q(\mathbf{A}) = -\mathbf{A}(\mathbf{A}-2\mathbf{I})$, and onto V_2 along V_1 it is $a(\mathbf{A})p(\mathbf{A}) = (\mathbf{A}-\mathbf{I})^2$. Computing,

$$-\mathbf{A}(\mathbf{A}-2\mathbf{I}) = \begin{pmatrix} 1 & 0 & 0 \\ -1 & 0 & 0 \\ 1 & 1 & 1 \end{pmatrix}, \qquad (\mathbf{A}-\mathbf{I})^2 = \begin{pmatrix} 0 & 0 & 0 \\ 1 & 1 & 0 \\ -1 & -1 & 0 \end{pmatrix}.$$

They add up to $\mathbf{I}$. The columns of the first satisfy $x+y=0$, so they lie in V_1; the columns of the second are multiples of $(0,-1,1)$, so they lie in V_2.

(d) $\mathbf{A}(-1,1,0) = (-1,1,0)$, $\mathbf{A}(0,0,1) = (1,-1,1) = -(-1,1,0)+(0,0,1)$, and $\mathbf{A}(0,-1,1) = (0,-2,2) = 2(0,-1,1)$. So the matrix is

$$\begin{pmatrix} 1 & -1 \\ 0 & 1 \end{pmatrix} \oplus (2),$$

block diagonal as Theorem 8.1.5 predicts, with first block of minimal polynomial $(x-1)^2$.

Exercise B3: Matrices with $\mathbf{A}^3 = \mathbf{A}$.

Let F have characteristic not 2, and let $\mathbf{A} \in M_n(F)$, $n \geq 1$, satisfy $\mathbf{A}^3 = \mathbf{A}$.

(a) Prove that $\mathbf{A}$ is diagonalizable, with $\operatorname{spec}(\mathbf{A}) \subseteq \{0, 1, -1\}$.

(b) Now let $F = \mathbb{R}$. Prove that $\operatorname{rank} \mathbf{A} = \operatorname{tr}(\mathbf{A}^2)$.

Solution.

(a) $x^3 - x = x(x-1)(x+1)$ annihilates $\mathbf{A}$. The roots $0, 1, -1$ are distinct: $1 \neq 0$, $-1 \neq 0$, and $1 \neq -1$ because $2 \neq 0$. By Theorem 8.8.2 ((c) $\Rightarrow$ (a)), $\mathbf{A}$ is diagonalizable, and its eigenvalues are roots of $m_{\mathbf{A}} \mid x^3 - x$, so they lie in $\{0, 1, -1\}$.

(b) Write $\mathbf{A} = \mathbf{P}\mathbf{D}\mathbf{P}^{-1}$ with $\mathbf{D}$ diagonal, entries in $\{0, 1, -1\}$. Then $\operatorname{rank} \mathbf{A} = \operatorname{rank} \mathbf{D}$ (Proposition 3.7.6 (a)), which is the number r of non-zero diagonal entries. Also $\mathbf{A}^2 = \mathbf{P}\mathbf{D}^2\mathbf{P}^{-1}$ (Theorem 8.4.3), and $\mathbf{D}^2$ is diagonal with r entries 1 and the rest 0. By Theorem 3.7.5, $\operatorname{tr} \mathbf{A}^2 = \operatorname{tr} \mathbf{D}^2 = r$.

8.8.5.3 C. Going deeper

Exercise C1: $\mathbf{A}^p = \mathbf{A}$ over $\mathbb{F}_p$.

Let p be a prime and $\mathbf{A} \in M_n(\mathbb{F}_p)$, $n \geq 1$, with $\mathbf{A}^p = \mathbf{A}$.

(a) Let $a \in \mathbb{F}_p$ be non-zero. Show that $b \mapsto ab$ is a bijection of $\mathbb{F}_p \setminus \{0\}$, and deduce $a^{p-1} = 1$. Conclude that $a^p = a$ for **every** $a \in \mathbb{F}_p$.

(b) Deduce that $x^p - x = \prod_{a \in \mathbb{F}_p} (x - a)$ in $\mathbb{F}_p[x]$.

(c) Prove that $\mathbf{A}$ is diagonalizable over $\mathbb{F}_p$.

(d) Show that $\mathbf{J} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$ satisfies $\mathbf{J}^p = \mathbf{I}$ over $\mathbb{F}_p$ but is not diagonalizable, and explain why this does not contradict (c).

Hint: for (a), compare the product of all non-zero elements with the product of all their multiples by a.

Solution.

(a) The map $b \mapsto ab$ sends non-zero elements to non-zero elements (Theorem 0.7.1), and it is injective, since $ab = ab'$ gives $b = b'$ after multiplying by a^{-1}. An injective map from the finite set $\mathbb{F}_p \setminus \{0\}$ to itself is bijective (Theorem 0.4.9). So the elements ab, for $b \neq 0$, are the non-zero elements in another order. Let c be the product of all non-zero elements; it is non-zero. Multiplying the $p-1$ elements ab gives $a^{p-1}c = c$, by commutativity, so $a^{p-1} = 1$. Multiplying by a gives $a^p = a$, which also holds for $a = 0$.

(b) By (a), each of the p distinct elements of $\mathbb{F}_p$ is a root of $f = x^p - x$. By Theorem 5.4.3, the multiplicities of these roots, each at least 1, add up to at most $\deg f = p$. So each multiplicity is 1, the sum equals p, and f splits; as f is monic, $f = \prod_{a \in \mathbb{F}_p} (x - a)$.

(c) By (b), $x^p - x$ is a product of distinct monic linear factors, and it annihilates $\mathbf{A}$. By Theorem 8.8.2 ((c) $\Rightarrow$ (a)), $\mathbf{A}$ is diagonalizable, with eigenvalues in $\mathbb{F}_p$.

(d) As in Example (Complex Matrices of Finite Order Are Diagonalizable), $\mathbf{J}^p = \begin{pmatrix} 1 & p \\ 0 & 1 \end{pmatrix} = \mathbf{I}$ in $\mathbb{F}_p$, while $m_{\mathbf{J}} = (x-1)^2$, so $\mathbf{J}$ is not diagonalizable. There is no contradiction: $\mathbf{J}$ satisfies $\mathbf{J}^p = \mathbf{I}$, not $\mathbf{J}^p = \mathbf{J}$ (for $p \geq 2$, $\mathbf{J}^p = \mathbf{I} \neq \mathbf{J}$). The

polynomial $x^p - 1$ has the multiple root 1, because its derivative px^{p-1} is 0 in $\mathbb{F}_p$ (Theorem 5.4.5 (a)).

Exercise C2: Irreducible minimal polynomials.

Let $V \neq \{\mathbf{0}\}$ be finite-dimensional, $T \in \mathcal{L}(V)$, and suppose m_T is **irreducible**, of degree d. For $\mathbf{v} \in V$, let $W_\mathbf{v} = \{q(T)\mathbf{v} : q \in F[x]\}$.

(a) Show that $W_\mathbf{v}$ is the smallest T-invariant subspace of V containing $\mathbf{v}$.

(b) Let $\mathbf{v} \neq \mathbf{0}$. Prove that $(\mathbf{v}, T\mathbf{v}, \dots, T^{d-1}\mathbf{v})$ is a basis of $W_\mathbf{v}$. In particular $\dim W_\mathbf{v} = d$.

(c) Deduce that the only T-invariant subspaces of $W_\mathbf{v}$ are $\{\mathbf{0}\}$ and $W_\mathbf{v}$.

(d) Prove that V is a direct sum of subspaces of the form $W_\mathbf{v}$, and hence that d divides $\dim V$.

(e) Illustrate with the rotation $\mathbf{R}$ of $\mathbb{R}^2$ and with $\mathbf{R} \oplus \mathbf{R}$ on $\mathbb{R}^4$.

Hint: for (b), use the gcd of m_T with a polynomial of degree less than d. For (d), take a direct sum $W_{\mathbf{v}_1} \oplus \cdots \oplus W_{\mathbf{v}_s}$ that is as large as possible.

Solution.

(a) $W_\mathbf{v}$ is the image of the linear map $F[x] \to V$, $q \mapsto q(T)\mathbf{v}$ (linear by Theorem 5.7.1 (a)), so it is a subspace (Theorem 3.2.2). It contains $\mathbf{v} = 1(T)\mathbf{v}$, and $T(q(T)\mathbf{v}) = (xq)(T)\mathbf{v} \in W_\mathbf{v}$, so it is invariant. If W is any invariant subspace containing $\mathbf{v}$, then $T^k\mathbf{v} \in W$ for all k by induction, so every $q(T)\mathbf{v} \in W$, and $W_\mathbf{v} \subseteq W$.

(b) *Independence.* Suppose $q(T)\mathbf{v} = \mathbf{0}$ for some non-zero q of degree less than d. Let $g = \gcd(q, m_T)$. It is a monic divisor of the irreducible m_T, so $g = 1$ or $g = m_T$ (Definition 5.3.1). It is not m_T, since $m_T \nmid q$ for degree reasons (Proposition 5.1.2 (c)). So $g = 1$, and $aq + bm_T = 1$ for some a, b (Corollary 5.2.4). Then $\mathbf{v} = a(T)q(T)\mathbf{v} + b(T)m_T(T)\mathbf{v} = \mathbf{0}$, a contradiction. So no non-trivial combination of $\mathbf{v}, \dots, T^{d-1}\mathbf{v}$ is $\mathbf{0}$.
Spanning. For $q \in F[x]$, divide: $q = s\,m_T + r$ with $\deg r < d$ (Theorem 5.1.1). Then $q(T)\mathbf{v} = r(T)\mathbf{v}$, a combination of $\mathbf{v}, \dots, T^{d-1}\mathbf{v}$.

(c) Let $W \subseteq W_\mathbf{v}$ be invariant and non-zero, and take $\mathbf{w} \in W$ with $\mathbf{w} \neq \mathbf{0}$. By (a), $W_\mathbf{w} \subseteq W$. By (b), $\dim W_\mathbf{w} = d = \dim W_\mathbf{v}$, so $W_\mathbf{w} = W_\mathbf{v}$ (Theorem 1.6.8), and hence $W = W_\mathbf{v}$.

(d) Among all families $\mathbf{v}_1, \dots, \mathbf{v}_s$ of non-zero vectors for which the sum $S = W_{\mathbf{v}_1} + \cdots + W_{\mathbf{v}_s}$ is direct, choose one with s as large as possible; this is possible since $\dim S = sd \leq \dim V$ by (b) and Theorem 1.7.5. Suppose $S \neq V$, and take $\mathbf{v} \in V \setminus S$. The subspace $W_\mathbf{v} \cap S$ is invariant (Proposition 8.1.4) and lies in $W_\mathbf{v}$, but does not contain $\mathbf{v}$; by (c) it is $\{\mathbf{0}\}$. Then the sum $S + W_\mathbf{v}$ is direct: if $\mathbf{u}_1 + \cdots + \mathbf{u}_s + \mathbf{w} = \mathbf{0}$ with $\mathbf{u}_j \in W_{\mathbf{v}_j}$ and $\mathbf{w} \in W_\mathbf{v}$, then $\mathbf{w} \in W_\mathbf{v} \cap S = \{\mathbf{0}\}$, and directness of S gives all $\mathbf{u}_j = \mathbf{0}$. This contradicts the maximality of s. So $V = W_{\mathbf{v}_1} \oplus \cdots \oplus W_{\mathbf{v}_s}$, and $\dim V = sd$.

(e) For the rotation $\mathbf{R}$, $m_\mathbf{R} = x^2 + 1$ is irreducible over $\mathbb{R}$, $d = 2$, and $W_\mathbf{v} = \mathbb{R}^2$ for every $\mathbf{v} \neq \mathbf{0}$: no line is invariant (Example (A Rotation Has No Invariant Lines)). For $\mathbf{R} \oplus \mathbf{R}$, $m = \operatorname{lcm}(x^2 + 1, x^2 + 1) = x^2 + 1$ (Proposition 8.5.6), and $\mathbb{R}^4 = W_{\mathbf{e}_1} \oplus W_{\mathbf{e}_3}$ with $W_{\mathbf{e}_1} = \operatorname{span}(\mathbf{e}_1, \mathbf{e}_2)$ and $W_{\mathbf{e}_3} = \operatorname{span}(\mathbf{e}_3, \mathbf{e}_4)$; indeed $2 \mid 4$.

8.9 Commuting Operators

So far we have diagonalized or triangularized one operator at a time. Many problems hand us several at once: two matrices that describe the same system, or a matrix together with all its powers. Can a single basis make **all** of them diagonal, or all of them triangular? A necessary condition is easy to spot, because diagonal matrices commute. This section shows that commuting is also enough, as long as each operator can be handled on its own. The whole argument rests on one observation: an operator that commutes with T maps each eigenspace of T into itself, so we can search for common eigenvectors inside an eigenspace.

8.9.1 When can two operators share a basis?

Let V be finite-dimensional and $S, T \in \mathcal{L}(V)$. Suppose one basis $\mathcal{B}$ makes both $[S]_{\mathcal{B}}$ and $[T]_{\mathcal{B}}$ diagonal. Diagonal matrices multiply entry by entry on the diagonal, so $[S]_{\mathcal{B}}[T]_{\mathcal{B}} = [T]_{\mathcal{B}}[S]_{\mathcal{B}}$. By Corollary 3.6.3 this says $[ST]_{\mathcal{B}} = [TS]_{\mathcal{B}}$, and since $T \mapsto [T]_{\mathcal{B}}$ is injective (Theorem 3.6.4), $ST = TS$. So **sharing a diagonalizing basis forces commuting**. The same is not true for triangular matrices: $\begin{pmatrix} 1 & 1 \\ 0 & 2 \end{pmatrix}$ and $\begin{pmatrix} 1 & 0 \\ 0 & 2 \end{pmatrix}$ are both upper triangular, and their products in the two orders are $\begin{pmatrix} 1 & 2 \\ 0 & 4 \end{pmatrix}$ and $\begin{pmatrix} 1 & 1 \\ 0 & 4 \end{pmatrix}$. We will see, though, that commuting is a convenient sufficient condition in the triangular case as well.

The question for this section is the converse: if $ST = TS$, can we find a common basis? Here are the commuting pairs to keep in mind.

- **Polynomials in one operator.** For every $p, q \in F[x]$, $p(T)q(T) = q(T)p(T)$ (Theorem 5.7.1 (c)). In particular T commutes with T^2, with T^{-1} when it exists (both products are id_V), and with every scalar operator $c\,\mathrm{id}_V$.
- **Diagonal matrices** commute with each other, and so do block diagonal matrices whose corresponding blocks commute (Theorem 7.1.4).
- **A non-commuting pair.** $\mathbf{E}_{12} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$ and $\mathbf{E}_{21} = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix}$ give $\mathbf{E}_{12}\mathbf{E}_{21} = \mathbf{E}_{11} \neq \mathbf{E}_{22} = \mathbf{E}_{21}\mathbf{E}_{12}$.

The last pair already shows that something must be assumed. Over any field, the eigenvectors of $\mathbf{E}_{12}$ are the non-zero multiples of $\mathbf{e}_1$, and those of $\mathbf{E}_{21}$ are the non-zero multiples of $\mathbf{e}_2$. They share no eigenvector at all, let alone a basis of them.

8.9.2 Commuting operators preserve eigenspaces

How does the hypothesis $ST = TS$ interact with eigenvectors? Take $T\mathbf{v} = \lambda\mathbf{v}$ and ask what T does to $S\mathbf{v}$. There is no S in the eigenvector equation yet, so we apply S to both sides.

> **Theorem 8.9.1 — Commuting Operators Preserve Eigenspaces**
>
> Let V be a vector space over F, and let $S, T \in \mathcal{L}(V)$ with $ST = TS$. Then for every $\lambda \in F$, the eigenspace $E_\lambda(T)$ is S-invariant.

Proof. Let $\mathbf{v} \in E_\lambda(T)$, so $T\mathbf{v} = \lambda\mathbf{v}$. Since $ST = TS$ and S is linear,

$$T(S\mathbf{v}) = (TS)\mathbf{v} = (ST)\mathbf{v} = S(\lambda\mathbf{v}) = \lambda\, S\mathbf{v}.$$

Hence $S\mathbf{v} \in E_\lambda(T)$ by Definition 8.2.2. This shows that S maps $E_\lambda(T)$ into itself. ∎

No finite dimension is needed, and λ need not be an eigenvalue (then $E_\lambda(T) = \{\mathbf{0}\}$ and there is nothing to prove). By symmetry, every eigenspace of S is T-invariant too.

In matrix language the theorem is a statement about block shapes. Take $T = \operatorname{diag}(1, 1, 2)$ on F^3, with $E_1(T) = \operatorname{span}(\mathbf{e}_1, \mathbf{e}_2)$ and $E_2(T) = \operatorname{span}(\mathbf{e}_3)$, and let S be any matrix with $ST = TS$. Both eigenspaces are S-invariant, and $F^3 = E_1(T) \oplus E_2(T)$, so by Theorem 8.1.5 the matrix S is block diagonal:

$$S = \begin{pmatrix} s_{11} & s_{12} & 0 \\ s_{21} & s_{22} & 0 \\ 0 & 0 & s_{33} \end{pmatrix}.$$

Conversely, every matrix of this shape commutes with T, since $T = \mathbf{I}_2 \oplus (2)$ and $\mathbf{I}_2$ commutes with every 2×2 block (Theorem 7.1.4). Inside the repeated eigenspace S can be anything; this freedom is what the rest of the section has to deal with.

Non-example. Take $T = \operatorname{diag}(1, 2)$ and the swap $S = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$. Then $S\mathbf{e}_1 = \mathbf{e}_2 \notin E_1(T) = \operatorname{span}(\mathbf{e}_1)$, so $E_1(T)$ is not S-invariant. The theorem is not contradicted: $ST = \begin{pmatrix} 0 & 2 \\ 1 & 0 \end{pmatrix}$ and $TS = \begin{pmatrix} 0 & 1 \\ 2 & 0 \end{pmatrix}$ differ.

Quick check. Let $T = \mathbf{I}_2$ and $S = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$ over $\mathbb{R}$. Do S and T commute? Is every eigenvector of T an eigenvector of S? Do S and T have a common eigenvector?

Solution. Yes, $\mathbf{I}_2$ commutes with every 2×2 matrix. No: every non-zero vector is an eigenvector of $\mathbf{I}_2$, but $S\mathbf{e}_2 = (1, 1)$ is not a multiple of $\mathbf{e}_2$. Yes: $\mathbf{e}_1$ is an eigenvector of both, for the eigenvalues 1 and 1. The theorem says S maps $E_1(T) = \mathbb{R}^2$ into itself, which is true but empty of information; the common eigenvector must be **searched for** inside that eigenspace, and here it is an eigenvector of S.

8.9.3 A common eigenvector

Here is the plan for finding a common eigenvector of commuting S and T. Pick an eigenvalue λ of T and put $U = E_\lambda(T) \neq \{\mathbf{0}\}$. By Theorem 8.9.1, S restricts to an operator $S|_U$ on U. If $S|_U$ has an eigenvector $\mathbf{u}$, then $S\mathbf{u} = \mu\mathbf{u}$ and, since $\mathbf{u} \in U$, also $T\mathbf{u} = \lambda\mathbf{u}$. So everything reduces to whether $S|_U$ has an eigenvalue. Over $\mathbb{C}$ it does (Theorem 8.2.4). Over a general field we need to know that the characteristic polynomial of a restriction splits when that of S does. We record this, together with the same fact for the induced operator on the quotient, since triangularization will need both.

Lemma 8.9.2 — Restrictions and Quotients Inherit Splitting

Let V be a finite-dimensional vector space over F, let $T \in \mathcal{L}(V)$, and let U be a T-invariant subspace with $\{\mathbf{0}\} \neq U \neq V$. If p_T splits over F, then $p_{T|_U}$ and $p_{\bar{T}}$ split over F, where $\bar{T}$ is the induced operator on V/U.

Idea. Section 1 factors p_T as $p_{T|_U}\, p_{\bar{T}}$, so the two factors can only have roots that p_T has. A polynomial splits exactly when its root multiplicities add up to its degree (Theorem 5.4.3). Count: the multiplicities of the two factors add up to those of p_T, which use up the whole degree; so neither factor can be short of its own degree.

Proof. By Theorem 8.1.3, $p_T = fg$ with $f = p_{T|_U}$ and $g = p_{\bar{T}}$, both monic (Theorem 6.10.2). Let $c_1, \ldots, c_k$ be the distinct roots of p_T in F. Every root of f or of g in F is a root of p_T (Theorem 0.8.5), so it is among the c_i, and a c_i that is not a root of f has $\operatorname{mult}_{c_i}(f) = 0$. Hence, by Theorem 5.4.3 applied to f and to g,

$$\sum_{i=1}^{k} \operatorname{mult}_{c_i}(f) \leq \deg f, \qquad \sum_{i=1}^{k} \operatorname{mult}_{c_i}(g) \leq \deg g.$$

Adding, and using Theorem 5.4.2 and then Theorem 5.4.3 for the split polynomial p_T,

$$\begin{aligned} \deg f + \deg g = \deg p_T &= \sum_{i=1}^{k} \operatorname{mult}_{c_i}(p_T) \\ &= \sum_{i=1}^{k} \operatorname{mult}_{c_i}(f) + \sum_{i=1}^{k} \operatorname{mult}_{c_i}(g) \\ &\leq \deg f + \deg g. \end{aligned}$$

So both inequalities above are equalities, and f and g split over F by Theorem 5.4.3.

■

Now the common eigenvector. We prove it for a whole family of commuting operators at once, possibly infinite, since the proof costs no more and the next theorems need it. A family $\mathcal{F} \subseteq \mathcal{L}(V)$ is **commuting** if $ST = TS$ for all $S, T \in \mathcal{F}$.

Theorem 8.9.3 — Commuting Operators Have a Common Eigenvector

Let $V \neq \{\mathbf{0}\}$ be a finite-dimensional vector space over F, and let $\mathcal{F} \subseteq \mathcal{L}(V)$ be a non-empty commuting family such that p_T splits over F for every $T \in \mathcal{F}$. Then there is a non-zero $\mathbf{v} \in V$ that is an eigenvector of **every** $T \in \mathcal{F}$. This applies to every commuting family when $F = \mathbb{C}$.

Idea. For two operators, the plan above works: an eigenvector of $S|_U$ with $U = E_\lambda(T)$. For many operators we would like to repeat it, shrinking U each time, and a family may be infinite. So we jump straight to the end of the shrinking: take a non-zero subspace W, invariant under the whole family, that is as small as possible. If some $T \in \mathcal{F}$ were not a scalar on W, an eigenspace of $T|_W$ would be a smaller such subspace. So every

operator in the family is a scalar on W, and any non-zero vector of W is a common eigenvector.

Proof. Call a subspace $\mathcal{F}$**-invariant** if it is T-invariant for every $T \in \mathcal{F}$. The space V is a non-zero $\mathcal{F}$-invariant subspace, so among all non-zero $\mathcal{F}$-invariant subspaces there is one, W, of smallest dimension.

Let $T \in \mathcal{F}$. Then $T|_W$ is an operator on $W \neq \{\mathbf{0}\}$, and $p_{T|_W}$ splits: if $W = V$ this is the hypothesis, and otherwise it is Lemma 8.9.2. Since $p_{T|_W}$ is monic of degree $\dim W \geq 1$, it has a root $\lambda \in F$, which is an eigenvalue of $T|_W$ by Theorem 8.2.1. Put

$$W' = \{\mathbf{w} \in W : T\mathbf{w} = \lambda \mathbf{w}\} = W \cap E_\lambda(T),$$

which is non-zero because it contains an eigenvector of $T|_W$. For every $S \in \mathcal{F}$, both W and $E_\lambda(T)$ are S-invariant, the first by the choice of W and the second by Theorem 8.9.1; so W' is S-invariant by Proposition 8.1.4. Hence W' is a non-zero $\mathcal{F}$-invariant subspace contained in W, and by the minimality of $\dim W$, $\dim W' = \dim W$. By Theorem 1.6.8, $W' = W$, that is, $T\mathbf{w} = \lambda \mathbf{w}$ for every $\mathbf{w} \in W$.

So every $T \in \mathcal{F}$ acts on W as multiplication by a scalar λ_T. Any non-zero $\mathbf{v} \in W$ then satisfies $T\mathbf{v} = \lambda_T \mathbf{v}$ for every $T \in \mathcal{F}$, as claimed. Over $\mathbb{C}$ every characteristic polynomial splits (Corollary 5.5.5), so the hypothesis holds automatically.

■

The proof never had to name the eigenvalues. It found a subspace on which every operator of the family is a scalar, and the scalars came for free.

Warning. **The splitting hypothesis cannot be dropped, and neither can commuting.** Over $\mathbb{R}$, the rotation $\mathbf{R} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$ commutes with itself, yet the family $\{\mathbf{R}\}$ has no real eigenvector at all, since $p_{\mathbf{R}} = x^2 + 1$ has no real root. Over $\mathbb{C}$, the non-commuting pair $\mathbf{E}_{12}, \mathbf{E}_{21}$ has no common eigenvector, as we saw above.

8.9.4 Simultaneous triangularization

Section 7 triangularized one operator by splitting off an eigenvector and passing to the quotient. For a commuting family the same recursion works, because the eigenvector we split off can be chosen common to all.

Theorem 8.9.4 — Simultaneous Triangularization

Let V be a finite-dimensional vector space over F with $\dim V = n \geq 1$, and let $\mathcal{F} \subseteq \mathcal{L}(V)$ be a non-empty commuting family such that p_T splits over F for every $T \in \mathcal{F}$. Then there is **one** basis $\mathcal{B}$ of V such that $[T]_{\mathcal{B}}$ is upper triangular for **every** $T \in \mathcal{F}$.

In particular, if $\mathbf{A}_1, \dots, \mathbf{A}_r \in M_n(\mathbb{C})$ commute pairwise, there is an invertible $\mathbf{P} \in M_n(\mathbb{C})$ such that $\mathbf{P}^{-1}\mathbf{A}_i\mathbf{P}$ is upper triangular for every i.

Idea. **Take one common eigenvector, extend, recurse.** ① Theorem 8.9.3 gives $\mathbf{v}_1$, an eigenvector of every $T \in \mathcal{F}$, so $U = \operatorname{span}(\mathbf{v}_1)$ is invariant under the family. ② On V/U, the induced operators still commute, and their characteristic polynomials still split. ③ By induction on the dimension, one basis of V/U triangularizes all of them. ④ Lift it back and put $\mathbf{v}_1$ in front; the block triangular form of Section 1 does the rest.

Proof. We use induction on n. If $n = 1$, every 1×1 matrix is upper triangular, so any basis works.

Let $n \geq 2$, and assume the theorem for spaces of dimension $n-1$. By Theorem 8.9.3 there is $\mathbf{v}_1 \neq \mathbf{0}$ with $T\mathbf{v}_1 = \lambda_T \mathbf{v}_1$ for every $T \in \mathcal{F}$. Let $U = \operatorname{span}(\mathbf{v}_1)$; it is T-invariant for every $T \in \mathcal{F}$ (Proposition 8.1.2), and $\{\mathbf{0}\} \neq U \neq V$ since $\dim U = 1 < n$. For $T \in \mathcal{F}$ let $\bar{T}$ be the induced operator on V/U (Definition 8.1.2), and put $\bar{\mathcal{F}} = \{\bar{T} : T \in \mathcal{F}\}$.

The family $\bar{\mathcal{F}}$ is commuting: for $S, T \in \mathcal{F}$ and $\mathbf{v} \in V$,

$$\bar{S}\bar{T}(\mathbf{v}+U) = \bar{S}(T\mathbf{v}+U) = ST\mathbf{v}+U = TS\mathbf{v}+U = \bar{T}\bar{S}(\mathbf{v}+U).$$

Each $p_{\bar{T}}$ splits by Lemma 8.9.2, and $\dim V/U = n-1$ by Theorem 3.9.5. By the induction hypothesis there are $\mathbf{w}_2, \dots, \mathbf{w}_n \in V$ such that $\bar{\mathcal{B}} = (\mathbf{w}_2 + U, \dots, \mathbf{w}_n + U)$ is a basis of V/U in which every $[\bar{T}]_{\bar{\mathcal{B}}}$ is upper triangular.

Let $\mathcal{B} = (\mathbf{v}_1, \mathbf{w}_2, \dots, \mathbf{w}_n)$. It is linearly independent: if $a_1\mathbf{v}_1 + a_2\mathbf{w}_2 + \cdots + a_n\mathbf{w}_n = \mathbf{0}$, then passing to V/U, where $\mathbf{v}_1 + U$ is the zero coset, gives $a_2(\mathbf{w}_2+U) + \cdots + a_n(\mathbf{w}_n+U) = \mathbf{0}$, so $a_2 = \cdots = a_n = 0$ by the independence of $\bar{\mathcal{B}}$; then $a_1\mathbf{v}_1 = \mathbf{0}$ with $\mathbf{v}_1 \neq \mathbf{0}$ gives $a_1 = 0$. A linearly independent list of length $n = \dim V$ is a basis (Theorem 1.6.4). Now $\mathcal{B}$ is a basis of U extended to a basis of V, and $\bar{\mathcal{B}}$ is exactly the list of cosets in Theorem 8.1.3. Hence for every $T \in \mathcal{F}$,

$$[T]_{\mathcal{B}} = \begin{pmatrix} \lambda_T & * \\ 0 & [\bar{T}]_{\bar{\mathcal{B}}} \end{pmatrix},$$

with a 1×1 upper-left block, a zero column below it, and an upper triangular lower-right block. Such a matrix is upper triangular. This completes the induction.

For the matrix statement, apply this to the family $\{T_{\mathbf{A}_1}, \dots, T_{\mathbf{A}_r}\}$ on $\mathbb{C}^n$, whose characteristic polynomials split by Corollary 5.5.5, and let $\mathbf{P}$ have the vectors of $\mathcal{B}$ as columns; then $\mathbf{P}^{-1}\mathbf{A}_i\mathbf{P} = [T_{\mathbf{A}_i}]_{\mathcal{B}}$ (Theorem 3.7.3).

■

A first use: if S and T commute and both characteristic polynomials split, the diagonal entries of $[S+T]_{\mathcal{B}}$ and $[ST]_{\mathcal{B}}$ are the sums and products of the diagonal entries of $[S]_{\mathcal{B}}$ and $[T]_{\mathcal{B}}$, position by position. For the sum this is entrywise; for the product, the (i,i)-entry of $\mathbf{XY}$ is $\sum_k x_{ik}y_{ki}$ (Definition 0.9.9), and when $\mathbf{X}$ and $\mathbf{Y}$ are upper triangular only $k = i$ can contribute, since $x_{ik} = 0$ for $k < i$ and $y_{ki} = 0$ for $k > i$. By Theorem 8.7.4, those diagonal entries are the eigenvalues. So the eigenvalues of $S+T$ are of the form $\lambda + \mu$, with λ an eigenvalue of S and μ one of T, **paired by position in a common triangular form**. Section 2 warned that nothing like this holds without commuting.

8.9.5 Simultaneous diagonalization

Diagonalization is the stronger wish, and it needs a stronger hypothesis: each operator must be diagonalizable on its own. The name for the goal:

Definition 8.9.1 — Simultaneously Diagonalizable

Let V be finite-dimensional. A family $\mathcal{F} \subseteq \mathcal{L}(V)$ is **simultaneously diagonalizable** if there is **one** basis $\mathcal{B}$ of V such that $[T]_{\mathcal{B}}$ is diagonal for **every** $T \in \mathcal{F}$. Matrices $\mathbf{A}_1, \dots, \mathbf{A}_r \in M_n(F)$ are simultaneously diagonalizable over F if there is **one** invertible $\mathbf{P} \in M_n(F)$ with every $\mathbf{P}^{-1}\mathbf{A}_i\mathbf{P}$ diagonal.

Equivalently, by the unwinding in Section 4, V has a basis whose vectors are eigenvectors of every $T \in \mathcal{F}$. The opening of this section showed that a simultaneously diagonalizable family is commuting. For diagonalizable operators the converse holds.

Theorem 8.9.5 — Simultaneous Diagonalization

Let V be a finite-dimensional vector space over F with $\dim V \geq 1$, and let $S, T \in \mathcal{L}(V)$ be diagonalizable. Then S and T are simultaneously diagonalizable if and only if $ST = TS$.

For matrices: if $\mathbf{A}, \mathbf{B} \in M_n(F)$ are diagonalizable over F, there is an invertible $\mathbf{P} \in M_n(F)$ with $\mathbf{P}^{-1}\mathbf{AP}$ and $\mathbf{P}^{-1}\mathbf{BP}$ both diagonal if and only if $\mathbf{AB} = \mathbf{BA}$.

Idea. Split V into the eigenspaces of T. On each piece T is a scalar, so **any** basis of the piece consists of eigenvectors of T; we are free to choose it to suit S. The piece is S-invariant because S commutes with T, and S restricted to it is diagonalizable because S is (Section 8). So each piece has a basis of eigenvectors of S, and gluing these bases together gives the common basis.

Proof. ($\Rightarrow$) Let $\mathcal{B}$ be a basis with $[S]_{\mathcal{B}}$ and $[T]_{\mathcal{B}}$ diagonal. Diagonal matrices commute, so by Corollary 3.6.3, $[ST]_{\mathcal{B}} = [S]_{\mathcal{B}}[T]_{\mathcal{B}} = [T]_{\mathcal{B}}[S]_{\mathcal{B}} = [TS]_{\mathcal{B}}$. The map $\mathbf{R} \mapsto [\mathbf{R}]_{\mathcal{B}}$ is injective (Theorem 3.6.4), so $ST = TS$.

($\Leftarrow$) Suppose $ST = TS$. Let $\lambda_1, \dots, \lambda_k$ be the distinct eigenvalues of T, and put $U_i = E_{\lambda_i}(T)$. Since T is diagonalizable, Theorem 8.4.1 (c) gives

$$V = U_1 \oplus \cdots \oplus U_k.$$

Each U_i is S-invariant (Theorem 8.9.1), and S is diagonalizable, so $S|_{U_i}$ is diagonalizable by Corollary 8.8.3. Hence U_i has a basis $\mathcal{B}_i$ of eigenvectors of $S|_{U_i}$ (Theorem 8.4.1 (b)), which are eigenvectors of S. They are also eigenvectors of T, being non-zero vectors of $U_i = E_{\lambda_i}(T)$. Let $\mathcal{B}$ be the list $\mathcal{B}_1, \dots, \mathcal{B}_k$. Since the sum is direct, $\mathcal{B}$ is a basis of V by Theorem 1.7.5 ((a) $\Rightarrow$ (d)). Every vector of $\mathcal{B}$ is an eigenvector of both S and T, so $[S]_{\mathcal{B}}$ and $[T]_{\mathcal{B}}$ are diagonal (Theorem 8.4.1, (a) $\Leftrightarrow$ (b)).

For matrices, apply this to $T_{\mathbf{A}}$ and $T_{\mathbf{B}}$ on F^n, which are diagonalizable because $\mathbf{A}$ and $\mathbf{B}$ are (Definition 8.4.1), and commute because $\mathbf{AB} = \mathbf{BA}$; let $\mathbf{P}$ have the common

eigenvectors as columns, as in Section 4.

■

The proof is also an algorithm. Diagonalize $\mathbf{A}$; in each eigenspace of $\mathbf{A}$ of dimension at least 2, write down the matrix of $\mathbf{B}$ restricted to it and diagonalize that small matrix; eigenspaces of dimension 1 need no work, since their basis vector is automatically an eigenvector of $\mathbf{B}$.

Example. (Diagonalizing Two Commuting Matrices Together)

Let

$$\mathbf{A} = \begin{pmatrix} 1 & 0 & 0 \\ -2 & 1 & 2 \\ -2 & 0 & 3 \end{pmatrix}, \qquad \mathbf{B} = \begin{pmatrix} 1 & -2 & 2 \\ 0 & 1 & 0 \\ 0 & -2 & 3 \end{pmatrix} \in M_3(\mathbb{R}).$$

Check that $\mathbf{AB} = \mathbf{BA}$, and find an invertible $\mathbf{P}$ such that $\mathbf{P}^{-1}\mathbf{AP}$ and $\mathbf{P}^{-1}\mathbf{BP}$ are both diagonal.

Solution. They commute. Multiplying out,

$$\mathbf{AB} = \begin{pmatrix} 1 & -2 & 2 \\ -2 & 1 & 2 \\ -2 & -2 & 5 \end{pmatrix} = \mathbf{BA}.$$

Diagonalize $\mathbf{A}$. Expanding $\det(x\mathbf{I} - \mathbf{A})$ along the first row, whose only non-zero entry is $x - 1$,

$$p_{\mathbf{A}}(x) = (x-1)\det\begin{pmatrix} x-1 & -2 \\ 0 & x-3 \end{pmatrix} = (x-1)^2(x-3).$$

For $\lambda = 1$, $\mathbf{A} - \mathbf{I} = \begin{pmatrix} 0 & 0 & 0 \\ -2 & 0 & 2 \\ -2 & 0 & 2 \end{pmatrix}$ has rank 1 and reduces to $x = z$, so $E_1(\mathbf{A})$ is the plane with basis $\mathbf{u}_1 = (0,1,0)$, $\mathbf{u}_2 = (1,0,1)$. For $\lambda = 3$, $\mathbf{A} - 3\mathbf{I} = \begin{pmatrix} -2 & 0 & 0 \\ -2 & -2 & 2 \\ -2 & 0 & 0 \end{pmatrix}$ gives $x = 0$ and $y = z$, so $E_3(\mathbf{A}) = \operatorname{span}((0,1,1))$. Since $g(1) = 2 = a(1)$ and $g(3) = 1 = a(3)$, $\mathbf{A}$ is diagonalizable. The same computation for $\mathbf{B}$ gives $p_{\mathbf{B}} = (x-1)^2(x-3)$, with $\mathbf{B} - \mathbf{I} = \begin{pmatrix} 0 & -2 & 2 \\ 0 & 0 & 0 \\ 0 & -2 & 2 \end{pmatrix}$ of rank 1 and $\mathbf{B} - 3\mathbf{I}$ of rank 2, so $\mathbf{B}$ is diagonalizable as well.

A basis of eigenvectors of $\mathbf{A}$ need not work for $\mathbf{B}$: $\mathbf{Bu}_1 = (-2,1,-2)$ is not a multiple of $\mathbf{u}_1$. This is where the search inside the eigenspace comes in.

The one-dimensional eigenspace. $E_3(\mathbf{A})$ is $\mathbf{B}$-invariant (Theorem 8.9.1) and one-dimensional, so $\mathbf{v}_3 = (0,1,1)$ is an eigenvector of $\mathbf{B}$: indeed $\mathbf{Bv}_3 = (0,1,1) = 1 \cdot \mathbf{v}_3$.

The plane $E_1(\mathbf{A})$. It is $\mathbf{B}$-invariant, and

$$\mathbf{Bu}_1 = (-2,1,-2) = \mathbf{u}_1 - 2\mathbf{u}_2, \qquad \mathbf{Bu}_2 = (3,0,3) = 3\mathbf{u}_2.$$

So the matrix of $\mathbf{B}|_{E_1(\mathbf{A})}$ in the basis $(\mathbf{u}_1, \mathbf{u}_2)$ is $\mathbf{M} = \begin{pmatrix} 1 & 0 \\ -2 & 3 \end{pmatrix}$, whose columns are the coordinates just found. It is lower triangular with eigenvalues 1 and 3. From $\mathbf{M} - \mathbf{I} =$

$\begin{pmatrix} 0 & 0 \\ -2 & 2 \end{pmatrix}$ the eigenvector is $(1,1)$, which stands for $\mathbf{u}_1 + \mathbf{u}_2 = (1,1,1)$; from $\mathbf{M} - 3\mathbf{I} = \begin{pmatrix} -2 & 0 \\ -2 & 0 \end{pmatrix}$ it is $(0,1)$, which stands for $\mathbf{u}_2 = (1,0,1)$.

The common basis. Put $\mathbf{v}_1 = (1,0,1)$, $\mathbf{v}_2 = (1,1,1)$, $\mathbf{v}_3 = (0,1,1)$ as columns:

$$\mathbf{P} = \begin{pmatrix} 1 & 1 & 0 \\ 0 & 1 & 1 \\ 1 & 1 & 1 \end{pmatrix}, \qquad \mathbf{P}^{-1}\mathbf{A}\mathbf{P} = \operatorname{diag}(1,1,3), \qquad \mathbf{P}^{-1}\mathbf{B}\mathbf{P} = \operatorname{diag}(3,1,1).$$

Check. $\mathbf{A}\mathbf{v}_1 = \mathbf{v}_1$, $\mathbf{A}\mathbf{v}_2 = \mathbf{v}_2$, $\mathbf{A}\mathbf{v}_3 = (0,3,3) = 3\mathbf{v}_3$; $\mathbf{B}\mathbf{v}_1 = (3,0,3) = 3\mathbf{v}_1$, $\mathbf{B}\mathbf{v}_2 = \mathbf{v}_2$, $\mathbf{B}\mathbf{v}_3 = \mathbf{v}_3$. Expanding along the first row, $\det \mathbf{P} = 1(1-1) - 1(0-1) + 0 = 1 \neq 0$, so $\mathbf{P}$ is invertible, with $\mathbf{P}^{-1} = \begin{pmatrix} 0 & -1 & 1 \\ 1 & 1 & -1 \\ -1 & 0 & 1 \end{pmatrix}$.

Notice that neither matrix alone determines $\mathbf{P}$: $\mathbf{A}$ cannot tell $\mathbf{v}_1$ from $\mathbf{v}_2$, and $\mathbf{B}$ cannot tell $\mathbf{v}_2$ from $\mathbf{v}_3$. Together they pin down all three lines.

Warning. **Commuting does not make an operator diagonalizable.** The theorem assumes that both S and T are diagonalizable. $\mathbf{J} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$ commutes with $\mathbf{I}_2$, and $\mathbf{I}_2$ is diagonal, but $\mathbf{J}$ is not diagonalizable (Section 4), so no basis makes both diagonal. What survives is Theorem 8.9.4: $\mathbf{J}$ and $\mathbf{I}_2$ are already upper triangular together.

The theorem extends from two operators to any number, and even to infinitely many. An infinite family looks hopeless for an induction, but it lives inside the finite-dimensional space $\mathcal{L}(V)$, so finitely many of its members already span everything the family spans.

Theorem 8.9.6 — Simultaneous Diagonalization of a Commuting Family

Let V be a finite-dimensional vector space over F with $\dim V \geq 1$, and let $\mathcal{F} \subseteq \mathcal{L}(V)$ be a family of diagonalizable operators. Then $\mathcal{F}$ is simultaneously diagonalizable if and only if it is commuting.

Idea. ① **Finite first.** For finitely many commuting diagonalizable $T_1, \ldots, T_r$, induct on r: split V into eigenspaces of T_1, and on each piece apply the case $r-1$ to the restrictions of $T_2, \ldots, T_r$. ② **Reduce to finite.** A longest linearly independent list $T_1, \ldots, T_r$ taken from $\mathcal{F}$ spans every member of $\mathcal{F}$, and has length at most $\dim \mathcal{L}(V)$. ③ A basis that diagonalizes $T_1, \ldots, T_r$ diagonalizes every linear combination of them.

Proof. ($\Rightarrow$) If one basis makes every $[T]_{\mathcal{B}}$ diagonal, any two of these matrices commute, and the argument of Theorem 8.9.5 ($\Rightarrow$) gives $ST = TS$ for all $S, T \in \mathcal{F}$.

($\Leftarrow$) Suppose $\mathcal{F}$ is commuting. If $\mathcal{F}$ is empty, any basis works; assume not.

Step 1: finitely many operators. We prove by induction on $r \geq 1$: for every non-zero finite-dimensional space W and all pairwise commuting diagonalizable $T_1, \ldots, T_r \in \mathcal{L}(W)$, some basis of W consists of eigenvectors of every T_i. For $r = 1$ this is Theorem 8.4.1. Let $r \geq 2$, and let $\lambda_1, \ldots, \lambda_k$ be the distinct eigenvalues of T_1,

with $U_j = E_{\lambda_j}(T_1) \neq \{\mathbf{0}\}$. By Theorem 8.4.1 (c), $W = U_1 \oplus \cdots \oplus U_k$. Each U_j is T_i-invariant for every i (Theorem 8.9.1), each $T_i|_{U_j}$ is diagonalizable (Corollary 8.8.3), and the restrictions $T_2|_{U_j}, \ldots, T_r|_{U_j}$ commute pairwise, since they agree with $T_2, \ldots, T_r$ on U_j. By the induction hypothesis, U_j has a basis $\mathcal{B}_j$ of common eigenvectors of $T_2, \ldots, T_r$; they are eigenvectors of T_1 too, as non-zero vectors of U_j. The list $\mathcal{B}_1, \ldots, \mathcal{B}_k$ is a basis of W by Theorem 1.7.5 ((a) $\Rightarrow$ (d)). This completes the induction.

Step 2: a finite spanning subfamily. Let $N = \dim \mathcal{L}(V) = (\dim V)^2$ (Theorem 3.6.4). Every linearly independent list in $\mathcal{L}(V)$ has length at most N (Theorem 1.6.5), so among the linearly independent lists of members of $\mathcal{F}$ there is one of greatest length, say $(T_1, \ldots, T_r)$, with $r \geq 1$ because a single non-zero member is independent (if every member of $\mathcal{F}$ is 0, any basis works). For every $T \in \mathcal{F}$, the list $(T_1, \ldots, T_r, T)$ is longer, hence dependent, so $T \in \operatorname{span}(T_1, \ldots, T_r)$ by Lemma 1.5.3.

Step 3. By Step 1 there is a basis $\mathcal{B}$ of V with every $[T_i]_{\mathcal{B}}$ diagonal. For $T \in \mathcal{F}$, write $T = c_1 T_1 + \cdots + c_r T_r$; then $[T]_{\mathcal{B}} = c_1[T_1]_{\mathcal{B}} + \cdots + c_r[T_r]_{\mathcal{B}}$ (Corollary 3.6.3), a linear combination of diagonal matrices, hence diagonal. So $\mathcal{B}$ diagonalizes every member of $\mathcal{F}$.

■

A typical infinite family is $\{p(T) : p \in F[x]\}$ for a diagonalizable T. It is commuting, each $p(T)$ is diagonalizable (Section 8), and here one basis works for the whole family without any of the theorem's machinery, namely an eigenbasis of T: an eigenvector of T for λ is an eigenvector of $p(T)$ for $p(\lambda)$ (Exercise (B3: Eigenvalues of powers and inverses)). The theorem says the same for families that are not generated by one operator in so visible a way.

8.9.6 Exercises

8.9.6.1 A. Check your understanding

Exercise A1.

(a) State the theorem relating commuting operators and eigenspaces.

(b) True or false: if $ST = TS$, then every eigenvector of T is an eigenvector of S. Justify your answer.

(c) True or false: any two commuting matrices in $M_2(\mathbb{R})$ have a common eigenvector in $\mathbb{R}^2$. Justify your answer.

(d) True or false: if $\mathbf{A}, \mathbf{B} \in M_n(F)$ are simultaneously diagonalizable, then $\mathbf{AB} = \mathbf{BA}$. Justify your answer.

(e) True or false: if $\mathbf{AB} = \mathbf{BA}$ and $\mathbf{A}$ is diagonalizable, then $\mathbf{B}$ is diagonalizable. Justify your answer.

(f) In the proof of Theorem 8.9.5, which hypothesis makes each eigenspace of T invariant under S, and which makes the restriction of S diagonalizable?

Solution.

(a) If $S, T \in \mathcal{L}(V)$ and $ST = TS$, then $E_\lambda(T)$ is S-invariant for every $\lambda \in F$ (Theorem 8.9.1).

(b) False. $T = \mathbf{I}_2$ commutes with $S = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$; the vector $\mathbf{e}_2$ is an eigenvector of T, but $S\mathbf{e}_2 = (1, 1)$ is not a multiple of $\mathbf{e}_2$.

(c) False. The rotation $\mathbf{R} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$ commutes with itself and has no real eigenvector, since $p_{\mathbf{R}} = x^2 + 1$ has no real root.

(d) True. If $\mathbf{P}^{-1}\mathbf{AP} = \mathbf{D}$ and $\mathbf{P}^{-1}\mathbf{BP} = \mathbf{D}'$ are diagonal, then $\mathbf{AB} = \mathbf{PDP}^{-1}\mathbf{PD}'\mathbf{P}^{-1} = \mathbf{PDD}'\mathbf{P}^{-1} = \mathbf{PD}'\mathbf{DP}^{-1} = \mathbf{BA}$, since diagonal matrices commute.

(e) False. $\mathbf{A} = \mathbf{I}_2$ is diagonalizable and commutes with $\mathbf{B} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$, which is not diagonalizable.

(f) The hypothesis $ST = TS$ gives the invariance (Theorem 8.9.1). The hypothesis that S is diagonalizable gives, through Corollary 8.8.3, that $S|_{E_\lambda(T)}$ is diagonalizable.

8.9.6.2 B. Practice

Exercise B1: Common eigenvectors.

Let

$$\mathbf{A} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 1 & -1 & 2 \end{pmatrix}, \qquad \mathbf{B} = \begin{pmatrix} 2 & 1 & 0 \\ -1 & 4 & 0 \\ 2 & -2 & 5 \end{pmatrix} \in M_3(\mathbb{R}).$$

(a) Verify that $\mathbf{AB} = \mathbf{BA}$.

(b) Find every common eigenvector of $\mathbf{A}$ and $\mathbf{B}$.

(c) Hence show that $\mathbf{A}$ and $\mathbf{B}$ are not simultaneously diagonalizable, and explain which hypothesis of Theorem 8.9.5 fails.

Solution.

(a) Multiplying out,

$$\mathbf{AB} = \begin{pmatrix} 2 & 1 & 0 \\ -1 & 4 & 0 \\ 7 & -7 & 10 \end{pmatrix} = \mathbf{BA}.$$

For instance, the $(3,1)$-entry of $\mathbf{AB}$ is row $(1, -1, 2)$ of $\mathbf{A}$ times column $(2, -1, 2)$ of $\mathbf{B}$, namely $2 + 1 + 4 = 7$, and that of $\mathbf{BA}$ is row $(2, -2, 5)$ of $\mathbf{B}$ times column $(1, 0, 1)$ of $\mathbf{A}$, namely $2 + 0 + 5 = 7$.

(b) $\mathbf{A}$ is lower triangular, so $p_{\mathbf{A}} = (x-1)^2(x-2)$. $\mathbf{A} - \mathbf{I} = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 1 & -1 & 1 \end{pmatrix}$ has rank 1, so $E_1(\mathbf{A}) = \{(x, y, z) : x - y + z = 0\}$ with basis $\mathbf{u}_1 = (1, 1, 0)$, $\mathbf{u}_2 = (-1, 0, 1)$. $\mathbf{A} - 2\mathbf{I} = \begin{pmatrix} -1 & 0 & 0 \\ 0 & -1 & 0 \\ 1 & -1 & 0 \end{pmatrix}$ gives $E_2(\mathbf{A}) = \operatorname{span}(\mathbf{e}_3)$.
A common eigenvector is an eigenvector of $\mathbf{A}$, so it lies in $E_1(\mathbf{A})$ or $E_2(\mathbf{A})$, and it must be an eigenvector of $\mathbf{B}$ there. On the line $E_2(\mathbf{A})$: $\mathbf{B}\mathbf{e}_3 = (0, 0, 5) = 5\mathbf{e}_3$, so every non-zero multiple of $\mathbf{e}_3$ is a common eigenvector. On the plane $E_1(\mathbf{A})$,

which is $\mathbf{B}$-invariant by Theorem 8.9.1:

$$\mathbf{B}\mathbf{u}_1 = (3,3,0) = 3\mathbf{u}_1, \qquad \mathbf{B}\mathbf{u}_2 = (-2,1,3) = \mathbf{u}_1 + 3\mathbf{u}_2.$$

So $[\mathbf{B}|_{E_1(\mathbf{A})}] = \begin{pmatrix} 3 & 1 \\ 0 & 3 \end{pmatrix}$ in the basis $(\mathbf{u}_1, \mathbf{u}_2)$. Its only eigenvalue is 3, and its eigenvectors are the non-zero multiples of $(1,0)$, that is, of $\mathbf{u}_1$. Hence the common eigenvectors are exactly the non-zero multiples of $(1,1,0)$ and the non-zero multiples of $(0,0,1)$.

(c) By (b), any list of common eigenvectors lies in $\operatorname{span}((1,1,0), \mathbf{e}_3)$, a plane, so no three of them form a basis of $\mathbb{R}^3$. Hence no basis diagonalizes both. The failing hypothesis is that $\mathbf{B}$ is diagonalizable: $p_{\mathbf{B}} = (x-3)^2(x-5)$ (from the block computation, $p_{\mathbf{B}} = p_{\mathbf{B}|_{E_1(\mathbf{A})}}\, p_{\bar{\mathbf{B}}}$, or directly), and $\mathbf{B} - 3\mathbf{I} = \begin{pmatrix} -1 & 1 & 0 \\ -1 & 1 & 0 \\ 2 & -2 & 2 \end{pmatrix}$ has rank 2, so $g_{\mathbf{B}}(3) = 1 < 2 = a_{\mathbf{B}}(3)$.

Exercise B2: Decide simultaneous diagonalizability.

For each pair of real matrices, determine whether they are simultaneously diagonalizable over $\mathbb{R}$. If they are, find a suitable $\mathbf{P}$. Justify your answer.

(a) $\mathbf{A} = \begin{pmatrix} 1 & 2 \\ 2 & 1 \end{pmatrix}$, $\mathbf{B} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$.

(b) $\mathbf{A} = \begin{pmatrix} 1 & 1 \\ 0 & 2 \end{pmatrix}$, $\mathbf{B} = \begin{pmatrix} 1 & 0 \\ 0 & 2 \end{pmatrix}$.

(c) $\mathbf{A} = \begin{pmatrix} 2 & 0 \\ 0 & 2 \end{pmatrix}$, $\mathbf{B} = \begin{pmatrix} 2 & 1 \\ 0 & 2 \end{pmatrix}$.

Solution.

(a) Yes. $\mathbf{AB} = \begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix} = \mathbf{BA}$. Both are diagonalizable: $\mathbf{A}$ has $p_{\mathbf{A}} = x^2 - 2x - 3 = (x-3)(x+1)$ and $\mathbf{B}$ has $p_{\mathbf{B}} = x^2 - 1 = (x-1)(x+1)$, each with distinct eigenvalues (Corollary 8.4.2). By Theorem 8.9.5 a common $\mathbf{P}$ exists. The eigenspaces of $\mathbf{A}$ are lines, so their spanning vectors $(1,1)$ and $(1,-1)$ work: $\mathbf{P} = \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}$, $\mathbf{P}^{-1}\mathbf{A}\mathbf{P} = \operatorname{diag}(3,-1)$, $\mathbf{P}^{-1}\mathbf{B}\mathbf{P} = \operatorname{diag}(1,-1)$, since $\mathbf{B}(1,1) = (1,1)$ and $\mathbf{B}(1,-1) = (-1,1)$.

(b) No. Both are diagonalizable (distinct eigenvalues $1, 2$), but $\mathbf{AB} = \begin{pmatrix} 1 & 2 \\ 0 & 4 \end{pmatrix} \neq \begin{pmatrix} 1 & 1 \\ 0 & 4 \end{pmatrix} = \mathbf{BA}$, so by Theorem 8.9.5 ($\Rightarrow$) no common $\mathbf{P}$ exists.

(c) No. They commute, since $\mathbf{A} = 2\mathbf{I}$. But $\mathbf{B}$ is not diagonalizable: $p_{\mathbf{B}} = (x-2)^2$ and $\mathbf{B} - 2\mathbf{I}$ has rank 1, so $g(2) = 1 < 2$. If $\mathbf{P}^{-1}\mathbf{B}\mathbf{P}$ were diagonal, $\mathbf{B}$ would be diagonalizable (Definition 8.4.1).

Exercise B3: Matrices commuting with a diagonal matrix.

(a) Let $\mathbf{D} = \operatorname{diag}(1,2,3) \in M_3(\mathbb{R})$. Prove that a matrix $\mathbf{B} \in M_3(\mathbb{R})$ commutes with

$\mathbf{D}$ if and only if $\mathbf{B}$ is diagonal.

(b) Let $\mathbf{D}' = \mathrm{diag}(1,1,2) \in M_3(\mathbb{R})$. Describe all $\mathbf{B} \in M_3(\mathbb{R})$ with $\mathbf{BD}' = \mathbf{D}'\mathbf{B}$, and find one that is not diagonalizable.

Solution.

(a) ($\Leftarrow$) Diagonal matrices commute. ($\Rightarrow$) Suppose $\mathbf{BD} = \mathbf{DB}$. The eigenspaces of $\mathbf{D}$ are $E_1(\mathbf{D}) = \mathrm{span}(\mathbf{e}_1)$, $E_2(\mathbf{D}) = \mathrm{span}(\mathbf{e}_2)$ and $E_3(\mathbf{D}) = \mathrm{span}(\mathbf{e}_3)$. By Theorem 8.9.1 each is $\mathbf{B}$-invariant, so $\mathbf{Be}_j \in \mathrm{span}(\mathbf{e}_j)$ for each j. The j-th column of $\mathbf{B}$ is $\mathbf{Be}_j$, so it has zeros off the diagonal, and $\mathbf{B}$ is diagonal. (Directly: $(\mathbf{DB})_{ij} = i\,b_{ij}$ and $(\mathbf{BD})_{ij} = b_{ij}\,j$, so $(i-j)b_{ij} = 0$, and $b_{ij} = 0$ for $i \neq j$.)

(b) As computed in the text for $\mathrm{diag}(1,1,2)$, $\mathbf{BD}' = \mathbf{D}'\mathbf{B}$ exactly when $\mathbf{B} = \begin{pmatrix} b_{11} & b_{12} & 0 \\ b_{21} & b_{22} & 0 \\ 0 & 0 & b_{33} \end{pmatrix}$ with arbitrary entries: $E_1(\mathbf{D}') = \mathrm{span}(\mathbf{e}_1, \mathbf{e}_2)$ and $E_2(\mathbf{D}') = \mathrm{span}(\mathbf{e}_3)$ are $\mathbf{B}$-invariant, which by Theorem 8.1.5 forces this shape, and conversely $\mathbf{D}' = \mathbf{I}_2 \oplus (2)$ commutes with every such block matrix (Theorem 7.1.4). For example $\mathbf{B} = \begin{pmatrix} 1 & 1 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \end{pmatrix}$ commutes with $\mathbf{D}'$, and it is not diagonalizable: $p_{\mathbf{B}} = x(x-1)^2$ and $\mathbf{B} - \mathbf{I}$ has rank 2, so $g(1) = 1 < 2 = a(1)$.

8.9.6.3 C. Going deeper

Exercise C1: The commutant of a matrix with distinct eigenvalues.

Let $\mathbf{A} \in M_n(F)$, $n \geq 1$, have n distinct eigenvalues $\lambda_1, \ldots, \lambda_n \in F$.

(a) Prove that if $\mathbf{AB} = \mathbf{BA}$, then $\mathbf{B}$ is diagonalizable and every eigenvector of $\mathbf{A}$ is an eigenvector of $\mathbf{B}$.

(b) Prove that if $\mathbf{AB} = \mathbf{BA}$, then $\mathbf{B} = q(\mathbf{A})$ for some $q \in F[x]$ of degree at most $n-1$.

(c) Deduce that $\{\mathbf{B} \in M_n(F) : \mathbf{AB} = \mathbf{BA}\}$ is a subspace of $M_n(F)$ of dimension n, with basis $(\mathbf{I}, \mathbf{A}, \ldots, \mathbf{A}^{n-1})$.

Hint: for (b), use Lagrange interpolation.

Solution.

(a) By Corollary 8.4.2, $\mathbf{A}$ is diagonalizable, say $\mathbf{P}^{-1}\mathbf{AP} = \mathbf{D}$ with $\mathbf{D}$ diagonal. A diagonal matrix is upper triangular, so its diagonal entries are the eigenvalues of $\mathbf{A}$, each occurring as often as its algebraic multiplicity (Theorem 8.7.4 (b)); here there are n distinct eigenvalues and n diagonal places, so each occurs once, and after permuting the columns of $\mathbf{P}$ and the diagonal entries of $\mathbf{D}$ together we may assume $\mathbf{D} = \mathrm{diag}(\lambda_1, \ldots, \lambda_n)$. Let $\mathbf{v}_i$ be column i of $\mathbf{P}$. Each $E_{\lambda_i}(\mathbf{A})$ has dimension at least 1, and the dimensions add up to at most n (Corollary 8.2.3), so each has dimension exactly 1 and $E_{\lambda_i}(\mathbf{A}) = \mathrm{span}(\mathbf{v}_i)$. Every eigenvector of $\mathbf{A}$ for λ_i is a non-zero multiple of $\mathbf{v}_i$. By Theorem 8.9.1, $\mathbf{Bv}_i \in \mathrm{span}(\mathbf{v}_i)$, so $\mathbf{Bv}_i = \mu_i \mathbf{v}_i$ for some $\mu_i \in F$, and $\mathbf{v}_i$, with every non-zero multiple of it, is an eigenvector of $\mathbf{B}$. The columns of $\mathbf{P}$ form a basis of eigenvectors of $\mathbf{B}$, so $\mathbf{P}^{-1}\mathbf{BP} = \mathrm{diag}(\mu_1, \ldots, \mu_n)$

and $\mathbf{B}$ is diagonalizable.

(b) The nodes $\lambda_1, \dots, \lambda_n$ are distinct, so by Theorem 5.6.1 there is $q \in F[x]$ with $\deg q \le n-1$ and $q(\lambda_i) = \mu_i$ for every i. By Theorem 8.4.3,

$$q(\mathbf{A}) = \mathbf{P}\,\operatorname{diag}\big(q(\lambda_1), \dots, q(\lambda_n)\big)\,\mathbf{P}^{-1} = \mathbf{P}\,\operatorname{diag}(\mu_1, \dots, \mu_n)\,\mathbf{P}^{-1} = \mathbf{B}.$$

(c) If $\mathbf{AB} = \mathbf{BA}$ and $\mathbf{AB}' = \mathbf{B}'\mathbf{A}$, then $\mathbf{A}(c\mathbf{B} + \mathbf{B}') = c\mathbf{BA} + \mathbf{B}'\mathbf{A} = (c\mathbf{B} + \mathbf{B}')\mathbf{A}$, and $\mathbf{A}0 = 0\mathbf{A}$; so the set $\mathcal{C}$ is a subspace. Each $\mathbf{A}^k$ commutes with $\mathbf{A}$, so $\operatorname{span}(\mathbf{I}, \mathbf{A}, \dots, \mathbf{A}^{n-1}) \subseteq \mathcal{C}$, and (b) gives the reverse inclusion. For independence, let $c_0\mathbf{I} + c_1\mathbf{A} + \cdots + c_{n-1}\mathbf{A}^{n-1} = 0$ and put $q = \sum_k c_k x^k$. By Theorem 8.4.3, $0 = q(\mathbf{A}) = \mathbf{P}\,\operatorname{diag}(q(\lambda_1), \dots, q(\lambda_n))\,\mathbf{P}^{-1}$, so $q(\lambda_i) = 0$ for all i. A polynomial of degree at most $n-1$ with n distinct roots is zero (Corollary 5.1.4), so every $c_k = 0$. Hence $(\mathbf{I}, \mathbf{A}, \dots, \mathbf{A}^{n-1})$ is a basis of $\mathcal{C}$, and $\dim \mathcal{C} = n$.

Exercise C2: Commuting nilpotent matrices.

Recall that $\mathbf{N} \in M_n(F)$ is **nilpotent** if $\mathbf{N}^a = 0$ for some $a \ge 1$ (Exercise (C2: Nilpotent operators)). Let $\mathbf{N}, \mathbf{M} \in M_n(F)$ with $\mathbf{NM} = \mathbf{MN}$, $\mathbf{N}^a = 0$ and $\mathbf{M}^b = 0$ for some $a, b \ge 1$.

(a) Prove that $\mathbf{NM}$ is nilpotent.

(b) Prove that $(\mathbf{N} + \mathbf{M})^{a+b-1} = 0$, so that $\mathbf{N} + \mathbf{M}$ is nilpotent.

(c) Show that both conclusions can fail without $\mathbf{NM} = \mathbf{MN}$.

(d) Now let $F = \mathbb{C}$. Give a second proof of (b) using Theorem 8.9.4.

Hint: for (b), expand the power as a sum of products of $a + b - 1$ factors, each equal to $\mathbf{N}$ or $\mathbf{M}$.

Solution.

(a) Since $\mathbf{NM} = \mathbf{MN}$, induction on k gives $(\mathbf{NM})^k = \mathbf{N}^k\mathbf{M}^k$: if it holds for k, then $(\mathbf{NM})^{k+1} = \mathbf{N}^k\mathbf{M}^k\mathbf{NM} = \mathbf{N}^k\mathbf{NM}^k\mathbf{M} = \mathbf{N}^{k+1}\mathbf{M}^{k+1}$, where $\mathbf{M}^k\mathbf{N} = \mathbf{NM}^k$ follows from $\mathbf{MN} = \mathbf{NM}$ by induction as well. With $k = a$, $(\mathbf{NM})^a = \mathbf{N}^a\mathbf{M}^a = 0 \cdot \mathbf{M}^a = 0$.

(b) Let $s = a + b - 1$. By distributivity, $(\mathbf{N} + \mathbf{M})^s$ is the sum of all 2^s products $\mathbf{X}_1\mathbf{X}_2 \cdots \mathbf{X}_s$ with each $\mathbf{X}_t \in \{\mathbf{N}, \mathbf{M}\}$. Since $\mathbf{N}$ and $\mathbf{M}$ commute, each such product can be rearranged, one adjacent swap at a time, into $\mathbf{N}^i\mathbf{M}^{s-i}$, where i is the number of factors equal to $\mathbf{N}$. If $i \ge a$, then $\mathbf{N}^i = \mathbf{N}^a\mathbf{N}^{i-a} = 0$. If $i \le a - 1$, then $s - i \ge s - a + 1 = b$, so $\mathbf{M}^{s-i} = 0$. Either way the product is 0, so $(\mathbf{N} + \mathbf{M})^s = 0$.

(c) Let $\mathbf{N} = \mathbf{E}_{12}$ and $\mathbf{M} = \mathbf{E}_{21}$ in $M_2(F)$. Both square to 0. But $\mathbf{NM} = \mathbf{E}_{11}$ satisfies $\mathbf{E}_{11}^k = \mathbf{E}_{11} \neq 0$ for all $k \ge 1$, and $\mathbf{N} + \mathbf{M} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$ satisfies $(\mathbf{N} + \mathbf{M})^2 = \mathbf{I}$, so $(\mathbf{N} + \mathbf{M})^k$ is $\mathbf{I}$ or $\mathbf{N} + \mathbf{M}$, never 0. Neither is nilpotent, and indeed $\mathbf{NM} = \mathbf{E}_{11} \neq \mathbf{E}_{22} = \mathbf{MN}$.

(d) By Theorem 8.9.4 there is an invertible $\mathbf{P} \in M_n(\mathbb{C})$ with $\mathbf{U} = \mathbf{P}^{-1}\mathbf{NP}$ and $\mathbf{U}' = \mathbf{P}^{-1}\mathbf{MP}$ upper triangular. Since $\mathbf{N}$ is nilpotent, $\operatorname{spec}(\mathbf{N}) = \{0\}$ (Exercise (C2: Nilpotent operators)), so every diagonal entry of $\mathbf{U}$ is 0 by Theorem 8.7.4; likewise for $\mathbf{U}'$. So $\mathbf{U} + \mathbf{U}' = \mathbf{P}^{-1}(\mathbf{N} + \mathbf{M})\mathbf{P}$ is upper triangular with zero diagonal. A matrix $\mathbf{X}$ of this kind is nilpotent: $\mathbf{Xe}_1 = \mathbf{0}$ and $\mathbf{Xe}_j \in \operatorname{span}(\mathbf{e}_1, \dots, \mathbf{e}_{j-1})$, so by

induction $\mathbf{X}^j\mathbf{e}_j = \mathbf{0}$ and $\mathbf{X}^n = 0$. Hence $(\mathbf{N}+\mathbf{M})^n = \mathbf{P}(\mathbf{U}+\mathbf{U}')^n\mathbf{P}^{-1} = 0$.

8.10 Spectral Mapping, Products in Both Orders, Left Eigenvectors

Once the eigenvalues of T are known, what can we say about the eigenvalues of T^2, of T^2-3T+I, or of any polynomial in T? And when two matrices are multiplied in the two possible orders, how are the eigenvalues of $\mathbf{AB}$ and $\mathbf{BA}$ related? This section answers both questions using the triangular forms of Section 7 and the block matrices of Chapter 7. Along the way it settles two debts: Chapter 6 showed $p_{\mathbf{AB}} = p_{\mathbf{BA}}$ only when $\mathbf{A}$ is invertible, and Chapter 7 proved that vanishing traces of all powers force a matrix to be nilpotent by a long computation, with no explanation of why. We end with left eigenvectors, the eigenvectors of the transpose, which pair with ordinary eigenvectors in a useful way and prepare the Markov chains of Section 11.

8.10.1 Eigenvalues of a polynomial in T

One half of the answer needs no theory. If $T\mathbf{v} = \lambda\mathbf{v}$ with $\mathbf{v} \neq \mathbf{0}$, then $T^k\mathbf{v} = \lambda^k\mathbf{v}$ for every k, and so $q(T)\mathbf{v} = q(\lambda)\mathbf{v}$ for every $q \in F[x]$ (Exercise (B3: Eigenvalues of powers and inverses)). So q **maps eigenvalues of T to eigenvalues of $q(T)$**, over every field and in every dimension.

The other half, that **every** eigenvalue of $q(T)$ arises this way, can fail. Part (c) of Exercise (B3: Eigenvalues of powers and inverses) already met the rotation $\mathbf{R} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$ on $\mathbb{R}^2$: it has no real eigenvalue, while $\mathbf{R}^2 = -\mathbf{I}$ has the eigenvalue -1. The eigenvalues of $\mathbf{R}$ that would map to -1, namely $\pm i$, are missing from $\mathbb{R}$. So we expect the full statement to need a characteristic polynomial that splits. With that hypothesis we even get the multiplicities, because a triangular form shows all the eigenvalues at once on its diagonal.

The eigenvalues of $q(T)$ are the values of q at the eigenvalues of T, counted with multiplicity.

Theorem 8.10.1 — Spectral Mapping Theorem

Let V be a finite-dimensional vector space over F with $\dim V = n \geq 1$, and let $T \in \mathcal{L}(V)$. Suppose p_T splits over F, say

$$p_T(x) = (x-\lambda_1)(x-\lambda_2)\cdots(x-\lambda_n),$$

where each eigenvalue appears as often as its algebraic multiplicity. Then for every $q \in F[x]$,

$$p_{q(T)}(x) = \big(x-q(\lambda_1)\big)\big(x-q(\lambda_2)\big)\cdots\big(x-q(\lambda_n)\big),$$

and consequently

$$\operatorname{spec}\big(q(T)\big) = q\big(\operatorname{spec}(T)\big) = \{q(\lambda) : \lambda \in \operatorname{spec}(T)\}.$$

In particular this holds for every operator on a non-zero finite-dimensional complex space, and for every $\mathbf{A} \in M_n(\mathbb{C})$.

Idea. Choose a basis in which T is upper triangular (Section 7). Its diagonal is $\lambda_1, \dots, \lambda_n$. Products and sums of upper triangular matrices are upper triangular, and their diagonals are computed position by position, so $q([T])$ is upper triangular with diagonal $q(\lambda_1), \dots, q(\lambda_n)$. The characteristic polynomial of a triangular matrix is read off its diagonal.

Proof. By Theorem 8.7.2 there is a basis $\mathcal{B}$ of V such that $\mathbf{U} = [T]_{\mathcal{B}}$ is upper triangular. By Theorem 8.7.4, its diagonal entries are $\lambda_1, \dots, \lambda_n$ in some order; renumbering the λ_i, we may assume $u_{ii} = \lambda_i$.

Claim. If $\mathbf{X}, \mathbf{Y} \in M_n(F)$ are upper triangular, then so are $\mathbf{X}+\mathbf{Y}$, $c\mathbf{X}$ for $c \in F$, and $\mathbf{XY}$, with diagonal entries $x_{ii}+y_{ii}$, cx_{ii} and $x_{ii}y_{ii}$.

Proof. The statements for $\mathbf{X}+\mathbf{Y}$ and $c\mathbf{X}$ are entrywise. For the product, $(\mathbf{XY})_{ij} = \sum_{k=1}^{n} x_{ik}y_{kj}$ (Definition 0.9.9). If $i > j$, every k has $k < i$ or $k \geq i > j$, so $x_{ik} = 0$ or $y_{kj} = 0$, and the sum is 0. If $i = j$, the only term that can be non-zero has $k \geq i$ and $k \leq i$, so $(\mathbf{XY})_{ii} = x_{ii}y_{ii}$.

■

By the claim and induction on k, $\mathbf{U}^k$ is upper triangular with diagonal entries $\lambda_1^k, \dots, \lambda_n^k$ (for $k = 0$, $\mathbf{U}^0 = \mathbf{I}$). Writing $q = \sum_k a_k x^k$, the claim again shows that $q(\mathbf{U}) = \sum_k a_k \mathbf{U}^k$ is upper triangular with diagonal entries $\sum_k a_k \lambda_i^k = q(\lambda_i)$. By Corollary 3.6.3, $[q(T)]_{\mathcal{B}} = q(\mathbf{U})$, so by Definition 6.10.2 and the examples after Definition 6.10.1,

$$p_{q(T)} = p_{q(\mathbf{U})} = \prod_{i=1}^{n} \big(x - q(\lambda_i)\big).$$

For the spectra: by Theorem 8.2.1, $\mu \in F$ is an eigenvalue of $q(T)$ if and only if $p_{q(T)}(\mu) = \prod_i (\mu - q(\lambda_i)) = 0$, that is, if and only if $\mu = q(\lambda_i)$ for some i, since a product of non-zero field elements is non-zero. The λ_i are exactly the eigenvalues of T, each listed at least once (Theorem 8.2.1). Hence $\operatorname{spec}(q(T)) = \{q(\lambda) : \lambda \in \operatorname{spec}(T)\}$. Over $\mathbb{C}$, p_T always splits by Corollary 5.5.5.

■

The formula for $p_{q(T)}$ carries more than the spectrum. The algebraic multiplicity of μ as an eigenvalue of $q(T)$ is the number of indices i with $q(\lambda_i) = \mu$ (Lemma 5.4.1), so several eigenvalues of T can merge into one eigenvalue of $q(T)$, and their multiplicities add. Combined with Theorem 8.3.3, applied to $q(T)$, whose characteristic polynomial splits by the theorem, we get the most used consequence.

Corollary 8.10.2 — Trace and Determinant of a Polynomial in T

Under the hypotheses of Theorem 8.10.1, for every $q \in F[x]$,

$$\operatorname{tr} q(T) = q(\lambda_1) + \cdots + q(\lambda_n), \qquad \det q(T) = q(\lambda_1) \cdots q(\lambda_n).$$

In particular $\operatorname{tr} T^k = \lambda_1^k + \cdots + \lambda_n^k$ for every $k \in \mathbb{N}$.

Proof. By Theorem 8.10.1, $p_{q(T)} = \prod_i (x - q(\lambda_i))$ splits. Group equal values: if $\mu_1, \dots, \mu_s$ are the distinct values among the $q(\lambda_i)$, then μ_j occurs exactly $a_{q(T)}(\mu_j)$ times in the list (Lemma 5.4.1). By Theorem 8.3.3 applied to $q(T)$, $\operatorname{tr} q(T) = \sum_j a_{q(T)}(\mu_j)\,\mu_j = \sum_i q(\lambda_i)$ and $\det q(T) = \prod_j \mu_j^{\,a_{q(T)}(\mu_j)} = \prod_i q(\lambda_i)$. Take $q = x^k$ for the last statement. ∎

Example. (A Polynomial in a Non-Diagonalizable Matrix)

Let $\mathbf{A} = \begin{pmatrix} 1 & 1 & 1 \\ 2 & 0 & 1 \\ -3 & 3 & 2 \end{pmatrix} \in M_3(\mathbb{R})$, for which Exercise (B1: Diagonalize or show impossible) found $p_{\mathbf{A}} = (x+1)(x-2)^2$ and showed that $\mathbf{A}$ is not diagonalizable. Without computing any eigenvectors, find $p_{\mathbf{A}^2}$, $\operatorname{tr} \mathbf{A}^2$ and $\det \mathbf{A}^2$. Then find $p_{q(\mathbf{A})}$ for $q = x^2 - x - 2$, and decide whether $q(\mathbf{A}) = 0$.

Solution. *The square.* $p_{\mathbf{A}}$ splits over $\mathbb{R}$ with the list $\lambda_1 = -1$, $\lambda_2 = \lambda_3 = 2$. By Theorem 8.10.1 with $q = x^2$, the list for $\mathbf{A}^2$ is $1, 4, 4$, so

$$p_{\mathbf{A}^2} = (x-1)(x-4)^2, \qquad \operatorname{tr} \mathbf{A}^2 = 1 + 4 + 4 = 9, \qquad \det \mathbf{A}^2 = 1 \cdot 4 \cdot 4 = 16$$

by Corollary 8.10.2. *Check.* Multiplying out,

$$\mathbf{A}^2 = \begin{pmatrix} 0 & 4 & 4 \\ -1 & 5 & 4 \\ -3 & 3 & 4 \end{pmatrix},$$

whose trace is $0 + 5 + 4 = 9$; and $\det \mathbf{A} = (-1) \cdot 2 \cdot 2 = -4$ by Theorem 8.3.3, so $\det \mathbf{A}^2 = (\det \mathbf{A})^2 = 16$ by Theorem 6.5.4.

The polynomial q. Here $q = (x-2)(x+1)$, so $q(-1) = 0$ and $q(2) = 0$. The list for $q(\mathbf{A})$ is $0, 0, 0$, and $p_{q(\mathbf{A})} = x^3$: the only eigenvalue of $q(\mathbf{A})$ is 0. Yet $q(\mathbf{A}) \neq 0$. Indeed

$$q(\mathbf{A}) = \mathbf{A}^2 - \mathbf{A} - 2\mathbf{I} = \begin{pmatrix} -3 & 3 & 3 \\ -3 & 3 & 3 \\ 0 & 0 & 0 \end{pmatrix},$$

and one checks $q(\mathbf{A})^2 = 0$. The spectral mapping theorem sees only eigenvalues, and a non-zero matrix can have 0 as its only eigenvalue. That $q(\mathbf{A}) \neq 0$ here is no accident: if $q(\mathbf{A}) = 0$, the minimal polynomial of $\mathbf{A}$ would divide (Theorem 8.5.1) $(x-2)(x+1)$, which has distinct roots, and $\mathbf{A}$ would be diagonalizable by Theorem 8.8.2.

Warning. **Without splitting, spectral mapping fails.** For the real rotation $\mathbf{R}$ above, $\operatorname{spec}(\mathbf{R}) = \varnothing$ in $\mathbb{R}$, so $q(\operatorname{spec}(\mathbf{R})) = \varnothing$ for $q = x^2$, while $\operatorname{spec}(\mathbf{R}^2) = \operatorname{spec}(-\mathbf{I}) = \{-1\}$. Over $\mathbb{C}$ the theorem is restored: $\operatorname{spec}(\mathbf{R}) = \{i, -i\}$, both square to -1, and $p_{\mathbf{R}^2} = (x+1)^2$. Also, the theorem is about eigenvalues and algebraic multiplicities only: $\mathbf{A} = \operatorname{diag}(1, -1)$ has two one-dimensional eigenspaces, while $\mathbf{A}^2 = \mathbf{I}$ has the single eigenspace $\mathbb{R}^2$.

Quick check. Let $\mathbf{A} \in M_2(\mathbb{C})$ have eigenvalues i and $-i$. Find $p_{\mathbf{A}^2}$ and $\det(\mathbf{A}^2 + \mathbf{I})$.

Solution. The list for $\mathbf{A}$ is $i, -i$ (two distinct roots of the degree-2 polynomial $p_{\mathbf{A}}$). By Theorem 8.10.1 with $q = x^2$, the list for $\mathbf{A}^2$ is $-1, -1$, so $p_{\mathbf{A}^2} = (x+1)^2$. With $q = x^2+1$, Corollary 8.10.2 gives $\det(\mathbf{A}^2 + \mathbf{I}) = q(i)\,q(-i) = 0 \cdot 0 = 0$.

8.10.2 Traces of powers detect nilpotency

Chapter 7 proved, in Exercise (C2: When $\mathbf{A}$ commutes with $[\mathbf{A}, \mathbf{B}]$), that a matrix $\mathbf{C}$ over a field of characteristic 0 with $\operatorname{tr} \mathbf{C}^k = 0$ for every $k \geq 1$ is nilpotent, by a careful argument with annihilating polynomials that gave no reason for the result. Here is the view through eigenvalues, for complex matrices. The traces of the powers are the **power sums** $\lambda_1^k + \cdots + \lambda_n^k$ of the eigenvalues (Corollary 8.10.2), and a nilpotent matrix is one whose eigenvalues are all 0. So the question becomes: if all power sums of n complex numbers vanish, must the numbers vanish? A Vandermonde determinant says yes.

Theorem 8.10.3 — Nilpotent Matrices via Eigenvalues and Traces

Let $n \geq 1$ and $\mathbf{A} \in M_n(\mathbb{C})$. The following are equivalent:

(a) $\mathbf{A}$ is nilpotent, that is, $\mathbf{A}^s = 0$ for some $s \geq 1$;
(b) $\operatorname{spec}(\mathbf{A}) = \{0\}$;
(c) $p_{\mathbf{A}} = x^n$;
(d) $\mathbf{A}^n = 0$;
(e) $\operatorname{tr} \mathbf{A}^k = 0$ for $k = 1, 2, \ldots, n$.

The same holds for $\mathbf{A} \in M_n(F)$ when F is a subfield of $\mathbb{C}$, such as $\mathbb{Q}$ or $\mathbb{R}$, with $\operatorname{spec}(\mathbf{A})$ in (b) taken over $\mathbb{C}$.

Idea. **Plan:** (a) $\Rightarrow$ (b) $\Rightarrow$ (c) $\Rightarrow$ (d) $\Rightarrow$ (a), and (c) $\Rightarrow$ (e) $\Rightarrow$ (b). All but one arrow are short. For (e) $\Rightarrow$ (b), suppose some eigenvalue is non-zero. Group the non-zero eigenvalues into distinct values $\mu_1, \ldots, \mu_r$ with multiplicities $m_1, \ldots, m_r \geq 1$. The vanishing traces say $\sum_j m_j \mu_j^k = 0$ for $k = 1, \ldots, r$: a square linear system for the vector $(m_1, \ldots, m_r)$, whose matrix is a Vandermonde matrix times the invertible $\operatorname{diag}(\mu_j)$. So the m_j would be 0, but they are positive integers, and positive integers are non-zero in $\mathbb{C}$.

Proof.

(a) $\Rightarrow$ (b). This is Exercise (C2: Nilpotent operators) (a), applied to $T_{\mathbf{A}}$ on $\mathbb{C}^n \neq \{\mathbf{0}\}$.

(b) $\Rightarrow$ (c). By Corollary 5.5.5, $p_{\mathbf{A}} = (x - z_1) \cdots (x - z_n)$ with $z_i \in \mathbb{C}$. Each z_i is an eigenvalue (Theorem 8.2.1), hence 0, so $p_{\mathbf{A}} = x^n$.

(c) $\Rightarrow$ (d). By Corollary 8.7.3, $\mathbf{A} = \mathbf{P}\mathbf{U}\mathbf{P}^{-1}$ with $\mathbf{P}$ invertible and $\mathbf{U}$ upper triangular, and by Theorem 8.7.4 the diagonal entries of $\mathbf{U}$ are the roots of $p_{\mathbf{A}} = x^n$, all 0. Then $\mathbf{U}\mathbf{e}_1 = \mathbf{0}$ and $\mathbf{U}\mathbf{e}_j \in \operatorname{span}(\mathbf{e}_1, \ldots, \mathbf{e}_{j-1})$ for $j \geq 2$, since column j of $\mathbf{U}$ has zeros from row j down. By induction on j, $\mathbf{U}^j \mathbf{e}_j = \mathbf{0}$, hence $\mathbf{U}^n \mathbf{e}_j = \mathbf{U}^{n-j}\mathbf{U}^j \mathbf{e}_j = \mathbf{0}$ for every j, and $\mathbf{U}^n = 0$. By Proposition 3.7.6 (c), $\mathbf{A}^n = \mathbf{P}\mathbf{U}^n\mathbf{P}^{-1} = 0$.

(d) $\Rightarrow$ (a). Take $s = n$.

(e) $\Rightarrow$ (e). The list of eigenvalues of $\mathbf{A}$ with multiplicity is $0, \ldots, 0$, so by Corol-

lary 8.10.2, $\operatorname{tr}\mathbf{A}^k = 0^k + \cdots + 0^k = 0$ for every $k \geq 1$.

(f) $\Rightarrow$ (b). By Corollary 5.5.5, $p_{\mathbf{A}}$ splits; let $\lambda_1, \ldots, \lambda_n$ be the list of its roots with multiplicity. Since $n \geq 1$, $\operatorname{spec}(\mathbf{A})$ is non-empty, so it suffices to show that every $\lambda_i = 0$. Suppose not, let $\mu_1, \ldots, \mu_r$ $(1 \leq r \leq n)$ be the distinct non-zero values among the λ_i, and let $m_j \geq 1$ be the number of indices i with $\lambda_i = \mu_j$. For $1 \leq k \leq r$, the zero eigenvalues contribute $0^k = 0$, so by Corollary 8.10.2 and (e),

$$\sum_{j=1}^{r} m_j \, \mu_j^k = \operatorname{tr}\mathbf{A}^k = 0.$$

In matrix form, $\mathbf{W}\mathbf{m} = \mathbf{0}$, where $\mathbf{m} = (m_1, \ldots, m_r) \in \mathbb{C}^r$ and $\mathbf{W} \in M_r(\mathbb{C})$ has (k, j)-entry $\mu_j^k = \mu_j^{k-1}\mu_j$. Hence $\mathbf{W} = V(\mu_1, \ldots, \mu_r)^{\top} \operatorname{diag}(\mu_1, \ldots, \mu_r)$, where $V(\mu_1, \ldots, \mu_r)$ is the Vandermonde matrix with (j, k)-entry μ_j^{k-1} (Theorem 6.8.1). The μ_j are distinct, so V is invertible (Corollary 6.8.2), and so is $V^{\top}$, with inverse $(V^{-1})^{\top}$ (Theorem 0.9.5). The μ_j are non-zero, so $\operatorname{diag}(\mu_1, \ldots, \mu_r)$ is invertible. Therefore $\mathbf{W}$ is invertible, and $\mathbf{m} = \mathbf{W}^{-1}\mathbf{0} = \mathbf{0}$. But m_1 is a positive integer, and $m_1 \neq 0$ in $\mathbb{C}$. This contradiction shows that every $\lambda_i = 0$, so $\operatorname{spec}(\mathbf{A}) = \{0\}$.

For a subfield $F \subseteq \mathbb{C}$, regard $\mathbf{A}$ as a complex matrix. Its powers, their traces, its characteristic polynomial and the condition $\mathbf{A}^s = 0$ are computed by the same arithmetic in F and in $\mathbb{C}$, so (a), (c), (d) and (e) mean the same thing over F and over $\mathbb{C}$, and the equivalences carry over.

■

In the setting of Exercise (C2: When $\mathbf{A}$ commutes with $[\mathbf{A}, \mathbf{B}]$), where $\mathbf{C} = [\mathbf{A}, \mathbf{B}]$ commutes with $\mathbf{A}$, part (a) of that exercise gives $\operatorname{tr}\mathbf{C}^k = 0$ for all $k \geq 1$, and for complex matrices the theorem now shows at once that $\mathbf{C}^n = 0$. That exercise remains the route for a general field of characteristic 0.

Warning. **The characteristic matters.** Over $\mathbb{F}_p$, the identity $\mathbf{I}_p \in M_p(\mathbb{F}_p)$ has $\operatorname{tr}\mathbf{I}_p^k = p \cdot 1 = 0$ for every k, yet $\mathbf{I}_p^k = \mathbf{I}_p \neq 0$. The proof above breaks exactly where it used that the positive integer m_1 is non-zero in the field: here the multiplicity $m_1 = p$ of the eigenvalue 1 is 0 in $\mathbb{F}_p$.

8.10.3 AB and BA

Chapter 6, in Exercise (B3: **AB** and **BA**), showed that $p_{\mathbf{AB}} = p_{\mathbf{BA}}$ for square $\mathbf{A}$ and $\mathbf{B}$ **when $\mathbf{A}$ is invertible**, because then $\mathbf{BA} = \mathbf{A}^{-1}(\mathbf{AB})\mathbf{A}$ is similar to $\mathbf{AB}$. Without invertibility the two products need not be similar, and for rectangular $\mathbf{A}$ and $\mathbf{B}$ they do not even have the same size: if $\mathbf{A}$ is $m \times n$ and $\mathbf{B}$ is $n \times m$, then $\mathbf{AB}$ is $m \times m$ and $\mathbf{BA}$ is $n \times n$. Their characteristic polynomials have degrees m and n. Multiplying by powers of x repairs the degrees, and the identity then holds in general.

Theorem 8.10.4 — AB and BA Have the Same Non-zero Eigenvalues

Let $m, n \geq 1$, $\mathbf{A} \in M_{m\times n}(F)$ and $\mathbf{B} \in M_{n\times m}(F)$. Then

$$x^n\, p_{\mathbf{AB}}(x) = x^m\, p_{\mathbf{BA}}(x).$$

Consequently:

(a) for every $\lambda \neq 0$ in F, $a_{\mathbf{AB}}(\lambda) = a_{\mathbf{BA}}(\lambda)$; in particular $\mathbf{AB}$ and $\mathbf{BA}$ have the same non-zero eigenvalues;

(b) if $m = n$, then $p_{\mathbf{AB}} = p_{\mathbf{BA}}$; and if $m \geq n$, then $p_{\mathbf{AB}} = x^{m-n}\, p_{\mathbf{BA}}$.

Idea. We want one big matrix that "contains" $\mathbf{AB}$ and another that "contains" $\mathbf{BA}$, and that are similar to each other. Put them in $(m+n)\times(m+n)$ block form:

$$\mathbf{M} = \begin{pmatrix} \mathbf{AB} & 0 \\ \mathbf{B} & 0 \end{pmatrix}, \qquad \mathbf{N} = \begin{pmatrix} 0 & 0 \\ \mathbf{B} & \mathbf{BA} \end{pmatrix}.$$

Both are block triangular, so their characteristic polynomials are $p_{\mathbf{AB}} \cdot x^n$ and $x^m \cdot p_{\mathbf{BA}}$. The invertible block matrix $\mathbf{S} = \begin{pmatrix} \mathbf{I}_m & \mathbf{A} \\ 0 & \mathbf{I}_n \end{pmatrix}$ turns one into the other: $\mathbf{MS}$ and $\mathbf{SN}$ are both $\begin{pmatrix} \mathbf{AB} & \mathbf{ABA} \\ \mathbf{B} & \mathbf{BA} \end{pmatrix}$.

Proof. Let $\mathbf{M}, \mathbf{N}, \mathbf{S} \in M_{m+n}(F)$ be the block matrices displayed in the Idea, partitioned by m, n in rows and columns. By Theorem 7.1.1,

$$\mathbf{MS} = \begin{pmatrix} \mathbf{AB}\cdot\mathbf{I}_m + 0 & \mathbf{AB}\cdot\mathbf{A} + 0 \\ \mathbf{B}\cdot\mathbf{I}_m + 0 & \mathbf{B}\cdot\mathbf{A} + 0 \end{pmatrix} = \begin{pmatrix} \mathbf{AB} & \mathbf{ABA} \\ \mathbf{B} & \mathbf{BA} \end{pmatrix},$$
$$\mathbf{SN} = \begin{pmatrix} 0 + \mathbf{AB} & 0 + \mathbf{A}\cdot\mathbf{BA} \\ 0 + \mathbf{B} & 0 + \mathbf{BA} \end{pmatrix} = \begin{pmatrix} \mathbf{AB} & \mathbf{ABA} \\ \mathbf{B} & \mathbf{BA} \end{pmatrix},$$

using associativity (Theorem 0.9.4). So $\mathbf{MS} = \mathbf{SN}$. The matrix $\mathbf{S}$ is invertible: by Theorem 7.1.1, $\begin{pmatrix} \mathbf{I}_m & \mathbf{A} \\ 0 & \mathbf{I}_n \end{pmatrix}\begin{pmatrix} \mathbf{I}_m & -\mathbf{A} \\ 0 & \mathbf{I}_n \end{pmatrix} = \begin{pmatrix} \mathbf{I}_m & -\mathbf{A}+\mathbf{A} \\ 0 & \mathbf{I}_n \end{pmatrix} = \mathbf{I}_{m+n}$, and Theorem 2.4.5 applies. Hence $\mathbf{S}^{-1}\mathbf{MS} = \mathbf{N}$, and $p_{\mathbf{M}} = p_{\mathbf{N}}$ by Theorem 6.10.3.

Now compute both sides. The matrix $x\mathbf{I}_{m+n} - \mathbf{M} = \begin{pmatrix} x\mathbf{I}_m - \mathbf{AB} & 0 \\ -\mathbf{B} & x\mathbf{I}_n \end{pmatrix}$ is lower block triangular with square diagonal blocks, so by Theorem 6.8.4, which holds over the commutative ring $F[x]$ (the remarks before Example (A 3×3 Characteristic Polynomial)), and by Theorem 6.4.6 for $x\mathbf{I}_n$,

$$p_{\mathbf{M}}(x) = \det(x\mathbf{I}_m - \mathbf{AB})\, \det(x\mathbf{I}_n) = p_{\mathbf{AB}}(x)\, x^n.$$

Likewise $x\mathbf{I}_{m+n} - \mathbf{N} = \begin{pmatrix} x\mathbf{I}_m & 0 \\ -\mathbf{B} & x\mathbf{I}_n - \mathbf{BA} \end{pmatrix}$ gives $p_{\mathbf{N}}(x) = x^m\, p_{\mathbf{BA}}(x)$. Since $p_{\mathbf{M}} = p_{\mathbf{N}}$, this proves $x^n p_{\mathbf{AB}} = x^m p_{\mathbf{BA}}$.

(a) Let $\lambda \neq 0$. Then λ is not a root of x^n, so $\mathrm{mult}_\lambda(x^n) = 0$, and similarly for x^m. By Theorem 5.4.2,

$$a_{\mathbf{AB}}(\lambda) = \mathrm{mult}_\lambda(x^n p_{\mathbf{AB}}) = \mathrm{mult}_\lambda(x^m p_{\mathbf{BA}}) = a_{\mathbf{BA}}(\lambda).$$

A scalar is an eigenvalue exactly when its algebraic multiplicity is positive (Theorem 8.2.1, Definition 5.4.1), so the non-zero eigenvalues agree.

(b) If $m \geq n$, then $x^n p_{\mathbf{AB}} = x^n\big(x^{m-n} p_{\mathbf{BA}}\big)$, and canceling the non-zero polynomial x^n (Corollary 0.8.4) gives $p_{\mathbf{AB}} = x^{m-n} p_{\mathbf{BA}}$. For $m = n$ this is $p_{\mathbf{AB}} = p_{\mathbf{BA}}$.

■

This pays off the promise of Exercise (B3: **AB** and **BA**): $p_{\mathbf{AB}} = p_{\mathbf{BA}}$ for **all** square $\mathbf{A}$ and $\mathbf{B}$, invertible or not. Comparing coefficients (Theorem 6.10.2) recovers $\operatorname{tr}(\mathbf{AB}) = \operatorname{tr}(\mathbf{BA})$ and $\det(\mathbf{AB}) = \det(\mathbf{BA})$ once more.

The eigenvectors travel between the two products as well, and by hand. If $\mathbf{ABw} = \lambda\mathbf{w}$ with $\lambda \neq 0$, then

$$\mathbf{BA}(\mathbf{Bw}) = \mathbf{B}(\mathbf{ABw}) = \lambda\,\mathbf{Bw},$$

and $\mathbf{Bw} \neq \mathbf{0}$, since $\mathbf{A}(\mathbf{Bw}) = \lambda\mathbf{w} \neq \mathbf{0}$. So $\mathbf{Bw}$ is an eigenvector of $\mathbf{BA}$ for the same λ: multiplying an eigenvector of $\mathbf{AB}$ by $\mathbf{B}$ produces one of $\mathbf{BA}$. For $\lambda = 0$ the recipe can fail, because $\mathbf{Bw}$ may be $\mathbf{0}$ — which is the warning below in another guise.

A rank-one example. Let $\mathbf{u}, \mathbf{v} \in F^n$ with $n \geq 2$. Take $\mathbf{A} = \mathbf{u} \in M_{n\times 1}(F)$ and $\mathbf{B} = \mathbf{v}^{\top} \in M_{1\times n}(F)$. Then $\mathbf{AB} = \mathbf{uv}^{\top}$ is $n \times n$, and $\mathbf{BA} = \mathbf{v}^{\top}\mathbf{u}$ is the 1×1 matrix whose entry is the number $c = \mathbf{v}^{\top}\mathbf{u}$, so $p_{\mathbf{BA}} = x - c$. Applying the theorem with its m equal to our n, and its n equal to 1, gives $x\,p_{\mathbf{uv}^{\top}} = x^n(x - c)$, and canceling x,

$$p_{\mathbf{uv}^{\top}}(x) = x^{n-1}\,(x - \mathbf{v}^{\top}\mathbf{u}).$$

For instance, the all-ones matrix $\mathbf{1}\mathbf{1}^{\top} \in M_n(\mathbb{R})$, with $\mathbf{1} = (1, \ldots, 1)$, has $p = x^{n-1}(x - n)$: eigenvalue 0 with multiplicity $n-1$, and eigenvalue n. Evaluating at -1 recovers Theorem 6.8.5: $\det(\mathbf{I}+\mathbf{uv}^{\top}) = (-1)^n \det(-\mathbf{I}-\mathbf{uv}^{\top}) = (-1)^n\, p_{\mathbf{uv}^{\top}}(-1) = (-1)^n(-1)^{n-1}(-1-\mathbf{v}^{\top}\mathbf{u}) = 1+\mathbf{v}^{\top}\mathbf{u}$.

Warning. **The zero eigenvalue behaves differently, and AB need not be similar to BA.** Take $\mathbf{A} = \mathbf{E}_{12}$ and $\mathbf{B} = \mathbf{E}_{11}$ in $M_2(F)$. Then $\mathbf{AB} = \mathbf{E}_{12}\mathbf{E}_{11} = 0$ and $\mathbf{BA} = \mathbf{E}_{11}\mathbf{E}_{12} = \mathbf{E}_{12}$. Both have $p = x^2$, as the theorem demands. But $g_{\mathbf{AB}}(0) = 2$ while $g_{\mathbf{BA}}(0) = 1$, and $\mathbf{AB} = 0$ is similar only to 0, so $\mathbf{AB} \not\sim \mathbf{BA}$. For rectangular matrices even the algebraic multiplicities of 0 differ, by $|m - n|$.

Quick check. Let $\mathbf{A} \in M_{2\times 5}(\mathbb{R})$ and $\mathbf{B} \in M_{5\times 2}(\mathbb{R})$ with $p_{\mathbf{AB}} = x^2 - 3x + 2$. What is $p_{\mathbf{BA}}$, and what are $\operatorname{tr}(\mathbf{BA})$ and $\det(\mathbf{BA})$?

Solution. By Theorem 8.10.4 with $m = 2$, $n = 5$, $x^5 p_{\mathbf{AB}} = x^2 p_{\mathbf{BA}}$, so $p_{\mathbf{BA}} = x^3(x^2 - 3x + 2) = x^5 - 3x^4 + 2x^3$. By Theorem 6.10.2, $\operatorname{tr}(\mathbf{BA}) = 3$ (equal to $\operatorname{tr}(\mathbf{AB})$), and $\det(\mathbf{BA}) = (-1)^5 \cdot 0 = 0$, as it must be, since $\mathbf{BA}$ has rank at most $2 < 5$.

8.10.4 Left eigenvectors

An eigenvector multiplies $\mathbf{A}$ from the right: $\mathbf{Av} = \lambda\mathbf{v}$. Row vectors can multiply from the left, and in applications, especially Markov chains, the row version is often the one with a meaning.

A left eigenvector is a row that $\mathbf{A}$ *only stretches when it acts from the right of the row.*

Definition 8.10.1 — Left Eigenvector

Let $\mathbf{A} \in M_n(F)$ and $\lambda \in F$. A **left eigenvector** of $\mathbf{A}$ for λ is a **non-zero** $\mathbf{y} \in F^n$ with

$$\mathbf{y}^\top \mathbf{A} = \lambda \mathbf{y}^\top.$$

To distinguish them, the eigenvectors of Definition 8.2.1 are also called **right eigenvectors**.

In words: $\mathbf{y}^\top$ is a $1 \times n$ row, $\mathbf{y}^\top \mathbf{A}$ is again a row, and we ask that it be a multiple of $\mathbf{y}^\top$. For example, $\mathbf{A} = \begin{pmatrix} 1 & 2 \\ 3 & 2 \end{pmatrix}$ and $\mathbf{y} = (1, 1)$ give $\mathbf{y}^\top \mathbf{A} = \begin{pmatrix} 4 & 4 \end{pmatrix} = 4\mathbf{y}^\top$, so $(1, 1)$ is a left eigenvector for 4, whereas the right eigenvectors for 4 are the multiples of $(2, 3)$ (Example (Eigenvalues and Eigenspaces of a 2×2 Matrix)). For a diagonal matrix, $\mathbf{e}_i$ is both a left and a right eigenvector for the i-th diagonal entry. And $\mathbf{y} = \mathbf{0}$ always satisfies the equation, which is why it is excluded, exactly as for right eigenvectors.

Non-example by minimal change. For the same $\mathbf{A}$, change $\mathbf{y} = (1, 1)$ to $\mathbf{y} = (1, -1)$. Then $\mathbf{y}^\top \mathbf{A} = \begin{pmatrix} 1-3 & 2-2 \end{pmatrix} = \begin{pmatrix} -2 & 0 \end{pmatrix}$, which is not a multiple of $\begin{pmatrix} 1 & -1 \end{pmatrix}$: the row is non-zero, but the defining equation $\mathbf{y}^\top \mathbf{A} = \lambda \mathbf{y}^\top$ has no solution λ. Note that $(1, -1)$ **is** a right eigenvector of $\mathbf{A}$, for -1; the two notions do not agree.

Transposing turns the definition into one we know.

Proposition 8.10.5 — Left Eigenvectors Are Eigenvectors of the Transpose

Let $\mathbf{A} \in M_n(F)$ and $\lambda \in F$.

(a) $\mathbf{y}$ is a left eigenvector of $\mathbf{A}$ for λ if and only if $\mathbf{y}$ is an eigenvector of $\mathbf{A}^\top$ for λ.

(b) $\mathbf{A}$ has a left eigenvector for λ if and only if $\lambda \in \operatorname{spec}(\mathbf{A})$. Moreover $p_{\mathbf{A}^\top} = p_{\mathbf{A}}$, and $a_{\mathbf{A}^\top}(\lambda) = a_{\mathbf{A}}(\lambda)$, $g_{\mathbf{A}^\top}(\lambda) = g_{\mathbf{A}}(\lambda)$.

Proof.

(a) By Theorem 0.9.5, $(\mathbf{y}^\top \mathbf{A})^\top = \mathbf{A}^\top \mathbf{y}$ and $(\lambda \mathbf{y}^\top)^\top = \lambda \mathbf{y}$. Since transposing twice gives back the original, $\mathbf{y}^\top \mathbf{A} = \lambda \mathbf{y}^\top$ if and only if $\mathbf{A}^\top \mathbf{y} = \lambda \mathbf{y}$.

(b) By Exercise (B2: Transpose), $p_{\mathbf{A}^\top} = p_{\mathbf{A}}$, so $a_{\mathbf{A}^\top}(\lambda) = a_{\mathbf{A}}(\lambda)$, and $\operatorname{spec}(\mathbf{A}^\top) = \operatorname{spec}(\mathbf{A})$ by Theorem 8.2.1. With (a), $\mathbf{A}$ has a left eigenvector for λ if and only if $\lambda \in \operatorname{spec}(\mathbf{A}^\top) = \operatorname{spec}(\mathbf{A})$. Finally, $\mathbf{A}^\top - \lambda \mathbf{I} = (\mathbf{A} - \lambda \mathbf{I})^\top$, which has the same rank as $\mathbf{A} - \lambda \mathbf{I}$ (Theorem 2.5.5), so by Theorem 2.5.7, $g_{\mathbf{A}^\top}(\lambda) = n - \operatorname{rank}(\mathbf{A} - \lambda \mathbf{I})^\top = n - \operatorname{rank}(\mathbf{A} - \lambda \mathbf{I}) = g_{\mathbf{A}}(\lambda)$.

■

Remark. For an operator T on V, left eigenvectors correspond to eigenvectors of the dual map T' on V^* (Chapter 4), whose matrix in the dual bases is the transpose (Theorem 4.4.2): an eigenvector of T' is a functional $\varphi \neq 0$ with $\varphi \circ T = \lambda \varphi$.

Left and right eigenvectors for the **same** eigenvalue are usually unrelated, as $(1, 1)$ and $(2, 3)$

show. For **different** eigenvalues, though, they are always orthogonal in the sense of the plain product $\mathbf{y}^{\top}\mathbf{v}$.

Theorem 8.10.6 — Left and Right Eigenvectors Are Biorthogonal

Let $\mathbf{A} \in M_n(F)$, let $\mathbf{y}$ be a left eigenvector of $\mathbf{A}$ for μ, and let $\mathbf{v}$ be a right eigenvector of $\mathbf{A}$ for λ. If $\lambda \neq \mu$, then $\mathbf{y}^{\top}\mathbf{v} = 0$.

Proof. Compute the 1×1 matrix $\mathbf{y}^{\top}\mathbf{A}\mathbf{v}$ in two ways, using associativity (Theorem 0.9.4):

$$\mu\,\mathbf{y}^{\top}\mathbf{v} = (\mathbf{y}^{\top}\mathbf{A})\mathbf{v} = \mathbf{y}^{\top}\mathbf{A}\mathbf{v} = \mathbf{y}^{\top}(\mathbf{A}\mathbf{v}) = \lambda\,\mathbf{y}^{\top}\mathbf{v}.$$

Hence $(\lambda-\mu)\,\mathbf{y}^{\top}\mathbf{v} = 0$. Since $\lambda - \mu \neq 0$, this forces $\mathbf{y}^{\top}\mathbf{v} = 0$ (Theorem 0.7.1). ∎

For the example, $(1,1)$ is a left eigenvector for 4 and $(1,-1)$ a right eigenvector for -1, and indeed $1-1=0$.

For a diagonalizable matrix the left eigenvectors come for free with the diagonalization, and they give a formula for all powers that we use in Section 11.

Proposition 8.10.7 — Expansion in Left and Right Eigenvectors

Let $\mathbf{A} = \mathbf{P}\mathbf{D}\mathbf{P}^{-1}$ with $\mathbf{P} \in M_n(F)$ invertible and $\mathbf{D} = \operatorname{diag}(\lambda_1,\dots,\lambda_n)$. Let $\mathbf{v}_1,\dots,\mathbf{v}_n$ be the columns of $\mathbf{P}$, and let $\mathbf{y}_1^{\top},\dots,\mathbf{y}_n^{\top}$ be the rows of $\mathbf{P}^{-1}$. Then:

(a) $\mathbf{v}_i$ is a right eigenvector and $\mathbf{y}_i$ a left eigenvector of $\mathbf{A}$ for λ_i;
(b) $\mathbf{y}_i^{\top}\mathbf{v}_j = 1$ if $i = j$ and 0 if $i \neq j$;
(c) for every $q \in F[x]$,

$$q(\mathbf{A}) = \sum_{i=1}^{n} q(\lambda_i)\,\mathbf{v}_i\mathbf{y}_i^{\top}, \qquad \text{in particular} \qquad \mathbf{A}^k = \sum_{i=1}^{n} \lambda_i^k\,\mathbf{v}_i\mathbf{y}_i^{\top} \quad (k \in \mathbb{N}).$$

Proof.

(a) From $\mathbf{A}\mathbf{P} = \mathbf{P}\mathbf{D}$, column i reads $\mathbf{A}\mathbf{v}_i = \lambda_i\mathbf{v}_i$ (Section 4), and $\mathbf{v}_i \neq \mathbf{0}$ because $\mathbf{P}$ is invertible. From $\mathbf{P}^{-1}\mathbf{A} = \mathbf{D}\mathbf{P}^{-1}$, row i reads $\mathbf{y}_i^{\top}\mathbf{A} = \lambda_i\mathbf{y}_i^{\top}$ (Theorem 0.9.2), and $\mathbf{y}_i \neq \mathbf{0}$ because $\mathbf{P}^{-1}$ is invertible.
(b) The (i,j)-entry of $\mathbf{P}^{-1}\mathbf{P} = \mathbf{I}$ is row i of $\mathbf{P}^{-1}$ times column j of $\mathbf{P}$, that is, $\mathbf{y}_i^{\top}\mathbf{v}_j$.
(c) By Theorem 8.4.3, $q(\mathbf{A}) = \mathbf{P}\,q(\mathbf{D})\,\mathbf{P}^{-1}$. The columns of $\mathbf{P}\,q(\mathbf{D})$ are $q(\lambda_i)\mathbf{v}_i$, and the rows of $\mathbf{P}^{-1}$ are $\mathbf{y}_i^{\top}$, so Corollary 7.1.3 gives $q(\mathbf{A}) = \sum_i q(\lambda_i)\mathbf{v}_i\mathbf{y}_i^{\top}$. Take $q = x^k$. ∎

Part (b) is biorthogonality with a normalization: $\mathbf{y}_i^{\top}\mathbf{v}_i = 1$. Part (c) splits $\mathbf{A}$ into rank-one pieces $\mathbf{v}_i\mathbf{y}_i^{\top}$, one per eigenvalue, and each piece is simply multiplied by λ_i^k when $\mathbf{A}$ is raised to the

power k. In the running example, $\mathbf{P} = \begin{pmatrix} 2 & 1 \\ 3 & -1 \end{pmatrix}$ and $\mathbf{D} = \operatorname{diag}(4, -1)$ give $\mathbf{P}^{-1} = \frac{1}{5}\begin{pmatrix} 1 & 1 \\ 3 & -2 \end{pmatrix}$, so $\mathbf{y}_1 = \frac{1}{5}(1, 1)$ and $\mathbf{y}_2 = \frac{1}{5}(3, -2)$, and

$$\mathbf{A}^k = \frac{4^k}{5}\begin{pmatrix} 2 & 2 \\ 3 & 3 \end{pmatrix} + \frac{(-1)^k}{5}\begin{pmatrix} 3 & -2 \\ -3 & 2 \end{pmatrix}.$$

For $k = 1$ this is $\frac{1}{5}\begin{pmatrix} 8-3 & 8+2 \\ 12+3 & 12-2 \end{pmatrix} = \begin{pmatrix} 1 & 2 \\ 3 & 2 \end{pmatrix}$, as it should be.

8.10.5 Exercises

8.10.5.1 A. Check your understanding

Exercise A1.

(a) State the Spectral Mapping Theorem, including its hypothesis on p_T.

(b) True or false: for every $\mathbf{A} \in M_n(\mathbb{R})$, every real eigenvalue of $\mathbf{A}^2$ is the square of a real eigenvalue of $\mathbf{A}$. Justify your answer.

(c) True or false: if $\mathbf{A} \in M_{2\times 3}(F)$ and $\mathbf{B} \in M_{3\times 2}(F)$, then $p_{\mathbf{AB}} = p_{\mathbf{BA}}$. Justify your answer.

(d) True or false: for all $\mathbf{A}, \mathbf{B} \in M_n(F)$, $\mathbf{AB}$ is similar to $\mathbf{BA}$. Justify your answer.

(e) Define a left eigenvector of $\mathbf{A} \in M_n(F)$, and say how left eigenvectors of $\mathbf{A}$ are related to $\mathbf{A}^\top$.

(f) True or false: a matrix $\mathbf{A} \in M_3(\mathbb{C})$ with $\operatorname{tr}\mathbf{A} = \operatorname{tr}\mathbf{A}^2 = \operatorname{tr}\mathbf{A}^3 = 0$ satisfies $\mathbf{A}^3 = 0$. Justify your answer.

Solution.

(a) If V is finite-dimensional with $\dim V = n \geq 1$, $T \in \mathcal{L}(V)$, and $p_T = \prod_{i=1}^{n}(x - \lambda_i)$ splits over F, then for every $q \in F[x]$, $p_{q(T)} = \prod_i (x - q(\lambda_i))$ and $\operatorname{spec}(q(T)) = q(\operatorname{spec}(T))$ (Theorem 8.10.1).

(b) False. The rotation $\mathbf{R} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$ has no real eigenvalue, while $\mathbf{R}^2 = -\mathbf{I}$ has the real eigenvalue -1.

(c) False. They have different degrees, 2 and 3. The correct identity is $x^3 p_{\mathbf{AB}} = x^2 p_{\mathbf{BA}}$, that is, $p_{\mathbf{BA}} = x\, p_{\mathbf{AB}}$ (Theorem 8.10.4).

(d) False. $\mathbf{A} = \mathbf{E}_{12}$, $\mathbf{B} = \mathbf{E}_{11}$ give $\mathbf{AB} = 0$ and $\mathbf{BA} = \mathbf{E}_{12} \neq 0$, and the only matrix similar to 0 is 0.

(e) A non-zero $\mathbf{y} \in F^n$ with $\mathbf{y}^\top \mathbf{A} = \lambda \mathbf{y}^\top$ for some $\lambda \in F$. Equivalently, $\mathbf{y}$ is an eigenvector of $\mathbf{A}^\top$ for λ (Proposition 8.10.5).

(f) True. By Theorem 8.10.3 with $n = 3$, (e) $\Rightarrow$ (d).

8.10.5.2 B. Practice

Exercise B1: Eigenvalues of a polynomial in A.

Let $\mathbf{A} \in M_3(\mathbb{C})$ have $p_{\mathbf{A}} = (x-1)^2(x+2)$.

(a) Find $p_{\mathbf{A}^2+\mathbf{A}+\mathbf{I}}$, $\operatorname{tr}(\mathbf{A}^2+\mathbf{A}+\mathbf{I})$ and $\det(\mathbf{A}^2+\mathbf{A}+\mathbf{I})$. Is $\mathbf{A}^2+\mathbf{A}+\mathbf{I}$ invertible?

(b) Find $p_{\mathbf{A}^2+\mathbf{A}-2\mathbf{I}}$. Hence show that $\mathbf{A}^2+\mathbf{A}-2\mathbf{I}$ is nilpotent.

(c) Find $\operatorname{tr}\mathbf{A}^5$ and $\det(\mathbf{A}^{-1})$.

Solution. The list of eigenvalues of $\mathbf{A}$ with multiplicity is $1, 1, -2$, since $p_{\mathbf{A}}$ splits.

(a) With $q = x^2+x+1$, $q(1) = 3$ and $q(-2) = 4-2+1 = 3$. By Theorem 8.10.1, $p_{q(\mathbf{A})} = (x-3)^3$, and by Corollary 8.10.2, $\operatorname{tr} q(\mathbf{A}) = 9$ and $\det q(\mathbf{A}) = 27 \neq 0$. So $\mathbf{A}^2+\mathbf{A}+\mathbf{I}$ is invertible (Theorem 6.5.3).

(b) With $r = x^2+x-2 = (x-1)(x+2)$, $r(1) = r(-2) = 0$, so $p_{r(\mathbf{A})} = x^3$ by Theorem 8.10.1. By Theorem 8.10.3 ((c) $\Rightarrow$ (d)), $r(\mathbf{A})^3 = 0$, so $\mathbf{A}^2+\mathbf{A}-2\mathbf{I}$ is nilpotent.

(c) By Corollary 8.10.2, $\operatorname{tr}\mathbf{A}^5 = 1+1+(-2)^5 = -30$. Also $\det\mathbf{A} = 1\cdot 1\cdot(-2) = -2 \neq 0$ (Theorem 8.3.3), so $\mathbf{A}$ is invertible and $\det(\mathbf{A}^{-1}) = (\det\mathbf{A})^{-1} = -\frac{1}{2}$ (Corollary 6.5.6).

Exercise B2: AB and BA for a 2×3 example.

Let $\mathbf{A} = \begin{pmatrix} 1 & 0 & 1 \\ 0 & 2 & 0 \end{pmatrix}$ and $\mathbf{B} = \begin{pmatrix} 1 & 0 \\ 0 & -1 \\ 1 & 1 \end{pmatrix}$.

(a) Compute $\mathbf{AB}$, $\mathbf{BA}$, $p_{\mathbf{AB}}$ and $p_{\mathbf{BA}}$, and verify that $x^3 p_{\mathbf{AB}} = x^2 p_{\mathbf{BA}}$.

(b) Hence list the eigenvalues of $\mathbf{BA}$ without further computation, and find an eigenvector of $\mathbf{BA}$ for each non-zero eigenvalue by applying $\mathbf{B}$ to eigenvectors of $\mathbf{AB}$.

Solution.

(a) By row-times-column,

$$\mathbf{AB} = \begin{pmatrix} 2 & 1 \\ 0 & -2 \end{pmatrix}, \qquad \mathbf{BA} = \begin{pmatrix} 1 & 0 & 1 \\ 0 & -2 & 0 \\ 1 & 2 & 1 \end{pmatrix}.$$

$\mathbf{AB}$ is upper triangular, so $p_{\mathbf{AB}} = (x-2)(x+2) = x^2-4$. Expanding $\det(x\mathbf{I}-\mathbf{BA})$ along the second row, whose only non-zero entry is $x+2$ in position $(2,2)$,

$$\begin{aligned} p_{\mathbf{BA}} &= (x+2)\det\begin{pmatrix} x-1 & -1 \\ -1 & x-1 \end{pmatrix} \\ &= (x+2)\big((x-1)^2-1\big) = (x+2)\,x\,(x-2) = x^3-4x. \end{aligned}$$

Then $x^3 p_{\mathbf{AB}} = x^5-4x^3 = x^2(x^3-4x) = x^2 p_{\mathbf{BA}}$.

(b) The eigenvalues of $\mathbf{BA}$ are the roots of $x(x-2)(x+2)$: $0, 2, -2$, matching Theorem 8.10.4 (the non-zero ones are those of $\mathbf{AB}$). If $\mathbf{ABw} = \lambda\mathbf{w}$, then $\mathbf{BA}(\mathbf{Bw}) = \mathbf{B}(\mathbf{ABw}) = \lambda\mathbf{Bw}$, so $\mathbf{Bw}$ is an eigenvector of $\mathbf{BA}$ as long as $\mathbf{Bw} \neq \mathbf{0}$. For $\lambda = 2$: $\mathbf{w} = (1,0)$, $\mathbf{Bw} = (1,0,1)$, and $\mathbf{BA}(1,0,1) = (2,0,2)$. For $\lambda = -2$: $\mathbf{AB}+2\mathbf{I} = \begin{pmatrix} 4 & 1 \\ 0 & 0 \end{pmatrix}$ gives $\mathbf{w} = (1,-4)$, $\mathbf{Bw} = (1,4,-3)$, and $\mathbf{BA}(1,4,-3) = (1-3,-8,1+8-3) = (-2,-8,6) = -2(1,4,-3)$.

Exercise B3: Left eigenvectors of a 2×2 matrix.

Let $\mathbf{A} = \begin{pmatrix} 0 & 1 \\ -6 & 5 \end{pmatrix} \in M_2(\mathbb{R})$, whose right eigenvectors $(1,2)$ for 2 and $(1,3)$ for 3 were found in Exercise (B1: Diagonalize or show impossible).

(a) Find a left eigenvector of $\mathbf{A}$ for each eigenvalue.

(b) Verify Theorem 8.10.6 for these vectors, and rescale the left eigenvectors so that $\mathbf{y}_i^{\top}\mathbf{v}_i = 1$.

(c) Hence write $\mathbf{A}^k$ as a combination of two rank-one matrices, and check the formula for $k = 0$ and $k = 1$.

Solution.

(a) By Proposition 8.10.5, we need eigenvectors of $\mathbf{A}^{\top} = \begin{pmatrix} 0 & -6 \\ 1 & 5 \end{pmatrix}$. For 2: $\mathbf{A}^{\top} - 2\mathbf{I} = \begin{pmatrix} -2 & -6 \\ 1 & 3 \end{pmatrix}$ gives $y_1 = -3y_2$, so $(3,-1)$. For 3: $\mathbf{A}^{\top} - 3\mathbf{I} = \begin{pmatrix} -3 & -6 \\ 1 & 2 \end{pmatrix}$ gives $y_1 = -2y_2$, so $(2,-1)$. Check: $\begin{pmatrix} 3 & -1 \end{pmatrix}\mathbf{A} = \begin{pmatrix} 6 & -2 \end{pmatrix}$ and $\begin{pmatrix} 2 & -1 \end{pmatrix}\mathbf{A} = \begin{pmatrix} 6 & -3 \end{pmatrix}$.

(b) $(3,-1)\cdot(1,3) = 0$ and $(2,-1)\cdot(1,2) = 0$, as the theorem predicts for different eigenvalues. Also $(3,-1)\cdot(1,2) = 1$ and $(2,-1)\cdot(1,3) = -1$, so take $\mathbf{y}_1 = (3,-1)$ and $\mathbf{y}_2 = (-2,1)$.

(c) With $\mathbf{P} = \begin{pmatrix} 1 & 1 \\ 2 & 3 \end{pmatrix}$, the rows of $\mathbf{P}^{-1} = \begin{pmatrix} 3 & -1 \\ -2 & 1 \end{pmatrix}$ are exactly $\mathbf{y}_1^{\top}, \mathbf{y}_2^{\top}$, and by Proposition 8.10.7,

$$\mathbf{A}^k = 2^k \begin{pmatrix} 1 \\ 2 \end{pmatrix} \begin{pmatrix} 3 & -1 \end{pmatrix} + 3^k \begin{pmatrix} 1 \\ 3 \end{pmatrix} \begin{pmatrix} -2 & 1 \end{pmatrix} = 2^k \begin{pmatrix} 3 & -1 \\ 6 & -2 \end{pmatrix} + 3^k \begin{pmatrix} -2 & 1 \\ -6 & 3 \end{pmatrix}.$$

For $k = 0$: $\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$. For $k = 1$: $\begin{pmatrix} 6-6 & -2+3 \\ 12-18 & -4+9 \end{pmatrix} = \begin{pmatrix} 0 & 1 \\ -6 & 5 \end{pmatrix} = \mathbf{A}$.

8.10.5.3 C. Going deeper

Exercise C1: Traces of powers of AB and BA.

Let $\mathbf{A} \in M_{m\times n}(F)$ and $\mathbf{B} \in M_{n\times m}(F)$.

(a) Prove that $\mathbf{B}(\mathbf{AB})^{k-1}\mathbf{A} = (\mathbf{BA})^k$ for every $k \geq 1$, and deduce that $\operatorname{tr}\big((\mathbf{AB})^k\big) = \operatorname{tr}\big((\mathbf{BA})^k\big)$.

(b) Now let $F = \mathbb{C}$. Give a second proof of the trace identity from Theorem 8.10.4 and Corollary 8.10.2.

Solution.

(a) By induction on k. For $k = 1$ both sides are $\mathbf{BA}$. If $\mathbf{B}(\mathbf{AB})^{k-1}\mathbf{A} = (\mathbf{BA})^k$, then by associativity

$$\begin{aligned} \mathbf{B}(\mathbf{AB})^k\mathbf{A} &= \mathbf{B}(\mathbf{AB})^{k-1}(\mathbf{AB})\mathbf{A} = \big(\mathbf{B}(\mathbf{AB})^{k-1}\mathbf{A}\big)(\mathbf{BA}) \\ &= (\mathbf{BA})^k(\mathbf{BA}) = (\mathbf{BA})^{k+1}. \end{aligned}$$

Now $(\mathbf{AB})^k = \mathbf{A}\left(\mathbf{B}(\mathbf{AB})^{k-1}\right)$, with $\mathbf{A}$ of size $m \times n$ and $\mathbf{B}(\mathbf{AB})^{k-1}$ of size $n \times m$. By Theorem 0.9.6 (3),

$$\operatorname{tr}\left((\mathbf{AB})^k\right) = \operatorname{tr}\left(\mathbf{A} \cdot \mathbf{B}(\mathbf{AB})^{k-1}\right) = \operatorname{tr}\left(\mathbf{B}(\mathbf{AB})^{k-1} \cdot \mathbf{A}\right) = \operatorname{tr}\left((\mathbf{BA})^k\right).$$

(b) Over $\mathbb{C}$, $p_{\mathbf{AB}}$ and $p_{\mathbf{BA}}$ split. Suppose $m \geq n$ (otherwise swap the roles of $\mathbf{A}$ and $\mathbf{B}$). By Theorem 8.10.4, $p_{\mathbf{AB}} = x^{m-n} p_{\mathbf{BA}}$, so if $\lambda_1, \ldots, \lambda_n$ is the list of eigenvalues of $\mathbf{BA}$ with multiplicity, then the list for $\mathbf{AB}$ is $\lambda_1, \ldots, \lambda_n$ together with $m - n$ zeros. For $k \geq 1$ the zeros contribute $0^k = 0$, so by Corollary 8.10.2, $\operatorname{tr}\left((\mathbf{AB})^k\right) = \sum_i \lambda_i^k = \operatorname{tr}\left((\mathbf{BA})^k\right)$.

Exercise C2: Adding a commuting nilpotent matrix.

Let $\mathbf{A}, \mathbf{N} \in M_n(\mathbb{C})$, $n \geq 1$, with $\mathbf{AN} = \mathbf{NA}$ and $\mathbf{N}$ nilpotent.

(a) Prove that $p_{\mathbf{A}+\mathbf{N}} = p_{\mathbf{A}}$; in particular $\operatorname{spec}(\mathbf{A}+\mathbf{N}) = \operatorname{spec}(\mathbf{A})$ and $\det(\mathbf{A}+\mathbf{N}) = \det \mathbf{A}$.

(b) Deduce that if $\mathbf{A}$ is invertible, so is $\mathbf{A}+\mathbf{N}$.

(c) Show that (a) fails without $\mathbf{AN} = \mathbf{NA}$.

Hint: triangularize $\mathbf{A}$ *and* $\mathbf{N}$ *together.*

Solution.

(a) By Theorem 8.9.4 there is an invertible $\mathbf{P}$ with $\mathbf{U} = \mathbf{P}^{-1}\mathbf{AP}$ and $\mathbf{U}' = \mathbf{P}^{-1}\mathbf{NP}$ upper triangular. Since $\mathbf{N}$ is nilpotent, $\operatorname{spec}(\mathbf{N}) = \{0\}$ (Exercise (C2: Nilpotent operators)), so every diagonal entry of $\mathbf{U}'$ is 0 by Theorem 8.7.4. Then $\mathbf{P}^{-1}(\mathbf{A}+\mathbf{N})\mathbf{P} = \mathbf{U}+\mathbf{U}'$ is upper triangular with the same diagonal as $\mathbf{U}$. By Theorem 6.10.3 and the examples after Definition 6.10.1,

$$p_{\mathbf{A}+\mathbf{N}} = p_{\mathbf{U}+\mathbf{U}'} = \prod_i (x - u_{ii}) = p_{\mathbf{U}} = p_{\mathbf{A}}.$$

Equal characteristic polynomials have the same roots (Theorem 8.2.1) and the same constant term $(-1)^n \det$ (Theorem 6.10.2).

(b) By (a), $\det(\mathbf{A}+\mathbf{N}) = \det \mathbf{A} \neq 0$, so $\mathbf{A}+\mathbf{N}$ is invertible (Theorem 6.5.3).

(c) Let $\mathbf{A} = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix}$ and $\mathbf{N} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$. Both are nilpotent, so $p_{\mathbf{A}} = x^2$, but $\mathbf{A}+\mathbf{N} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$ has $p = x^2 - 1$ and eigenvalues ± 1. Here $\mathbf{AN} = \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix} \neq \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} = \mathbf{NA}$.

Exercise C3: How many traces, and which field?.

(a) Let $\omega = e^{2\pi i/3} \in \mathbb{C}$ and $\mathbf{C} = \operatorname{diag}(1, \omega, \omega^2)$. Show that $\operatorname{tr} \mathbf{C} = \operatorname{tr} \mathbf{C}^2 = 0$ but $\mathbf{C}$ is not nilpotent. Explain why this does not contradict Theorem 8.10.3.

(b) Let $n \geq 2$. Give a matrix $\mathbf{C} \in M_n(\mathbb{C})$ with $\operatorname{tr} \mathbf{C}^k = 0$ for $k = 1, \ldots, n-1$ that is not nilpotent.

(c) Let $\mathbf{A}, \mathbf{B} \in M_n(\mathbb{C})$ and suppose $\mathbf{C} = \mathbf{AB} - \mathbf{BA}$ commutes with $\mathbf{A}$. Prove that $\mathbf{C}^n = 0$.

(d) Over $\mathbb{F}_2$, find a non-nilpotent $\mathbf{C} \in M_2(\mathbb{F}_2)$ with $\operatorname{tr} \mathbf{C}^k = 0$ for every $k \geq 1$.

Solution.

(a) $\omega^3 = 1$ and $\omega \neq 1$, so $0 = \omega^3 - 1 = (\omega - 1)(\omega^2 + \omega + 1)$ gives $1 + \omega + \omega^2 = 0$. Hence $\operatorname{tr} \mathbf{C} = 1 + \omega + \omega^2 = 0$, and $\operatorname{tr} \mathbf{C}^2 = 1 + \omega^2 + \omega^4 = 1 + \omega^2 + \omega = 0$. But $\mathbf{C}^k = \operatorname{diag}(1, \omega^k, \omega^{2k}) \neq 0$ for every k. No contradiction: the theorem, for $n = 3$, requires $\operatorname{tr} \mathbf{C}^k = 0$ for $k = 1, 2, 3$, and $\operatorname{tr} \mathbf{C}^3 = 1 + 1 + 1 = 3 \neq 0$.

(b) Let $\zeta = e^{2\pi i/n}$ and $\mathbf{C} = \operatorname{diag}(1, \zeta, \dots, \zeta^{n-1})$. For $1 \leq k \leq n-1$, $\zeta^k \neq 1$ and $(\zeta^k)^n = 1$, so $\operatorname{tr} \mathbf{C}^k = \sum_{j=0}^{n-1} (\zeta^k)^j = \frac{(\zeta^k)^n - 1}{\zeta^k - 1} = 0$ by the geometric sum. But $\mathbf{C}^k$ has the entry 1 in position $(1, 1)$ for all k, so $\mathbf{C}$ is not nilpotent.

(c) By Exercise (C2: When $\mathbf{A}$ commutes with $[\mathbf{A}, \mathbf{B}]$) (a), $\operatorname{tr} \mathbf{C}^k = 0$ for every $k \geq 1$, in particular for $k = 1, \dots, n$. By Theorem 8.10.3 ((e) $\Rightarrow$ (d)), $\mathbf{C}^n = 0$.

(d) $\mathbf{C} = \mathbf{I}_2$: $\operatorname{tr} \mathbf{C}^k = 1 + 1 = 0$ in $\mathbb{F}_2$ for every k, and $\mathbf{C}^k = \mathbf{I}_2 \neq 0$.

8.11 Powers, Recurrences and Markov Chains

Section 4 promised that diagonalization is a tool for computation, and the Fibonacci numbers gave a first taste. This section collects three situations in which a quantity evolves in discrete steps by a fixed linear rule: a vector recurrence $\mathbf{x}_{k+1} = \mathbf{A}\mathbf{x}_k$, a scalar recurrence such as $a_{k+3} = 2a_{k+2} + a_{k+1} - 2a_k$, and a system that moves at random between finitely many states. In each case the state after k steps is a matrix power applied to the starting state, and the eigenvalues decide what happens in the long run. We use only the explicit formula $\mathbf{A}^k = \mathbf{P}\mathbf{D}^k\mathbf{P}^{-1}$ and limits of sequences of numbers, one entry at a time.

8.11.1 Vector recurrences

A **linear recurrence** of first order is a rule $\mathbf{x}_{k+1} = \mathbf{A}\mathbf{x}_k$ for $k \in \mathbb{N}$, with $\mathbf{A} \in M_n(F)$ fixed and a starting vector $\mathbf{x}_0 \in F^n$. By induction on k, the unique sequence obeying the rule is $\mathbf{x}_k = \mathbf{A}^k\mathbf{x}_0$. The question is how to see this power, and diagonalization answers it by changing to coordinates in which $\mathbf{A}$ acts coordinate by coordinate.

Theorem 8.11.1 — Solving a Diagonalizable Recurrence

Let $\mathbf{A} \in M_n(F)$ be diagonalizable, with $\mathbf{A} = \mathbf{P}\mathbf{D}\mathbf{P}^{-1}$, $\mathbf{D} = \operatorname{diag}(\lambda_1, \dots, \lambda_n)$, and let $\mathbf{v}_1, \dots, \mathbf{v}_n$ be the columns of $\mathbf{P}$. Let $\mathbf{x}_0 \in F^n$, and let $(c_1, \dots, c_n) = \mathbf{P}^{-1}\mathbf{x}_0$, so that $\mathbf{x}_0 = c_1\mathbf{v}_1 + \cdots + c_n\mathbf{v}_n$. Then the sequence defined by $\mathbf{x}_{k+1} = \mathbf{A}\mathbf{x}_k$ is

$$\mathbf{x}_k = \mathbf{A}^k\mathbf{x}_0 = c_1\lambda_1^k\,\mathbf{v}_1 + c_2\lambda_2^k\,\mathbf{v}_2 + \cdots + c_n\lambda_n^k\,\mathbf{v}_n \qquad (k \in \mathbb{N}).$$

Proof. By induction on k, $\mathbf{x}_k = \mathbf{A}^k\mathbf{x}_0$: this holds for $k = 0$ since $\mathbf{A}^0 = \mathbf{I}$, and $\mathbf{x}_{k+1} = \mathbf{A}\mathbf{x}_k = \mathbf{A} \cdot \mathbf{A}^k\mathbf{x}_0 = \mathbf{A}^{k+1}\mathbf{x}_0$. By Theorem 8.4.3, $\mathbf{A}^k\mathbf{x}_0 = \mathbf{P}\mathbf{D}^k\mathbf{P}^{-1}\mathbf{x}_0 = \mathbf{P}\mathbf{D}^k\mathbf{c}$ with $\mathbf{c} = (c_1, \dots, c_n)$. Now $\mathbf{D}^k\mathbf{c} = (\lambda_1^k c_1, \dots, \lambda_n^k c_n)$, and by Theorem 0.9.3, $\mathbf{P}$ times this

vector is $\sum_i \lambda_i^k c_i \mathbf{v}_i$. Finally, $\mathbf{Pc} = \mathbf{x}_0$ says $\mathbf{x}_0 = \sum_i c_i \mathbf{v}_i$, by the same result.

■

In words: expand the starting vector in a basis of eigenvectors; each coordinate is then multiplied by its own eigenvalue at every step, independently of the others. Over $\mathbb{R}$ or $\mathbb{C}$, where absolute values are available, the long-run behavior is visible at once. Terms with $|\lambda_i| < 1$ die out, terms with $|\lambda_i| > 1$ grow, and the largest $|\lambda_i|$ with $c_i \neq 0$ wins. The worked Fibonacci example (Example (A Closed Formula for the Fibonacci Numbers)) is the case $n = 2$.

8.11.2 Scalar recurrences and companion matrices

A recurrence such as $a_{k+3} = 2a_{k+2} + a_{k+1} - 2a_k$ involves one number sequence but several previous terms. The trick of Example (A Closed Formula for the Fibonacci Numbers) turns it into a vector recurrence: remember the last few terms as one vector.

Let $n \geq 1$ and $c_0, \ldots, c_{n-1} \in F$, and consider sequences $(a_k)_{k \in \mathbb{N}}$ in F with

$$a_{k+n} + c_{n-1}a_{k+n-1} + \cdots + c_1 a_{k+1} + c_0 a_k = 0 \qquad \text{for every } k \in \mathbb{N}. \tag{$*$}$$

Such a sequence is determined by its **initial values** $a_0, \ldots, a_{n-1}$, because $(*)$ computes each later term from the n before it. The polynomial

$$p(x) = x^n + c_{n-1}x^{n-1} + \cdots + c_1 x + c_0$$

is called the **characteristic polynomial of the recurrence**; the name is justified below. Put $\mathbf{x}_k = (a_k, a_{k+1}, \ldots, a_{k+n-1}) \in F^n$. Then $(*)$ says exactly $\mathbf{x}_{k+1} = \mathbf{C}\mathbf{x}_k$, where

$$\mathbf{C} = \begin{pmatrix} 0 & 1 & 0 & \cdots & 0 \\ 0 & 0 & 1 & \cdots & 0 \\ \vdots & & & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & 1 \\ -c_0 & -c_1 & -c_2 & \cdots & -c_{n-1} \end{pmatrix}:$$

the first $n-1$ rows shift the window by one, and the last row is $(*)$ solved for a_{k+n}. For $n \geq 2$, $\mathbf{C}$ is the transpose of the companion matrix $\mathbf{C}(p)$ of Exercise (C1: Companion matrices), so $p_{\mathbf{C}} = p_{\mathbf{C}(p)} = p$ by Exercise (B2: Transpose) and Exercise (C1: Companion matrices) (for $n = 1$, $\mathbf{C} = (-c_0)$ and $p_{\mathbf{C}} = x + c_0 = p$). The eigenvalues of $\mathbf{C}$ are the roots of p.

Theorem 8.11.2 — Scalar Recurrences with Distinct Roots

Let $n \geq 1$, $c_0, \ldots, c_{n-1} \in F$, and suppose $p = x^n + c_{n-1}x^{n-1} + \cdots + c_0$ has n **distinct** roots $\lambda_1, \ldots, \lambda_n \in F$. Then a sequence $(a_k)_{k \in \mathbb{N}}$ in F satisfies $(*)$ if and only if there are $b_1, \ldots, b_n \in F$ with

$$a_k = b_1\lambda_1^k + b_2\lambda_2^k + \cdots + b_n\lambda_n^k \qquad \text{for every } k \in \mathbb{N}.$$

In that case $b_1, \ldots, b_n$ are uniquely determined by the initial values $a_0, \ldots, a_{n-1}$.

Idea. Why powers of the roots? A geometric sequence $a_k = \lambda^k$ satisfies $(*)$ exactly when $\lambda^k p(\lambda) = 0$, so the roots of p give n solutions. To see that there are no others, use the matrix $\mathbf{C}$: its eigenvector for λ_i is the window $(1, \lambda_i, \dots, \lambda_i^{n-1})$ of the geometric sequence, these eigenvectors form an invertible Vandermonde matrix, and Theorem 8.11.1 does the rest.

Proof. $(\Leftarrow)$ For each i and k, $\lambda_i^{k+n} + c_{n-1}\lambda_i^{k+n-1} + \cdots + c_0\lambda_i^k = \lambda_i^k\, p(\lambda_i) = 0$. If $a_k = \sum_i b_i \lambda_i^k$, then the left side of $(*)$ is $\sum_i b_i \cdot 0 = 0$, after regrouping the finite sums.

$(\Rightarrow)$ Let (a_k) satisfy $(*)$, and let $\mathbf{x}_k$ and $\mathbf{C}$ be as above, so $\mathbf{x}_{k+1} = \mathbf{C}\mathbf{x}_k$. For each i, let $\mathbf{w}_i = (1, \lambda_i, \lambda_i^2, \dots, \lambda_i^{n-1})$. Then $\mathbf{C}\mathbf{w}_i = \lambda_i \mathbf{w}_i$: for $r \le n-1$, entry r of $\mathbf{C}\mathbf{w}_i$ is entry $r+1$ of $\mathbf{w}_i$, which is $\lambda_i^r = \lambda_i \cdot \lambda_i^{r-1}$; and the last entry is $-(c_0 + c_1\lambda_i + \cdots + c_{n-1}\lambda_i^{n-1}) = \lambda_i^n - p(\lambda_i) = \lambda_i^n = \lambda_i \cdot \lambda_i^{n-1}$. Let $\mathbf{W}$ be the matrix with columns $\mathbf{w}_1, \dots, \mathbf{w}_n$. Its (r,i)-entry is λ_i^{r-1}, so $\mathbf{W} = \mathbf{V}(\lambda_1, \dots, \lambda_n)^\top$ in the notation of Theorem 6.8.1, and $\mathbf{W}$ is invertible, since the λ_i are distinct: $\det \mathbf{W} = \det \mathbf{V}(\lambda_1, \dots, \lambda_n) \neq 0$ by Theorem 6.4.5 and Theorem 6.8.1, and Theorem 6.5.2 applies. The columns of $\mathbf{C}\mathbf{W}$ are $\lambda_i \mathbf{w}_i$, which are the columns of $\mathbf{W}\ \mathrm{diag}(\lambda_1, \dots, \lambda_n)$, so $\mathbf{C} = \mathbf{W}\ \mathrm{diag}(\lambda_1, \dots, \lambda_n)\, \mathbf{W}^{-1}$.

By Theorem 8.11.1, with $(b_1, \dots, b_n) = \mathbf{W}^{-1}\mathbf{x}_0$,

$$\mathbf{x}_k = b_1\lambda_1^k\, \mathbf{w}_1 + \cdots + b_n\lambda_n^k\, \mathbf{w}_n.$$

The first entry of $\mathbf{x}_k$ is a_k, and the first entry of each $\mathbf{w}_i$ is 1, so $a_k = \sum_i b_i \lambda_i^k$.

For uniqueness, suppose $a_k = \sum_i b_i \lambda_i^k$ for all k. Taking $k = 0, \dots, n-1$ gives $\mathbf{W}\mathbf{b} = (a_0, \dots, a_{n-1}) = \mathbf{x}_0$, so $\mathbf{b} = \mathbf{W}^{-1}\mathbf{x}_0$ is determined by the initial values.

■

So solving a recurrence with distinct roots comes down to three steps: find the roots of p, write the general form $\sum b_i \lambda_i^k$, and fit $b_1, \dots, b_n$ to the initial values by solving a Vandermonde system.

Example. (A Third-Order Recurrence)

Find a formula for the sequence with $a_0 = 3$, $a_1 = 2$, $a_2 = 6$ and

$$a_{k+3} = 2a_{k+2} + a_{k+1} - 2a_k \qquad (k \in \mathbb{N}).$$

Solution. In the form $(*)$, $a_{k+3} - 2a_{k+2} - a_{k+1} + 2a_k = 0$, so $p(x) = x^3 - 2x^2 - x + 2$. Grouping, $p = x^2(x-2) - (x-2) = (x-2)(x-1)(x+1)$, with the distinct roots $1, -1, 2$. The window matrix is

$$\mathbf{C} = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ -2 & 1 & 2 \end{pmatrix},$$

with eigenvectors $(1,1,1)$, $(1,-1,1)$, $(1,2,4)$; for instance $\mathbf{C}(1,2,4) = (2, 4, -2+2+8) = 2(1,2,4)$.

By Theorem 8.11.2, $a_k = b_1 + b_2(-1)^k + b_3 2^k$. The initial values give the Vandermonde system

$$b_1 + b_2 + b_3 = 3, \qquad b_1 - b_2 + 2b_3 = 2, \qquad b_1 + b_2 + 4b_3 = 6.$$

Subtracting the first equation from the third gives $3b_3 = 3$, so $b_3 = 1$. Then $b_1 + b_2 = 2$

and $b_1 - b_2 = 0$, so $b_1 = b_2 = 1$. Hence

$$a_k = 1 + (-1)^k + 2^k.$$

Check. The recurrence gives $a_3 = 2 \cdot 6 + 2 - 2 \cdot 3 = 8$ and $a_4 = 2 \cdot 8 + 6 - 2 \cdot 2 = 18$; the formula gives $1 - 1 + 8 = 8$ and $1 + 1 + 16 = 18$. For large k, $a_k \approx 2^k$: the root of largest absolute value dominates.

Repeated roots. When p has a repeated root, $\mathbf{C}$ is not diagonalizable: for a root λ, every eigenvector $(w_1, \dots, w_n)$ of $\mathbf{C}$ satisfies $w_{r+1} = \lambda w_r$, so it is a multiple of $(1, \lambda, \dots, \lambda^{n-1})$, and $g_{\mathbf{C}}(\lambda) = 1$ whatever $a_{\mathbf{C}}(\lambda)$ is. The general answer involves terms $k\lambda^k, k^2\lambda^k, \dots$, and it follows from the Jordan canonical form of Chapter 9. The 2×2 case can be done by hand.

Example. (A Repeated Root)

Over $\mathbb{R}$, find all sequences with $a_{k+2} = 4a_{k+1} - 4a_k$ for every $k \in \mathbb{N}$.

Solution. Here $p = x^2 - 4x + 4 = (x-2)^2$, and the window matrix is $\mathbf{C} = \begin{pmatrix} 0 & 1 \\ -4 & 4 \end{pmatrix}$. It is not diagonalizable, since $\mathbf{C} - 2\mathbf{I} = \begin{pmatrix} -2 & 1 \\ -4 & 2 \end{pmatrix}$ has rank 1, so $g(2) = 1 < 2 = a(2)$. But $\mathbf{N} = \mathbf{C} - 2\mathbf{I}$ satisfies

$$\mathbf{N}^2 = \begin{pmatrix} 4-4 & -2+2 \\ 8-8 & -4+4 \end{pmatrix} = 0.$$

Claim: $\mathbf{C}^k = 2^k\mathbf{I} + k2^{k-1}\mathbf{N}$ for all $k \in \mathbb{N}$. For $k = 0$ both sides are $\mathbf{I}$. If it holds for k, then, since $\mathbf{C} = 2\mathbf{I} + \mathbf{N}$ and $\mathbf{N}^2 = 0$,

$$\begin{aligned} \mathbf{C}^{k+1} &= \big(2^k\mathbf{I} + k2^{k-1}\mathbf{N}\big)(2\mathbf{I} + \mathbf{N}) \\ &= 2^{k+1}\mathbf{I} + 2^k\mathbf{N} + k2^k\mathbf{N} + k2^{k-1}\mathbf{N}^2 = 2^{k+1}\mathbf{I} + (k+1)2^k\mathbf{N}. \end{aligned}$$

Now $\mathbf{x}_k = \mathbf{C}^k\mathbf{x}_0$ with $\mathbf{x}_0 = (a_0, a_1)$, and a_k is the first entry. Row 1 of $\mathbf{C}^k$ is $\big(2^k - 2k2^{k-1},\ k2^{k-1}\big) = \big((1-k)2^k,\ k2^{k-1}\big)$, so

$$a_k = (1-k)2^k a_0 + k2^{k-1}a_1 = \Big(a_0 + \big(\tfrac{a_1}{2} - a_0\big)k\Big)2^k.$$

So the solutions are exactly the sequences $a_k = (b_1 + b_2 k)2^k$ with $b_1, b_2 \in \mathbb{R}$: every solution has this form with $b_1 = a_0$, $b_2 = a_1/2 - a_0$, and every such sequence is the solution with $a_0 = b_1$, $a_1 = 2b_1 + 2b_2$. For example, $a_0 = 1$, $a_1 = 4$ gives $a_k = (1+k)2^k$, and indeed $a_2 = 4 \cdot 4 - 4 \cdot 1 = 12 = 3 \cdot 4$. The new term $k2^k$ is the footprint of the missing eigenvector, just as the entry k was for $\begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}^k$ in Section 4.

8.11.3 Stochastic matrices

Now a system that moves at random. A shared bicycle is parked each night at one of a few stations; a machine is either working or under repair. We do not know the state for sure, but we know the probability of each state, and a fixed table of probabilities for moving from one state to another in one step.

Take states $1, \dots, n$. Record the probabilities of the states at step k as a column $\mathbf{x}_k \in \mathbb{R}^n$, and let a_{ij} be the probability of moving to state i in one step, given that the system is in state j. The probability of being in state i at step $k+1$ is the sum over the previous state j of "was in j" times "moved from j to i", that is, $\sum_j a_{ij}(\mathbf{x}_k)_j$. So $\mathbf{x}_{k+1} = \mathbf{A}\mathbf{x}_k$: a linear recurrence. The matrix $\mathbf{A}$ has two features: its entries are probabilities, and from each state j the system must go **somewhere**, so column j adds up to 1.

A stochastic matrix is a table of transition probabilities, one column for each starting state.

Definition 8.11.1 — Stochastic Matrix, Probability Vector

Let $n \geq 1$.

(a) A vector $\mathbf{x} \in \mathbb{R}^n$ is a **probability vector** if $x_i \geq 0$ for every i and $x_1 + \cdots + x_n = 1$.

(b) A matrix $\mathbf{A} \in M_n(\mathbb{R})$ is **stochastic** if every column of $\mathbf{A}$ is a probability vector: $a_{ij} \geq 0$ for **all** i, j, and $\sum_{i=1}^n a_{ij} = 1$ for **every** j.

In words: the entries are non-negative and each **column** sums to 1. With $\mathbf{1} = (1, \dots, 1) \in \mathbb{R}^n$, the column condition reads $\mathbf{1}^\top \mathbf{A} = \mathbf{1}^\top$, and $\mathbf{1}^\top \mathbf{x} = 1$ says that the entries of $\mathbf{x}$ add up to 1.

Examples.

- $\begin{pmatrix} 9/10 & 1/5 \\ 1/10 & 4/5 \end{pmatrix}$: columns $(9/10, 1/10)$ and $(1/5, 4/5)$ are probability vectors.
- **Degenerate cases.** $\mathbf{I}_n$ is stochastic: every state stays put. The 1×1 matrix (1) is the only 1×1 stochastic matrix. Every **permutation matrix** is stochastic, since each column is a standard basis vector; it moves the system deterministically.
- $\frac{1}{4}\begin{pmatrix} 2 & 1 & 0 \\ 1 & 2 & 1 \\ 1 & 1 & 3 \end{pmatrix}$: the columns sum to $\frac{4}{4}$, and all entries are non-negative.

Non-example by minimal change. Transpose the first example: $\begin{pmatrix} 9/10 & 1/10 \\ 1/5 & 4/5 \end{pmatrix}$ still has non-negative entries, and its **rows** sum to 1, but its first column sums to $11/10$. It fails the column condition. Likewise $\begin{pmatrix} 3/2 & 0 \\ -1/2 & 1 \end{pmatrix}$ has columns summing to 1 but a negative entry.

Why this convention. Many books write probability vectors as **rows** and multiply on the left, $\mathbf{x}_{k+1}^\top = \mathbf{x}_k^\top \mathbf{M}$; their "stochastic" matrices have rows summing to 1, and they are the transposes of ours. We keep column vectors and $\mathbf{x}_{k+1} = \mathbf{A}\mathbf{x}_k$, in line with the rest of the book, so our stochastic matrices are **column-stochastic**. Translating between the conventions is a transpose, which changes neither eigenvalues nor their algebraic multiplicities (Proposition 8.10.5).

The first properties follow from $\mathbf{1}^\top \mathbf{A} = \mathbf{1}^\top$.

Proposition 8.11.3 — Basic Properties of Stochastic Matrices

Let $\mathbf{A}, \mathbf{B} \in M_n(\mathbb{R})$ be stochastic and $\mathbf{x} \in \mathbb{R}^n$ a probability vector. Then:

(a) $\mathbf{A}\mathbf{x}$ is a probability vector;

(b) $\mathbf{A}\mathbf{B}$ is stochastic, and so is $\mathbf{A}^k$ for every $k \in \mathbb{N}$;

(c) $\mathbf{1}$ is a left eigenvector of $\mathbf{A}$ for the eigenvalue 1; in particular $1 \in \operatorname{spec}(\mathbf{A})$.

Proof.

(a) Each entry $(\mathbf{Ax})_i = \sum_j a_{ij}x_j$ is a sum of products of non-negative numbers, so it is non-negative. By associativity, $\mathbf{1}^\top(\mathbf{Ax}) = (\mathbf{1}^\top\mathbf{A})\mathbf{x} = \mathbf{1}^\top\mathbf{x} = 1$.

(b) By Theorem 0.9.2, column j of $\mathbf{AB}$ is $\mathbf{Ab}_j$, where $\mathbf{b}_j$ is column j of $\mathbf{B}$, a probability vector. By (a), $\mathbf{Ab}_j$ is a probability vector, so $\mathbf{AB}$ is stochastic. By induction on k, $\mathbf{A}^k$ is stochastic: $\mathbf{A}^0 = \mathbf{I}$ is, and $\mathbf{A}^{k+1} = \mathbf{A}^k\mathbf{A}$.

(c) $\mathbf{1}^\top\mathbf{A} = \mathbf{1}^\top$ with $\mathbf{1} \neq \mathbf{0}$ is Definition 8.10.1 with $\lambda = 1$, and Proposition 8.10.5 gives $1 \in \operatorname{spec}(\mathbf{A})$.

■

Warning. **The all-ones vector is a left eigenvector, not a right one.** For $\mathbf{A} = \begin{pmatrix} 9/10 & 1/5 \\ 1/10 & 4/5 \end{pmatrix}$, $\mathbf{A1} = (11/10, 9/10) \neq \mathbf{1}$. The right eigenvectors for 1 are the multiples of $(2, 1)$, and they carry the interesting information: the long-run probabilities. Only when the **rows** also sum to 1 is $\mathbf{1}$ a right eigenvector.

8.11.4 Markov chains

Definition 8.11.2 — Markov Chain, Steady State

Let $\mathbf{A} \in M_n(\mathbb{R})$ be stochastic. The **Markov chain** with **transition matrix** $\mathbf{A}$ and initial probability vector $\mathbf{x}_0$ is the sequence of probability vectors $\mathbf{x}_{k+1} = \mathbf{Ax}_k$, that is, $\mathbf{x}_k = \mathbf{A}^k\mathbf{x}_0$. A **steady state** of $\mathbf{A}$ is a probability vector $\mathbf{v}$ with $\mathbf{Av} = \mathbf{v}$.

Each $\mathbf{x}_k$ is a probability vector by Proposition 8.11.3. A steady state is a right eigenvector for the eigenvalue 1, scaled so that its entries add up to 1 and required to have non-negative entries; if the chain starts there, it stays there.

To talk about the long run we need limits, and we use the simplest kind. A sequence of complex matrices $\mathbf{M}_k \in M_{m\times n}(\mathbb{C})$ **converges entrywise** to $\mathbf{M}$ if, for every position (r, s), the number sequence $(\mathbf{M}_k)_{rs}$ converges to $\mathbf{M}_{rs}$. We use four facts about sequences of complex numbers from calculus: sums and constant multiples of convergent sequences converge to the sums and multiples of the limits; $z_k \to 0$ if and only if $|z_k| \to 0$; $r^k \to 0$ for real $0 \leq r < 1$; and a convergent sequence of real numbers ≥ 0 has a real limit ≥ 0. In particular, if $|\lambda| < 1$, then $|\lambda^k| = |\lambda|^k \to 0$ (Theorem 0.6.2), so $\lambda^k \to 0$.

Example. (A Two-State Chain)

A machine is either working (state 1) or under repair (state 2) each day. A working machine is still working the next day with probability 9/10; a machine under repair is back to work the next day with probability 1/5. So the transition matrix is

$$\mathbf{A} = \begin{pmatrix} 9/10 & 1/5 \\ 1/10 & 4/5 \end{pmatrix}.$$

Find $\mathbf{A}^k$, its entrywise limit, and the long-run probability that the machine is working, if it is working on day 0.

Solution. Eigenvalues. $\operatorname{tr}\mathbf{A} = 17/10$ and $\det\mathbf{A} = 36/50 - 1/50 = 7/10$, so, by the 2×2 formula $p_{\mathbf{A}} = x^2 - (\operatorname{tr}\mathbf{A})x + \det\mathbf{A}$ (the examples after Definition 6.10.1), $p_{\mathbf{A}} = x^2 - \frac{17}{10}x + \frac{7}{10} = (x-1)\left(x - \frac{7}{10}\right)$. The eigenvalue 1 was guaranteed by Proposition 8.11.3.

Eigenvectors. $\mathbf{A} - \mathbf{I} = \begin{pmatrix} -1/10 & 1/5 \\ 1/10 & -1/5 \end{pmatrix}$ gives $x = 2y$, eigenvector $(2,1)$. $\mathbf{A} - \frac{7}{10}\mathbf{I} = \begin{pmatrix} 1/5 & 1/5 \\ 1/10 & 1/10 \end{pmatrix}$ gives $y = -x$, eigenvector $(1,-1)$. The eigenvalues are distinct, so

$$\mathbf{P} = \begin{pmatrix} 2 & 1 \\ 1 & -1 \end{pmatrix}, \qquad \mathbf{D} = \operatorname{diag}\left(1, \tfrac{7}{10}\right), \qquad \mathbf{P}^{-1} = \frac{1}{3}\begin{pmatrix} 1 & 1 \\ 1 & -2 \end{pmatrix},$$

using Theorem 0.9.8 with $\det\mathbf{P} = -3$.

Powers. By Theorem 8.4.3, writing $t = (7/10)^k$,

$$\mathbf{A}^k = \mathbf{P}\begin{pmatrix} 1 & 0 \\ 0 & t \end{pmatrix}\mathbf{P}^{-1} = \frac{1}{3}\begin{pmatrix} 2 & t \\ 1 & -t \end{pmatrix}\begin{pmatrix} 1 & 1 \\ 1 & -2 \end{pmatrix} = \frac{1}{3}\begin{pmatrix} 2+t & 2-2t \\ 1-t & 1+2t \end{pmatrix}.$$

Check: for $k = 1$, $t = 7/10$ and $\frac{1}{3}\begin{pmatrix} 27/10 & 6/10 \\ 3/10 & 24/10 \end{pmatrix} = \mathbf{A}$; each column of $\mathbf{A}^k$ sums to 1, as Proposition 8.11.3 requires.

The limit. Since $0 \le 7/10 < 1$, $t \to 0$, so entrywise

$$\mathbf{A}^k \to \frac{1}{3}\begin{pmatrix} 2 & 2 \\ 1 & 1 \end{pmatrix} = \begin{pmatrix} 2/3 \\ 1/3 \end{pmatrix}\begin{pmatrix} 1 & 1 \end{pmatrix}.$$

Starting from $\mathbf{x}_0 = \mathbf{e}_1$, $\mathbf{x}_k = \mathbf{A}^k\mathbf{e}_1 = \left(\frac{2+t}{3}, \frac{1-t}{3}\right) \to \left(\frac{2}{3}, \frac{1}{3}\right)$. In the long run the machine works on two days out of three. The limit does not depend on the start: for any probability vector $\mathbf{x}_0 = (s, 1-s)$, $\mathbf{A}^k\mathbf{x}_0 \to \frac{1}{3}(2s + 2(1-s),\ s + (1-s)) = \left(\frac{2}{3}, \frac{1}{3}\right)$. The vector $\mathbf{v} = \left(\frac{2}{3}, \frac{1}{3}\right)$ is the steady state, the eigenvector $(2,1)$ scaled to sum 1.

The example shows the general mechanism. The eigenvalue 1 survives in $\mathbf{D}^k$, all others fade, and the surviving rank-one piece is (right eigenvector for 1) times (left eigenvector for 1), which for a stochastic matrix is the steady state times $\mathbf{1}^\top$.

Theorem 8.11.4 — Long-Run Behavior of a Diagonalizable Markov Chain

Let $\mathbf{A} \in M_n(\mathbb{R})$, $n \ge 1$, be stochastic. Suppose that $\mathbf{A}$ is diagonalizable over $\mathbb{C}$, that $a_{\mathbf{A}}(1) = 1$, and that every other eigenvalue $\lambda \in \mathbb{C}$ of $\mathbf{A}$ has $|\lambda| < 1$. Then:

(a) $\mathbf{A}$ has exactly one steady state $\mathbf{v}$;

(b) $\mathbf{A}^k \to \mathbf{v}\mathbf{1}^\top$ entrywise as $k \to \infty$;

(c) for every probability vector $\mathbf{x}_0$, the Markov chain $\mathbf{x}_k = \mathbf{A}^k\mathbf{x}_0$ converges entrywise to $\mathbf{v}$.

Idea. Use the expansion $\mathbf{A}^k = \sum_i \lambda_i^k \, \mathbf{v}_i \mathbf{y}_i^\top$ of Section 10. The terms with $|\lambda_i| < 1$ tend to 0, which leaves the single term for $\lambda_1 = 1$. Its left eigenvector $\mathbf{y}_1$ must be a multiple of $\mathbf{1}$, because the left eigenvectors for 1 form a line and $\mathbf{1}$ is one of them. Rescaling turns $\mathbf{v}_1 \mathbf{y}_1^\top$ into $\mathbf{v}\mathbf{1}^\top$, and the non-negativity of $\mathbf{v}$ comes for free as a limit of non-negative entries.

Proof. Since $\mathbf{A}$ is diagonalizable over $\mathbb{C}$, there are an invertible $\mathbf{P} \in M_n(\mathbb{C})$ and $\mathbf{D} = \operatorname{diag}(\lambda_1, \dots, \lambda_n)$ with $\mathbf{A} = \mathbf{P}\mathbf{D}\mathbf{P}^{-1}$. A diagonal matrix is upper triangular, so each eigenvalue occurs on the diagonal of $\mathbf{D}$ as often as its algebraic multiplicity (Theorem 8.7.4 (b)); in particular 1 occurs exactly once, because $a_{\mathbf{A}}(1) = 1$. Permuting the columns of $\mathbf{P}$ and the diagonal entries of $\mathbf{D}$ together leaves $\mathbf{A} = \mathbf{P}\mathbf{D}\mathbf{P}^{-1}$ intact, so we may assume $\lambda_1 = 1$, and then $|\lambda_i| < 1$ for $i \geq 2$ by hypothesis. Let $\mathbf{v}_i$ be the columns of $\mathbf{P}$ and $\mathbf{y}_i^\top$ the rows of $\mathbf{P}^{-1}$. By Proposition 8.10.7, for every k,

$$\mathbf{A}^k = \mathbf{v}_1 \mathbf{y}_1^\top + \sum_{i=2}^{n} \lambda_i^k \, \mathbf{v}_i \mathbf{y}_i^\top .$$

Each entry of the sum is $\sum_{i \geq 2} \lambda_i^k \, z_i$ for fixed complex numbers z_i, and $\lambda_i^k \to 0$ for $i \geq 2$. Hence $\mathbf{A}^k \to Ł = \mathbf{v}_1 \mathbf{y}_1^\top$ entrywise.

The shape of Ł. By Proposition 8.10.7, $\mathbf{y}_1$ is a left eigenvector for 1, and so is $\mathbf{1}$ (Proposition 8.11.3). Both lie in $E_1(\mathbf{A}^\top) \subseteq \mathbb{C}^n$ (Proposition 8.10.5 (a)), which has dimension $g_{\mathbf{A}^\top}(1) = g_{\mathbf{A}}(1) \leq a_{\mathbf{A}}(1) = 1$ by Proposition 8.10.5 (b) and Theorem 8.3.1. Since $\mathbf{1} \neq \mathbf{0}$, $\mathbf{y}_1 = c\mathbf{1}$ for some $c \in \mathbb{C}$. Put $\mathbf{v} = c\mathbf{v}_1$. Then $Ł = \mathbf{v}\mathbf{1}^\top$, $\mathbf{A}\mathbf{v} = c\,\mathbf{A}\mathbf{v}_1 = \mathbf{v}$, and $\mathbf{1}^\top \mathbf{v} = \mathbf{y}_1^\top \mathbf{v}_1 = 1$ by Proposition 8.10.7 (b).

$\mathbf{v}$ *is a steady state.* Column 1 of $Ł = \mathbf{v}\mathbf{1}^\top$ is $\mathbf{v}$. It is the limit of column 1 of $\mathbf{A}^k$, and $\mathbf{A}^k$ is stochastic (Proposition 8.11.3), so every entry of $\mathbf{v}$ is a limit of real numbers ≥ 0, hence real and ≥ 0. With $\mathbf{1}^\top \mathbf{v} = 1$, $\mathbf{v}$ is a probability vector, and $\mathbf{A}\mathbf{v} = \mathbf{v}$.

Uniqueness. If $\mathbf{w}$ is a steady state, then $\mathbf{w} \in E_1(\mathbf{A})$, a subspace of $\mathbb{C}^n$ of dimension $g_{\mathbf{A}}(1) \leq 1$ that contains $\mathbf{v} \neq \mathbf{0}$. So $\mathbf{w} = s\mathbf{v}$ for some $s \in \mathbb{C}$, and $1 = \mathbf{1}^\top \mathbf{w} = s\,\mathbf{1}^\top \mathbf{v} = s$. Hence $\mathbf{w} = \mathbf{v}$. This proves (a) and (b).

(c) Entry r of $\mathbf{A}^k \mathbf{x}_0$ is $\sum_s (\mathbf{A}^k)_{rs} (\mathbf{x}_0)_s$, which by (b) converges to $\sum_s v_r (\mathbf{x}_0)_s = v_r \, (\mathbf{1}^\top \mathbf{x}_0) = v_r$.

■

In practice: find the eigenvalues, check the hypotheses, and compute $\mathbf{v}$ by solving $(\mathbf{A} - \mathbf{I})\mathbf{v} = \mathbf{0}$ and scaling. Then (c) gives the long run **without** computing $\mathbf{P}^{-1}$ at all.

Example. (Bicycles at Three Stations)

A shared bicycle is parked each night at station 1, 2 or 3. The transition matrix is

$$\mathbf{A} = \frac{1}{4} \begin{pmatrix} 2 & 1 & 0 \\ 1 & 2 & 1 \\ 1 & 1 & 3 \end{pmatrix} ;$$

for instance a bicycle at station 3 stays there with probability $3/4$ and never goes to station 1 in one night. Find $\mathbf{A}^k$, its limit, and the long-run distribution of the bicycle.

Solution. Eigenvectors. We check three candidates:

$$\mathbf{A}\begin{pmatrix}1\\2\\3\end{pmatrix}=\frac{1}{4}\begin{pmatrix}4\\8\\12\end{pmatrix},\qquad \mathbf{A}\begin{pmatrix}-1\\0\\1\end{pmatrix}=\frac{1}{4}\begin{pmatrix}-2\\0\\2\end{pmatrix},\qquad \mathbf{A}\begin{pmatrix}-1\\1\\0\end{pmatrix}=\frac{1}{4}\begin{pmatrix}-1\\1\\0\end{pmatrix}.$$

So $1, \frac{1}{2}, \frac{1}{4}$ are eigenvalues, with eigenvectors $\mathbf{v}_1=(1,2,3)$, $\mathbf{v}_2=(-1,0,1)$, $\mathbf{v}_3=(-1,1,0)$. A 3×3 matrix has at most three eigenvalues (Corollary 8.2.3), so these are all; they are distinct, so $\mathbf{A}$ is diagonalizable (Corollary 8.4.2) and $a_{\mathbf{A}}(1)=1$. As a check, $\operatorname{tr}\mathbf{A}=\frac{7}{4}=1+\frac{1}{2}+\frac{1}{4}$. The hypotheses of Theorem 8.11.4 hold.

The expansion. With $\mathbf{P}=\begin{pmatrix}1&-1&-1\\2&0&1\\3&1&0\end{pmatrix}$, whose determinant is -6,

$$\mathbf{P}^{-1}=\begin{pmatrix}1/6&1/6&1/6\\-1/2&-1/2&1/2\\-1/3&2/3&-1/3\end{pmatrix},$$

as multiplying out $\mathbf{P}^{-1}\mathbf{P}=\mathbf{I}$ confirms. The first row is $\frac{1}{6}\mathbf{1}^{\top}$, a multiple of $\mathbf{1}^{\top}$ as the proof of the theorem predicts. By Proposition 8.10.7,

$$\mathbf{A}^k=\frac{1}{6}\begin{pmatrix}1&1&1\\2&2&2\\3&3&3\end{pmatrix}+\frac{1}{2^k}\cdot\frac{1}{2}\begin{pmatrix}1&1&-1\\0&0&0\\-1&-1&1\end{pmatrix}+\frac{1}{4^k}\cdot\frac{1}{3}\begin{pmatrix}1&-2&1\\-1&2&-1\\0&0&0\end{pmatrix}.$$

For example, the $(1,1)$-entry of $\mathbf{A}^k$ is $\frac{1}{6}+\frac{1}{2}\cdot 2^{-k}+\frac{1}{3}\cdot 4^{-k}$, which is 1 for $k=0$ and $\frac{1}{6}+\frac{1}{4}+\frac{1}{12}=\frac{1}{2}$ for $k=1$, matching $a_{11}=2/4$.

The limit. As $k\to\infty$, $2^{-k}\to 0$ and $4^{-k}\to 0$, so

$$\mathbf{A}^k\to\frac{1}{6}\begin{pmatrix}1&1&1\\2&2&2\\3&3&3\end{pmatrix}=\mathbf{v}\mathbf{1}^{\top},\qquad \mathbf{v}=\left(\frac{1}{6},\frac{1}{3},\frac{1}{2}\right).$$

Wherever the bicycle starts, in the long run it is at station 1, 2, 3 with probabilities $\frac{1}{6},\frac{1}{3},\frac{1}{2}$. Directly, $\mathbf{v}=\frac{1}{6}\mathbf{v}_1$ and $\mathbf{A}\mathbf{v}=\mathbf{v}$. The slowest-fading term is the one with $\frac{1}{2}$: each entry's gap to its limit roughly halves every night.

Warning. **A stochastic matrix need not have convergent powers.** The swap $\mathbf{S}=\begin{pmatrix}0&1\\1&0\end{pmatrix}$ is stochastic, and $\mathbf{S}^k$ is $\mathbf{I}$ for even k and $\mathbf{S}$ for odd k, so $\mathbf{S}^k$ does not converge. Starting from $\mathbf{x}_0=\mathbf{e}_1$, the chain alternates $\mathbf{e}_1,\mathbf{e}_2,\mathbf{e}_1,\dots$ forever, although $\mathbf{S}$ has the steady state $(\frac{1}{2},\frac{1}{2})$. The theorem does not apply: $\mathbf{S}$ has the eigenvalue -1, with $|-1|=1$. At the other extreme, $\mathbf{I}_2$ has convergent powers, but $a(1)=2$, every probability vector is a steady state, and the limit of $\mathbf{x}_k$ depends on $\mathbf{x}_0$.

Chapter 18 proves the Perron–Frobenius theorem, which gives the conclusions of Theorem 8.11.4 for every stochastic matrix with some power having all entries positive, without assuming diagonalizability and without computing eigenvalues. The exercises prove the first ingredient: no

eigenvalue of a stochastic matrix has $|\lambda| > 1$.

Quick check. Is $\mathbf{A} = \begin{pmatrix} 1/2 & 1/3 \\ 1/2 & 2/3 \end{pmatrix}$ stochastic? If so, find its steady state.

Solution. Yes: the entries are non-negative and the columns sum to 1. From $(\mathbf{A}-\mathbf{I})\mathbf{v} = \mathbf{0}$, the first row gives $-\frac{1}{2}v_1 + \frac{1}{3}v_2 = 0$, so $v_2 = \frac{3}{2}v_1$. Scaling to sum 1: $v_1 + \frac{3}{2}v_1 = 1$ gives $\mathbf{v} = (\frac{2}{5}, \frac{3}{5})$. (The eigenvalues are 1 and $\operatorname{tr}\mathbf{A} - 1 = \frac{1}{6}$; they are distinct, so $\mathbf{A}$ is diagonalizable with $a_{\mathbf{A}}(1) = 1$, and $\mathbf{v}$ is the only steady state and the long-run distribution, by Theorem 8.11.4.)

8.11.5 A population model

Not every matrix of this kind is stochastic. In a population divided into age classes, individuals are born, age, and die, and the total need not be preserved. A **Leslie matrix** records, in its first row, the average number of offspring per individual of each age class, and just below the diagonal, the fraction surviving into the next class. The population vector evolves by $\mathbf{x}_{k+1} = Ł\mathbf{x}_k$, and Theorem 8.11.1 describes the long run.

Example. (Three Age Classes)

A species is counted once a year in three age classes: young, juvenile and adult. Half of the young survive to become juveniles, and half of the juveniles survive to become adults; no adult survives another year. Each juvenile has on average 7/2 offspring and each adult 3. The Leslie matrix is

$$Ł = \begin{pmatrix} 0 & 7/2 & 3 \\ 1/2 & 0 & 0 \\ 0 & 1/2 & 0 \end{pmatrix}.$$

Starting from $\mathbf{x}_0 = (20, 10, 5)$ (in hundreds of animals), find $\mathbf{x}_k$ and describe the long-run growth and age distribution.

Solution. Characteristic polynomial. Expanding $\det(x\mathbf{I} - Ł)$ along the first column,

$$\begin{aligned} p_Ł &= x\det\begin{pmatrix} x & 0 \\ -1/2 & x \end{pmatrix} + \frac{1}{2}\det\begin{pmatrix} -7/2 & -3 \\ -1/2 & x \end{pmatrix} \\ &= x^3 + \frac{1}{2}\Big(-\frac{7}{2}x - \frac{3}{2}\Big) = x^3 - \frac{7}{4}x - \frac{3}{4}. \end{aligned}$$

Trying simple values, $p_Ł(-1) = -1 + \frac{7}{4} - \frac{3}{4} = 0$, and dividing, $p_Ł = (x+1)\big(x^2 - x - \frac{3}{4}\big) = (x+1)\big(x - \frac{3}{2}\big)\big(x + \frac{1}{2}\big)$. The eigenvalues $\frac{3}{2}, -1, -\frac{1}{2}$ are distinct, so Ł is diagonalizable.

Eigenvectors. $Ł(w_1, w_2, w_3) = \lambda(w_1, w_2, w_3)$ forces $\frac{1}{2}w_1 = \lambda w_2$ and $\frac{1}{2}w_2 = \lambda w_3$, so taking $w_3 = 1$ gives $w_2 = 2\lambda$, $w_1 = 4\lambda^2$. Hence, after scaling,

$$\lambda = \tfrac{3}{2}:\ (9,3,1), \qquad \lambda = -1:\ (4,-2,1), \qquad \lambda = -\tfrac{1}{2}:\ (1,-1,1).$$

For instance $Ł(9,3,1) = \big(\frac{21}{2} + 3, \frac{9}{2}, \frac{3}{2}\big) = \frac{3}{2}(9,3,1)$.

The initial vector. Solving $c_1(9,3,1) + c_2(4,-2,1) + c_3(1,-1,1) = (20,10,5)$ gives $c_1 = 3$,

$c_2 = -3$, $c_3 = 5$: indeed $(27-12+5,\ 9+6-5,\ 3-3+5) = (20, 10, 5)$. By Theorem 8.11.1,

$$\mathbf{x}_k = 3\Big(\frac{3}{2}\Big)^k \begin{pmatrix} 9 \\ 3 \\ 1 \end{pmatrix} - 3(-1)^k \begin{pmatrix} 4 \\ -2 \\ 1 \end{pmatrix} + 5\Big(-\frac{1}{2}\Big)^k \begin{pmatrix} 1 \\ -1 \\ 1 \end{pmatrix}.$$

Check. For $k = 1$: $\big(\frac{81}{2} + 12 - \frac{5}{2},\ \frac{27}{2} - 6 + \frac{5}{2},\ \frac{9}{2} + 3 - \frac{5}{2}\big) = (50, 10, 5)$, and directly $\text{Ł}\mathbf{x}_0 = (35 + 15, 10, 5)$.

The long run. Divide by $(3/2)^k$:

$$\Big(\frac{2}{3}\Big)^k \mathbf{x}_k = 3 \begin{pmatrix} 9 \\ 3 \\ 1 \end{pmatrix} - 3\Big(-\frac{2}{3}\Big)^k \begin{pmatrix} 4 \\ -2 \\ 1 \end{pmatrix} + 5\Big(-\frac{1}{3}\Big)^k \begin{pmatrix} 1 \\ -1 \\ 1 \end{pmatrix} \longrightarrow \begin{pmatrix} 27 \\ 9 \\ 3 \end{pmatrix},$$

since $|-\frac{2}{3}| < 1$ and $|-\frac{1}{3}| < 1$. So the population eventually grows by the factor $\frac{3}{2}$ each year, and the age classes approach the proportions $9 : 3 : 1$, the entries of the eigenvector for the largest eigenvalue. The eigenvalue -1 makes the population oscillate from year to year, but its effect is bounded while the dominant term grows, so its share fades.

8.11.6 Exercises

8.11.6.1 A. Check your understanding

Exercise A1.

(a) Define a stochastic matrix, and say which convention (rows or columns) this book uses.

(b) True or false: for every stochastic $\mathbf{A}$, the powers $\mathbf{A}^k$ converge entrywise. Justify your answer.

(c) True or false: $\mathbf{1}$ is a right eigenvector of every stochastic matrix. Justify your answer.

(d) True or false: every stochastic matrix is invertible. Justify your answer.

(e) Write down the general solution of $a_{k+2} = 5a_{k+1} - 6a_k$ over $\mathbb{R}$.

(f) In Theorem 8.11.1, what are the numbers $c_1, \dots, c_n$?

Solution.

(a) $\mathbf{A} \in M_n(\mathbb{R})$ is stochastic if all entries are non-negative and every **column** sums to 1 (Definition 8.11.1). This book uses columns, with $\mathbf{x}_{k+1} = \mathbf{A}\mathbf{x}_k$.

(b) False. The swap $\mathbf{S} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$ has $\mathbf{S}^k$ alternating between $\mathbf{I}$ and $\mathbf{S}$.

(c) False. $\mathbf{A} = \begin{pmatrix} 1 & 1/2 \\ 0 & 1/2 \end{pmatrix}$ is stochastic, and $\mathbf{A}\mathbf{1} = (3/2, 1/2)$ is not a multiple of $\mathbf{1}$. It is a **left** eigenvector (Proposition 8.11.3).

(d) False. $\begin{pmatrix} 1/2 & 1/2 \\ 1/2 & 1/2 \end{pmatrix}$ is stochastic with determinant 0.

(e) $p = x^2 - 5x + 6 = (x-2)(x-3)$, so by Theorem 8.11.2 the solutions are $a_k =$

$b_1 2^k + b_2 3^k$ with $b_1, b_2 \in \mathbb{R}$.

(f) The coordinates of $\mathbf{x}_0$ in the basis of eigenvectors $\mathbf{v}_1, \dots, \mathbf{v}_n$: $(c_1, \dots, c_n) = \mathbf{P}^{-1}\mathbf{x}_0$.

8.11.6.2 B. Practice

Exercise B1: Two recurrences.

(a) Solve $a_{k+2} = a_{k+1} + 2a_k$ with $a_0 = 0$, $a_1 = 3$.

(b) Solve $a_{k+2} = 6a_{k+1} - 9a_k$ with $a_0 = 1$, $a_1 = 6$, by the method of Example (A Repeated Root).

Solution.

(a) $p = x^2 - x - 2 = (x-2)(x+1)$ has distinct roots, so by Theorem 8.11.2, $a_k = b_1 2^k + b_2(-1)^k$. From $a_0 = b_1 + b_2 = 0$ and $a_1 = 2b_1 - b_2 = 3$, $3b_1 = 3$, so $b_1 = 1$, $b_2 = -1$. Hence $a_k = 2^k - (-1)^k$. Check: $a_2 = 3 + 0 = 3 = 4 - 1$, $a_3 = 3 + 6 = 9 = 8 + 1$.

(b) The window matrix is $\mathbf{C} = \begin{pmatrix} 0 & 1 \\ -9 & 6 \end{pmatrix}$, with $p = (x-3)^2$. Put $\mathbf{N} = \mathbf{C} - 3\mathbf{I} = \begin{pmatrix} -3 & 1 \\ -9 & 3 \end{pmatrix}$; then $\mathbf{N}^2 = \begin{pmatrix} 9-9 & -3+3 \\ 27-27 & -9+9 \end{pmatrix} = 0$. As in the example, by induction $\mathbf{C}^k = 3^k\mathbf{I} + k3^{k-1}\mathbf{N}$: the step is $(3^k\mathbf{I} + k3^{k-1}\mathbf{N})(3\mathbf{I} + \mathbf{N}) = 3^{k+1}\mathbf{I} + 3^k\mathbf{N} + k3^k\mathbf{N}$. Row 1 of $\mathbf{C}^k$ is $\big(3^k - 3k3^{k-1},\ k3^{k-1}\big) = \big((1-k)3^k,\ k3^{k-1}\big)$, so

$$a_k = (1-k)3^k \cdot 1 + k3^{k-1} \cdot 6 = (1 - k + 2k)3^k = (1+k)3^k.$$

Check: $a_2 = 36 - 9 = 27 = 3 \cdot 9$, $a_3 = 6 \cdot 27 - 9 \cdot 6 = 108 = 4 \cdot 27$.

Exercise B2: A three-state chain.

Let

$$\mathbf{A} = \begin{pmatrix} 1/2 & 1/2 & 1/4 \\ 1/4 & 0 & 1/4 \\ 1/4 & 1/2 & 1/2 \end{pmatrix}.$$

(a) Verify that $\mathbf{A}$ is stochastic, and find its steady state.

(b) Verify that $(-1, 0, 1)$ and $(1, -2, 1)$ are eigenvectors of $\mathbf{A}$, and find their eigenvalues.

(c) Hence find the entrywise limit of $\mathbf{A}^k$, and the limit of the chain started at $\mathbf{x}_0 = \mathbf{e}_2$.

Solution.

(a) All entries are non-negative; the columns sum to $\frac{1}{2} + \frac{1}{4} + \frac{1}{4} = 1$, $\frac{1}{2} + 0 + \frac{1}{2} = 1$ and $\frac{1}{4} + \frac{1}{4} + \frac{1}{2} = 1$. For the steady state, solve $(\mathbf{A} - \mathbf{I})\mathbf{v} = \mathbf{0}$:

$$\mathbf{A} - \mathbf{I} = \begin{pmatrix} -1/2 & 1/2 & 1/4 \\ 1/4 & -1 & 1/4 \\ 1/4 & 1/2 & -1/2 \end{pmatrix}.$$

Multiplying the rows by 4: $-2v_1 + 2v_2 + v_3 = 0$, $v_1 - 4v_2 + v_3 = 0$, $v_1 + 2v_2 - 2v_3 = 0$.

Subtracting the second from the third gives $6v_2 - 3v_3 = 0$, so $v_3 = 2v_2$; then the second gives $v_1 = 4v_2 - 2v_2 = 2v_2$, and the first holds: $-4v_2 + 2v_2 + 2v_2 = 0$. So $E_1(\mathbf{A}) = \operatorname{span}((2,1,2))$, and scaling to sum 1, the steady state is $\mathbf{v} = (\frac{2}{5}, \frac{1}{5}, \frac{2}{5})$.

(b) $\mathbf{A}(-1,0,1) = (-\frac{1}{2} + \frac{1}{4},\ -\frac{1}{4} + \frac{1}{4},\ -\frac{1}{4} + \frac{1}{2}) = (-\frac{1}{4}, 0, \frac{1}{4}) = \frac{1}{4}(-1,0,1)$, eigenvalue $\frac{1}{4}$. $\mathbf{A}(1,-2,1) = (\frac{1}{2} - 1 + \frac{1}{4},\ \frac{1}{4} + \frac{1}{4},\ \frac{1}{4} - 1 + \frac{1}{2}) = (-\frac{1}{4}, \frac{1}{2}, -\frac{1}{4}) = -\frac{1}{4}(1,-2,1)$, eigenvalue $-\frac{1}{4}$.

(c) The eigenvalues $1, \frac{1}{4}, -\frac{1}{4}$ are distinct, so they are all the eigenvalues of $\mathbf{A}$, $\mathbf{A}$ is diagonalizable (Corollary 8.4.2), $a_{\mathbf{A}}(1) = 1$, and the other two have absolute value $\frac{1}{4} < 1$. By Theorem 8.11.4,

$$\mathbf{A}^k \to \mathbf{v}\mathbf{1}^\top = \frac{1}{5}\begin{pmatrix} 2 & 2 & 2 \\ 1 & 1 & 1 \\ 2 & 2 & 2 \end{pmatrix},$$

and every chain, in particular the one started at $\mathbf{e}_2$, converges to $\mathbf{v} = (\frac{2}{5}, \frac{1}{5}, \frac{2}{5})$.

Exercise B3: The limit of a matrix power.

Let $\mathbf{A} = \begin{pmatrix} 0 & 1 \\ -1/2 & 3/2 \end{pmatrix} \in M_2(\mathbb{R})$.

(a) Diagonalize $\mathbf{A}$, and find a formula for $\mathbf{A}^k$.

(b) Find the entrywise limit of $\mathbf{A}^k$.

(c) Hence find $\lim_{k\to\infty} a_k$ for the sequence with $a_{k+2} = \frac{3}{2}a_{k+1} - \frac{1}{2}a_k$, in terms of a_0 and a_1.

Solution.

(a) $\operatorname{tr}\mathbf{A} = \frac{3}{2}$ and $\det\mathbf{A} = \frac{1}{2}$, so $p_{\mathbf{A}} = x^2 - \frac{3}{2}x + \frac{1}{2} = (x-1)(x-\frac{1}{2})$. $\mathbf{A} - \mathbf{I} = \begin{pmatrix} -1 & 1 \\ -1/2 & 1/2 \end{pmatrix}$ gives the eigenvector $(1,1)$; $\mathbf{A} - \frac{1}{2}\mathbf{I} = \begin{pmatrix} -1/2 & 1 \\ -1/2 & 1 \end{pmatrix}$ gives $(2,1)$. So $\mathbf{P} = \begin{pmatrix} 1 & 2 \\ 1 & 1 \end{pmatrix}$, $\mathbf{D} = \operatorname{diag}(1, \frac{1}{2})$, $\mathbf{P}^{-1} = \begin{pmatrix} -1 & 2 \\ 1 & -1 \end{pmatrix}$ ($\det\mathbf{P} = -1$, Theorem 0.9.8). By Theorem 8.4.3, with $t = 2^{-k}$,

$$\mathbf{A}^k = \begin{pmatrix} 1 & 2t \\ 1 & t \end{pmatrix}\begin{pmatrix} -1 & 2 \\ 1 & -1 \end{pmatrix} = \begin{pmatrix} -1+2t & 2-2t \\ -1+t & 2-t \end{pmatrix}.$$

For $k = 1$, $t = \frac{1}{2}$ gives $\begin{pmatrix} 0 & 1 \\ -1/2 & 3/2 \end{pmatrix} = \mathbf{A}$.

(b) Since $t = 2^{-k} \to 0$, $\mathbf{A}^k \to \begin{pmatrix} -1 & 2 \\ -1 & 2 \end{pmatrix}$ entrywise.

(c) $\mathbf{A}$ is the window matrix of this recurrence, so $(a_k, a_{k+1}) = \mathbf{A}^k(a_0, a_1)$ and $a_k = (-1+2t)a_0 + (2-2t)a_1$. Hence $a_k \to 2a_1 - a_0$. (For instance $a_0 = 0$, $a_1 = 1$ gives $0, 1, \frac{3}{2}, \frac{7}{4}, \cdots \to 2$.)

8.11.6.3 C. Going deeper

Exercise C1: Eigenvalues of a stochastic matrix.

Let $\mathbf{A} \in M_n(\mathbb{R})$ be stochastic, regarded as a complex matrix, and let $\lambda \in \mathbb{C}$ be an eigenvalue of $\mathbf{A}$.

(a) Prove that $|\lambda| \le 1$.

(b) Refine the argument: prove that $|\lambda - a_{ii}| \le 1 - a_{ii}$ for some index i.

(c) Deduce that if every diagonal entry of $\mathbf{A}$ is positive, then -1 is not an eigenvalue of $\mathbf{A}$.

(d) Show by an example that (c) fails if a diagonal entry is 0.

Hint: take a left eigenvector $\mathbf{y}$ for λ and an index i with $|y_i|$ as large as possible.

Solution.

(a) By Proposition 8.10.5 (over $\mathbb{C}$), there is $\mathbf{y} \in \mathbb{C}^n$, $\mathbf{y} \neq \mathbf{0}$, with $\mathbf{A}^{\top}\mathbf{y} = \lambda\mathbf{y}$. Choose i with $|y_i| \ge |y_j|$ for all j; then $|y_i| > 0$, since $\mathbf{y} \neq \mathbf{0}$. Entry i of $\mathbf{A}^{\top}\mathbf{y} = \lambda\mathbf{y}$ reads $\sum_j a_{ji} y_j = \lambda y_i$, because row i of $\mathbf{A}^{\top}$ is column i of $\mathbf{A}$. By Theorem 0.6.2 (d) and Theorem 0.6.4, applied to the n-term sum by induction on n, and since $a_{ji} \ge 0$ and column i sums to 1,

$$|\lambda|\,|y_i| = \Big|\sum_j a_{ji} y_j\Big| \le \sum_j a_{ji}|y_j| \le \sum_j a_{ji}|y_i| = |y_i|.$$

Dividing by $|y_i| > 0$ gives $|\lambda| \le 1$.

(b) With the same i, move the diagonal term across: $(\lambda - a_{ii})y_i = \sum_{j \neq i} a_{ji} y_j$. Hence, as in (a),

$$|\lambda - a_{ii}|\,|y_i| \le \sum_{j \neq i} a_{ji}|y_j| \le \Big(\sum_{j \neq i} a_{ji}\Big)|y_i| = (1 - a_{ii})|y_i|,$$

and dividing by $|y_i|$ gives $|\lambda - a_{ii}| \le 1 - a_{ii}$.

(c) Suppose $\lambda = -1$. By (b), some i has $|-1 - a_{ii}| \le 1 - a_{ii}$. Since $a_{ii} \ge 0$, $|-1 - a_{ii}| = 1 + a_{ii}$, so $1 + a_{ii} \le 1 - a_{ii}$ and $a_{ii} \le 0$. This contradicts $a_{ii} > 0$.

(d) The swap $\mathbf{S} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$ is stochastic with zero diagonal, and $\mathbf{S}(1, -1) = (-1, 1)$, so -1 is an eigenvalue.

Exercise C2: Two-state chains.

Let $0 \le p, q \le 1$ and $\mathbf{A} = \begin{pmatrix} 1 - p & q \\ p & 1 - q \end{pmatrix}$.

(a) Show that $\mathbf{A}$ is stochastic, with eigenvalues 1 and $1 - p - q$.

(b) Suppose $0 < p + q < 2$. Prove that $\mathbf{A}^k$ converges entrywise, and find the limit and the steady state.

(c) In particular, if $\mathbf{A}$ has no zero entry, then $\mathbf{A}^k$ converges. What happens when $p + q = 0$ and when $p + q = 2$?

Solution.

(a) The entries lie in $[0,1]$, and the columns sum to $(1-p)+p=1$ and $q+(1-q)=1$. Since $\operatorname{tr}\mathbf{A} = 2-p-q$ and $\det\mathbf{A} = (1-p)(1-q)-pq = 1-p-q$, $p_{\mathbf{A}} = x^2-(2-p-q)x+(1-p-q) = (x-1)\big(x-(1-p-q)\big)$, as multiplying out confirms.

(b) Put $r = 1-p-q$. Since $0<p+q<2$, $-1<r<1$, so $r\neq 1$ and $|r|<1$. The eigenvalues $1\neq r$ are distinct, so $\mathbf{A}$ is diagonalizable (Corollary 8.4.2). From $\mathbf{A}-\mathbf{I} = \begin{pmatrix} -p & q \\ p & -q \end{pmatrix}$, (q,p) is an eigenvector for 1, non-zero because $p+q>0$; from $\mathbf{A}-r\mathbf{I} = \begin{pmatrix} q & q \\ p & p \end{pmatrix}$, $(1,-1)$ is one for r. So

$$\mathbf{P} = \begin{pmatrix} q & 1 \\ p & -1 \end{pmatrix}, \qquad \mathbf{P}^{-1} = \frac{1}{p+q}\begin{pmatrix} 1 & 1 \\ p & -q \end{pmatrix},$$

with $\det\mathbf{P} = -(p+q)\neq 0$. By Theorem 8.4.3,

$$\mathbf{A}^k = \frac{1}{p+q}\begin{pmatrix} q & r^k \\ p & -r^k \end{pmatrix}\begin{pmatrix} 1 & 1 \\ p & -q \end{pmatrix} = \frac{1}{p+q}\begin{pmatrix} q+pr^k & q-qr^k \\ p-pr^k & p+qr^k \end{pmatrix}.$$

Since $|r|<1$, $r^k\to 0$, and

$$\mathbf{A}^k \to \frac{1}{p+q}\begin{pmatrix} q & q \\ p & p \end{pmatrix}, \qquad \mathbf{v} = \Big(\frac{q}{p+q}, \frac{p}{p+q}\Big).$$

The limit is $\mathbf{v}\mathbf{1}^{\top}$, and $\mathbf{v}$ is the steady state, in agreement with Theorem 8.11.4.

(c) If no entry is zero, then $1-p>0$ and $p>0$, so $0<p<1$, and likewise $0<q<1$; hence $0<p+q<2$ and (b) applies. If $p+q=0$, then $p=q=0$ and $\mathbf{A}=\mathbf{I}$: the powers converge (to $\mathbf{I}$), but every probability vector is a steady state. If $p+q=2$, then $p=q=1$ and $\mathbf{A}$ is the swap, whose powers do not converge.

Chapter 9

Canonical Forms

Chapter 8 left one question open. Two matrices represent the same operator in different bases exactly when they are similar, and we can now decide similarity in easy cases: diagonalizable matrices are similar precisely when they have the same eigenvalues with the same multiplicities. But the matrices $\begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$ and I_2 share their characteristic and minimal polynomials, their rank, their trace and their determinant, and they are still not similar. Something is missing.

This chapter supplies it. When the characteristic polynomial splits, every operator has a **Jordan form**: a direct sum of blocks with one eigenvalue on the diagonal and ones just above it, unique up to the order of the blocks. Two matrices are similar exactly when their Jordan forms agree, so the similarity problem is solved. Over a field where the polynomial does not split, the **rational canonical form** does the same job, and the Smith normal form of $x\mathbf{I} - \mathbf{A}$ computes it. The chapter closes with what these forms are for: functions of matrices, the exponential $e^{t\mathbf{A}}$ and linear differential equations, and a complete answer to when the powers $\mathbf{A}^m$ converge.

What you need. From Chapter 1, direct sums, basis extension and complexification (Theorem 1.7.5, Theorem 1.6.5, Definition 1.9.2). From Chapter 5, the arithmetic of $F[x]$: division, gcds, Bézout and unique factorization (Theorem 5.1.1, Corollary 5.2.4, Theorem 5.3.5), and interpolation (Theorem 5.6.4). From Chapter 6, determinants of block triangular matrices, Cauchy–Binet and the companion matrix of a monic polynomial (Theorem 6.8.4, Theorem 6.7.2, Exercise (C1: Companion matrices)). From Chapter 8, the minimal polynomial, primary decomposition and triangularization (Definition 8.5.1, Theorem 8.8.1, Theorem 8.7.2).

9.0.1 Roadmap

- **Generalized eigenspaces.** Enlarging an eigenspace until it is big enough, and the decomposition it produces.
- **Nilpotent operators.** Chains of vectors, the block structure they give, and how ranks of powers determine it.
- **The Jordan canonical form.** Existence, uniqueness, and the complete answer to the similarity question over a splitting field.
- **The real Jordan form and the Weyr form.** Avoiding complex numbers for a real matrix, and a rearrangement of the Jordan form with its own uses.
- **Cyclic subspaces and companion matrices.** One vector and its images can generate everything.

- **The rational canonical form.** A canonical form over every field, with invariant factors as the complete invariants.
- **Polynomial matrices and the Smith normal form.** Row and column operations on $x\mathbf{I} - \mathbf{A}$ compute the invariant factors.
- **Semisimple operators and the Jordan–Chevalley decomposition.** Every operator splits uniquely into a diagonalizable part plus a commuting nilpotent part.
- **Functions of matrices, the exponential and linear differential equations.** $f(\mathbf{A})$ from the Jordan form, and $x' = \mathbf{A}x$ solved by $e^{t\mathbf{A}}$.
- **Convergent and power-bounded matrices.** Exactly when $\mathbf{A}^m$ converges, and to what.

9.0.2 Named moves

- **Enlarge the kernel.** When $\ker(T - \lambda I)$ is too small, pass to $\ker(T - \lambda I)^k$ until the chain stops growing.
- **Reduce to the nilpotent case.** On each generalized eigenspace, $T - \lambda I$ is nilpotent, so the whole structure question is about nilpotent operators.
- **Read the chain off the columns.** The columns of a Jordan block say $N\mathbf{v}_1 = \mathbf{0}$ and $N\mathbf{v}_j = \mathbf{v}_{j-1}$: a chain.
- **Count ranks of powers.** The block sizes are second differences of $\operatorname{rank} N^j$, so they can be found without finding a single chain.
- **A cyclic vector gives a companion matrix.** If $\mathbf{v}, T\mathbf{v}, \dots$ span, the matrix of T is built from one polynomial.

9.1 Generalized Eigenspaces

Chapter 8 left one gap wide open. When an operator has too few eigenvectors, its eigenspaces are too small to fill the space, and diagonalization fails. The remedy of this chapter is to enlarge each eigenspace until the enlarged pieces do fill the space. This section builds the enlargement, shows that the enlarging process stops after finitely many steps, and proves that the pieces split V whenever the characteristic polynomial splits.

9.1.1 Enlarging an eigenspace

Take the standing counterexample of Chapter 8,

$$\mathbf{J} = \begin{pmatrix} 2 & 1 \\ 0 & 2 \end{pmatrix} \in M_2(F),$$

and let $\mathbf{N} = \mathbf{J} - 2\mathbf{I}$. The only eigenvalue is 2, and $E_2(\mathbf{J}) = \ker \mathbf{N} = \operatorname{span}(\mathbf{e}_1)$ is a line: one eigenvector direction where we need two, so $\mathbf{J}$ is not diagonalizable over any field (Theorem 8.4.1 (e)).

Now look at what $\mathbf{N}$ does to the missing direction $\mathbf{e}_2$. One application does not kill $\mathbf{e}_2$, but two do:

$$\mathbf{N}\mathbf{e}_2 = \mathbf{e}_1, \qquad \mathbf{N}^2\mathbf{e}_2 = \mathbf{N}\mathbf{e}_1 = \mathbf{0}.$$

So $\mathbf{e}_2$ is killed by $\mathbf{N}^2$, and $\ker \mathbf{N}^2 = F^2$ is everything. The eigenspace was too small, but the kernel of the **square** is as big as we could wish.

This is the whole idea. Instead of asking for vectors killed by $T - \lambda \operatorname{id}_V$, ask for vectors killed by **some power** of $T - \lambda \operatorname{id}_V$. The eigenvectors are still there (they are killed at the first step), and there may be more.

A generalized eigenvector is a vector that some power of $T - \lambda \operatorname{id}_V$ kills, not necessarily the first power.

9.1.2 Generalized eigenvectors and generalized eigenspaces

Definition 9.1.1 — Generalized Eigenvector

Let V be a vector space over F, let $T \in \mathcal{L}(V)$ and $\lambda \in F$. A **generalized eigenvector** of T for λ is a vector $\mathbf{v} \in V$ with $\mathbf{v} \neq \mathbf{0}$ such that

$$(T - \lambda \operatorname{id}_V)^k \mathbf{v} = \mathbf{0} \qquad \text{for some integer } k \geq 1.$$

In words: the vector must be **non-zero**, exactly as for an eigenvector; the scalar λ must lie **in** F; and the power k is not fixed in advance — it may depend on $\mathbf{v}$. Taking $k = 1$ recovers the eigenvector condition, so **every eigenvector for λ is a generalized eigenvector for λ.**

Collecting all of them, together with $\mathbf{0}$, gives the space we are after.

Definition 9.1.2 — Generalized Eigenspace

Let V be a vector space over F, let $T \in \mathcal{L}(V)$ and $\lambda \in F$. The **generalized eigenspace** of T for λ is

$$\begin{aligned} G_\lambda(T) &\coloneqq \{\, \mathbf{v} \in V : (T - \lambda \operatorname{id}_V)^k \mathbf{v} = \mathbf{0} \text{ for some integer } k \geq 1 \,\} \\ &= \bigcup_{k \geq 1} \ker(T - \lambda \operatorname{id}_V)^k. \end{aligned}$$

For $\mathbf{A} \in M_n(F)$ we write $G_\lambda(\mathbf{A}) = G_\lambda(T_{\mathbf{A}})$.

So $G_\lambda(T)$ consists of $\mathbf{0}$ together with all generalized eigenvectors for λ. Writing $N = T - \lambda \operatorname{id}_V$ for the rest of this subsection, the definition says $G_\lambda(T) = \ker N \cup \ker N^2 \cup \ker N^3 \cup \dots$.

Well-definedness: it really is a subspace. A union of subspaces is almost never a subspace (Proposition 1.2.3), so this needs a check. What saves us is that the union is **increasing**: if $N^k \mathbf{v} = \mathbf{0}$, then $N^{k+1}\mathbf{v} = N(N^k \mathbf{v}) = N\mathbf{0} = \mathbf{0}$, so

$$\ker N \subseteq \ker N^2 \subseteq \ker N^3 \subseteq \dots$$

Now use the subspace test (Theorem 1.2.1). We have $\mathbf{0} \in \ker N \subseteq G_\lambda(T)$, so the set is non-empty. If $\mathbf{u}, \mathbf{v} \in G_\lambda(T)$, say $N^j \mathbf{u} = \mathbf{0}$ and $N^k \mathbf{v} = \mathbf{0}$, put $m = \max(j, k)$; then $\mathbf{u}, \mathbf{v} \in \ker N^m$ by the inclusions above, and $\ker N^m$ is a subspace, so $\mathbf{u} + \mathbf{v}$ and $c\mathbf{u}$ lie in $\ker N^m \subseteq G_\lambda(T)$ for every $c \in F$. Hence $G_\lambda(T)$ is a subspace of V.

Examples.

- **The standing counterexample.** For $\mathbf{J} = \begin{pmatrix} 2 & 1 \\ 0 & 2 \end{pmatrix}$, we computed $\ker(\mathbf{J} - 2\mathbf{I}) = \operatorname{span}(\mathbf{e}_1)$

and $\ker(\mathbf{J}-2\mathbf{I})^2 = F^2$. So $G_2(\mathbf{J}) = F^2$, while $E_2(\mathbf{J})$ is only a line. The generalized eigenspace is strictly bigger than the eigenspace, and it is all of F^2.

- **A diagonalizable operator gains nothing.** Let $\mathbf{A} = \operatorname{diag}(2,5)$ over $\mathbb{Q}$. Then $(\mathbf{A}-2\mathbf{I})^k = \operatorname{diag}(0,3^k)$, whose kernel is $\operatorname{span}(\mathbf{e}_1)$ for every $k \geq 1$. So $G_2(\mathbf{A}) = E_2(\mathbf{A}) = \operatorname{span}(\mathbf{e}_1)$, and likewise $G_5(\mathbf{A}) = E_5(\mathbf{A}) = \operatorname{span}(\mathbf{e}_2)$. Enlarging an eigenspace of a diagonalizable operator does nothing, a fact we prove in general below.
- **Differentiation.** Let $D \in \mathcal{L}(F[x]_{\leq n})$ be differentiation. Then $D^{n+1} = 0$ (Example (Differentiation Is Nilpotent)), so **every** polynomial is killed by a power of D, that is, of $D - 0\,\mathrm{id}$, and $G_0(D) = F[x]_{\leq n}$. By contrast $E_0(D) = \ker D$ is the line of constants when $F = \mathbb{R}$. Here the generalized eigenspace for the single eigenvalue 0 is the whole space, of dimension $n+1$.
- **A scalar not among the eigenvalues.** For the same $\mathbf{A} = \operatorname{diag}(2,5)$ and $\lambda = 7$, the matrix $(\mathbf{A}-7\mathbf{I})^k = \operatorname{diag}((-5)^k,(-2)^k)$ is invertible, so its kernel is $\{\mathbf{0}\}$ for every k. Hence $G_7(\mathbf{A}) = \{\mathbf{0}\}$. The definition makes sense for every $\lambda \in F$, and gives the zero space unless λ is an eigenvalue.
- **A degenerate case.** On a space of dimension 1, every operator is λ id for one scalar λ, and $G_\lambda = V$, $G_\mu = \{\mathbf{0}\}$ for $\mu \neq \lambda$. Small as it is, this is the model for a 1×1 Jordan block.
- **No eigenvalues at all.** The rotation R of $\mathbb{R}^2$ by a right angle has no real eigenvalue (Example (A Rotation Has No Invariant Lines)), and indeed $G_\lambda(R) = \{\mathbf{0}\}$ for every $\lambda \in \mathbb{R}$: if $(R-\lambda\mathbf{I})^k\mathbf{v} = \mathbf{0}$ with $\mathbf{v} \neq \mathbf{0}$, then $R - \lambda\mathbf{I}$ would not be injective, so λ would be an eigenvalue. Over $\mathbb{C}$, where $p_R = x^2+1 = (x-i)(x+i)$ splits, $G_i(R)$ and $G_{-i}(R)$ are the two eigenlines.

Non-example by minimal change. Keep $\mathbf{A} = \operatorname{diag}(2,5)$ over $\mathbb{Q}$ and take $\mathbf{v} = (1,1)$. This vector **is** killed by a polynomial in $\mathbf{A}$ whose roots are eigenvalues:

$$(\mathbf{A}-2\mathbf{I})(\mathbf{A}-5\mathbf{I})\mathbf{v} = \mathbf{0},$$

as one checks entry by entry. But it is a generalized eigenvector for **neither** eigenvalue: $(\mathbf{A}-2\mathbf{I})^k\mathbf{v} = (0,3^k) \neq \mathbf{0}$ and $(\mathbf{A}-5\mathbf{I})^k\mathbf{v} = ((-3)^k,0) \neq \mathbf{0}$ for every $k \geq 1$. The failing clause is that the definition demands a power of a **single** factor $T - \lambda\,\mathrm{id}_V$, not a product of different factors. (Of course $\mathbf{v} = \mathbf{e}_1 + \mathbf{e}_2$ is a *sum* of two generalized eigenvectors; that is the decomposition theorem below, not the definition.)

Why this definition. Three clauses are doing work. The vector must be non-zero, or every G_λ would contain a "generalized eigenvector" and the word would carry no information. The exponent must be allowed to grow, because nothing tells us in advance how many steps a vector needs: for D on $\mathbb{R}[x]_{\leq n}$ the polynomial x^n needs $n+1$ steps. And the power is a power of one factor, which is what makes G_λ one piece attached to one eigenvalue. The name is the honest one: these are the vectors that behave like eigenvectors after enough applications of $T - \lambda\,\mathrm{id}_V$.

> *Warning.* $G_\lambda(T)$ **is usually bigger than** $E_\lambda(T)$**, and "generalized eigenvector" includes the ordinary ones.** The inclusion $E_\lambda(T) \subseteq G_\lambda(T)$ always holds, and it is strict exactly when T has too few eigenvectors for λ: for $\mathbf{J} = \begin{pmatrix} 2 & 1 \\ 0 & 2 \end{pmatrix}$, $\dim E_2 = 1$ and $\dim G_2 = 2$. So a generalized eigenvector need not satisfy $T\mathbf{v} = \lambda\mathbf{v}$: the vector $\mathbf{e}_2$ satisfies $\mathbf{J}\mathbf{e}_2 = \mathbf{e}_1 + 2\mathbf{e}_2$. Conversely, do not read "generalized" as "not an eigenvector": every eigenvector is a generalized eigenvector.

9.1.3 The kernel chain stabilizes

The definition of $G_\lambda(T)$ is an infinite union, which is awkward: to decide membership we would have to try every k. In finite dimension this is an illusion. The chain $\ker N \subseteq \ker N^2 \subseteq \dots$ is a chain of subspaces of V, and their dimensions cannot keep growing. Once the chain stops growing, it stops forever.

Theorem 9.1.1 — The Kernel Chain Stabilizes

Let V be a finite-dimensional vector space over F with $\dim V = n$, let $N \in \mathcal{L}(V)$, and write $K_k = \ker N^k$ for $k \geq 0$, so that $K_0 = \{\mathbf{0}\}$. Then:

(a) $K_0 \subseteq K_1 \subseteq K_2 \subseteq \dots$, and every K_k is N-invariant;

(b) if $K_m = K_{m+1}$ for some $m \geq 0$, then $K_{m+j} = K_m$ for **every** $j \geq 0$;

(c) there is a **least** index $s \geq 0$ with $K_s = K_{s+1}$; it satisfies $s \leq n$, the inclusions

$$K_0 \subsetneq K_1 \subsetneq \cdots \subsetneq K_s$$

are **strict**, and $K_k = K_s$ for every $k \geq s$;

(d) in particular $\ker N^n = \ker N^{n+j}$ for every $j \geq 0$.

Idea. The only real point is (b): equality at one step propagates. Read it backwards. To put $\mathbf{v} \in K_{m+j+1}$ into K_{m+j}, look at $\mathbf{w} = N^j\mathbf{v}$. It lies in K_{m+1}, which by hypothesis is K_m, and that is exactly the statement $N^{m+j}\mathbf{v} = \mathbf{0}$. Then (c) and (d) are bookkeeping: while the inclusions are strict the dimensions go up by at least 1, so strictness cannot survive past step n.

Proof.

(a) If $N^k\mathbf{v} = \mathbf{0}$, then $N^{k+1}\mathbf{v} = N(N^k\mathbf{v}) = \mathbf{0}$, so $K_k \subseteq K_{k+1}$. Each $K_k = \ker N^k$ is the kernel of a polynomial in N, hence N-invariant by Theorem 5.7.4 (b).

(b) Suppose $K_m = K_{m+1}$. We prove $K_{m+j} = K_m$ by induction on $j \geq 0$. For $j = 0$ there is nothing to prove. Assume $K_{m+j} = K_m$, and let $\mathbf{v} \in K_{m+j+1}$. Then

$$N^{m+1}(N^j\mathbf{v}) = N^{m+j+1}\mathbf{v} = \mathbf{0},$$

so $N^j\mathbf{v} \in K_{m+1} = K_m$, which says $N^{m+j}\mathbf{v} = N^m(N^j\mathbf{v}) = \mathbf{0}$. Hence $\mathbf{v} \in K_{m+j} = K_m$. Together with $K_m \subseteq K_{m+j+1}$ from (a), this gives $K_{m+j+1} = K_m$.

(c) First, some m with $0 \leq m \leq n$ satisfies $K_m = K_{m+1}$. Otherwise $K_m \subsetneq K_{m+1}$ for every $m = 0, 1, \dots, n$, so $\dim K_{m+1} \geq \dim K_m + 1$ for those m, and hence $\dim K_{n+1} \geq n + 1$, contradicting $\dim K_{n+1} \leq \dim V = n$ (Theorem 1.6.7). By the well-ordering principle (Theorem 0.2.11) there is a least such index; call it s, and $s \leq n$. For $k < s$ minimality gives $K_k \neq K_{k+1}$, so the inclusion $K_k \subseteq K_{k+1}$ of (a) is strict. For $k \geq s$, (b) gives $K_k = K_s$.

(d) Since $s \leq n$, (c) gives $K_n = K_s = K_{n+j}$ for every $j \geq 0$.

■

Quick check. Can $\ker N \subsetneq \ker N^2 = \ker N^3$ happen? Can $\ker N = \ker N^2 \subsetneq \ker N^3$ happen?

Solution. The first can: for $\mathbf{N} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$ on F^2 we have $\ker \mathbf{N} = \operatorname{span}(\mathbf{e}_1)$ and $\ker \mathbf{N}^2 = F^2 = \ker \mathbf{N}^3$, since $\mathbf{N}^2 = 0$. Here $s = 2$.

The second cannot, by Theorem 9.1.1 (b) with $m = 1$: equality at one step forces equality at every later step. This is why the theorem says the strict inclusions come **first** and the equalities **after**; the chain never resumes growing.

The index s will come up often enough to name. We call the least $s \geq 0$ with $\ker N^s = \ker N^{s+1}$ the **stabilization index** of N. Part (d) is the useful form: the chain has certainly stopped by step $n = \dim V$, whatever N is. Applying this to $N = T - \lambda \operatorname{id}_V$ turns the infinite union in Definition 9.1.2 into a single kernel.

Corollary 9.1.2 — The Generalized Eigenspace Is One Kernel

Let V be a finite-dimensional vector space over F with $\dim V = n$, let $T \in \mathcal{L}(V)$ and $\lambda \in F$, and put $N = T - \lambda \operatorname{id}_V$ with stabilization index s. Then:

(a) $G_\lambda(T) = \ker N^s = \ker N^n$;

(b) $G_\lambda(T)$ is T-invariant, and $E_\lambda(T) \subseteq G_\lambda(T)$;

(c) $G_\lambda(T) \neq \{\mathbf{0}\}$ if and only if λ is an eigenvalue of T;

(d) if $\mathbf{v} \in G_\lambda(T)$ is non-zero and $k \geq 1$ is **least** with $N^k\mathbf{v} = \mathbf{0}$, then $N^{k-1}\mathbf{v}$ is an eigenvector of T for λ.

Proof.

(a) Every $\ker N^k$ with $k \geq 1$ is contained in $\ker N^{\max(k,n)} = \ker N^n$ by Theorem 9.1.1 (a) and (d), so the union $G_\lambda(T)$ equals $\ker N^n$; and $\ker N^n = \ker N^s$ by (c) of the same theorem, since $s \leq n$.

(b) By (a), $G_\lambda(T) = \ker N^n$ is the kernel of a polynomial in T, so T maps it into itself (Theorem 5.7.4 (b)). And $E_\lambda(T) = \ker N \subseteq \ker N^n$.

(c) ($\Leftarrow$) If λ is an eigenvalue, then $E_\lambda(T) \neq \{\mathbf{0}\}$ (Theorem 8.2.1), and $E_\lambda(T) \subseteq G_\lambda(T)$ by (b). ($\Rightarrow$) If $\mathbf{v} \in G_\lambda(T)$ is non-zero, take $k \geq 1$ least with $N^k\mathbf{v} = \mathbf{0}$, which exists by the definition of $G_\lambda(T)$ and Theorem 0.2.11. Then $\mathbf{w} = N^{k-1}\mathbf{v} \neq \mathbf{0}$ by minimality of k (for $k = 1$ this reads $\mathbf{w} = \mathbf{v} \neq \mathbf{0}$), while $N\mathbf{w} = N^k\mathbf{v} = \mathbf{0}$. So $\mathbf{w} \in \ker N$ is non-zero and λ is an eigenvalue.

(d) This is the computation just made: $\mathbf{w} = N^{k-1}\mathbf{v}$ is non-zero and lies in $\ker N = E_\lambda(T)$.

■

Part (d) is a move worth remembering: **to get a genuine eigenvector out of a generalized one, apply $T - \lambda \operatorname{id}_V$ as many times as possible without reaching 0.** It is the reason the enlargement never produces eigenvalues out of thin air, and it will start every Jordan chain in Section 2.

9.1.4 The generalized eigenspace decomposition

We can now state the payoff. Chapter 8's primary decomposition (Theorem 8.8.1) already splits V into invariant pieces, one for each irreducible factor of m_T. When p_T splits, all those factors are linear, the pieces are kernels of powers of $T-\lambda_i\,\mathrm{id}_V$ — and those are exactly the generalized eigenspaces. The extra information here is that the piece attached to λ_i has dimension $a_T(\lambda_i)$, so the sizes are read off the characteristic polynomial.

When the characteristic polynomial splits, the generalized eigenspaces fill the space, and the one for λ has dimension the algebraic multiplicity of λ.

Theorem 9.1.3 — Generalized Eigenspace Decomposition

Let V be a finite-dimensional vector space over F with $\dim V = n \geq 1$, let $T \in \mathcal{L}(V)$, and suppose p_T **splits** over F, with distinct eigenvalues $\lambda_1, \ldots, \lambda_k$ and

$$p_T = (x-\lambda_1)^{a_1}\cdots(x-\lambda_k)^{a_k}, \qquad m_T = (x-\lambda_1)^{s_1}\cdots(x-\lambda_k)^{s_k},$$

where $a_i = a_T(\lambda_i)$ and $1 \leq s_i \leq a_i$. Write $G_i = G_{\lambda_i}(T)$ and $N_i = (T-\lambda_i\,\mathrm{id}_V)|_{G_i}$. Then:

(a) $G_i = \ker(T-\lambda_i\,\mathrm{id}_V)^{s_i}$, and

$$V = G_1 \oplus G_2 \oplus \cdots \oplus G_k;$$

(b) each G_i is T-invariant and non-zero, with $E_{\lambda_i}(T) \subseteq G_i$, and $E_{\lambda_i}(T) = G_i$ if and only if $s_i = 1$;

(c) $\dim G_i = a_i$ and $p_{T|_{G_i}} = (x-\lambda_i)^{a_i}$;

(d) $N_i^{a_i} = 0$; that is, $T|_{G_i} = \lambda_i\,\mathrm{id}_{G_i} + N_i$ with N_i nilpotent, of stabilization index s_i;

(e) if $\mathcal{B}$ is a basis of V obtained by writing bases of $G_1, \ldots, G_k$ one after another, then

$$[T]_{\mathcal{B}} = [T|_{G_1}] \;\oplus\; \ldots \;\oplus\; [T|_{G_k}]$$

is block diagonal, with the i-th block of size a_i.

Idea. Almost everything is already proved; the one new step is (a), the identification $G_i = \ker(T-\lambda_i\,\mathrm{id}_V)^{s_i}$. One inclusion is free, since $\ker(T-\lambda_i)^{s_i}$ sits inside the union defining G_i. For the other, count. Chapter 8 says the primary piece $\ker(T-\lambda_i)^{s_i}$ has dimension a_i, so it is enough to show $\dim G_i \leq a_i$. Now G_i is invariant, and the only eigenvalue of T on G_i is λ_i: an eigenvector in G_i for μ is killed by $(\mu-\lambda_i)^n$, which forces $\mu = \lambda_i$. So the characteristic polynomial of the restriction is a power of $x-\lambda_i$ dividing p_T, and its degree $\dim G_i$ is at most a_i.

Proof. Since p_T splits and $m_T \mid p_T$, Corollary 8.6.2 (b) gives the displayed factorization of m_T with $1 \leq s_i \leq a_i$. Put $V_i = \ker(T-\lambda_i\,\mathrm{id}_V)^{s_i}$. The polynomials $x-\lambda_i$ are distinct monic irreducibles, so Theorem 8.8.1 applies to $m_T = \prod_i (x-\lambda_i)^{s_i}$ and gives

$$V = V_1 \oplus \cdots \oplus V_k,$$

with each V_i invariant and non-zero. By Corollary 8.8.4, $\dim V_i = a_i$, $p_{T|_{V_i}} = (x-\lambda_i)^{a_i}$, and $E_{\lambda_i}(T) \subseteq V_i$ with equality if and only if $s_i = 1$.

Claim: $G_i = V_i$. Fix i and write $G = G_i$, $\lambda = \lambda_i$, $a = a_i$, $N = T - \lambda\,\mathrm{id}_V$.

($\supseteq$) $V_i = \ker N^{s_i} \subseteq \bigcup_{j\geq 1} \ker N^j = G$.

($\subseteq$) It suffices to prove $\dim G \leq a$: then $V_i \subseteq G$ and $\dim V_i = a \geq \dim G$ force $\dim V_i = \dim G$, and Theorem 1.6.8, applied to the subspace V_i of G, gives $V_i = G$.

First, *the only eigenvalue of* $T|_G$ *is* λ. Indeed, G is T-invariant (Corollary 9.1.2 (b)), so the restriction makes sense (Definition 8.1.2). Let $\mu \in F$ be an eigenvalue of $T|_G$, with eigenvector $\mathbf{v} \in G$, $\mathbf{v} \neq \mathbf{0}$. From $T\mathbf{v} = \mu\mathbf{v}$ we get $N\mathbf{v} = (\mu-\lambda)\mathbf{v}$, hence $N^n\mathbf{v} = (\mu-\lambda)^n\mathbf{v}$ by induction. But $G = \ker N^n$ by Corollary 9.1.2 (a), so $(\mu - \lambda)^n\mathbf{v} = \mathbf{0}$ with $\mathbf{v} \neq \mathbf{0}$, which forces the scalar $(\mu - \lambda)^n$ to be 0 (Theorem 1.1.9), and so $\mu = \lambda$, since a field has no zero divisors (Theorem 0.7.1).

Now compare characteristic polynomials. $G \neq \{\mathbf{0}\}$, since λ is an eigenvalue of T (Corollary 9.1.2 (c)). If $G = V$, then every root of p_T is an eigenvalue of $T = T|_G$ (Theorem 8.2.1), so λ is the only root; as p_T splits and is monic of degree n (Theorem 6.10.2), $p_T = (x - \lambda)^n$ and $a = n = \dim G$. If $G \neq V$, then Theorem 8.1.3 (b) applies to the invariant subspace G and gives

$$p_T = p_{T|_G}\, p_{\bar{T}},$$

so $p_{T|_G}$ is a monic divisor of $p_T = \prod_j (x - \lambda_j)^{a_j}$. By Lemma 8.5.2, $p_{T|_G} = \prod_j (x - \lambda_j)^{c_j}$ with $0 \leq c_j \leq a_j$. Its roots are the eigenvalues of $T|_G$ (Theorem 8.2.1, applied to $T|_G$), which we just showed to be λ alone, so $c_j = 0$ for $j \neq i$. Hence $p_{T|_G} = (x - \lambda)^{c_i}$, and comparing degrees (Theorem 6.10.2) gives $\dim G = c_i \leq a$. This proves the claim, and with it (a), (b) and (c), since $G_i = V_i$.

(d) By Theorem 8.8.1 (c) and the claim, $m_{T|_{G_i}} = (x - \lambda_i)^{s_i}$. For an integer $j \geq 0$, the operator N_i^j is $(x - \lambda_i)^j$ evaluated at $T|_{G_i}$, so $N_i^j = 0$ if and only if $(x - \lambda_i)^{s_i}$ divides $(x - \lambda_i)^j$ (Theorem 8.5.1), that is, if and only if $j \geq s_i$. Since $s_i \leq a_i$, this gives $N_i^{a_i} = 0$, and it identifies s_i as the least exponent killing N_i. Hence $\ker N_i^{s_i} = G_i$ while $\ker N_i^{s_i-1} \subsetneq G_i$, so the stabilization index of N_i is s_i.

(e) Each G_i is invariant and non-zero, and $V = \bigoplus_i G_i$, so Theorem 8.1.5 gives the block diagonal shape, the i-th block being $[T|_{G_i}]$ in the chosen basis of G_i, of size $\dim G_i = a_i$.

■

Read (d) again, since it is the plan for the rest of the chapter. **On its generalized eigenspace, T is a scalar plus a nilpotent operator.** The scalar part is as simple as an operator can be. So the only question left is what a nilpotent operator looks like in a well-chosen basis, and that is the subject of the next section. Once it is answered, (e) assembles the answers for the different eigenvalues into one matrix for T.

Two consistency checks. Summing dimensions in (a) and using (c) gives $\sum_i a_i = n$, which is the degree count for a split p_T. And if T is diagonalizable, then every $s_i = 1$ (Theorem 8.8.2), so (b) says $G_i = E_{\lambda_i}(T)$ and (a) becomes the eigenspace decomposition $V = \bigoplus_i E_{\lambda_i}(T)$ of Theorem 8.4.1 (c). Nothing is lost, and nothing new is gained, in the diagonalizable case.

Example. (Generalized Eigenspaces of a 4×4 Matrix)

Let

$$\mathbf{A} = \begin{pmatrix} 2 & 1 & -1 & -2 \\ -3 & 3 & -1 & 1 \\ 3 & -1 & 3 & -1 \\ -3 & 1 & -1 & 3 \end{pmatrix} \in M_4(\mathbb{Q}), \qquad p_{\mathbf{A}} = (x-2)^3(x-5).$$

Find $E_2(\mathbf{A})$, $G_2(\mathbf{A})$, $G_5(\mathbf{A})$, the stabilization index of $\mathbf{A} - 2\mathbf{I}$, and the minimal polynomial. Verify Theorem 9.1.3 on this matrix.

Solution. The eigenspace. Write $\mathbf{N} = \mathbf{A} - 2\mathbf{I}$, so

$$\mathbf{N} = \begin{pmatrix} 0 & 1 & -1 & -2 \\ -3 & 1 & -1 & 1 \\ 3 & -1 & 1 & -1 \\ -3 & 1 & -1 & 1 \end{pmatrix}.$$

Rows 2 and 4 are equal and row 3 is their negative, so the row space is spanned by rows 1 and 2, which are not proportional; hence $\operatorname{rank}\mathbf{N} = 2$ and $\operatorname{nullity}\mathbf{N} = 2$ (Theorem 2.5.7). The kernel is cut out by

$$x_2 - x_3 - 2x_4 = 0, \qquad -3x_1 + x_2 - x_3 + x_4 = 0.$$

Subtracting the first equation from the second gives $-3x_1 + 3x_4 = 0$, so $x_1 = x_4$, and then $x_2 = x_3 + 2x_4$. With $x_3 = s$ and $x_4 = t$ free,

$$E_2(\mathbf{A}) = \{(t,\, s+2t,\, s,\, t)\} = \operatorname{span}\big((0,1,1,0),\ (1,2,0,1)\big), \qquad g_{\mathbf{A}}(2) = 2.$$

Since $a_{\mathbf{A}}(2) = 3 > 2$, the matrix is not diagonalizable (Theorem 8.4.1 (e)).

The generalized eigenspace. Squaring,

$$\mathbf{N}^2 = 9\begin{pmatrix} 0 & 0 & 0 & 0 \\ -1 & 0 & 0 & 1 \\ 1 & 0 & 0 & -1 \\ -1 & 0 & 0 & 1 \end{pmatrix},$$

which has rank 1, so $\ker\mathbf{N}^2$ has dimension 3 and is the hyperplane

$$\ker\mathbf{N}^2 = \{\,\mathbf{x} : x_1 = x_4\,\} = \operatorname{span}\big(\mathbf{e}_2,\ \mathbf{e}_3,\ \mathbf{e}_1 + \mathbf{e}_4\big).$$

The chain of kernels has dimensions $0, 2, 3$ so far. Since $\ker\mathbf{N}^2 \subseteq G_2(\mathbf{A})$ and $\dim G_2(\mathbf{A}) = a_{\mathbf{A}}(2) = 3 = \dim\ker\mathbf{N}^2$ by part (c) of the theorem, we get $G_2(\mathbf{A}) = \ker\mathbf{N}^2$, and the stabilization index is $s = 2$. One can see the stabilization by hand as well: multiplying out gives $\mathbf{N}^3 = 3\mathbf{N}^2$, so $\ker\mathbf{N}^3 = \ker\mathbf{N}^2$ directly.

The second generalized eigenspace. Here $a_{\mathbf{A}}(5) = 1$, so $\dim G_5(\mathbf{A}) = 1$ and $G_5(\mathbf{A}) = E_5(\mathbf{A})$ by part (b) — its s must be 1. Solving $(\mathbf{A} - 5\mathbf{I})\mathbf{x} = \mathbf{0}$ gives $G_5(\mathbf{A}) = E_5(\mathbf{A}) = \operatorname{span}\big((0,1,-1,1)\big)$. As a check, $\mathbf{A}(0,1,-1,1) = (1{+}1{-}2,\ 3{+}1{+}1,\ -1{-}3{-}1,\ 1{+}1{+}3) = (0,5,-5,5)$.

The decomposition. $\mathbb{Q}^4 = G_2(\mathbf{A}) \oplus G_5(\mathbf{A})$, of dimensions $3{+}1 = 4$, and the sum is direct because $(0,1,-1,1) \notin G_2(\mathbf{A})$: its first and last coordinates are $0 \neq 1$.

The minimal polynomial. The stabilization indices are $s_1 = 2$ at $\lambda = 2$ and $s_2 = 1$ at $\lambda = 5$, and part (d) of the theorem identifies these indices as the exponents in $m_{\mathbf{A}}$, so

$m_{\mathbf{A}} = (x-2)^2(x-5)$. Consistently, $(\mathbf{A}-2\mathbf{I})(\mathbf{A}-5\mathbf{I}) \neq 0$: the two factors are coprime, so the kernel of the product is $\ker(\mathbf{A}-2\mathbf{I}) \oplus \ker(\mathbf{A}-5\mathbf{I})$ (Theorem 5.7.5 (a)), of dimension $2+1=3<4$.

A basis adapted to the splitting. Take $\mathcal{B} = \big(\mathbf{e}_2,\ \mathbf{e}_3,\ \mathbf{e}_1+\mathbf{e}_4,\ (0,1,-1,1)\big)$, a basis of G_2 followed by one of G_5. By part (e), $[T_{\mathbf{A}}]_{\mathcal{B}}$ is block diagonal with a 3×3 block and the 1×1 block (5).

Warning. **The dimension of G_λ is the algebraic multiplicity, not the number of steps the chain takes.** In the example, $\dim G_2 = 3$ while the chain $\{\mathbf{0}\} \subsetneq \ker \mathbf{N} \subsetneq \ker \mathbf{N}^2 = G_2$ stabilizes after $s=2$ steps. The two numbers measure different things: $a(\lambda) = \dim G_\lambda$ is the total size of the piece, and s is the exponent of $x-\lambda$ in the minimal polynomial. All that holds in general is $1 \le s \le a(\lambda)$ and $g(\lambda) \le a(\lambda)$ (Theorem 8.3.1).

Finally, a word on what we may not yet assume. The decomposition needs p_T to split, which is automatic over $\mathbb{C}$ (Corollary 5.5.5) but fails, for instance, for a rotation of $\mathbb{R}^2$, whose generalized eigenspaces over $\mathbb{R}$ are all $\{\mathbf{0}\}$ and certainly do not fill $\mathbb{R}^2$. Operators over an arbitrary field need the coarser primary decomposition of Chapter 8, whose pieces we return to in Section 6.

9.1.5 Exercises

9.1.5.1 A. Check your understanding

Exercise A1.

(a) Define a generalized eigenvector and the generalized eigenspace $G_\lambda(T)$.

(b) State what Theorem 9.1.1 says about the chain $\ker N \subseteq \ker N^2 \subseteq \ldots$, including the bound on where it stabilizes.

(c) True or false: every generalized eigenvector of T for λ satisfies $T\mathbf{v} = \lambda\mathbf{v}$. Justify your answer.

(d) True or false: if λ is not an eigenvalue of T, then $G_\lambda(T) = \{\mathbf{0}\}$. Justify your answer.

(e) Let $\dim V = 6$ and let $p_T = (x-1)^4(x-3)^2$ split over F. What are $\dim G_1(T)$ and $\dim G_3(T)$?

(f) In the situation of (e), what can you say about $\dim E_1(T)$?

Solution.

(a) A generalized eigenvector of T for $\lambda \in F$ is a **non-zero** $\mathbf{v} \in V$ with $(T-\lambda\,\mathrm{id}_V)^k\mathbf{v} = \mathbf{0}$ for **some** $k \ge 1$ (Definition 9.1.1); $G_\lambda(T)$ is the set of all of them together with $\mathbf{0}$, that is, $\bigcup_{k\ge 1} \ker(T-\lambda\,\mathrm{id}_V)^k$ (Definition 9.1.2).

(b) The kernels increase; once two consecutive ones are equal, all later ones equal them; the strict inclusions come first, and the chain has stabilized by step $\dim V$, so $G_\lambda(T) = \ker(T-\lambda\,\mathrm{id}_V)^{\dim V}$.

(c) False. For $\mathbf{J} = \begin{pmatrix} 2 & 1 \\ 0 & 2 \end{pmatrix}$, the vector $\mathbf{e}_2$ lies in $G_2(\mathbf{J})$ but $\mathbf{J}\mathbf{e}_2 = \mathbf{e}_1 + 2\mathbf{e}_2 \neq 2\mathbf{e}_2$. Only the vectors of $E_\lambda(T) \subseteq G_\lambda(T)$ satisfy the eigenvector equation.

(d) True, by Corollary 9.1.2 (c).

(e) $\dim G_1(T) = a_T(1) = 4$ and $\dim G_3(T) = a_T(3) = 2$ (Theorem 9.1.3 (c)).

(f) Only $1 \le \dim E_1(T) \le 4$, since $E_1(T) \subseteq G_1(T)$ and $1 \le g_T(1) \le a_T(1)$ (Theorem 8.3.1). All four values occur, as the Jordan forms of Section 3 will show.

9.1.5.2 B. Practice

Exercise B1: Computing generalized eigenspaces.

For each operator, find all generalized eigenspaces, and compare each with the corresponding eigenspace.

(a) $\mathbf{A}_1 = \begin{pmatrix} 3 & 1 \\ 0 & 3 \end{pmatrix} \in M_2(\mathbb{Q})$.

(b) $\mathbf{A}_2 = \begin{pmatrix} 2 & 1 & 1 \\ 0 & 1 & -1 \\ -1 & -1 & 1 \end{pmatrix} \in M_3(\mathbb{R})$, which has $m_{\mathbf{A}_2} = (x-1)^2(x-2)$ (Exercise (B2: Decomposing $\mathbb{R}^3$)).

(c) $D \in \mathcal{L}(\mathbb{R}[x]_{\le 3})$, differentiation.

(d) The rotation $\mathbf{R} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$, first over $\mathbb{R}$ and then over $\mathbb{C}$.

Solution.

(a) $p_{\mathbf{A}_1} = (x-3)^2$, so 3 is the only eigenvalue, and $G_\lambda = \{\mathbf{0}\}$ for $\lambda \neq 3$ (Corollary 9.1.2 (c)). Since $(\mathbf{A}_1 - 3\mathbf{I})^2 = 0$, $G_3(\mathbf{A}_1) = \mathbb{Q}^2$, while $E_3(\mathbf{A}_1) = \ker \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} = \operatorname{span}(\mathbf{e}_1)$ is a line.

(b) From $m_{\mathbf{A}_2} = (x-1)^2(x-2)$ and Theorem 9.1.3 (a), $G_1 = \ker(\mathbf{A}_2 - \mathbf{I})^2$ and $G_2 = \ker(\mathbf{A}_2 - 2\mathbf{I})$. Chapter 8 computed these: $G_1 = \operatorname{span}((-1,1,0),(0,0,1))$, the plane $x + y = 0$, and $G_2 = \operatorname{span}((0,-1,1))$. The eigenspace $E_1(\mathbf{A}_2) = \operatorname{span}((-1,1,0))$ is a line strictly inside G_1, while $E_2(\mathbf{A}_2) = G_2$ because $s_2 = 1$. All other G_λ are $\{\mathbf{0}\}$.

(c) $D^4 = 0$ (Example (Differentiation Is Nilpotent)), so $G_0(D) = \mathbb{R}[x]_{\le 3}$, of dimension 4, while $E_0(D) = \ker D = \mathbb{R}$ is the line of constants. Since $p_D = x^4$ has 0 as its only root, every other generalized eigenspace is $\{\mathbf{0}\}$.

(d) Over $\mathbb{R}$, $p_{\mathbf{R}} = x^2 + 1$ has no root, so $\mathbf{R}$ has no eigenvalue and $G_\lambda(\mathbf{R}) = \{\mathbf{0}\}$ for every $\lambda \in \mathbb{R}$. The generalized eigenspaces do **not** fill $\mathbb{R}^2$; the hypothesis that $p_{\mathbf{R}}$ splits fails. Over $\mathbb{C}$, $p_{\mathbf{R}} = (x-i)(x+i)$ splits with $a(i) = a(-i) = 1$, so $G_i(\mathbf{R}) = E_i(\mathbf{R}) = \operatorname{span}((1,-i))$ and $G_{-i}(\mathbf{R}) = E_{-i}(\mathbf{R}) = \operatorname{span}((1,i))$, and $\mathbb{C}^2 = G_i \oplus G_{-i}$. (Check: $\mathbf{R}(1,-i) = (i,1) = i(1,-i)$.)

Exercise B2: The image chain stabilizes too.

Let V be finite-dimensional with $\dim V = n$, and let $N \in \mathcal{L}(V)$.

(a) Prove that $\operatorname{im} N \supseteq \operatorname{im} N^2 \supseteq \operatorname{im} N^3 \supseteq \dots$, and that each $\operatorname{im} N^k$ is N-invariant.

(b) Prove that $\operatorname{im} N^m = \operatorname{im} N^{m+1}$ if and only if $\ker N^m = \ker N^{m+1}$.

(c) Deduce that $\operatorname{im} N^n = \operatorname{im} N^{n+j}$ for every $j \ge 0$, and that the image chain stabilizes

at exactly the same index s as the kernel chain.

Solution.

(a) $\operatorname{im} N^{k+1} = \{N^{k+1}\mathbf{v} : \mathbf{v} \in V\} = \{N^k(N\mathbf{v}) : \mathbf{v} \in V\} \subseteq \operatorname{im} N^k$. Each $\operatorname{im} N^k$ is the image of a polynomial in N, hence N-invariant (Theorem 5.7.4 (b)).

(b) By Theorem 3.3.1, $\dim \operatorname{im} N^k + \dim \ker N^k = n$ for every k. The inclusions $\operatorname{im} N^{m+1} \subseteq \operatorname{im} N^m$ and $\ker N^m \subseteq \ker N^{m+1}$ are equalities exactly when the dimensions agree (Theorem 1.6.8), and $\dim \operatorname{im} N^m = \dim \operatorname{im} N^{m+1}$ if and only if $\dim \ker N^m = \dim \ker N^{m+1}$ by the displayed identity.

(c) By Theorem 9.1.1 (d), $\ker N^n = \ker N^{n+j}$; iterating (b) at each step from n to $n+j$ gives $\operatorname{im} N^n = \operatorname{im} N^{n+j}$. And by (b), the least index at which two consecutive images agree is the least index at which two consecutive kernels agree, namely s.

Exercise B3: Reading the dimensions off a triangular matrix.

Let

$$\mathbf{A} = \begin{pmatrix} 1 & 1 & 0 & 0 \\ 0 & 1 & 1 & 0 \\ 0 & 0 & 2 & 1 \\ 0 & 0 & 0 & 2 \end{pmatrix} \in M_4(\mathbb{Q}).$$

(a) Write down $p_{\mathbf{A}}$ and the algebraic multiplicities.

(b) Compute $E_1(\mathbf{A})$, $G_1(\mathbf{A})$, $E_2(\mathbf{A})$ and $G_2(\mathbf{A})$, and check $\dim G_\lambda = a_{\mathbf{A}}(\lambda)$.

(c) Verify that $\mathbb{Q}^4 = G_1(\mathbf{A}) \oplus G_2(\mathbf{A})$, and find $m_{\mathbf{A}}$.

Solution.

(a) $\mathbf{A}$ is upper triangular, so $p_{\mathbf{A}} = (x-1)^2(x-2)^2$ (Theorem 6.4.6), and $a_{\mathbf{A}}(1) = a_{\mathbf{A}}(2) = 2$.

(b) $\mathbf{A} - \mathbf{I} = \begin{pmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 1 \end{pmatrix}$ has rank 3 (rows $1, 2, 4$ are independent and row 3 is the sum of rows 2 and 4), so $E_1(\mathbf{A}) = \operatorname{span}(\mathbf{e}_1)$. Squaring,

$$(\mathbf{A} - \mathbf{I})^2 = \begin{pmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 1 & 1 \\ 0 & 0 & 1 & 2 \\ 0 & 0 & 0 & 1 \end{pmatrix},$$

of rank 2, with kernel $\operatorname{span}(\mathbf{e}_1, \mathbf{e}_2)$; so $G_1(\mathbf{A}) = \operatorname{span}(\mathbf{e}_1, \mathbf{e}_2)$, of dimension $2 = a_{\mathbf{A}}(1)$. (Membership can be seen directly: $(\mathbf{A} - \mathbf{I})\mathbf{e}_2 = \mathbf{e}_1$ and $(\mathbf{A} - \mathbf{I})\mathbf{e}_1 = \mathbf{0}$.)

Similarly $\mathbf{A} - 2\mathbf{I} = \begin{pmatrix} -1 & 1 & 0 & 0 \\ 0 & -1 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \end{pmatrix}$ has rank 3, so $E_2(\mathbf{A})$ is a line; solv-

ing gives $E_2(\mathbf{A}) = \operatorname{span}((1,1,1,0))$. And $(\mathbf{A}-2\mathbf{I})^2 = \begin{pmatrix} 1 & -2 & 1 & 0 \\ 0 & 1 & -1 & 1 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}$ has rank 2; its kernel is cut out by $x_1 - 2x_2 + x_3 = 0$ and $x_2 - x_3 + x_4 = 0$, so $G_2(\mathbf{A}) = \operatorname{span}((1,1,1,0),(-2,-1,0,1))$, of dimension $2 = a_{\mathbf{A}}(2)$. (Check: $(\mathbf{A}-2\mathbf{I})(-2,-1,0,1) = (1,1,1,0)$, the eigenvector.)

(c) The four vectors $\mathbf{e}_1, \mathbf{e}_2, (1,1,1,0), (-2,-1,0,1)$ form a basis of $\mathbb{Q}^4$: the matrix with these columns is upper triangular with diagonal $1,1,1,1$, hence invertible. So the sum is direct and equals $\mathbb{Q}^4$, as Theorem 9.1.3 (a) predicts. Both stabilization indices are 2 (the eigenspaces are lines, the generalized eigenspaces planes), so $m_{\mathbf{A}} = (x-1)^2(x-2)^2 = p_{\mathbf{A}}$.

9.1.5.3 C. Going deeper

Exercise C1: The Fitting decomposition.

Let V be finite-dimensional with $\dim V = n$, and let $N \in \mathcal{L}(V)$ be **any** operator. Put $U = \ker N^n$ and $W = \operatorname{im} N^n$.

(a) Prove that $U \cap W = \{\mathbf{0}\}$, and deduce $V = U \oplus W$.

(b) Prove that U and W are N-invariant, that $N|_U$ is nilpotent, and that $N|_W$ is invertible.

(c) Identify U as a generalized eigenspace of N.

(d) Compute U and W for $\mathbf{N} = \begin{pmatrix} 0 & 1 \\ 0 & 1 \end{pmatrix} \in M_2(\mathbb{Q})$.

Hint: for (a), if $\mathbf{v} = N^n\mathbf{w}$ and $N^n\mathbf{v} = \mathbf{0}$, look at which kernel $\mathbf{w}$ lies in.

Solution.

(a) Let $\mathbf{v} \in U \cap W$, say $\mathbf{v} = N^n\mathbf{w}$ with $N^n\mathbf{v} = \mathbf{0}$. Then $N^{2n}\mathbf{w} = N^n\mathbf{v} = \mathbf{0}$, so $\mathbf{w} \in \ker N^{2n} = \ker N^n$ by Theorem 9.1.1 (d), and therefore $\mathbf{v} = N^n\mathbf{w} = \mathbf{0}$. By Theorem 3.3.1, $\dim U + \dim W = n$, so $\dim(U+W) = \dim U + \dim W - \dim(U \cap W) = n$ (Theorem 1.7.3), whence $U + W = V$ (Theorem 1.6.8) and the sum is direct (Theorem 1.7.4).

(b) Both are invariant by Theorem 5.7.4 (b). On U we have $(N|_U)^n = 0$ by definition of U, so $N|_U$ is nilpotent. On W, the map $N|_W \colon W \to W$ is surjective: $N(W) = N(\operatorname{im} N^n) = \operatorname{im} N^{n+1} = \operatorname{im} N^n = W$ by Exercise (B2: The image chain stabilizes too) (c). A surjective operator on a finite-dimensional space is invertible (Corollary 3.3.2 (e)).

(c) $U = \ker N^n = G_0(N)$, by Corollary 9.1.2 (a) with $\lambda = 0$. So the Fitting decomposition splits V into the generalized eigenspace for 0 and a part on which N is invertible.

(d) Here $n = 2$ and $\mathbf{N}^2 = \begin{pmatrix} 0 & 1 \\ 0 & 1 \end{pmatrix} = \mathbf{N}$, so $U = \ker \mathbf{N} = \operatorname{span}(\mathbf{e}_1)$ and $W = \operatorname{im} \mathbf{N} = \operatorname{span}((1,1))$. Indeed $\mathbb{Q}^2 = \operatorname{span}(\mathbf{e}_1) \oplus \operatorname{span}((1,1))$, $\mathbf{N}$ is zero on U, and $\mathbf{N}(1,1) = (1,1)$, so $\mathbf{N}|_W$ is the identity.

Exercise C2: Commuting operators preserve generalized eigenspaces.

Let V be finite-dimensional, and let $S, T \in \mathcal{L}(V)$ with $ST = TS$.

(a) Prove that $S\big(G_\lambda(T)\big) \subseteq G_\lambda(T)$ for every $\lambda \in F$.

(b) Deduce that if p_T splits, then every generalized eigenspace of T is invariant under every polynomial in T and under S, and that V has a basis in which both S and T have block diagonal matrices with blocks of sizes $a_T(\lambda_1), \dots, a_T(\lambda_k)$.

(c) Show by example that part (a) can be vacuous: find commuting S, T on $\mathbb{Q}^2$ and a λ with $E_\lambda(T)$ a line, $G_\lambda(T) = \mathbb{Q}^2$, and S not a scalar multiple of the identity.

Solution.

(a) Since $ST = TS$, S commutes with every polynomial in T (Theorem 5.7.1 (d)), in particular with N^k, where $N = T - \lambda\,\mathrm{id}_V$. Let $\mathbf{v} \in G_\lambda(T)$, say $N^k\mathbf{v} = \mathbf{0}$. Then

$$N^k(S\mathbf{v}) = S(N^k\mathbf{v}) = S\mathbf{0} = \mathbf{0},$$

so $S\mathbf{v} \in \ker N^k \subseteq G_\lambda(T)$. (This is Theorem 5.7.4 (a) with $R = N^k$.)

(b) Invariance under polynomials in T is Theorem 5.7.4 (b), and invariance under S is (a). If p_T splits, then $V = \bigoplus_i G_{\lambda_i}(T)$ with $\dim G_{\lambda_i}(T) = a_T(\lambda_i)$ (Theorem 9.1.3), and a basis assembled from bases of the summands makes both matrices block diagonal, by Theorem 8.1.5 applied to T and to S.

(c) Take $T = \begin{pmatrix} 2 & 1 \\ 0 & 2 \end{pmatrix}$ and $S = T$. They commute, $E_2(T) = \mathrm{span}(\mathbf{e}_1)$ is a line, $G_2(T) = \mathbb{Q}^2$, and S is not a scalar matrix. Consistently with Theorem 8.9.1, S maps the line $\mathrm{span}(\mathbf{e}_1)$ into itself, and by (a) it maps $G_2(T) = \mathbb{Q}^2$ into itself, which says nothing. The lesson is that (a) is informative only when $G_\lambda(T) \neq V$.

9.2 Nilpotent Operators

Section 1 reduced our problem to one piece at a time: on the generalized eigenspace $G_\lambda(T)$, the operator is $\lambda\,\mathrm{id} + N$ with some power of N equal to zero (Theorem 9.1.3 (d)). The scalar part needs no work, so everything now depends on a single question: what does an operator all of whose powers eventually vanish look like in the right basis? This section answers it completely, and the answer is a list of numbers — the sizes of the staircases the operator builds.

9.2.1 Operators killed by a power

The objects have already appeared several times. Differentiation on $F[x]_{\le n}$ satisfies $D^{n+1} = 0$ (Example (Differentiation Is Nilpotent)). The matrix $\begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$ has square 0. Over a field of characteristic 0, a commutator $[\mathbf{A}, \mathbf{B}]$ that commutes with $\mathbf{A}$ has some power equal to 0 (Exercise (C2: When $\mathbf{A}$ commutes with $[\mathbf{A}, \mathbf{B}]$)). Chapter 3 gave these operators their name in passing; here is the definition in full, with the one extra piece of data we shall need.

A nilpotent operator is one that some power annihilates: repeated application destroys every

vector.

Definition 9.2.1 — Nilpotent Operator, Index of Nilpotency

Let V be a vector space over F and $N \in \mathcal{L}(V)$. We say N is **nilpotent** if

$$N^s = 0 \qquad \text{for some integer } s \geq 1.$$

If $V \neq \{\mathbf{0}\}$ and N is nilpotent, the **index of nilpotency** of N is the **least** such s; equivalently, $N^s = 0$ and $N^{s-1} \neq 0$. A matrix $\mathbf{A} \in M_n(F)$ is **nilpotent** if $\mathbf{A}^s = 0$ for some $s \geq 1$, that is, if $T_{\mathbf{A}}$ is nilpotent.

In words: one **single** exponent must kill **every** vector at once, and the exponent is at least 1, so the zero operator is nilpotent (index 1) but the identity on $V \neq \{\mathbf{0}\}$ is not. The index is well defined: the exponents $s \geq 1$ with $N^s = 0$ form a non-empty set of positive integers, which has a least element (Theorem 0.2.11).

Examples.

- **The shift.** On F^k, let $N\mathbf{e}_1 = \mathbf{0}$ and $N\mathbf{e}_j = \mathbf{e}_{j-1}$ for $j \geq 2$. Then N^k kills every $\mathbf{e}_j$, while $N^{k-1}\mathbf{e}_k = \mathbf{e}_1 \neq \mathbf{0}$, so N is nilpotent of index k. Its matrix in the standard basis has a 1 in each position $(j-1, j)$ and zeros elsewhere. This matrix is the model for everything in this section, and we write it

$$\mathbf{J}_k(0) \coloneqq \begin{pmatrix} 0 & 1 & & \\ & 0 & \ddots & \\ & & \ddots & 1 \\ & & & 0 \end{pmatrix} \in M_k(F),$$

  with 1 in every **superdiagonal** entry $(j, j+1)$ and 0 everywhere else. (Section 3 writes $\mathbf{J}_k(\lambda) = \lambda\mathbf{I}_k + \mathbf{J}_k(0)$ and calls it a Jordan block.) For $k = 1$, $\mathbf{J}_1(0) = (0)$.
- **Differentiation.** D on $F[x]_{\leq n}$ has $D^{n+1} = 0$, and over $\mathbb{R}$ the index is exactly $n+1$, since $D^n x^n = n! \neq 0$ (Example (Differentiation Is Nilpotent)). Over $\mathbb{R}$, in the basis $(1, x, x^2/2!, \ldots, x^n/n!)$, its matrix is exactly $\mathbf{J}_{n+1}(0)$, because $D(x^j/j!) = x^{j-1}/(j-1)!$.
- **All entries non-zero.** $\mathbf{A} = \begin{pmatrix} 2 & 4 \\ -1 & -2 \end{pmatrix}$ has $\mathbf{A}^2 = \begin{pmatrix} 4-4 & 8-8 \\ -2+2 & -4+4 \end{pmatrix} = 0$, so $\mathbf{A}$ is nilpotent of index 2, although no entry of $\mathbf{A}$ is 0. Nilpotency is not visible from the shape of the entries.
- **The degenerate case.** On a space of dimension 1 the only nilpotent operator is 0: if $N = c\,\mathrm{id}$ and $N^s = 0$, then $c^s = 0$, so $c = 0$. Small as it is, this is why a 1×1 block in a nilpotent normal form carries a 0 and nothing else.

Non-example by minimal change. Move the 1 in $\begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$ to the other off-diagonal position and take $\mathbf{S} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$, the swap of the two coordinates. It is just as sparse, but $\mathbf{S}^2 = \mathbf{I}$, so $\mathbf{S}^{2k} = \mathbf{I} \neq 0$ and $\mathbf{S}^{2k+1} = \mathbf{S} \neq 0$ for every k: **no** power vanishes, and the defining clause fails outright. A gentler non-example is $\mathrm{diag}(0, 1)$, which is singular and has 0 as an eigenvalue, yet $\mathrm{diag}(0,1)^k = \mathrm{diag}(0,1) \neq 0$; being non-invertible is far from being nilpotent.

Why this definition. The clause "for some s" cannot be replaced by a fixed exponent without losing the class, since on $\mathbb{R}[x]_{\leq n}$ differentiation needs $n+1$ steps. On the other hand the

exponent may always be taken to be $\dim V$, as the next proposition shows, so the definition is not as open-ended as it looks. The name says "zero power": *nil* (nothing) and *potens* (power).

Warning. **Nilpotent is a statement about one exponent killing everything, not about each vector separately, and not about the entries.** Differentiation on $\mathbb{R}[x]$ (**all** polynomials) kills every **single** polynomial after enough steps, yet no power of it is 0, because the number of steps needed is unbounded; the space is infinite-dimensional. And the matrix $\begin{pmatrix} 2 & 4 \\ -1 & -2 \end{pmatrix}$ is nilpotent with no zero entry, while $\operatorname{diag}(0,1)$ has a zero entry, a zero eigenvalue, and is not nilpotent.

The first payoff collects the facts we shall use constantly. Note the interplay with Section 1: a nilpotent operator is one whose generalized eigenspace for 0 is everything.

Proposition 9.2.1 — Basic Properties of Nilpotent Operators

Let V be a finite-dimensional vector space over F with $\dim V = n \geq 1$, and let $N \in \mathcal{L}(V)$. Then:

(a) N is nilpotent if and only if $N^n = 0$, if and only if $G_0(N) = V$;

(b) if N is nilpotent with index s, then $s \leq n$, $m_N = x^s$ and $p_N = x^n$;

(c) if N is nilpotent, then $\operatorname{spec}(N) = \{0\}$, and there is a basis in which the matrix of N is upper triangular with zero diagonal;

(d) conversely, if $p_N = x^n$, then N is nilpotent.

Idea. For (a) and (b), the kernel chain of Section 1 does the work: $N^s = 0$ says $\ker N^s = V$, and the chain has stopped growing by step n. For the triangular matrix in (c), build the basis along the chain: take a basis of $\ker N$, extend it to one of $\ker N^2$, and so on. A vector first appearing at level k is sent by N into $\ker N^{k-1}$, which is spanned by vectors listed **earlier**, so every column has zeros from the diagonal down.

Proof.

(a) If $N^s = 0$ for some $s \geq 1$, then $\ker N^s = V$, so $V = \ker N^{\max(s,n)} = \ker N^n$ by Theorem 9.1.1 (a) and (d), that is, $N^n = 0$. The converse is the definition with $s = n$. And $G_0(N) = \ker N^n$ by Corollary 9.1.2 (a) with $\lambda = 0$, so $G_0(N) = V$ if and only if $N^n = 0$.

(b) Let s be the index and put $K_k = \ker N^k$, so $\{\mathbf{0}\} = K_0 \subseteq K_1 \subseteq \cdots \subseteq K_s = V$ by (a) and Theorem 9.1.1 (a). Choose a basis $\mathcal{B}_1$ of K_1; extend it to a basis $\mathcal{B}_2$ of K_2; and continuing, extend $\mathcal{B}_{k-1}$ to a basis $\mathcal{B}_k$ of K_k for $k = 2, \ldots, s$ (Theorem 1.6.5, legitimate because $\mathcal{B}_{k-1}$ is an independent list in K_k). Then $\mathcal{B} = \mathcal{B}_s = (\mathbf{v}_1, \ldots, \mathbf{v}_n)$ is a basis of V, and for each k the first $\dim K_k$ of its vectors form a basis of K_k. Let $1 \leq j \leq n$ and let k be the level at which $\mathbf{v}_j$ was added, so $\mathbf{v}_j \in K_k$ and $\dim K_{k-1} < j$. Then $N\mathbf{v}_j \in K_{k-1} = \operatorname{span}(\mathbf{v}_1, \ldots, \mathbf{v}_{\dim K_{k-1}}) \subseteq \operatorname{span}(\mathbf{v}_1, \ldots, \mathbf{v}_{j-1})$. So the j-th column of $[N]_{\mathcal{B}}$ has zeros in rows $j, j+1, \ldots, n$ (Definition 3.6.1, Theorem 1.5.1): the matrix is upper triangular with zero diagonal. Its diagonal entries are, with multiplicity, the eigenvalues of N (Theorem 8.7.4 (b)), and they are all 0, so $\operatorname{spec}(N) = \{0\}$.

(c) By (a), $N^n = 0$, so $s \leq n$. The polynomial x^s annihilates N, and x^{s-1} does not, so $m_N \mid x^s$ and $m_N \nmid x^{s-1}$ (Theorem 8.5.1). Every monic divisor of x^s is x^j with

$0 \le j \le s$ (Lemma 8.5.2), so $m_N = x^s$. For p_N, use the basis $\mathcal{B}$ of (c): there $x\mathbf{I}_n - [N]_{\mathcal{B}}$ is upper triangular with every diagonal entry equal to x, so $p_N = x^n$ by Theorem 6.4.6 and Definition 6.10.2.

(d) If $p_N = x^n$, then $p_N(N) = N^n = 0$ by Theorem 8.6.1.

■

So nilpotency is detected by the characteristic polynomial: N is nilpotent exactly when $p_N = x^n$, which over $\mathbb{C}$ is exactly $\operatorname{spec}(N) = \{0\}$, as Chapter 8 found by a different route (Theorem 8.10.3). Part (c) also follows abstractly from Theorem 8.7.2, since x^n splits over every field; the proof above builds the basis explicitly. But a strictly upper triangular matrix still has $n(n-1)/2$ entries to describe, and almost all of them can be cleared away. That is the content of the structure theorem.

9.2.2 What one chain looks like

Look again at $\mathbf{J}_k(0)$ and read its columns, which is where a matrix always tells us what the operator does to basis vectors. With $\mathcal{B} = (\mathbf{b}_1, \dots, \mathbf{b}_k)$ the standard basis of F^k, the matrix $\mathbf{J}_k(0)$ says

$$N\mathbf{b}_1 = \mathbf{0}, \qquad N\mathbf{b}_2 = \mathbf{b}_1, \qquad N\mathbf{b}_3 = \mathbf{b}_2, \quad \dots, \quad N\mathbf{b}_k = \mathbf{b}_{k-1}.$$

Reading this from the right, the last basis vector $\mathbf{b}_k$ generates all the others: $\mathbf{b}_{k-1} = N\mathbf{b}_k$, $\mathbf{b}_{k-2} = N^2\mathbf{b}_k$, and so on down to $\mathbf{b}_1 = N^{k-1}\mathbf{b}_k$, which is an eigenvector, killed at the next step. So one Jordan block is one vector together with its successive images, a staircase descending to $\mathbf{0}$. Such a list deserves a name.

Definition 9.2.2 — Jordan Chain

Let V be a vector space over F, let $N \in \mathcal{L}(V)$ and let $\mathbf{u} \in V$ with $\mathbf{u} \neq \mathbf{0}$. Suppose $N^k\mathbf{u} = \mathbf{0}$ and $N^{k-1}\mathbf{u} \neq \mathbf{0}$ for an integer $k \ge 1$. The **Jordan chain generated by $\mathbf{u}$** is the ordered list

$$\left(N^{k-1}\mathbf{u},\ N^{k-2}\mathbf{u},\ \dots,\ N\mathbf{u},\ \mathbf{u}\right),$$

of **length** k, and $\mathbf{u}$ is called the **top** of the chain. For $T \in \mathcal{L}(V)$ and $\lambda \in F$, a Jordan chain of T for λ means a Jordan chain of $N = T - \lambda\,\mathrm{id}_V$.

The order matters, and we always write it with the **eigenvector first** and the top last, so that N moves each entry to the one before it and kills the first. The first entry $N^{k-1}\mathbf{u}$ is indeed an eigenvector for 0, by the argument of Corollary 9.1.2 (d). For example, the chain generated by $\mathbf{e}_2$ under $\begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$ is $(\mathbf{e}_1, \mathbf{e}_2)$, of length 2.

A chain is automatically independent, which is the first sign that chains are good building blocks.

Lemma 9.2.2 — A Jordan Chain Is Independent

Let $N \in \mathcal{L}(V)$ and let $(N^{k-1}\mathbf{u}, \dots, N\mathbf{u}, \mathbf{u})$ be a Jordan chain, so $N^k\mathbf{u} = \mathbf{0} \neq N^{k-1}\mathbf{u}$. Then:

(a) the list is linearly independent, so $k \le \dim V$ when V is finite-dimensional;

(b) $C = \operatorname{span}(\mathbf{u}, N\mathbf{u}, \dots, N^{k-1}\mathbf{u})$ is N-invariant of dimension k, and the matrix of $N|_C$ in the chain, taken in the order of Definition 9.2.2, is $\mathbf{J}_k(0)$.

Proof.

(a) Suppose $a_0\mathbf{u} + a_1 N\mathbf{u} + \cdots + a_{k-1}N^{k-1}\mathbf{u} = \mathbf{0}$ with $a_j \in F$. Apply N^{k-1}. Every term with $j \geq 1$ becomes $a_j N^{k-1+j}\mathbf{u} = \mathbf{0}$, since $N^k\mathbf{u} = \mathbf{0}$ and $k-1+j \geq k$. What remains is $a_0 N^{k-1}\mathbf{u} = \mathbf{0}$, and $N^{k-1}\mathbf{u} \neq \mathbf{0}$, so $a_0 = 0$ (Theorem 1.1.9). Now apply N^{k-2} to the relation with $a_0 = 0$: by the same cancellation only $a_1 N^{k-1}\mathbf{u} = \mathbf{0}$ survives, so $a_1 = 0$. Repeating this for $N^{k-3}, \dots, N^0$ gives $a_2 = \cdots = a_{k-1} = 0$. Hence the list is independent, and an independent list has at most $\dim V$ entries (Theorem 1.6.5).

(b) By (a) the k spanning vectors are independent, so $\dim C = k$. Write $\mathbf{b}_j = N^{k-j}\mathbf{u}$ for $j = 1, \dots, k$, the chain in order. Then $N\mathbf{b}_1 = N^k\mathbf{u} = \mathbf{0}$ and $N\mathbf{b}_j = N^{k-j+1}\mathbf{u} = \mathbf{b}_{j-1}$ for $j \geq 2$, so all images lie in C and C is N-invariant (Lemma 8.1.1). The j-th column of the matrix of $N|_C$ is the coordinate vector of $N\mathbf{b}_j$, which is $\mathbf{0}$ for $j = 1$ and $\mathbf{e}_{j-1}$ for $j \geq 2$ (Definition 3.6.1). That is precisely $\mathbf{J}_k(0)$.

■

9.2.3 The structure theorem

Now the goal. If a nilpotent operator could be split into chains, its matrix would be a direct sum of blocks $\mathbf{J}_{k_i}(0)$, and nothing would be left to describe except the list of lengths. That is exactly what happens.

Every nilpotent operator is a disjoint union of staircases: the space breaks into chains, and the operator shifts each chain one step down.

Theorem 9.2.3 — Structure Theorem for Nilpotent Operators

Let V be a finite-dimensional vector space over F with $\dim V = n \geq 1$, and let $N \in \mathcal{L}(V)$ be nilpotent. Then there are an integer $r \geq 1$, vectors $\mathbf{u}_1, \dots, \mathbf{u}_r \in V$ and integers

$$k_1 \geq k_2 \geq \cdots \geq k_r \geq 1, \qquad k_1 + k_2 + \cdots + k_r = n,$$

such that:

(a) $N^{k_i}\mathbf{u}_i = \mathbf{0}$ for each i, and the list $\mathcal{B}$ obtained by writing the r Jordan chains one after another,

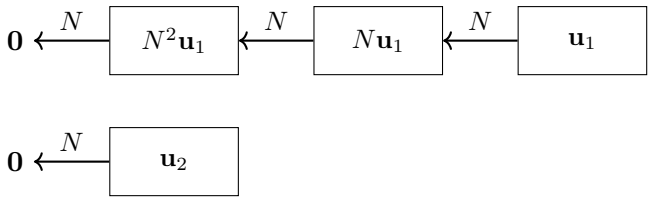
$$\mathcal{B} = \big(\underbrace{N^{k_1-1}\mathbf{u}_1, \dots, N\mathbf{u}_1, \mathbf{u}_1}_{\text{chain } 1}, \ \dots, \ \underbrace{N^{k_r-1}\mathbf{u}_r, \dots, N\mathbf{u}_r, \mathbf{u}_r}_{\text{chain } r}\big),$$

is a basis of V;

(b) with $C_i = \operatorname{span}(\mathbf{u}_i, N\mathbf{u}_i, \dots, N^{k_i-1}\mathbf{u}_i)$, each C_i is N-invariant, $V = C_1 \oplus \cdots \oplus C_r$, and

$$[N]_{\mathcal{B}} = \mathbf{J}_{k_1}(0) \oplus \mathbf{J}_{k_2}(0) \oplus \cdots \oplus \mathbf{J}_{k_r}(0).$$

A basis as in (a) is called a **Jordan basis** for N. Before the proof, here is the picture the proof builds. Each chain is a row of boxes, the top of the chain on the right, and N moves one box to the left, off the diagram at the left edge. For lengths $(3, 1)$:



the boxes in the left column, $N^2\mathbf{u}_1$ and $\mathbf{u}_2$, form a basis of $\ker N$

Idea. Induction on $\dim V$, with the smaller object found inside: $W = \operatorname{im} N$. It is N-invariant, $N|_W$ is nilpotent, and $\dim W < \dim V$ because a nilpotent operator on a non-zero space is not injective. So W already has chains. Each chain of W is one box short of what we want: its top $\mathbf{w}_i$ lies in $\operatorname{im} N$, so $\mathbf{w}_i = N\mathbf{u}_i$ for some $\mathbf{u}_i \in V$, and we can extend the chain by one box on the right, gaining $\mathbf{u}_i$. What is still missing is counted by $\ker N$: the ends $N^{l_i}\mathbf{u}_i$ of the extended chains are independent vectors of $\ker N$, and any basis extension of them inside $\ker N$ supplies the chains of length 1. Then the count comes out exactly right, by Rank–Nullity (Theorem 3.3.1), and independence follows by applying N once and using the basis of W.

Proof. We argue by induction on $n = \dim V \geq 1$, the statement being: for every nilpotent N on a space of dimension n, chains as in (a) exist.

Base case $n = 1$. Here $N = 0$, as noted after Definition 9.2.1. Take $r = 1$, $k_1 = 1$ and $\mathbf{u}_1$ any non-zero vector; then $N^1\mathbf{u}_1 = \mathbf{0}$ and $\mathcal{B} = (\mathbf{u}_1)$ is a basis.

Induction step. Let $n \geq 2$ and assume the statement for all spaces of dimension less than n. Let $N \in \mathcal{L}(V)$ be nilpotent with $\dim V = n$.

N is not injective: if it were, then N^s would be injective for every s (a composition of injective maps is injective, Theorem 0.4.3 (a)), contradicting $N^s = 0$ on $V \neq \{\mathbf{0}\}$. So $\operatorname{nullity} N \geq 1$, and with $W = \operatorname{im} N$ Rank–Nullity gives $\dim W = n - \operatorname{nullity} N \leq n - 1$ (Theorem 3.3.1).

Step 1. Chains inside $\operatorname{im} N$**.** If $W = \{\mathbf{0}\}$, then $N = 0$; take $r = n$, all $k_i = 1$ and $(\mathbf{u}_1, \dots, \mathbf{u}_n)$ any basis of V, and (a) holds. So assume $W \neq \{\mathbf{0}\}$. Then W is N-invariant (Theorem 5.7.4 (b)), $N|_W$ is nilpotent ($(N|_W)^s = (N^s)|_W = 0$), and $1 \leq \dim W < n$. By the induction hypothesis there are $\mathbf{w}_1, \dots, \mathbf{w}_q \in W$ and $l_1 \geq \cdots \geq l_q \geq 1$ with $\sum_i l_i = \dim W$, $(N|_W)^{l_i}\mathbf{w}_i = \mathbf{0}$, and

$$\mathcal{C} = \left(N^{l_1-1}\mathbf{w}_1, \dots, \mathbf{w}_1,\ \dots,\ N^{l_q-1}\mathbf{w}_q, \dots, \mathbf{w}_q\right)$$

a basis of W.

Step 2. Lift each chain by one box. Each $\mathbf{w}_i$ lies in $W = \operatorname{im} N$, so we may choose $\mathbf{u}_i \in V$ with $N\mathbf{u}_i = \mathbf{w}_i$ for $i = 1, \dots, q$. Put $k_i = l_i + 1$. Then

$$N^j\mathbf{u}_i = N^{j-1}\mathbf{w}_i \quad (j \geq 1), \qquad \text{so} \qquad N^{k_i}\mathbf{u}_i = N^{l_i}\mathbf{w}_i = \mathbf{0}.$$

Step 3. Fill up $\ker N$**.** The q vectors $N^{l_i}\mathbf{u}_i = N^{l_i-1}\mathbf{w}_i$ $(i = 1, \dots, q)$ are members of the

basis $\mathcal{C}$, hence linearly independent, and each lies in $\ker N$, because $N(N^{l_i}\mathbf{u}_i) = N^{k_i}\mathbf{u}_i = \mathbf{0}$. By Theorem 1.6.5 applied inside $\ker N$, there are vectors $\mathbf{u}_{q+1}, \dots, \mathbf{u}_r \in \ker N$ such that

$$\left(N^{l_1}\mathbf{u}_1, \dots, N^{l_q}\mathbf{u}_q,\ \mathbf{u}_{q+1}, \dots, \mathbf{u}_r\right)$$

is a basis of $\ker N$; in particular $r = \operatorname{nullity} N$. Put $k_i = 1$ for $q < i \le r$, so that $N^{k_i}\mathbf{u}_i = N\mathbf{u}_i = \mathbf{0}$ for those i as well.

Step 4. The combined list is a basis. Let $\mathcal{B}$ be the list of all $N^j\mathbf{u}_i$ with $1 \le i \le r$ and $0 \le j \le k_i - 1$, the chains written one after another as in (a). Its length is

$$\sum_{i=1}^{q}(l_i + 1) + (r - q) = \dim W + q + (r - q) = \operatorname{rank} N + \operatorname{nullity} N = n$$

by Step 1 and Theorem 3.3.1. So by Theorem 1.6.4 (a) it is enough to prove independence.

Suppose

$$\sum_{i=1}^{r}\sum_{j=0}^{k_i-1} a_{ij}\, N^j\mathbf{u}_i = \mathbf{0} \qquad (*)$$

with $a_{ij} \in F$. Apply N to $(*)$. For $i > q$ we have $k_i = 1$ and $N\mathbf{u}_i = \mathbf{0}$, so those terms die. For $i \le q$ and $j = k_i - 1 = l_i$ we get $N^{l_i+1}\mathbf{u}_i = \mathbf{0}$ by Step 2, so those terms die too. The rest is, using $N^{j+1}\mathbf{u}_i = N^j\mathbf{w}_i$,

$$\sum_{i=1}^{q}\sum_{j=0}^{l_i-1} a_{ij}\, N^j\mathbf{w}_i = \mathbf{0}.$$

This is a linear combination of the members of the basis $\mathcal{C}$ of W, so

$$a_{ij} = 0 \qquad \text{for } 1 \le i \le q,\ 0 \le j \le l_i - 1.$$

Substituting these zeros back into $(*)$ leaves only the terms with $i \le q,\ j = l_i$ and those with $i > q,\ j = 0$:

$$\sum_{i=1}^{q} a_{il_i} N^{l_i}\mathbf{u}_i + \sum_{i=q+1}^{r} a_{i0}\mathbf{u}_i = \mathbf{0}.$$

This is a linear combination of the members of the basis of $\ker N$ from Step 3, so all the remaining coefficients vanish as well. Hence $\mathcal{B}$ is independent, and therefore a basis of V. The lengths satisfy $\sum_i k_i = n$ by the count above, and reindexing the chains so that the lengths decrease — a permutation of the chains — arranges $k_1 \ge \cdots \ge k_r$. This proves (a), and completes the induction.

(b) Each C_i is N-invariant of dimension k_i, with $[N|_{C_i}] = \mathbf{J}_{k_i}(0)$ in its chain, by Lemma 9.2.2 (b). The chains together form the basis $\mathcal{B}$ of V, so $V = C_1 + \cdots + C_r$. The sum is direct: if $\mathbf{c}_1 + \cdots + \mathbf{c}_r = \mathbf{0}$ with $\mathbf{c}_i \in C_i$, then writing each $\mathbf{c}_i$ in terms of its own chain turns this into a linear combination of the members of the basis $\mathcal{B}$ equal to $\mathbf{0}$, so every coefficient is 0 and every $\mathbf{c}_i = \mathbf{0}$; now apply Theorem 1.7.5 ((b) $\Rightarrow$ (a)). Finally Theorem 8.1.5 gives that $[N]_{\mathcal{B}}$ is block diagonal with blocks $[N|_{C_i}] = \mathbf{J}_{k_i}(0)$.

■

The theorem says that a nilpotent operator carries no information beyond the list of chain lengths. In matrix terms: **every nilpotent $\mathbf{A} \in M_n(F)$ is similar to $\mathbf{J}_{k_1}(0) \oplus \cdots \oplus \mathbf{J}_{k_r}(0)$ for some $k_1 \geq \cdots \geq k_r \geq 1$ summing to n** (apply the theorem to $T_{\mathbf{A}}$ and use Theorem 3.7.4). The index of nilpotency is k_1, the largest block (it is also the stabilization index of the kernel chain of Theorem 9.1.1, since $\ker N^{k_1} = V$): $\mathbf{J}_k(0)^k = 0$ and $\mathbf{J}_k(0)^{k-1} \neq 0$, and powers of a block diagonal matrix act blockwise (Theorem 7.1.4 (b)). Two questions remain: are the lengths unique, and how do we find them without finding the chains? One computation answers both.

9.2.4 Block sizes from the ranks of the powers

The lengths are visible in the ranks of the powers of N, which are similarity invariants. This is the practical algorithm and the uniqueness proof at once.

Theorem 9.2.4 — Block Sizes from Ranks of Powers

Let V be finite-dimensional with $\dim V = n \geq 1$, let $N \in \mathcal{L}(V)$ be nilpotent, and suppose $\mathcal{B}$ is a Jordan basis for N with chain lengths $k_1 \geq \cdots \geq k_r \geq 1$, as in Theorem 9.2.3. Write $r_j = \operatorname{rank} N^j$ for $j \geq 0$, so $r_0 = n$. Then:

(a) for every integer $j \geq 0$,

$$\operatorname{rank} N^j = \sum_{i=1}^{r} \max(k_i - j,\, 0) \qquad \text{and} \qquad \dim \ker N^j = \sum_{i=1}^{r} \min(k_i,\, j);$$

(b) for every integer $j \geq 1$, the number of chains of length **at least** j is

$$\#\{\, i : k_i \geq j \,\} = r_{j-1} - r_j;$$

(c) for every integer $j \geq 1$, the number of chains of length **exactly** j is

$$\#\{\, i : k_i = j \,\} = r_{j-1} - 2r_j + r_{j+1};$$

(d) consequently the list $k_1 \geq \cdots \geq k_r$ is determined by N alone: any two Jordan bases for N have the same chain lengths. Moreover $r = n - \operatorname{rank} N = \operatorname{nullity} N$ and k_1 is the index of nilpotency of N.

Idea. Everything follows from what N^j does to the basis: it shifts each chain j boxes to the left, so the surviving images are the boxes at least j steps from the left edge. They are members of the basis, hence independent, and we can just count them: chain i contributes $k_i - j$ of them, or none if it is too short. Then (b) is a telescoping difference, because lengthening the shift by one step loses one box from every chain that still had one.

Proof.

(a) The basis $\mathcal{B}$ consists of the vectors $N^m \mathbf{u}_i$ with $1 \leq i \leq r$ and $0 \leq m \leq k_i - 1$. Fix $j \geq 0$. Applying N^j to a member gives $N^j(N^m \mathbf{u}_i) = N^{m+j}\mathbf{u}_i$, which is $\mathbf{0}$ when $m + j \geq k_i$, because $N^{k_i}\mathbf{u}_i = \mathbf{0}$, and is a member of $\mathcal{B}$, hence non-zero, when

$m+j \le k_i-1$. Since the image is spanned by the images of a basis (Theorem 3.2.4),

$$\operatorname{im} N^j = \operatorname{span}\big(N^m \mathbf{u}_i : 1 \le i \le r,\ j \le m \le k_i - 1 \big).$$

This spanning list is a sublist of the basis $\mathcal{B}$, hence linearly independent, so it is a basis of $\operatorname{im} N^j$ and $\operatorname{rank} N^j$ is its length: for each i, the number of integers m with $j \le m \le k_i - 1$ is $k_i - j$ if $k_i > j$, and 0 otherwise, that is $\max(k_i - j, 0)$. This gives the first formula, and the second follows from Theorem 3.3.1 and $\sum_i k_i = n$:

$$\dim \ker N^j = n - \operatorname{rank} N^j = \sum_{i=1}^{r} \big(k_i - \max(k_i - j, 0)\big) = \sum_{i=1}^{r} \min(k_i, j).$$

(b) By (a), $r_{j-1} - r_j = \sum_i \big(\max(k_i - j + 1, 0) - \max(k_i - j, 0)\big)$. For a single i, the bracket is $(k_i - j + 1) - (k_i - j) = 1$ if $k_i \ge j$, and $0 - 0 = 0$ if $k_i \le j - 1$. Summing over i counts the indices with $k_i \ge j$.

(c) Subtract the count in (b) for $j+1$ from the count for j: a chain has length exactly j if and only if its length is at least j but not at least $j+1$. This gives $(r_{j-1} - r_j) - (r_j - r_{j+1})$.

(d) The numbers $r_j = \operatorname{rank} N^j$ are defined from N with no reference to a basis, so by (c) the number of chains of each length is determined by N; hence so is the list of lengths in decreasing order. Taking $j = 1$ in (b) gives $r = \#\{i : k_i \ge 1\} = r_0 - r_1 = n - \operatorname{rank} N$, which is nullity N by Theorem 3.3.1. Finally $N^{k_1} = 0$ and $N^{k_1 - 1} \ne 0$, since by (a) $\operatorname{rank} N^{k_1} = 0$ and $\operatorname{rank} N^{k_1 - 1} \ge k_1 - (k_1 - 1) = 1$; so k_1 is the index.

■

Corollary 9.2.5 — Similarity of Nilpotent Matrices

Let $\mathbf{A}, \mathbf{B} \in M_n(F)$, $n \ge 1$, both nilpotent. Then $\mathbf{A} \sim \mathbf{B}$ if and only if

$$\operatorname{rank} \mathbf{A}^j = \operatorname{rank} \mathbf{B}^j \qquad \text{for every } j = 1, 2, \dots, n-1.$$

Equivalently, $\mathbf{A} \sim \mathbf{B}$ if and only if their chain lengths, as lists in decreasing order, agree.

Proof. ($\Rightarrow$) If $\mathbf{A} \sim \mathbf{B}$, say $\mathbf{B} = \mathbf{P}^{-1}\mathbf{A}\mathbf{P}$, then $\mathbf{B}^j = \mathbf{P}^{-1}\mathbf{A}^j\mathbf{P}$ (Proposition 3.7.6 (c)), so $\operatorname{rank} \mathbf{A}^j = \operatorname{rank} \mathbf{B}^j$ (Proposition 3.7.6 (a)).

($\Leftarrow$) Since $\operatorname{rank} T_{\mathbf{A}}^j = \operatorname{rank} \mathbf{A}^j$ and $\operatorname{rank} T_{\mathbf{B}}^j = \operatorname{rank} \mathbf{B}^j$ for every j (Theorem 3.6.5 (a)), the hypothesis is a statement about the operators. By Theorem 9.2.3 applied to $T_{\mathbf{A}}$ and to $T_{\mathbf{B}}$, together with Theorem 3.7.4, $\mathbf{A}$ is similar to $\mathbf{J}_{k_1}(0) \oplus \cdots \oplus \mathbf{J}_{k_r}(0)$ and $\mathbf{B}$ to $\mathbf{J}_{k'_1}(0) \oplus \cdots \oplus \mathbf{J}_{k'_{r'}}(0)$, with both lists decreasing. Equal ranks of all powers force equal lists, by Theorem 9.2.4 (c) (the ranks for $j \ge n$ are all 0, so the listed range suffices). Hence $\mathbf{A}$ and $\mathbf{B}$ are similar to the same matrix, and $\mathbf{A} \sim \mathbf{B}$ because similarity is an equivalence relation (Example (Similarity)).

■

Warning. **The successive differences count the blocks of size at least j, not the blocks of size exactly j; to get the exact counts, subtract twice.** Suppose

$n = 5$ and $\operatorname{rank} N = 3$, $\operatorname{rank} N^2 = 1$, $\operatorname{rank} N^3 = 0$. Then $r_0 - r_1 = 2$ chains have length ≥ 1, $r_1 - r_2 = 2$ have length ≥ 2, and $r_2 - r_3 = 1$ has length ≥ 3. Reading these as exact counts would suggest two chains of length 1, two of length 2 and one of length 3, that is, lengths $1, 1, 2, 2, 3$, summing to 9 instead of 5. The correct counts are the second differences of Theorem 9.2.4 (c): exactly $2 - 2 = 0$ chains of length 1, exactly $2 - 1 = 1$ of length 2, and exactly $1 - 0 = 1$ of length 3. The partition is $(3, 2)$, and $3 + 2 = 5$ as it must be.

Quick check. A nilpotent N on a space of dimension 6 has $\operatorname{rank} N = 3$ and $\operatorname{rank} N^2 = 1$. What are its chain lengths?

Solution. Here $r_0 = 6$, $r_1 = 3$ and $r_2 = 1$, so there are $r_0 - r_1 = 3$ chains by part (b) of Theorem 9.2.4. Also $r_3 = 0$: a chain of length ≥ 4 would contribute at least 2 to $r_2 = \sum_i \max(k_i - 2, 0) = 1$, so every $k_i \leq 3$ and $r_3 = \sum_i \max(k_i - 3, 0) = 0$. By part (c) the exact counts are $r_0 - 2r_1 + r_2 = 1$ chain of length 1, $r_1 - 2r_2 + r_3 = 1$ of length 2, and $r_2 - 2r_3 + r_4 = 1$ of length 3. So the lengths are $(3, 2, 1)$, which indeed sum to 6.

9.2.5 Partitions and Young diagrams

The data left over is a list of decreasing positive integers with a given sum. Such lists have a name.

Definition 9.2.3 — Partition of an Integer, Young Diagram, Dual Partition

Let $n \geq 1$. A **partition of** n is a finite list of integers

$$k_1 \geq k_2 \geq \cdots \geq k_r \geq 1 \qquad \text{with} \qquad k_1 + k_2 + \cdots + k_r = n.$$

Its **Young diagram** is the left-justified array of n boxes with k_i boxes in row i. The **dual partition** $k_1^* \geq k_2^* \geq \ldots$ is the list of **column** lengths of the diagram,

$$k_j^* = \#\{\, i : k_i \geq j \,\},$$

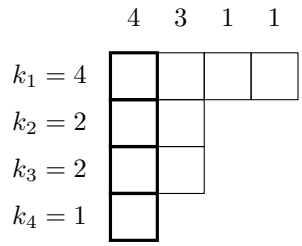
which is again a partition of n.

(The word *partition* is also used for a partition of a **set** into blocks (Definition 0.5.4) and for a partition of the row and column indices of a block matrix (Definition 7.1.1). Those are different notions; here the blocks are boxes in a diagram and the data is a list of numbers.)

For a nilpotent N on a space of dimension n, the chain lengths form a partition of n, and Theorem 9.2.4 (b) identifies the dual partition:

$$k_j^* = \#\{i : k_i \geq j\} = r_{j-1} - r_j = \dim \ker N^j - \dim \ker N^{j-1},$$

using Theorem 3.3.1 for the last equality. **The rows of the diagram are the chains; the columns are the jumps of the kernel chain.** In particular the first column is a basis of $\ker N$ (its boxes are the vectors $N^{k_i - 1}\mathbf{u}_i$), the first two columns span $\ker N^2$, and so on. Here is the diagram for the partition $(4, 2, 2, 1)$ of 9, with the columns marked:



column lengths, above: the dual partition $(4, 3, 1, 1)$
rows: the chain lengths $(4, 2, 2, 1)$
the thick first column: a basis of $\ker N$
$\dim \ker N^j = 4, 7, 8, 9$ for $j = 1, 2, 3, 4$

Reading the diagram by rows gives the Jordan blocks; reading it by columns gives the dimensions $\dim \ker N^j = k_1^* + \cdots + k_j^*$. Transposing the diagram exchanges a partition with its dual.

> *Remark.* For each n, the nilpotent operators on an n-dimensional space, up to similarity, correspond exactly to the partitions of n, and the correspondence does not depend on the field. For $n = 4$ the partitions are
>
> $$(4), \quad (3,1), \quad (2,2), \quad (2,1,1), \quad (1,1,1,1),$$
>
> so there are exactly five similarity classes of nilpotent 4×4 matrices over any field, with indices of nilpotency $4, 3, 2, 2, 1$.

9.2.6 Finding a Jordan basis

The proof of Theorem 9.2.3 is an algorithm, but run from the inside out. For small matrices it is easier to work from the longest chain down, using the rank data to know what to look for.

> *Algorithm.* **Jordan basis of a nilpotent operator.**
>
> 1. Compute $r_j = \operatorname{rank} N^j$ until $r_j = 0$, and read off the chain lengths by Theorem 9.2.4 (c).
> 2. For each length in decreasing order, choose a top $\mathbf{u}$ with $N^{k-1}\mathbf{u} \neq \mathbf{0}$, keeping the chains collected so far independent, and write down its chain.
> 3. Chains of length 1 are vectors completing a basis of $\ker N$ together with the ends $N^{k_i-1}\mathbf{u}_i$ of the longer chains. Once n vectors are collected, Theorem 1.6.4 confirms a basis.

> **Example. (A Jordan Basis for a 4×4 Nilpotent Matrix)**
>
> Let
>
> $$\mathbf{N} = \begin{pmatrix} 1 & 0 & 1 & 1 \\ 1 & -1 & 1 & 1 \\ 1 & -1 & 1 & 1 \\ -1 & 0 & -1 & -1 \end{pmatrix} \in M_4(\mathbb{Q}).$$
>
> Show that $\mathbf{N}$ is nilpotent, find its chain lengths, and find a Jordan basis together with an invertible $\mathbf{P}$ with $\mathbf{P}^{-1}\mathbf{N}\mathbf{P}$ a direct sum of blocks $\mathbf{J}_k(0)$.

Solution. Nilpotency and ranks. Multiplying out,

$$\mathbf{N}^2 = \begin{pmatrix} 1 & -1 & 1 & 1 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ -1 & 1 & -1 & -1 \end{pmatrix}, \qquad \mathbf{N}^3 = 0,$$

the last because every row of $\mathbf{N}^2$ is a multiple of $(1,-1,1,1)$, while

$$\begin{aligned}(1,-1,1,1)\,\mathbf{N} &= (1-1+1-1,\quad 0+1-1+0,\quad 1-1+1-1,\quad 1-1+1-1)\\ &= 0.\end{aligned}$$

Since $\mathbf{N}^2 \neq 0$, the index is 3. Rows 2 and 3 of $\mathbf{N}$ are equal and row 4 = −row 1, so $\operatorname{rank}\mathbf{N} = 2$, and $\operatorname{rank}\mathbf{N}^2 = 1$. Thus

$$r_0 = 4, \quad r_1 = 2, \quad r_2 = 1, \quad r_3 = 0.$$

By Theorem 9.2.4 (c), the number of chains of length 1 is $r_0 - 2r_1 + r_2 = 4-4+1 = 1$, of length 2 is $r_1 - 2r_2 + r_3 = 2-2+0 = 0$, and of length 3 is $r_2 - 2r_3 + r_4 = 1-0+0 = 1$. The partition is $(3,1)$: one chain of length 3 and one of length 1, matching the picture drawn after Theorem 9.2.3.

The long chain. We need $\mathbf{u}_1 \notin \ker\mathbf{N}^2$. Try $\mathbf{u}_1 = \mathbf{e}_1$: the first column of $\mathbf{N}^2$ is $(1,0,0,-1) \neq \mathbf{0}$, so $\mathbf{N}^2\mathbf{e}_1 \neq \mathbf{0}$ and $\mathbf{e}_1$ works. Its chain, read off the first columns of $\mathbf{N}$ and $\mathbf{N}^2$, is

$$\mathbf{N}^2\mathbf{e}_1 = (1,0,0,-1), \qquad \mathbf{N}\mathbf{e}_1 = (1,1,1,-1), \qquad \mathbf{e}_1.$$

The short chain. $\ker\mathbf{N}$ has dimension 2 (Theorem 2.5.7). The equations $x_1+x_3+x_4 = 0$ (row 1) and $x_1 - x_2 + x_3 + x_4 = 0$ (row 2) give $x_2 = 0$ and $x_1 = -x_3 - x_4$, so

$$\ker\mathbf{N} = \operatorname{span}\big((-1,0,1,0),\ (-1,0,0,1)\big).$$

The end of the long chain, $\mathbf{N}^2\mathbf{e}_1 = (1,0,0,-1)$, is the second of these basis vectors with a minus sign, so we complete it to a basis of $\ker\mathbf{N}$ with $\mathbf{u}_2 = (-1,0,1,0)$.

The basis and the matrix. Take

$$\mathcal{B} = \big((1,0,0,-1),\ (1,1,1,-1),\ \mathbf{e}_1,\ (-1,0,1,0)\big),$$

$$\mathbf{P} = \begin{pmatrix} 1 & 1 & 1 & -1 \\ 0 & 1 & 0 & 0 \\ 0 & 1 & 0 & 1 \\ -1 & -1 & 0 & 0 \end{pmatrix},$$

the matrix whose columns are the vectors of $\mathcal{B}$. Its third column has a single non-zero entry, the 1 in row 1, so expanding along that column (Theorem 6.6.1) gives

$$\det\mathbf{P} = \det\begin{pmatrix} 0 & 1 & 0 \\ 0 & 1 & 1 \\ -1 & -1 & 0 \end{pmatrix} = -1,$$

the last determinant computed by expanding along its own first column. So $\mathbf{P}$ is invertible and $\mathcal{B}$ is a basis. Then

$$\mathbf{P}^{-1}N\mathbf{P} = \mathbf{J}_3(0) \oplus \mathbf{J}_1(0) = \begin{pmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}.$$

There is no need to invert $\mathbf{P}$ to check this: the claim $\mathbf{P}^{-1}N\mathbf{P} = \mathbf{J}$ is the same as $N\mathbf{P} = \mathbf{P}\mathbf{J}$, which reads column by column as

$$\begin{aligned} \mathbf{N}(1,0,0,-1) &= \mathbf{0}, \\ \mathbf{N}(1,1,1,-1) &= (1,0,0,-1), \\ \mathbf{N}\mathbf{e}_1 &= (1,1,1,-1), \\ \mathbf{N}(-1,0,1,0) &= \mathbf{0}, \end{aligned}$$

and these four statements are exactly how the chains were built (the first and last say that the two chain ends lie in $\ker \mathbf{N}$). As a sample verification, the second row of $\mathbf{N}(1,1,1,-1)$ is $1-1+1-1=0$, matching the second coordinate of $(1,0,0,-1)$.

9.2.7 Exercises

9.2.7.1 A. Check your understanding

Exercise A1.

(a) Define a nilpotent operator and its index of nilpotency.

(b) State the structure theorem for nilpotent operators, and say what a Jordan basis is.

(c) Write down the formula for the number of chains of length at least j in terms of the ranks of the powers.

(d) True or false: a singular matrix is nilpotent. Justify your answer.

(e) True or false: two nilpotent matrices in $M_n(F)$ with the same rank are similar. Justify your answer.

(f) How many similarity classes of nilpotent matrices are there in $M_3(F)$, and what are their indices of nilpotency?

Solution.

(a) $N \in \mathcal{L}(V)$ is nilpotent if $N^s = 0$ for **some** integer $s \geq 1$; the index is the least such s (Definition 9.2.1).

(b) For nilpotent N on V with $\dim V = n \geq 1$, there are chains generated by $\mathbf{u}_1, \ldots, \mathbf{u}_r$ of lengths $k_1 \geq \cdots \geq k_r \geq 1$ summing to n whose concatenation is a basis of V — a Jordan basis — and in it $[N] = \mathbf{J}_{k_1}(0) \oplus \cdots \oplus \mathbf{J}_{k_r}(0)$ (Theorem 9.2.3).

(c) $\#\{i : k_i \geq j\} = \operatorname{rank} N^{j-1} - \operatorname{rank} N^j$ (Theorem 9.2.4 (b)).

(d) False. $\operatorname{diag}(0,1)$ is singular, and $\operatorname{diag}(0,1)^k = \operatorname{diag}(0,1) \neq 0$ for every $k \geq 1$. What is true is the converse: a nilpotent matrix on a non-zero space is singular, since $0 \in \operatorname{spec}(N)$ (Proposition 9.2.1 (c)).

(e) False for $n \geq 4$. The partitions $(3,1)$ and $(2,2)$ of 4 both give rank 2, but $\operatorname{rank} N^2$ is 1 and 0 respectively, so the matrices are not similar (Corollary 9.2.5). (For $n \leq 3$ the rank does determine the partition.)

(f) Three, one for each partition of 3: $(3), (2,1), (1,1,1)$, with indices $3, 2, 1$.

9.2.7.2 B. Practice

Exercise B1: Block sizes from rank data.

In each case N is nilpotent on a space of dimension n over F. Determine the chain lengths, or explain why no such operator exists.

(a) $n = 7$, $\operatorname{rank} N = 4$, $\operatorname{rank} N^2 = 2$, $\operatorname{rank} N^3 = 1$, $\operatorname{rank} N^4 = 0$.

(b) $n = 6$, $\operatorname{rank} N = 3$, $\operatorname{rank} N^2 = 1$, $\operatorname{rank} N^3 = 0$.

(c) $n = 6$, $\operatorname{rank} N = 4$, $\operatorname{rank} N^2 = 3$, $\operatorname{rank} N^3 = 0$.

Solution.

(a) With $r_0, \dots, r_4 = 7, 4, 2, 1, 0$, the exact counts from Theorem 9.2.4 (c) are: length 1: $7 - 8 + 2 = 1$; length 2: $4 - 4 + 1 = 1$; length 3: $2 - 2 + 0 = 0$; length 4: $1 - 0 + 0 = 1$. The lengths are $(4, 2, 1)$, and $4 + 2 + 1 = 7$.

(b) With $r_0, \dots, r_3 = 6, 3, 1, 0$: length 1: $6 - 6 + 1 = 1$; length 2: $3 - 2 + 0 = 1$; length 3: $1 - 0 + 0 = 1$. The lengths are $(3, 2, 1)$, summing to 6.

(c) No such operator exists. By (b) of the theorem, the number of chains of length ≥ 2 would be $r_1 - r_2 = 1$, while the number of length ≥ 3 would be $r_2 - r_3 = 3$, which is impossible: a chain of length ≥ 3 has length ≥ 2, so the counts must be non-increasing in j. (Equivalently, Theorem 9.2.4 (c) would give $r_1 - 2r_2 + r_3 = 4 - 6 + 0 = -2$ chains of length 2, which is absurd.)

Exercise B2: The five classes in dimension four.

Let F be any field.

(a) List the five partitions of 4, and for each write down the corresponding nilpotent matrix in $M_4(F)$ as a direct sum of blocks $\mathbf{J}_k(0)$.

(b) For each, compute $\operatorname{rank} \mathbf{N}$, $\operatorname{rank} \mathbf{N}^2$, $\operatorname{rank} \mathbf{N}^3$ and the index of nilpotency.

(c) Which pairs among them share the same rank? Which invariant separates each such pair?

(d) Deduce that $\operatorname{rank} \mathbf{N}$ alone is not a complete invariant of nilpotent matrices, but the full list of ranks of powers is.

Solution.

(a) (4): $\mathbf{J}_4(0)$; $(3,1)$: $\mathbf{J}_3(0) \oplus \mathbf{J}_1(0)$; $(2,2)$: $\mathbf{J}_2(0) \oplus \mathbf{J}_2(0)$; $(2,1,1)$: $\mathbf{J}_2(0) \oplus \mathbf{J}_1(0) \oplus \mathbf{J}_1(0)$; $(1,1,1,1)$: the zero matrix.

(b) Using $\operatorname{rank} \mathbf{N}^j = \sum_i \max(k_i - j, 0)$ (Theorem 9.2.4 (a)), the ranks $(\operatorname{rank} \mathbf{N}, \operatorname{rank} \mathbf{N}^2, \operatorname{rank} \mathbf{N}^3)$ and the index are:

- (4): ranks $3, 2, 1$; index 4.

- $(3,1)$: ranks $2,1,0$; index 3.
- $(2,2)$: ranks $2,0,0$; index 2.
- $(2,1,1)$: ranks $1,0,0$; index 2.
- $(1,1,1,1)$: ranks $0,0,0$; index 1.

(c) Only $(3,1)$ and $(2,2)$ share a rank, namely 2. They are separated by $\operatorname{rank}\mathbf{N}^2$ (1 against 0), equivalently by the index (3 against 2) or the minimal polynomial (x^3 against x^2, Proposition 9.2.1 (b)).

(d) The pair in (c) shows that equal rank does not imply similarity, while equality of $\operatorname{rank}\mathbf{N}^j$ for all j does (Corollary 9.2.5).

Exercise B3: A Jordan basis by hand.

Let

$$\mathbf{M} = \begin{pmatrix} -1 & -1 & 1 & -1 \\ 1 & 2 & -2 & 1 \\ 1 & 2 & -2 & 1 \\ 1 & 1 & -1 & 1 \end{pmatrix} \in M_4(\mathbb{Q}).$$

(a) Show that $\mathbf{M}^2 = 0$ and compute $\operatorname{rank}\mathbf{M}$.

(b) Determine the chain lengths of $\mathbf{M}$.

(c) Find a Jordan basis and an invertible $\mathbf{P}$ with $\mathbf{P}^{-1}\mathbf{M}\mathbf{P}$ a direct sum of blocks $\mathbf{J}_k(0)$. Verify your answer by checking $\mathbf{M}\mathbf{P} = \mathbf{P}\mathbf{J}$ column by column.

Hint: for (c), the tops of the chains may be taken among the standard basis vectors.

Solution.

(a) Write $\mathbf{m}_1, \dots, \mathbf{m}_4$ for the columns of $\mathbf{M}$, so $\mathbf{m}_1 = (-1,1,1,1)$, $\mathbf{m}_2 = (-1,2,2,1)$, $\mathbf{m}_3 = -\mathbf{m}_2$ and $\mathbf{m}_4 = \mathbf{m}_1$. The columns of $\mathbf{M}^2$ are $\mathbf{M}\mathbf{m}_1, \dots, \mathbf{M}\mathbf{m}_4$, so it is enough to check the first two. Row by row,

$$\begin{aligned} \mathbf{M}\mathbf{m}_1 &= (1-1+1-1,\ -1+2-2+1,\ -1+2-2+1,\ -1+1-1+1) \\ &= \mathbf{0}, \end{aligned}$$

$$\begin{aligned} \mathbf{M}\mathbf{m}_2 &= (1-2+2-1,\ -1+4-4+1,\ -1+4-4+1,\ -1+2-2+1) \\ &= \mathbf{0}. \end{aligned}$$

Hence $\mathbf{M}\mathbf{m}_3 = -\mathbf{M}\mathbf{m}_2 = \mathbf{0}$ and $\mathbf{M}\mathbf{m}_4 = \mathbf{M}\mathbf{m}_1 = \mathbf{0}$, so $\mathbf{M}^2 = 0$. Also $\operatorname{im}\mathbf{M} = \operatorname{span}(\mathbf{m}_1, \mathbf{m}_2)$ by the relations among the columns, and $\mathbf{m}_1, \mathbf{m}_2$ are not proportional, so $\operatorname{rank}\mathbf{M} = 2$.

(b) $r_0, r_1, r_2 = 4, 2, 0$. Chains of length 1: $r_0 - 2r_1 + r_2 = 4 - 4 + 0 = 0$; of length 2: $r_1 - 2r_2 + r_3 = 2$. So the partition is $(2,2)$: two chains of length 2.

(c) We need two tops $\mathbf{u}, \mathbf{w}$ with $\mathbf{M}\mathbf{u}, \mathbf{M}\mathbf{w}$ independent; since $\operatorname{rank}\mathbf{M} = 2$ and $\operatorname{im}\mathbf{M} = \operatorname{span}(\mathbf{m}_1, \mathbf{m}_2)$, the vectors $\mathbf{u} = \mathbf{e}_1$ and $\mathbf{w} = \mathbf{e}_2$ do it, with $\mathbf{M}\mathbf{e}_1 = \mathbf{m}_1 = (-1,1,1,1)$ and $\mathbf{M}\mathbf{e}_2 = \mathbf{m}_2 = (-1,2,2,1)$. Take

$$\mathcal{B} = \big((-1,1,1,1),\ \mathbf{e}_1,\ (-1,2,2,1),\ \mathbf{e}_2 \big), \qquad \mathbf{P} = \begin{pmatrix} -1 & 1 & -1 & 0 \\ 1 & 0 & 2 & 1 \\ 1 & 0 & 2 & 0 \\ 1 & 0 & 1 & 0 \end{pmatrix}.$$

The last column of $\mathbf{P}$ has a single non-zero entry, the 1 in row 2, so expanding along it (Theorem 6.6.1) gives

$$\det \mathbf{P} = \det \begin{pmatrix} -1 & 1 & -1 \\ 1 & 0 & 2 \\ 1 & 0 & 1 \end{pmatrix} = -1 \cdot (1 \cdot 1 - 2 \cdot 1) = 1 \neq 0,$$

where the second determinant was expanded along its second column. So $\mathcal{B}$ is a basis, and

$$\mathbf{P}^{-1}\mathbf{M}\mathbf{P} = \mathbf{J}_2(0) \oplus \mathbf{J}_2(0).$$

Column by column, $\mathbf{MP} = \mathbf{PJ}$ says: $\mathbf{M}(-1,1,1,1) = \mathbf{0}$ (first column of $\mathbf{PJ}$ is $\mathbf{0}$); $\mathbf{M}\mathbf{e}_1 = (-1,1,1,1)$ (second column of $\mathbf{PJ}$ is the first column of $\mathbf{P}$); $\mathbf{M}(-1,2,2,1) = \mathbf{0}$; and $\mathbf{M}\mathbf{e}_2 = (-1,2,2,1)$. All four were verified in (a) and (c).

9.2.7.3 C. Going deeper

Exercise C1: A nilpotent matrix is similar to its transpose.

Let $\mathbf{A} \in M_n(F)$ be nilpotent.

(a) Prove that $\mathbf{A}^\top$ is nilpotent and that $\operatorname{rank}(\mathbf{A}^\top)^j = \operatorname{rank} \mathbf{A}^j$ for every $j \geq 1$.

(b) Deduce that $\mathbf{A} \sim \mathbf{A}^\top$.

(c) For $\mathbf{A} = \mathbf{J}_3(0)$, find an explicit $\mathbf{P}$ with $\mathbf{P}^{-1}\mathbf{A}\mathbf{P} = \mathbf{A}^\top$.

Solution.

(a) $(\mathbf{A}^\top)^j = (\mathbf{A}^j)^\top$ (Theorem 0.9.5), so $(\mathbf{A}^\top)^n = (\mathbf{A}^n)^\top = 0$ by Proposition 9.2.1 (a), and $\mathbf{A}^\top$ is nilpotent. A matrix and its transpose have the same rank (Theorem 2.5.5), so $\operatorname{rank}(\mathbf{A}^\top)^j = \operatorname{rank}(\mathbf{A}^j)^\top = \operatorname{rank} \mathbf{A}^j$.

(b) Both matrices are nilpotent with equal ranks of all powers, so Corollary 9.2.5 gives $\mathbf{A} \sim \mathbf{A}^\top$.

(c) $\mathbf{J}_3(0)$ sends $\mathbf{e}_1 \mapsto \mathbf{0}$, $\mathbf{e}_2 \mapsto \mathbf{e}_1$, $\mathbf{e}_3 \mapsto \mathbf{e}_2$, while $\mathbf{J}_3(0)^\top$ sends $\mathbf{e}_1 \mapsto \mathbf{e}_2 \mapsto \mathbf{e}_3 \mapsto \mathbf{0}$, that is, it is the shift in the reversed basis. So take the reversal permutation matrix

$$\mathbf{P} = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 1 & 0 \\ 1 & 0 & 0 \end{pmatrix}, \qquad \mathbf{P}^{-1} = \mathbf{P}.$$

Then $\mathbf{P}^{-1}\mathbf{J}_3(0)\mathbf{P} = \mathbf{J}_3(0)^\top$, as one checks column by column: $\mathbf{J}_3(0)\mathbf{P}$ has columns $\mathbf{J}_3(0)\mathbf{e}_3 = \mathbf{e}_2$, $\mathbf{J}_3(0)\mathbf{e}_2 = \mathbf{e}_1$, $\mathbf{J}_3(0)\mathbf{e}_1 = \mathbf{0}$, and $\mathbf{P}\,\mathbf{J}_3(0)^\top$ has columns $\mathbf{P}\mathbf{e}_2 = \mathbf{e}_2$, $\mathbf{P}\mathbf{e}_3 = \mathbf{e}_1$, $\mathbf{P}\mathbf{0} = \mathbf{0}$. (The same reversal works for every $\mathbf{J}_k(0)$, and hence, blockwise, for every nilpotent matrix in Jordan form.)

Exercise C2: One long chain.

Let V be finite-dimensional with $\dim V = n \geq 1$, and let $N \in \mathcal{L}(V)$ be nilpotent with $N^{n-1} \neq 0$.

(a) Prove that there is a basis of V in which the matrix of N is $\mathbf{J}_n(0)$.

(b) Deduce that $m_N = p_N = x^n$, and that nullity $N = 1$.

(c) Show that the conclusion of (a) fails for $\mathbf{N} = \mathbf{J}_2(0) \oplus \mathbf{J}_1(0)$ on a space of dimension 3, and say which hypothesis fails.

Hint: for (a), take a vector outside $\ker N^{n-1}$*, which exists precisely because* $N^{n-1} \neq 0$*.*

Solution.

(a) Since $N^{n-1} \neq 0$, there is $\mathbf{u} \in V$ with $N^{n-1}\mathbf{u} \neq \mathbf{0}$, while $N^n\mathbf{u} = \mathbf{0}$ by Proposition 9.2.1 (a). So $\mathbf{u}$ generates a Jordan chain of length n (Definition 9.2.2), which is a linearly independent list of $n = \dim V$ vectors (Lemma 9.2.2 (a)), hence a basis of V (Theorem 1.6.4 (a)). In it the matrix of N is $\mathbf{J}_n(0)$, by Lemma 9.2.2 (b) with $C = V$.

(b) In that basis $\operatorname{rank} N^j = n - j$ for $0 \leq j \leq n$ (Theorem 9.2.4 (a) with the single length $k_1 = n$), so nullity $N = 1$ by Theorem 3.3.1 and the index of nilpotency is n. Hence $m_N = x^n$ by Proposition 9.2.1 (b), and $p_N = x^n$ as well; they coincide, which by Corollary 8.6.2 is the extreme case $\deg m_N = n$.

(c) For $\mathbf{N} = \mathbf{J}_2(0) \oplus \mathbf{J}_1(0)$ on F^3 we have $\mathbf{N}^2 = 0$, so $\mathbf{N}^{n-1} = \mathbf{N}^2 = 0$ and the hypothesis $\mathbf{N}^{n-1} \neq 0$ fails. Accordingly $\mathbf{N}$ is not similar to $\mathbf{J}_3(0)$: its rank is 1, while $\operatorname{rank} \mathbf{J}_3(0) = 2$, and similar matrices have equal ranks (Proposition 3.7.6 (a)). Its partition is $(2, 1)$, not (3).

9.3 The Jordan Canonical Form

Chapter 3 asked how simple the matrix of an operator can be made by choosing the basis well, and Chapter 8 answered it only for operators with enough eigenvectors. The two previous sections have quietly finished the job: the space splits into generalized eigenspaces, and on each of them the operator is a scalar plus a nilpotent operator, which is a disjoint union of chains. Assembling these pieces gives the best matrix there is, and it is unique. This section states that theorem, proves it, reads the familiar invariants off it, and turns it into a similarity test.

9.3.1 The shape we are aiming for

Here is the goal, stated before its parts are named. **If p_T splits, then V has a basis in which the matrix of T is diagonal except for some ones immediately above the diagonal, and that matrix is unique up to the order of its diagonal blocks.** A diagonal matrix is the special case with no ones at all. So the dream of Chapter 3 comes true, with one extra ingredient beyond a diagonal matrix: the superdiagonal ones, one for each step of a Jordan chain.

The building block is the matrix of $\lambda\,\mathrm{id} + N$ on a single chain. By Lemma 9.2.2 (b), the nilpotent part contributes $\mathbf{J}_k(0)$, so the block is $\lambda\mathbf{I}_k + \mathbf{J}_k(0)$.

Definition 9.3.1 — Jordan Block

Let $k \geq 1$ and $\lambda \in F$. The **Jordan block** of size k for λ is the matrix

$$\mathbf{J}_k(\lambda) \coloneqq \lambda \mathbf{I}_k + \mathbf{J}_k(0) = \begin{pmatrix} \lambda & 1 & & \\ & \lambda & \ddots & \\ & & \ddots & 1 \\ & & & \lambda \end{pmatrix} \in M_k(F),$$

with λ in every diagonal entry, 1 in every **superdiagonal** entry $(j, j+1)$, and 0 elsewhere. In particular $\mathbf{J}_1(\lambda) = (\lambda)$.

Reading its columns: if $[T]_{\mathcal{B}} = \mathbf{J}_k(\lambda)$ for a basis $\mathcal{B} = (\mathbf{b}_1, \dots, \mathbf{b}_k)$, then $T\mathbf{b}_1 = \lambda \mathbf{b}_1$ and $T\mathbf{b}_j = \mathbf{b}_{j-1} + \lambda \mathbf{b}_j$ for $j \geq 2$; equivalently $(T - \lambda \operatorname{id}_V)\mathbf{b}_j = \mathbf{b}_{j-1}$ and $(T - \lambda \operatorname{id}_V)\mathbf{b}_1 = \mathbf{0}$, so $\mathcal{B}$ is the Jordan chain generated by $\mathbf{b}_k$ (Definition 9.2.2). The single eigenvalue is λ, with $a(\lambda) = k$ and $g(\lambda) = 1$, since $\mathbf{J}_k(\lambda) - \lambda \mathbf{I}_k = \mathbf{J}_k(0)$ has rank $k - 1$.

A Jordan matrix is a diagonal matrix with some chains glued in: blocks along the diagonal, each block one eigenvalue with ones above it.

Definition 9.3.2 — Jordan Matrix, Jordan Basis, Jordan Form

A **Jordan matrix** is a matrix of the form

$$\mathbf{J} = \mathbf{J}_{k_1}(\lambda_1) \oplus \mathbf{J}_{k_2}(\lambda_2) \oplus \cdots \oplus \mathbf{J}_{k_m}(\lambda_m)$$

for some $m \geq 1$, sizes $k_i \geq 1$ and scalars $\lambda_i \in F$, **not** assumed distinct. Let V be a finite-dimensional vector space over F with $\dim V \geq 1$ and $T \in \mathcal{L}(V)$. A **Jordan form** of T is a Jordan matrix $\mathbf{J}$ with $[T]_{\mathcal{B}} = \mathbf{J}$ for **some** basis $\mathcal{B}$ of V; such a basis is called a **Jordan basis** for T. For $\mathbf{A} \in M_n(F)$, a **Jordan form** of $\mathbf{A}$ is a Jordan matrix $\mathbf{J}$ with $\mathbf{A} \sim \mathbf{J}$.

In words: the matrix is block diagonal (Definition 7.1.2), and each diagonal block is a single Jordan block. Different blocks may carry the same eigenvalue or different ones, and the sizes may repeat. A Jordan basis is a basis that is a concatenation of Jordan chains, one chain per block. The two descriptions match for $\mathbf{A} \in M_n(F)$ and $T = T_{\mathbf{A}}$, by Theorem 3.7.4.

The order of the blocks never matters. Reordering the blocks of $\mathbf{J}$ permutes the segments of the basis $\mathcal{B}$, so the reordered matrix is the matrix of the **same** operator in the permuted basis, hence similar to $\mathbf{J}$ (Theorem 3.7.4 (a)). This is why the uniqueness statement below can only be "up to the order of the blocks", and why it costs nothing to list the blocks in any convenient order.

Examples.

- **Diagonal matrices.** $\operatorname{diag}(d_1, \dots, d_n) = \mathbf{J}_1(d_1) \oplus \cdots \oplus \mathbf{J}_1(d_n)$ is a Jordan matrix with all blocks of size 1. So every diagonalizable operator has a Jordan form, namely a diagonal one.
- **The standing counterexample.** $\begin{pmatrix} 2 & 1 \\ 0 & 2 \end{pmatrix} = \mathbf{J}_2(2)$ is its own Jordan form, and $(\mathbf{e}_1, \mathbf{e}_2)$ is a Jordan basis: $\mathbf{e}_1$ is an eigenvector and $(\mathbf{J} - 2\mathbf{I})\mathbf{e}_2 = \mathbf{e}_1$.
- **Nilpotent operators.** By Theorem 9.2.3, a nilpotent operator has the Jordan form $\mathbf{J}_{k_1}(0) \oplus \cdots \oplus \mathbf{J}_{k_r}(0)$, all eigenvalues 0. Section 2 is exactly the case $\lambda = 0$ of this section.
- **Mixed blocks.** $\mathbf{J} = \mathbf{J}_2(3) \oplus \mathbf{J}_1(3) \oplus \mathbf{J}_2(1) \in M_5(F)$ has $p_{\mathbf{J}} = (x-3)^3(x-1)^2$, $g(3) = 2$

and $g(1) = 1$. It is the answer to the worked example at the end of this section.

- **The degenerate case.** On a space of dimension 1, every operator is $(\lambda) = \mathbf{J}_1(\lambda)$. One block, size one, no superdiagonal to speak of.

Non-example by minimal change. The matrix $\begin{pmatrix} 2 & 1 \\ 0 & 3 \end{pmatrix}$ is upper triangular with a superdiagonal 1, but it is **not** a Jordan matrix: a 1 above the diagonal may only join two **equal** diagonal entries, because it records the step of a chain for a single eigenvalue. (Indeed this matrix has distinct eigenvalues, so it is diagonalizable, and its Jordan form is $\operatorname{diag}(2, 3)$.) Changing the superdiagonal entry instead, $\begin{pmatrix} 2 & 2 \\ 0 & 2 \end{pmatrix}$ is not a Jordan matrix either, since the entry above the diagonal must be 1; it is similar to $\mathbf{J}_2(2)$, by rescaling the second basis vector.

Why this definition. Two conventions are being fixed. First, the ones sit **above** the diagonal, which matches the chain order "eigenvector first" of Definition 9.2.2; putting them below the diagonal gives the transposed matrix, which is just as good and appears in some books. Second, the off-diagonal entries are 1 rather than arbitrary non-zero scalars: a non-zero entry c can be turned into a 1 by scaling one basis vector, so nothing is lost, and the normalization is what makes the form unique. Nothing else is allowed: if any further entry were permitted, the form would no longer be determined by the operator.

Warning. **A Jordan form exists only when p_T splits, so it depends on the field.** The rotation $\mathbf{R} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} \in M_2(\mathbb{R})$ has no Jordan form over $\mathbb{R}$, since $p_{\mathbf{R}} = x^2 + 1$ has no real root, and a Jordan matrix is triangular with its eigenvalues on the diagonal. Over $\mathbb{C}$ its Jordan form is $\operatorname{diag}(i, -i)$. Over $\mathbb{Q}$ the matrix $\begin{pmatrix} 0 & 2 \\ 1 & 0 \end{pmatrix}$ has no Jordan form either, and over $\mathbb{R}$ it becomes $\operatorname{diag}(\sqrt{2}, -\sqrt{2})$. Section 6 gives a canonical form valid over **every** field.

9.3.2 The theorem

Every operator whose characteristic polynomial splits is a direct sum of Jordan blocks, in exactly one way.

Theorem 9.3.1 — Jordan Canonical Form Theorem

Let V be a finite-dimensional vector space over F with $\dim V = n \geq 1$, and let $T \in \mathcal{L}(V)$.

(a) **(Existence)** T has a Jordan form if and only if p_T splits over F.

(b) **(Uniqueness)** Suppose $\mathbf{J}$ is a Jordan form of T. Then for every $\lambda \in F$ and every integer $j \geq 1$, the number of blocks $\mathbf{J}_k(\lambda)$ in $\mathbf{J}$ with $k \geq j$ equals

$$\operatorname{rank}(T - \lambda \operatorname{id}_V)^{j-1} - \operatorname{rank}(T - \lambda \operatorname{id}_V)^{j},$$

a number depending only on T, λ and j. Consequently any two Jordan forms of T have the same blocks, up to the order in which they are listed.

Equivalently, for $\mathbf{A} \in M_n(F)$ with $p_{\mathbf{A}}$ split: $\mathbf{A}$ is similar to a Jordan matrix, and that matrix is unique up to the order of its blocks. We call it **the** Jordan form of $\mathbf{A}$.

Idea. Existence is an assembly of the two previous sections, in three steps. ① Split $V = \bigoplus_i G_{\lambda_i}(T)$ (Theorem 9.1.3). ② On G_{λ_i} write $T = \lambda_i \operatorname{id} + N_i$ with N_i nilpotent, and take a Jordan basis for N_i (Theorem 9.2.3); adding $\lambda_i \mathbf{I}$ turns each $\mathbf{J}_k(0)$ into $\mathbf{J}_k(\lambda_i)$. ③ Put the bases together: the matrix is block diagonal. For uniqueness, count ranks. A block $\mathbf{J}_k(\mu) - \lambda\mathbf{I}$ with $\mu \neq \lambda$ is invertible, so it contributes its full size to every power and drops out of differences; a block with $\mu = \lambda$ becomes $\mathbf{J}_k(0)$, whose j-th power has rank $\max(k - j, 0)$. So the difference of two consecutive ranks counts the λ-blocks that are still long enough.

Proof.

(a) ($\Leftarrow$) Suppose p_T splits, with distinct eigenvalues $\lambda_1, \dots, \lambda_d$.
Step 1. Split the space. By Theorem 9.1.3, $V = G_1 \oplus \cdots \oplus G_d$ with $G_i = G_{\lambda_i}(T)$ non-zero and T-invariant, $\dim G_i = a_i := a_T(\lambda_i)$, and

$$T|_{G_i} = \lambda_i \operatorname{id}_{G_i} + N_i, \qquad N_i = (T - \lambda_i \operatorname{id}_V)|_{G_i} \text{ nilpotent.}$$

Step 2. One eigenvalue at a time. Fix i. By Theorem 9.2.3 applied to $N_i \in \mathcal{L}(G_i)$, there is a basis $\mathcal{B}_i$ of G_i, a concatenation of Jordan chains of N_i, with

$$[N_i]_{\mathcal{B}_i} = \mathbf{J}_{k_{i1}}(0) \oplus \cdots \oplus \mathbf{J}_{k_{ir_i}}(0), \qquad \textstyle\sum_l k_{il} = a_i.$$

Since $[\,\cdot\,]_{\mathcal{B}_i}$ is linear (Theorem 3.6.4) and $[\operatorname{id}_{G_i}]_{\mathcal{B}_i} = \mathbf{I}_{a_i} = \mathbf{I}_{k_{i1}} \oplus \cdots \oplus \mathbf{I}_{k_{ir_i}}$,

$$\begin{aligned}
[T|_{G_i}]_{\mathcal{B}_i} &= \lambda_i \mathbf{I}_{a_i} + [N_i]_{\mathcal{B}_i} \\
&= \left(\lambda_i \mathbf{I}_{k_{i1}} + \mathbf{J}_{k_{i1}}(0)\right) \oplus \cdots \oplus \left(\lambda_i \mathbf{I}_{k_{ir_i}} + \mathbf{J}_{k_{ir_i}}(0)\right) \\
&= \mathbf{J}_{k_{i1}}(\lambda_i) \oplus \cdots \oplus \mathbf{J}_{k_{ir_i}}(\lambda_i),
\end{aligned}$$

where the middle equality is the blockwise addition of Theorem 7.1.4 (a) and the last is Definition 9.3.1.
Step 3. Assemble. Let $\mathcal{B}$ be the basis of V obtained by writing $\mathcal{B}_1, \dots, \mathcal{B}_d$ one after another. By Theorem 8.1.5,

$$[T]_{\mathcal{B}} = [T|_{G_1}]_{\mathcal{B}_1} \oplus \cdots \oplus [T|_{G_d}]_{\mathcal{B}_d},$$

which by Step 2 is a direct sum of Jordan blocks, that is, a Jordan matrix. So T has a Jordan form, and $\mathcal{B}$ is a Jordan basis.
($\Rightarrow$) Suppose $[T]_{\mathcal{B}} = \mathbf{J}$ is a Jordan matrix. Each Jordan block is upper triangular, so $\mathbf{J}$ is upper triangular, and T is triangularizable (Definition 8.7.1). By Theorem 8.7.2, p_T splits over F.

(b) Let $\mathbf{J} = \mathbf{J}_{k_1}(\mu_1) \oplus \cdots \oplus \mathbf{J}_{k_m}(\mu_m) = [T]_{\mathcal{B}}$, with $\mu_1, \dots, \mu_m \in F$ not necessarily distinct; fix $\lambda \in F$ and let $j \geq 0$. Then $[T - \lambda \operatorname{id}_V]_{\mathcal{B}} = \mathbf{J} - \lambda \mathbf{I}_n$, which is block diagonal with blocks $\mathbf{J}_{k_i}(\mu_i) - \lambda \mathbf{I}_{k_i}$, so by Theorem 7.1.4 (b),

$$\left[(T - \lambda \operatorname{id}_V)^j\right]_{\mathcal{B}} = \left(\mathbf{J}_{k_1}(\mu_1) - \lambda \mathbf{I}_{k_1}\right)^j \oplus \cdots \oplus \left(\mathbf{J}_{k_m}(\mu_m) - \lambda \mathbf{I}_{k_m}\right)^j,$$

and the rank of a block diagonal matrix is the sum of the ranks of its blocks (Theorem 7.2.1 (b), applied $m - 1$ times). Also $\operatorname{rank}(T - \lambda \operatorname{id}_V)^j$ equals the rank of this matrix (Theorem 3.6.5 (a)). Now compute block by block.

Blocks with $\mu_i \neq \lambda$. Here $\mathbf{J}_{k_i}(\mu_i) - \lambda \mathbf{I}_{k_i}$ is upper triangular with every diagonal entry equal to $\mu_i - \lambda \neq 0$, so its determinant is $(\mu_i - \lambda)^{k_i} \neq 0$ (Theorem 6.4.6) and it is

invertible (Theorem 6.5.2). Hence its j-th power is invertible too, of rank k_i, for every $j \geq 0$.

Blocks with $\mu_i = \lambda$. Here $\mathbf{J}_{k_i}(\lambda) - \lambda \mathbf{I}_{k_i} = \mathbf{J}_{k_i}(0)$, whose standard basis is a single Jordan chain of length k_i, so $\operatorname{rank} \mathbf{J}_{k_i}(0)^j = \max(k_i - j, 0)$ by Theorem 9.2.4 (a) with the one-element list of lengths (k_i).

Adding up, with $c = \sum_{\mu_i \neq \lambda} k_i$ independent of j,

$$\operatorname{rank}(T - \lambda \operatorname{id}_V)^j = c + \sum_{\mu_i = \lambda} \max(k_i - j,\, 0).$$

Subtracting the values at j and $j-1$, the constant c cancels and each remaining bracket $\max(k_i - j + 1, 0) - \max(k_i - j, 0)$ equals 1 if $k_i \geq j$ and 0 otherwise, exactly as in the proof of Theorem 9.2.4 (b). Therefore

$$\operatorname{rank}(T - \lambda \operatorname{id}_V)^{j-1} - \operatorname{rank}(T - \lambda \operatorname{id}_V)^j = \#\{\, i : \mu_i = \lambda \text{ and } k_i \geq j \,\}.$$

The left-hand side is defined from T alone. So for each λ and each j the number of λ-blocks of size at least j, and hence by subtraction the number of size exactly j, is the same for every Jordan form of T. Two Jordan forms therefore consist of the same blocks with the same multiplicities, and differ only in the order in which the blocks are listed.

For a matrix $\mathbf{A} \in M_n(F)$ with $p_{\mathbf{A}}$ split, apply all of this to $T_{\mathbf{A}}$, using Theorem 3.7.4 to pass between bases and similarity.

■

Step 1 → Step 2 → Step 3, and the dream comes true: **for every complex square matrix there is a basis in which the matrix is diagonal apart from some ones on the superdiagonal**, since $p_{\mathbf{A}}$ always splits over $\mathbb{C}$ (Corollary 5.5.5). The proof also tells us where the basis comes from: one chain per block, found inside one generalized eigenspace at a time.

Quick check. How many Jordan forms, up to the order of the blocks, are possible for an operator with $p_T = (x-2)^2(x-3)$? Write them down, and say which invariant tells them apart.

Solution. The 3-blocks must have sizes summing to $a(3) = 1$, so there is exactly one, of size 1. The 2-blocks have sizes summing to $a(2) = 2$, so they form a partition of 2: either (2) or $(1,1)$. The two possibilities are

$$\mathbf{J}_2(2) \oplus \mathbf{J}_1(3) \qquad \text{and} \qquad \mathbf{J}_1(2) \oplus \mathbf{J}_1(2) \oplus \mathbf{J}_1(3) = \operatorname{diag}(2,2,3).$$

They are told apart by $g(2)$, which is the number of 2-blocks: 1 in the first case, 2 in the second. Equivalently by $m_T = (x-2)^2(x-3)$ against $(x-2)(x-3)$, or by $\operatorname{rank}(T-2\,\mathrm{id})$, which is 2 against 1.

9.3.3 Reading the invariants off the blocks

The Jordan form makes every invariant of Chapter 8 visible at a glance.

Corollary 9.3.2 — Invariants from the Jordan Form

Let V be finite-dimensional with $\dim V = n \geq 1$, let $T \in \mathcal{L}(V)$ with p_T split, let $\mathbf{J}$ be a Jordan form of T, and let $\lambda \in F$. Then:

(a) $a_T(\lambda)$ is the **sum of the sizes** of the λ-blocks of $\mathbf{J}$; in particular $\lambda \in \operatorname{spec}(T)$ if and only if $\mathbf{J}$ has a λ-block;

(b) $g_T(\lambda)$ is the **number** of λ-blocks of $\mathbf{J}$;

(c) the exponent of $x - \lambda$ in m_T is the **largest size** of a λ-block of $\mathbf{J}$ (and 0 when $\mathbf{J}$ has no λ-block);

(d) $\dim \ker(T - \lambda \operatorname{id}_V)^j = \sum \min(k_i, j)$, summed over the sizes k_i of the λ-blocks, for every $j \geq 0$;

(e) T is diagonalizable if and only if every block of $\mathbf{J}$ has size 1, that is, if and only if $\mathbf{J}$ is diagonal.

Proof. Write $\mathbf{J} = \mathbf{J}_{k_1}(\mu_1) \oplus \cdots \oplus \mathbf{J}_{k_m}(\mu_m)$, with $\mu_i \in F$ not necessarily distinct, and $\mathcal{B}$ for a Jordan basis, so $[T]_{\mathcal{B}} = \mathbf{J}$.

(a) $\mathbf{J}$ is upper triangular with diagonal entries μ_i repeated k_i times, so $p_T = \prod_{i=1}^{m} (x - \mu_i)^{k_i}$ (Theorem 6.4.6, Definition 6.10.2). Grouping equal μ_i and using that the multiplicity of λ as a root of a product of powers of distinct linear factors is the exponent it carries (Lemma 5.4.1), $a_T(\lambda) = \sum_{\mu_i = \lambda} k_i$. The last claim follows since $\operatorname{spec}(T)$ is the set of roots of p_T (Theorem 8.2.1).

(b) Take $j = 1$ in Theorem 9.3.1 (b): the number of λ-blocks of size ≥ 1, which is all of them, equals $\operatorname{rank}(T - \lambda \operatorname{id}_V)^0 - \operatorname{rank}(T - \lambda \operatorname{id}_V) = n - \operatorname{rank}(T - \lambda \operatorname{id}_V) = \dim \ker(T - \lambda \operatorname{id}_V) = g_T(\lambda)$, by Theorem 3.3.1 and Definition 8.3.2.

(c) First, $m_{\mathbf{J}_k(\nu)} = (x - \nu)^k$ for every $\nu \in F$: the polynomial $(x - \nu)^k$ annihilates $\mathbf{J}_k(\nu)$ because $\mathbf{J}_k(\nu) - \nu \mathbf{I} = \mathbf{J}_k(0)$ and $\mathbf{J}_k(0)^k = 0$, while $\mathbf{J}_k(0)^{k-1} \neq 0$, so no smaller power of $x - \nu$ annihilates it; and $m_{\mathbf{J}_k(\nu)}$ divides $p_{\mathbf{J}_k(\nu)} = (x - \nu)^k$ (Corollary 8.6.2), hence is a power of $x - \nu$ (Lemma 8.5.2). Applying Proposition 8.5.6 $m - 1$ times,

$$m_T = m_{\mathbf{J}} = \operatorname{lcm}\left((x - \mu_1)^{k_1}, \ldots, (x - \mu_m)^{k_m}\right) = \prod_{\nu \in \operatorname{spec}(T)} (x - \nu)^{\max\{k_i \,:\, \mu_i = \nu\}},$$

the last equality because the least common multiple of powers of linear factors takes, for each factor, the largest exponent occurring (Definition 5.2.4, Theorem 5.3.5).

(d) The proof of Theorem 9.3.1 (b) computed

$$\operatorname{rank}(T - \lambda \operatorname{id}_V)^j = c + \sum_{\mu_i = \lambda} \max(k_i - j,\, 0), \qquad c := \sum_{\mu_i \neq \lambda} k_i.$$

Since $\sum_{i=1}^{m} k_i = n$, we have $n - c = \sum_{\mu_i=\lambda} k_i$, so by Theorem 3.3.1

$$\begin{aligned}\dim\ker(T-\lambda\,\mathrm{id}_V)^j &= n - c - \sum_{\mu_i=\lambda} \max(k_i - j, 0)\\ &= \sum_{\mu_i=\lambda} \big(k_i - \max(k_i - j, 0)\big)\\ &= \sum_{\mu_i=\lambda} \min(k_i, j).\end{aligned}$$

(e) If every block has size 1, then $\mathbf{J}$ is diagonal and T is diagonalizable (Definition 8.4.1). Conversely, if T is diagonalizable, then m_T is a product of distinct linear factors (Theorem 8.8.2), so every exponent in (c) is 1, which says that every block has size 1.

■

Parts (a) and (b) give the practical reading: **the total size of the λ-blocks is $a(\lambda)$, and their number is $g(\lambda)$.** The gap $a(\lambda) - g(\lambda)$, which Chapter 8 could only measure, is now explained: it counts the superdiagonal ones belonging to λ.

Warning. **The multiplicities $a(\lambda)$ and $g(\lambda)$ do not always determine the blocks.** For $n = 7$ and one eigenvalue λ with $a(\lambda) = 7$ and $g(\lambda) = 3$, the block sizes form a partition of 7 into 3 parts, and there are four of those: $(5,1,1)$, $(4,2,1)$, $(3,3,1)$, $(3,2,2)$. Knowing $a(\lambda)$ and $g(\lambda)$ means knowing $\dim\ker(T-\lambda\,\mathrm{id}_V)^j$ for $j = 1$ and for j large; the intermediate values $j = 2, 3, \ldots$ are genuinely new information, and Theorem 9.3.1 (b) needs them all.

9.3.4 Deciding similarity

We can now settle the question Chapter 3 raised and Chapter 6 sharpened: which data decide whether two matrices are similar?

Corollary 9.3.3 — Similarity via the Jordan Form

Let $\mathbf{A}, \mathbf{B} \in M_n(F)$, $n \geq 1$, and suppose $p_{\mathbf{A}}$ splits over F. The following are equivalent:

(a) $\mathbf{A} \sim \mathbf{B}$;

(b) $p_{\mathbf{B}}$ splits over F, and $\mathbf{A}$ and $\mathbf{B}$ have the same Jordan form, up to the order of the blocks;

(c) $p_{\mathbf{A}} = p_{\mathbf{B}}$ and $\operatorname{rank}(\mathbf{A}-\lambda\mathbf{I})^j = \operatorname{rank}(\mathbf{B}-\lambda\mathbf{I})^j$ for every $\lambda \in \operatorname{spec}(\mathbf{A})$ and every $j = 1, \ldots, n$.

Proof.

(a) $\Rightarrow$ (c). Similar matrices have the same characteristic polynomial (Theorem 6.10.3). If $\mathbf{B} = \mathbf{P}^{-1}\mathbf{A}\mathbf{P}$, then $(\mathbf{B}-\lambda\mathbf{I})^j = \mathbf{P}^{-1}(\mathbf{A}-\lambda\mathbf{I})^j\mathbf{P}$ for every λ and j (Proposition 3.7.6 (c) applied to the polynomial $(x-\lambda)^j$), so the ranks agree (Proposition 3.7.6 (a)).

(b) $\Rightarrow$ (b). From $p_{\mathbf{B}} = p_{\mathbf{A}}$ we get that $p_{\mathbf{B}}$ splits and that $\operatorname{spec}(\mathbf{B}) = \operatorname{spec}(\mathbf{A})$ (Theorem 8.2.1). By Theorem 9.3.1 (a) both matrices have Jordan forms, and by (b) of that theorem the number of λ-blocks of each size in each of them is determined by the ranks $\operatorname{rank}(\cdot - \lambda\mathbf{I})^j$, with $j \le n$ sufficing because $(\mathbf{A} - \lambda\mathbf{I})^n$ and all higher powers have the same rank (Theorem 9.1.1 (d), Theorem 3.3.1). These numbers agree by hypothesis for $\lambda \in \operatorname{spec}(\mathbf{A}) = \operatorname{spec}(\mathbf{B})$, and for $\lambda \notin \operatorname{spec}(\mathbf{A})$ neither form has a λ-block (Corollary 9.3.2 (a)). So the two Jordan forms have the same blocks.

(c) $\Rightarrow$ (a). Let $\mathbf{J}$ be a Jordan form of $\mathbf{A}$ and $\mathbf{J}'$ one of $\mathbf{B}$, with the same blocks in possibly different orders. Then $\mathbf{J} \sim \mathbf{J}'$, because reordering blocks is a change of basis, as noted after Definition 9.3.2. Hence $\mathbf{A} \sim \mathbf{J} \sim \mathbf{J}' \sim \mathbf{B}$, and similarity is an equivalence relation (Example (Similarity)).

■

This is the promise of Chapter 3 kept, and of Chapter 6: when $p_{\mathbf{A}}$ splits — always, over $\mathbb{C}$ — the characteristic polynomial together with the ranks of the powers $(\mathbf{A} - \lambda\mathbf{I})^j$ is a **complete** set of similarity invariants. Chapter 3's warning pair is decided instantly: $\mathbf{I}_2$ has Jordan form $\operatorname{diag}(1,1)$ and $\begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix} = \mathbf{J}_2(1)$ is its own, so they are not similar. And the sharper failure of Chapter 8 becomes transparent.

Remark. The matrices $\mathbf{J}_2(1) \oplus \mathbf{J}_2(1)$ and $\mathbf{J}_2(1) \oplus \mathbf{J}_1(1) \oplus \mathbf{J}_1(1)$ in $M_4(F)$ have the same characteristic polynomial $(x-1)^4$ **and** the same minimal polynomial $(x-1)^2$, yet they are not similar: their Jordan forms differ, and $\operatorname{rank}(\mathbf{A} - \mathbf{I})$ is 2 against 1. So no pair of polynomials can decide similarity; the block sizes carry strictly more information.

When $p_{\mathbf{A}}$ does not split, the Jordan form does not exist and this test says nothing. Section 6 replaces it by the rational canonical form, which works over every field.

Warning. **The Jordan form is not stable under small changes of the matrix.** For $\varepsilon \neq 0$, $\mathbf{A}_\varepsilon = \begin{pmatrix} 0 & 1 \\ \varepsilon & 0 \end{pmatrix}$ over $\mathbb{C}$ has $p = x^2 - \varepsilon$ with two distinct roots $\pm\sqrt{\varepsilon}$, so $\mathbf{A}_\varepsilon$ is diagonalizable and its Jordan form is $\operatorname{diag}(\sqrt{\varepsilon}, -\sqrt{\varepsilon})$, with **no** superdiagonal one. At $\varepsilon = 0$ the Jordan form jumps to $\mathbf{J}_2(0)$. So arbitrarily small perturbations change the form completely, which is why numerical work avoids it; Chapter 19 returns to this point.

9.3.5 Computing a Jordan form

The proof is an algorithm: it says to work one eigenvalue at a time and to find chains inside each generalized eigenspace. The rank data tell us the shape before we look for a single vector.

Algorithm. **Jordan form and a Jordan basis of $\mathbf{A} \in M_n(F)$.**

1. Factor $p_{\mathbf{A}}$. If it does not split over F, stop: there is no Jordan form.
2. For each eigenvalue λ, compute $\operatorname{rank}(\mathbf{A} - \lambda\mathbf{I})^j$ for $j = 0, 1, 2, \ldots$ until the rank stops changing, and get the λ-block sizes from Theorem 9.3.1 (b), subtracting twice for the exact counts.
3. For each λ, find a Jordan basis of the nilpotent $(\mathbf{A} - \lambda\mathbf{I})$ restricted to $G_\lambda(\mathbf{A})$, as in Section 2: tops of long chains first, then vectors of $\ker(\mathbf{A} - \lambda\mathbf{I})$ to complete.

4. Let $\mathbf{P}$ be the matrix whose columns are all the chains, in order; then $\mathbf{P}^{-1}\mathbf{AP} = \mathbf{J}$. Check the answer as $\mathbf{AP} = \mathbf{PJ}$, column by column.

Example. (The Jordan Form of a 5×5 Matrix)

Let

$$\mathbf{A} = \begin{pmatrix} 3 & 1 & 0 & 0 & -1 \\ -2 & 2 & 2 & -2 & -1 \\ 1 & 0 & 2 & -1 & 1 \\ 1 & 0 & -1 & 2 & 1 \\ -2 & -1 & 2 & -2 & 2 \end{pmatrix} \in M_5(\mathbb{Q}), \qquad p_{\mathbf{A}} = (x-3)^3(x-1)^2.$$

Find the Jordan form $\mathbf{J}$ of $\mathbf{A}$, a Jordan basis, and an invertible $\mathbf{P}$ with $\mathbf{P}^{-1}\mathbf{AP} = \mathbf{J}$. Verify the answer by hand.

Solution. The eigenvalue 3. Put $\mathbf{N} = \mathbf{A} - 3\mathbf{I}$, so

$$\mathbf{N} = \begin{pmatrix} 0 & 1 & 0 & 0 & -1 \\ -2 & -1 & 2 & -2 & -1 \\ 1 & 0 & -1 & -1 & 1 \\ 1 & 0 & -1 & -1 & 1 \\ -2 & -1 & 2 & -2 & -1 \end{pmatrix}.$$

Rows 3 and 4 are equal, and so are rows 2 and 5, so the row space is spanned by rows $1, 2, 3$. Those three are independent: their entries in columns $1, 2, 4$ form the matrix $\begin{pmatrix} 0 & 1 & 0 \\ -2 & -1 & -2 \\ 1 & 0 & -1 \end{pmatrix}$, of determinant $-4 \neq 0$. Hence $\operatorname{rank}\mathbf{N} = 3$ and $\operatorname{nullity}\mathbf{N} = 2$ (Theorem 2.5.7). Solving $\mathbf{Nx} = \mathbf{0}$ means solving

$$x_2 - x_5 = 0, \qquad -2x_1 - x_2 + 2x_3 - 2x_4 - x_5 = 0, \qquad x_1 - x_3 - x_4 + x_5 = 0.$$

The first gives $x_2 = x_5$; substituting into the second gives $-2x_1 + 2x_3 - 2x_4 - 2x_5 = 0$, that is, $x_1 = x_3 - x_4 - x_5$; and the third then reads $(x_3 - x_4 - x_5) - x_3 - x_4 + x_5 = -2x_4 = 0$, so $x_4 = 0$. Hence

$$E_3(\mathbf{A}) = \ker\mathbf{N} = \operatorname{span}\big((1,0,1,0,0),\ (-1,1,0,0,1)\big), \qquad g_{\mathbf{A}}(3) = 2.$$

Squaring,

$$\mathbf{N}^2 = 4\begin{pmatrix} 0 & 0 & 0 & 0 & 0 \\ 1 & 0 & -1 & 1 & 1 \\ -1 & 0 & 1 & 0 & -1 \\ -1 & 0 & 1 & 0 & -1 \\ 1 & 0 & -1 & 1 & 1 \end{pmatrix},$$

whose non-zero rows span a 2-dimensional space, so $\operatorname{rank}\mathbf{N}^2 = 2$. Since $\dim G_3(\mathbf{A}) = a_{\mathbf{A}}(3) = 3$ and $\dim\ker\mathbf{N}^2 = 3$ (Theorem 2.5.7), we have $G_3(\mathbf{A}) = \ker\mathbf{N}^2$, so $\operatorname{rank}\mathbf{N}^3 = \operatorname{rank}\mathbf{N}^2 = 2$. The block sizes for $\lambda = 3$ follow from Theorem 9.3.1 (b) with $r_0, r_1, r_2, r_3 = 5, 3, 2, 2$: blocks of size ≥ 1: $5 - 3 = 2$; of size ≥ 2: $3 - 2 = 1$; of size ≥ 3: $2 - 2 = 0$. So the 3-blocks have sizes 2 and 1.

The chain for 3. We need a top $\mathbf{u} \in \ker\mathbf{N}^2 \setminus \ker\mathbf{N}$. The second column of $\mathbf{N}^2$ is $\mathbf{0}$, so $\mathbf{e}_2 \in \ker\mathbf{N}^2$, while the second column of $\mathbf{N}$ is $(1,-1,0,0,-1) \neq \mathbf{0}$, so $\mathbf{e}_2 \notin \ker\mathbf{N}$. Take

$\mathbf{u} = \mathbf{e}_2$; its chain is

$$\mathbf{Nu} = (1,-1,0,0,-1), \qquad \mathbf{u} = \mathbf{e}_2.$$

For the block of size 1 we need a vector of $\ker \mathbf{N}$ completing $\{\mathbf{Nu}\}$ to a basis of $\ker \mathbf{N}$. The vectors $\mathbf{Nu} = (1,-1,0,0,-1)$ and $\mathbf{v} = (1,0,1,0,0)$ are not proportional (their second entries are -1 and 0, their first entries both 1), so, $\ker \mathbf{N}$ being 2-dimensional, they form a basis of it (Theorem 1.6.4 (a)) and $\mathbf{v}$ does it.

The eigenvalue 1. Put $\mathbf{M} = \mathbf{A} - \mathbf{I}$ and solve $\mathbf{Mx} = \mathbf{0}$. Rows 3 and 4 of $\mathbf{M}$ read $x_1 + x_3 - x_4 + x_5 = 0$ and $x_1 - x_3 + x_4 + x_5 = 0$; adding and subtracting them gives $x_1 + x_5 = 0$ and $x_3 = x_4$. Row 1 reads $2x_1 + x_2 - x_5 = 0$, and row 2, after using $x_3 = x_4$, reads $-2x_1 + x_2 - x_5 = 0$; adding and subtracting these two gives $x_2 = x_5$ and $x_1 = 0$, hence $x_5 = 0$ and $x_2 = 0$. So

$$E_1(\mathbf{A}) = \ker \mathbf{M} = \operatorname{span}\big((0,0,1,1,0)\big), \qquad g_{\mathbf{A}}(1) = 1.$$

Since $a_{\mathbf{A}}(1) = 2$, the only partition of 2 with one part is (2): there is a single 1-block, of size 2. Its chain needs a top $\mathbf{w} \in \ker \mathbf{M}^2 \setminus \ker \mathbf{M}$. Computing,

$$\mathbf{M}^2 = 4\begin{pmatrix} 1 & 1 & 0 & 0 & -1 \\ -1 & 0 & 1 & -1 & 0 \\ 0 & 0 & 1 & -1 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ -1 & -1 & 1 & -1 & 1 \end{pmatrix},$$

whose kernel is cut out by $x_1 + x_2 - x_5 = 0$, $-x_1 + x_3 - x_4 = 0$ and $x_3 - x_4 = 0$, giving $x_1 = 0$, $x_3 = x_4$, $x_2 = x_5$; so $\ker \mathbf{M}^2 = \operatorname{span}\big((0,0,1,1,0),\ (0,1,0,0,1)\big)$, of dimension $2 = a_{\mathbf{A}}(1)$ as expected. Take $\mathbf{w} = (0,1,0,0,1)$; then

$$\begin{aligned} \mathbf{Mw} &= (\text{column } 2 + \text{column } 5 \text{ of } \mathbf{M}) \\ &= (1,1,0,0,-1) + (-1,-1,1,1,1) = (0,0,1,1,0), \end{aligned}$$

which is the eigenvector, as it must be.

The answer. Writing the three chains one after another,

$$\mathcal{B} = \big((1,-1,0,0,-1),\ \mathbf{e}_2,\ (1,0,1,0,0),\ (0,0,1,1,0),\ (0,1,0,0,1)\big),$$

$$\mathbf{P} = \begin{pmatrix} 1 & 0 & 1 & 0 & 0 \\ -1 & 1 & 0 & 0 & 1 \\ 0 & 0 & 1 & 1 & 0 \\ 0 & 0 & 0 & 1 & 0 \\ -1 & 0 & 0 & 0 & 1 \end{pmatrix},$$

$$\mathbf{J} = \mathbf{J}_2(3) \oplus \mathbf{J}_1(3) \oplus \mathbf{J}_2(1) = \begin{pmatrix} 3 & 1 & 0 & 0 & 0 \\ 0 & 3 & 0 & 0 & 0 \\ 0 & 0 & 3 & 0 & 0 \\ 0 & 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 0 & 1 \end{pmatrix}.$$

$\mathbf{P}$ is invertible: its fourth row is $(0,0,0,1,0)$, so expanding $\det \mathbf{P}$ along that row (Theorem 6.6.1) leaves

$$\det \mathbf{P} = \det \begin{pmatrix} 1 & 0 & 1 & 0 \\ -1 & 1 & 0 & 1 \\ 0 & 0 & 1 & 0 \\ -1 & 0 & 0 & 1 \end{pmatrix} = \det \begin{pmatrix} 1 & 0 & 0 \\ -1 & 1 & 1 \\ -1 & 0 & 1 \end{pmatrix} = 1,$$

expanding along the third row and then along the first row.

The check, column by column. The claim $\mathbf{P}^{-1}\mathbf{A}\mathbf{P} = \mathbf{J}$ is the same as $\mathbf{A}\mathbf{P} = \mathbf{P}\mathbf{J}$. Writing $\mathbf{p}_1, \dots, \mathbf{p}_5$ for the columns of $\mathbf{P}$, the five columns of $\mathbf{P}\mathbf{J}$ are

$$3\mathbf{p}_1, \quad \mathbf{p}_1 + 3\mathbf{p}_2, \quad 3\mathbf{p}_3, \quad \mathbf{p}_4, \quad \mathbf{p}_4 + \mathbf{p}_5,$$

read straight off the columns of $\mathbf{J}$. So the identity $\mathbf{A}\mathbf{P} = \mathbf{P}\mathbf{J}$ is the list of five statements

$$\mathbf{A}\mathbf{p}_1 = 3\mathbf{p}_1, \quad \mathbf{A}\mathbf{p}_2 = \mathbf{p}_1 + 3\mathbf{p}_2, \quad \mathbf{A}\mathbf{p}_3 = 3\mathbf{p}_3, \quad \mathbf{A}\mathbf{p}_4 = \mathbf{p}_4, \quad \mathbf{A}\mathbf{p}_5 = \mathbf{p}_4 + \mathbf{p}_5,$$

which are exactly how the chains were constructed: $\mathbf{p}_1, \mathbf{p}_3 \in \ker(\mathbf{A} - 3\mathbf{I})$, $(\mathbf{A} - 3\mathbf{I})\mathbf{p}_2 = \mathbf{p}_1$, $\mathbf{p}_4 \in \ker(\mathbf{A} - \mathbf{I})$ and $(\mathbf{A} - \mathbf{I})\mathbf{p}_5 = \mathbf{p}_4$. Two of them verified in full:

$$\mathbf{A}\mathbf{p}_2 = \mathbf{A}\mathbf{e}_2 = (1,2,0,0,-1) = (1,-1,0,0,-1) + 3(0,1,0,0,0) = \mathbf{p}_1 + 3\mathbf{p}_2,$$

reading the second column of $\mathbf{A}$; and

$$\begin{aligned} \mathbf{A}\mathbf{p}_4 = \mathbf{A}(0,0,1,1,0) &= (0+0,\ 2-2,\ 2-1,\ -1+2,\ 2-2) \\ &= (0,0,1,1,0) = \mathbf{p}_4, \end{aligned}$$

adding the third and fourth columns of $\mathbf{A}$. The remaining three are the same kind of one-line computation.

Cross-checks. The diagonal of $\mathbf{J}$ gives $\operatorname{tr}\mathbf{A} = 3+3+3+1+1 = 11$, and adding the diagonal of $\mathbf{A}$ gives $3+2+2+2+2 = 11$. By Corollary 9.3.2, $a(3) = 2+1 = 3$, $g(3) = 2$, $a(1) = 2$, $g(1) = 1$ and $m_{\mathbf{A}} = (x-3)^2(x-1)^2$, all matching the computations above.

9.3.6 Exercises

9.3.6.1 A. Check your understanding

Exercise A1.

(a) Define a Jordan block and a Jordan matrix, and state what a Jordan form of T is.

(b) State the Jordan Canonical Form Theorem, including the uniqueness clause.

(c) How do you read $a(\lambda)$, $g(\lambda)$ and the exponent of $x - \lambda$ in m_T off a Jordan form?

(d) True or false: every matrix in $M_n(\mathbb{R})$ has a Jordan form over $\mathbb{R}$. Justify your answer.

(e) True or false: if $\mathbf{A}$ and $\mathbf{B}$ have the same characteristic and the same minimal polynomial, they are similar. Justify your answer.

(f) Is $\begin{pmatrix} 5 & 1 \\ 0 & 4 \end{pmatrix}$ a Jordan matrix? What is its Jordan form?

Solution.

(a) $\mathbf{J}_k(\lambda) = \lambda \mathbf{I}_k + \mathbf{J}_k(0)$ has λ on the diagonal and 1 on the superdiagonal (Definition 9.3.1); a Jordan matrix is a direct sum of Jordan blocks; a Jordan form of T is a Jordan matrix equal to $[T]_{\mathcal{B}}$ for some basis $\mathcal{B}$ (Definition 9.3.2).

(b) T has a Jordan form if and only if p_T splits, and then the number of λ-blocks of size at least j is $\operatorname{rank}(T - \lambda \operatorname{id}_V)^{j-1} - \operatorname{rank}(T - \lambda \operatorname{id}_V)^{j}$, so the blocks are unique up to their order (Theorem 9.3.1).

(c) $a(\lambda)$ is the total size of the λ-blocks, $g(\lambda)$ their number, and the exponent in m_T the largest of their sizes (Corollary 9.3.2).

(d) False. A Jordan matrix is triangular, so its existence forces p_T to split; the rotation by a right angle has $p = x^2 + 1$, which does not split over $\mathbb{R}$.

(e) False. $\mathbf{J}_2(1) \oplus \mathbf{J}_2(1)$ and $\mathbf{J}_2(1) \oplus \mathbf{J}_1(1) \oplus \mathbf{J}_1(1)$ share $p = (x-1)^4$ and $m = (x-1)^2$ but have different Jordan forms, hence are not similar (Corollary 9.3.3).

(f) No: a superdiagonal 1 may only stand between two equal diagonal entries. The eigenvalues 5 and 4 are distinct, so the matrix is diagonalizable (Corollary 8.4.2) and its Jordan form is $\operatorname{diag}(5, 4)$.

9.3.6.2 B. Practice

Exercise B1: Jordan forms from polynomial data.

In each case T is an operator on a complex vector space with the given characteristic and minimal polynomials. List all possible Jordan forms, up to the order of the blocks, and say what extra data would pin the answer down.

(a) $p_T = (x-2)^4$, $m_T = (x-2)^2$.

(b) $p_T = (x-1)^3(x+1)^2$, $m_T = (x-1)^3(x+1)$.

(c) $p_T = (x-5)^5$, $m_T = (x-5)^3$.

Solution. By Corollary 9.3.2, the λ-block sizes form a partition of $a(\lambda)$ whose largest part is the exponent of $x - \lambda$ in m_T.

(a) Partitions of 4 with largest part 2: $(2, 2)$ and $(2, 1, 1)$. So $\mathbf{J}_2(2) \oplus \mathbf{J}_2(2)$ or $\mathbf{J}_2(2) \oplus \mathbf{J}_1(2) \oplus \mathbf{J}_1(2)$. The value of $g(2)$ — that is, 2 against 3 — decides.

(b) For 1: partitions of 3 with largest part 3, only (3). For -1: partitions of 2 with largest part 1, only $(1, 1)$. So the Jordan form is $\mathbf{J}_3(1) \oplus \mathbf{J}_1(-1) \oplus \mathbf{J}_1(-1)$, and no extra data is needed.

(c) Partitions of 5 with largest part 3: $(3, 2)$ and $(3, 1, 1)$. So $\mathbf{J}_3(5) \oplus \mathbf{J}_2(5)$ or $\mathbf{J}_3(5) \oplus \mathbf{J}_1(5) \oplus \mathbf{J}_1(5)$, told apart by $g(5) = 2$ against 3, or by $\dim \ker(T - 5 \operatorname{id})^2 = 4$ against 5.

Exercise B2: Jordan forms and Jordan bases.

For each matrix, find the Jordan form $\mathbf{J}$ and an invertible $\mathbf{P}$ with $\mathbf{P}^{-1}\mathbf{A}\mathbf{P} = \mathbf{J}$. Verify

your $\mathbf{P}$ by checking $\mathbf{AP} = \mathbf{PJ}$ column by column.

(a) $\mathbf{A}_1 = \begin{pmatrix} -1 & -1 & -2 \\ 1 & 2 & 1 \\ 1 & 0 & 2 \end{pmatrix} \in M_3(\mathbb{Q})$, with $p_{\mathbf{A}_1} = (x-1)^3$.

(b) $\mathbf{A}_2 = \begin{pmatrix} 2 & -1 & -1 \\ -3 & 4 & -1 \\ 3 & -2 & 3 \end{pmatrix} \in M_3(\mathbb{Q})$, with $p_{\mathbf{A}_2} = (x-2)^2(x-5)$.

(c) $\mathbf{A}_3 = \begin{pmatrix} 2 & 1 & 1 & -2 \\ -3 & 1 & -1 & -1 \\ -3 & -1 & 1 & -1 \\ -3 & -1 & -1 & 1 \end{pmatrix} \in M_4(\mathbb{Q})$, with $p_{\mathbf{A}_3} = (x-2)^3(x+1)$.

Solution.

(a) $\mathbf{A}_1 - \mathbf{I} = \begin{pmatrix} -2 & -1 & -2 \\ 1 & 1 & 1 \\ 1 & 0 & 1 \end{pmatrix}$ has rank 2, so $g(1) = 1$ and there is one block, of size 3: $\mathbf{J} = \mathbf{J}_3(1)$. A top must satisfy $(\mathbf{A}_1 - \mathbf{I})^2\mathbf{u} \neq \mathbf{0}$, and $(\mathbf{A}_1 - \mathbf{I})^2 = \begin{pmatrix} 1 & 1 & 1 \\ 0 & 0 & 0 \\ -1 & -1 & -1 \end{pmatrix}$ has non-zero first column, so $\mathbf{u} = \mathbf{e}_1$ works. The chain is

$$(\mathbf{A}_1 - \mathbf{I})^2\mathbf{e}_1 = (1, 0, -1), \qquad (\mathbf{A}_1 - \mathbf{I})\mathbf{e}_1 = (-2, 1, 1), \qquad \mathbf{e}_1,$$

so $\mathbf{P} = \begin{pmatrix} 1 & -2 & 1 \\ 0 & 1 & 0 \\ -1 & 1 & 0 \end{pmatrix}$, with $\det \mathbf{P} = 1$. The check $\mathbf{A}_1\mathbf{P} = \mathbf{P}\mathbf{J}_3(1)$ reads $\mathbf{A}_1\mathbf{p}_1 = \mathbf{p}_1$, $\mathbf{A}_1\mathbf{p}_2 = \mathbf{p}_1 + \mathbf{p}_2$, $\mathbf{A}_1\mathbf{p}_3 = \mathbf{p}_2 + \mathbf{p}_3$, which are the three chain relations.

(b) $\mathbf{A}_2 - 2\mathbf{I} = \begin{pmatrix} 0 & -1 & -1 \\ -3 & 2 & -1 \\ 3 & -2 & 1 \end{pmatrix}$ has rank 2, so $g(2) = 1$ and the single 2-block has size $a(2) = 2$; the eigenvalue 5 gives one block of size 1. So $\mathbf{J} = \mathbf{J}_2(2) \oplus \mathbf{J}_1(5)$. For the chain, the third column of $\mathbf{A}_2 - 2\mathbf{I}$ is $(-1, -1, 1) \neq \mathbf{0}$ and $(\mathbf{A}_2 - 2\mathbf{I})(-1, -1, 1) = \mathbf{0}$, so $\mathbf{u} = \mathbf{e}_3$ is a top with $(\mathbf{A}_2 - 2\mathbf{I})\mathbf{e}_3 = (-1, -1, 1)$. Solving $(\mathbf{A}_2 - 5\mathbf{I})\mathbf{x} = \mathbf{0}$ gives $\operatorname{span}((0, -1, 1))$. Hence

$$\mathbf{P} = \begin{pmatrix} -1 & 0 & 0 \\ -1 & 0 & -1 \\ 1 & 1 & 1 \end{pmatrix}, \qquad \det \mathbf{P} = -1,$$

and $\mathbf{A}_2\mathbf{P} = \mathbf{P}\mathbf{J}$ reads $\mathbf{A}_2\mathbf{p}_1 = 2\mathbf{p}_1$, $\mathbf{A}_2\mathbf{p}_2 = \mathbf{p}_1 + 2\mathbf{p}_2$, $\mathbf{A}_2\mathbf{p}_3 = 5\mathbf{p}_3$.

(c) $\mathbf{A}_3 - 2\mathbf{I} = \begin{pmatrix} 0 & 1 & 1 & -2 \\ -3 & -1 & -1 & -1 \\ -3 & -1 & -1 & -1 \\ -3 & -1 & -1 & -1 \end{pmatrix}$ has rank 2 (rows $2, 3, 4$ are equal), so $g(2) = 2$: with $a(2) = 3$ the 2-blocks have sizes 2 and 1. The eigenvalue -1 has $a = 1$, so $\mathbf{J} = \mathbf{J}_2(2) \oplus \mathbf{J}_1(2) \oplus \mathbf{J}_1(-1)$. Now $\ker(\mathbf{A}_3 - 2\mathbf{I}) = \operatorname{span}\big((0, -1, 1, 0), (-1, 2, 0, 1)\big)$, and the second column of $\mathbf{A}_3 - 2\mathbf{I}$ is $(1, -1, -1, -1)$, which is non-zero and lies in that kernel, so $\mathbf{u} = \mathbf{e}_2$ is the top of the 2-chain. Completing $\{(1, -1, -1, -1)\}$ to a basis of $\ker(\mathbf{A}_3 - 2\mathbf{I})$ with $(0, -1, 1, 0)$, and solving $(\mathbf{A}_3 + \mathbf{I})\mathbf{x} = \mathbf{0}$ to get

span$((0,1,1,1))$, we obtain

$$\mathbf{P} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ -1 & 1 & -1 & 1 \\ -1 & 0 & 1 & 1 \\ -1 & 0 & 0 & 1 \end{pmatrix}, \qquad \det \mathbf{P} = 1,$$

and $\mathbf{A}_3\mathbf{P} = \mathbf{P}\mathbf{J}$ reads $\mathbf{A}_3\mathbf{p}_1 = 2\mathbf{p}_1$, $\mathbf{A}_3\mathbf{p}_2 = \mathbf{p}_1 + 2\mathbf{p}_2$, $\mathbf{A}_3\mathbf{p}_3 = 2\mathbf{p}_3$, $\mathbf{A}_3\mathbf{p}_4 = -\mathbf{p}_4$. For instance the second of these is $\mathbf{A}_3\mathbf{e}_2 = (1,1,-1,-1) = (1,-1,-1,-1) + 2(0,1,0,0)$, read off the second column of $\mathbf{A}_3$.

Exercise B3: Similar or not?.

Determine whether each pair of matrices is similar. Justify your answer.

(a) $\mathbf{J}_2(4) \oplus \mathbf{J}_1(4)$ and $\mathbf{J}_1(4) \oplus \mathbf{J}_2(4)$.

(b) $\mathbf{J}_3(0) \oplus \mathbf{J}_1(0)$ and $\mathbf{J}_2(0) \oplus \mathbf{J}_2(0)$.

(c) $\mathbf{J}_2(1) \oplus \mathbf{J}_2(1)$ and $\mathbf{J}_2(1) \oplus \mathbf{J}_1(1) \oplus \mathbf{J}_1(1)$.

(d) $\operatorname{diag}(2,2,5)$ and the matrix $\mathbf{A}_2$ of Exercise (B2: Jordan forms and Jordan bases) (b).

Solution.

(a) Similar: the blocks are the same and only their order differs, which is a change of basis, as noted after Definition 9.3.2.

(b) Not similar. Both are nilpotent of rank 2, but $\operatorname{rank}(\mathbf{J}_3(0) \oplus \mathbf{J}_1(0))^2 = 1$ while $(\mathbf{J}_2(0) \oplus \mathbf{J}_2(0))^2 = 0$ (Theorem 7.1.4 (b)). By Corollary 9.3.3 (or Corollary 9.2.5) they are not similar; their partitions are $(3,1)$ and $(2,2)$.

(c) Not similar, although p and m agree, as in the remark after Corollary 9.3.3: $\operatorname{rank}(\mathbf{A} - \mathbf{I}) = 2$ for the first and 1 for the second, so $g(1)$ is 2 against 3.

(d) Not similar. $\operatorname{diag}(2,2,5)$ is diagonal, so $g(2) = 2$, while $\mathbf{A}_2$ has $g(2) = 1$ by Exercise (B2: Jordan forms and Jordan bases) (b); its Jordan form is $\mathbf{J}_2(2) \oplus \mathbf{J}_1(5)$, which is not diagonal. The characteristic polynomials agree, so this pair is another witness that $p_{\mathbf{A}}$ alone decides nothing.

9.3.6.3 C. Going deeper

Exercise C1: A matrix is similar to its transpose.

Let $\mathbf{A} \in M_n(F)$ with $p_{\mathbf{A}}$ split over F.

(a) Let $\mathbf{R} \in M_k(F)$ be the reversal permutation matrix, with 1 in each position $(j, k+1-j)$ and 0 elsewhere. Prove that $\mathbf{R}^{-1} = \mathbf{R}$ and $\mathbf{R}^{-1}\mathbf{J}_k(\lambda)\mathbf{R} = \mathbf{J}_k(\lambda)^{\top}$.

(b) Deduce that every Jordan matrix $\mathbf{J}$ satisfies $\mathbf{J} \sim \mathbf{J}^{\top}$.

(c) Deduce that $\mathbf{A} \sim \mathbf{A}^{\top}$.

Hint: for (c), transpose a similarity $\mathbf{A} = \mathbf{P}\mathbf{J}\mathbf{P}^{-1}$. The conclusion holds over every field; Section 7 removes the hypothesis that $p_{\mathbf{A}}$ splits.

Solution.

(a) $\mathbf{R}\mathbf{e}_j = \mathbf{e}_{k+1-j}$, so $\mathbf{R}^2\mathbf{e}_j = \mathbf{e}_j$ for every j and $\mathbf{R}^2 = \mathbf{I}_k$, that is, $\mathbf{R}^{-1} = \mathbf{R}$. Since $\mathbf{J}_k(\lambda) = \lambda\mathbf{I}_k + \mathbf{J}_k(0)$ and $\mathbf{R}^{-1}(\lambda\mathbf{I}_k)\mathbf{R} = \lambda\mathbf{I}_k$, it suffices to prove $\mathbf{R}^{-1}\mathbf{J}_k(0)\mathbf{R} = \mathbf{J}_k(0)^{\top}$. Both sides are computed on basis vectors: $\mathbf{J}_k(0)\mathbf{e}_1 = \mathbf{0}$ and $\mathbf{J}_k(0)\mathbf{e}_j = \mathbf{e}_{j-1}$ for $j \geq 2$, so

$$\mathbf{R}\mathbf{J}_k(0)\mathbf{R}\,\mathbf{e}_j = \mathbf{R}\,\mathbf{J}_k(0)\,\mathbf{e}_{k+1-j} = \begin{cases} \mathbf{R}\,\mathbf{e}_{k-j} = \mathbf{e}_{j+1}, & j \leq k-1, \\ \mathbf{R}\,\mathbf{0} = \mathbf{0}, & j = k, \end{cases}$$

which is exactly the action of $\mathbf{J}_k(0)^{\top}$, whose columns satisfy $\mathbf{J}_k(0)^{\top}\mathbf{e}_j = \mathbf{e}_{j+1}$ for $j \leq k-1$ and $\mathbf{J}_k(0)^{\top}\mathbf{e}_k = \mathbf{0}$. Hence $\mathbf{R}^{-1}\mathbf{J}_k(\lambda)\mathbf{R} = \mathbf{J}_k(\lambda)^{\top}$.

(b) Let $\mathbf{J} = \mathbf{J}_{k_1}(\lambda_1) \oplus \cdots \oplus \mathbf{J}_{k_m}(\lambda_m)$ and let $\mathbf{Q} = \mathbf{R}_{k_1} \oplus \cdots \oplus \mathbf{R}_{k_m}$, the direct sum of the reversal matrices of the block sizes. Then $\mathbf{Q}$ is invertible with $\mathbf{Q}^{-1} = \mathbf{R}_{k_1}^{-1} \oplus \cdots \oplus \mathbf{R}_{k_m}^{-1}$ (Theorem 7.1.4 (c)), and multiplying blockwise (Theorem 7.1.4 (a)),

$$\mathbf{Q}^{-1}\mathbf{J}\mathbf{Q} = \left(\mathbf{R}_{k_1}^{-1}\mathbf{J}_{k_1}(\lambda_1)\mathbf{R}_{k_1}\right) \oplus \cdots = \mathbf{J}_{k_1}(\lambda_1)^{\top} \oplus \cdots \oplus \mathbf{J}_{k_m}(\lambda_m)^{\top} = \mathbf{J}^{\top},$$

the last equality because transposing a block diagonal matrix transposes each block (Proposition 7.1.2).

(c) By Theorem 9.3.1 there are a Jordan matrix $\mathbf{J}$ and an invertible $\mathbf{P}$ with $\mathbf{A} = \mathbf{P}\mathbf{J}\mathbf{P}^{-1}$. Transposing and using $(\mathbf{X}\mathbf{Y})^{\top} = \mathbf{Y}^{\top}\mathbf{X}^{\top}$ and $(\mathbf{P}^{-1})^{\top} = (\mathbf{P}^{\top})^{-1}$ (Theorem 0.9.5, Theorem 0.9.7),

$$\mathbf{A}^{\top} = (\mathbf{P}^{-1})^{\top}\mathbf{J}^{\top}\mathbf{P}^{\top} = (\mathbf{P}^{\top})^{-1}\mathbf{J}^{\top}\mathbf{P}^{\top},$$

so $\mathbf{A}^{\top} \sim \mathbf{J}^{\top}$. By (b), $\mathbf{J}^{\top} \sim \mathbf{J} \sim \mathbf{A}$, and similarity is an equivalence relation (Example (Similarity)), so $\mathbf{A} \sim \mathbf{A}^{\top}$.

Exercise C2: How much do p and m decide?.

Work over $\mathbb{C}$.

(a) Find all Jordan forms with $p_T = (x-1)^3(x-2)^2$ and $m_T = (x-1)^2(x-2)$.

(b) Find all Jordan forms with $p_T = (x-1)^4(x-2)^2$ and $m_T = (x-1)^2(x-2)$.

(c) In (b), what is the least amount of extra information that determines the Jordan form?

(d) Prove that p_T and m_T determine the Jordan form whenever $a(\lambda) \leq 3$ for every eigenvalue λ.

Solution.

(a) For $\lambda = 1$: partitions of 3 with largest part 2, so $(2,1)$ only. For $\lambda = 2$: partitions of 2 with largest part 1, so $(1,1)$ only. There is exactly one Jordan form,

$$\mathbf{J}_2(1) \oplus \mathbf{J}_1(1) \oplus \mathbf{J}_1(2) \oplus \mathbf{J}_1(2).$$

(b) For $\lambda = 1$: partitions of 4 with largest part 2, namely $(2,2)$ and $(2,1,1)$. For $\lambda = 2$:

$(1,1)$ as before. So there are two Jordan forms,

$$\mathbf{J}_2(1)\oplus\mathbf{J}_2(1)\oplus\mathbf{J}_1(2)\oplus\mathbf{J}_1(2)$$
$$\text{and}\quad \mathbf{J}_2(1)\oplus\mathbf{J}_1(1)\oplus\mathbf{J}_1(1)\oplus\mathbf{J}_1(2)\oplus\mathbf{J}_1(2).$$

(c) The single number $g(1)$, which is 2 for the first and 3 for the second; equivalently $\operatorname{rank}(T-\mathrm{id}_V)$ or $\dim\ker(T-\mathrm{id}_V)$ (Corollary 9.3.2 (b)).

(d) Fix λ with $a=a(\lambda)\le 3$ and let s be the exponent of $x-\lambda$ in m_T, which is the largest block size (Corollary 9.3.2 (c)). The λ-blocks form a partition of a with largest part s. For $a=1$ the only partition is (1). For $a=2$: $s=2$ gives (2), and $s=1$ gives $(1,1)$. For $a=3$: $s=3$ gives (3), $s=2$ gives $(2,1)$, and $s=1$ gives $(1,1,1)$. In every case the pair (a,s) determines the partition, so the blocks for each eigenvalue, and hence the whole Jordan form, are determined by p_T and m_T. The first ambiguity appears at $a=4$, $s=2$, which is part (a) of Exercise (B1: Jordan forms from polynomial data).

9.4 The Real Jordan Form and the Weyr Form

The Jordan form of Section 3 exists only when p_T splits, and over $\mathbb{R}$ that often fails: a rotation of the plane has no real eigenvalue at all. But a real matrix is also a complex matrix, and its complex eigenvalues come in conjugate pairs (Theorem 8.2.5). This section turns a complex Jordan basis into a **real** one by pairing each chain with its conjugate; the price for a conjugate pair is a 2×2 rotation-scaling block instead of a scalar, and the result is the best real matrix there is. The second half rearranges the same data in another way, the Weyr form, which is the form to reach for when a second operator commutes with the first.

9.4.1 A block for a conjugate pair

The obstruction is visible in the smallest case. The rotation $\mathbf{R}=\begin{pmatrix}0&-1\\1&0\end{pmatrix}\in M_2(\mathbb{R})$ has $p_{\mathbf{R}}=x^2+1$, so $\mathbf{R}$ has no real eigenvalue and no real eigenvector (Example (A Rotation Has No Invariant Lines)). Every real matrix similar to $\mathbf{R}$ therefore has no real eigenvalue either, so it cannot be triangular: whatever basis of $\mathbb{R}^2$ we choose, the matrix of $\mathbf{R}$ keeps two off-diagonal entries. So $\mathbf{R}$ is already as simple as it will ever get over $\mathbb{R}$, and the honest thing to do is to promote it to a building block.

More generally, for $\lambda=a+bi\in\mathbb{C}$ with $b\neq 0$, consider

$$\mathbf{\Lambda}=\begin{pmatrix}a&-b\\b&a\end{pmatrix}\in M_2(\mathbb{R}),\qquad p_{\mathbf{\Lambda}}=(x-a)^2+b^2=\big(x-(a+bi)\big)\big(x-(a-bi)\big).$$

This matrix carries the conjugate pair $\lambda,\overline{\lambda}$ as its complex eigenvalues, has trace $2a=2\operatorname{Re}\lambda$ and determinant $a^2+b^2=|\lambda|^2$, and is a scaled rotation: it stretches by $|\lambda|$ and turns by the argument of λ. It is the real substitute for the 1×1 block (λ), and it costs one extra dimension.

A real Jordan block is a Jordan block with the scalar λ replaced by the 2×2 rotation-scaling matrix it needs over $\mathbb{R}$, and the superdiagonal 1 replaced by $\mathbf{I}_2$.

Definition 9.4.1 — Rotation-Scaling Block, Real Jordan Block

Let $\lambda = a + bi \in \mathbb{C}$ with $a, b \in \mathbb{R}$ and $b \neq 0$. The **rotation-scaling block** of the conjugate pair $\{\lambda, \overline{\lambda}\}$ is

$$\mathbf{\Lambda}(\lambda) := \begin{pmatrix} a & -b \\ b & a \end{pmatrix} \in M_2(\mathbb{R}).$$

For an integer $k \geq 1$, the **real Jordan block** of size k for the pair $\{\lambda, \overline{\lambda}\}$ is the matrix $\mathbf{C}_k(\lambda) \in M_{2k}(\mathbb{R})$, partitioned into $k \times k$ blocks of size 2×2, with $\mathbf{\Lambda}(\lambda)$ in every diagonal block, $\mathbf{I}_2$ in every **superdiagonal** block, and the zero matrix elsewhere:

$$\mathbf{C}_k(\lambda) := \begin{pmatrix} \mathbf{\Lambda}(\lambda) & \mathbf{I}_2 & & \\ & \mathbf{\Lambda}(\lambda) & \ddots & \\ & & \ddots & \mathbf{I}_2 \\ & & & \mathbf{\Lambda}(\lambda) \end{pmatrix}.$$

A **real Jordan matrix** is a direct sum of ordinary Jordan blocks $\mathbf{J}_k(\mu)$ with $\mu \in \mathbb{R}$ and real Jordan blocks $\mathbf{C}_k(\lambda)$ with $\lambda \notin \mathbb{R}$ and $\operatorname{Im} \lambda > 0$.

In words: $\mathbf{C}_k(\lambda)$ is built exactly like $\mathbf{J}_k(\lambda)$ (Definition 9.3.1), but every entry of $\mathbf{J}_k(\lambda)$ is replaced by a 2×2 block — the diagonal λ by $\mathbf{\Lambda}(\lambda)$, the superdiagonal 1 by $\mathbf{I}_2$, and each 0 by the 2×2 zero matrix. It has size $2k$, not k. The last clause matters: $\mathbf{\Lambda}(\overline{\lambda}) = \mathbf{\Lambda}(\lambda)^\top$, so the pair $\{\lambda, \overline{\lambda}\}$ offers two candidate blocks of each size, and a real Jordan matrix is required to use the member with $b > 0$, which makes $\mathbf{\Lambda}(\lambda)$ a rotation through a positive angle. Without that normalization the uniqueness below would fail, since $\mathbf{C}_k(\lambda)$ and $\mathbf{C}_k(\overline{\lambda})$ are similar over $\mathbb{R}$.

Examples.

- **Size one.** $\mathbf{C}_1(\lambda) = \mathbf{\Lambda}(\lambda)$. For $\lambda = i$ this is the rotation $\mathbf{R}$ above; for $\lambda = 2 + 3i$ it is $\begin{pmatrix} 2 & -3 \\ 3 & 2 \end{pmatrix}$.
- **Size two.** For $\lambda = 1 + i$,

$$\mathbf{C}_2(1+i) = \begin{pmatrix} 1 & -1 & 1 & 0 \\ 1 & 1 & 0 & 1 \\ 0 & 0 & 1 & -1 \\ 0 & 0 & 1 & 1 \end{pmatrix} \in M_4(\mathbb{R}).$$

  Its characteristic polynomial is $\big((x-1)^2+1\big)^2 = (x^2-2x+2)^2$, by Theorem 6.8.4 applied to the block upper triangular shape.
- **A real Jordan matrix mixing the two kinds.** $\mathbf{J}_2(3) \oplus \mathbf{C}_1(i) \in M_4(\mathbb{R})$ has characteristic polynomial $(x-3)^2(x^2+1)$.

Non-example by minimal change. Change the sign of the lower-left entry: $\begin{pmatrix} a & -b \\ -b & a \end{pmatrix}$ is still real, still has trace $2a$, and looks just as harmless. But it is symmetric, its characteristic polynomial is $(x-a)^2 - b^2$, and its eigenvalues $a \pm b$ are **real**; for $a = 0, b = 1$ it is the coordinate swap, which is diagonalizable over $\mathbb{R}$. The clause that fails is that the two off-diagonal entries must have **opposite** signs; that is what makes the eigenvalues non-real.

Why this definition. Two conventions are being fixed, and both are only conventions. First, the sign of b: replacing $\mathbf{\Lambda}(\lambda)$ by $\mathbf{\Lambda}(\overline{\lambda}) = \mathbf{\Lambda}(\lambda)^\top$ amounts to changing the sign of every second

basis vector, so the two choices give similar matrices. Second, the ones: a real Jordan block could be written with $\mathbf{I}_2$ below the diagonal instead, giving the transpose. What is **not** a convention is the size: a conjugate pair cannot be carried by a 1×1 real block, because a 1×1 real matrix has a real eigenvalue.

The following computation is the whole idea of the section, and we will use it twice: once to see what $\mathbf{C}_k(\lambda)$ is over $\mathbb{C}$, and once to build the real basis.

Lemma 9.4.1 — Realifying a Conjugate Pair of Chains

Let $\mathbf{A} \in M_n(\mathbb{R})$, let $\lambda = a+bi$ with $a, b \in \mathbb{R}$ and $b \neq 0$, and let $(\mathbf{w}_1, \dots, \mathbf{w}_k)$ be a Jordan chain of $\mathbf{A}$ for λ in $\mathbb{C}^n$, so that

$$(\mathbf{A} - \lambda\mathbf{I})\mathbf{w}_1 = \mathbf{0} \qquad \text{and} \qquad (\mathbf{A} - \lambda\mathbf{I})\mathbf{w}_j = \mathbf{w}_{j-1} \quad (2 \le j \le k).$$

Write $\mathbf{w}_j = \mathbf{u}_j - i\mathbf{v}_j$ with $\mathbf{u}_j, \mathbf{v}_j \in \mathbb{R}^n$, and put $\mathbf{u}_0 = \mathbf{v}_0 = \mathbf{0}$. Then:

(a) $\mathbf{A}\mathbf{u}_j = a\mathbf{u}_j + b\mathbf{v}_j + \mathbf{u}_{j-1}$ and $\mathbf{A}\mathbf{v}_j = -b\mathbf{u}_j + a\mathbf{v}_j + \mathbf{v}_{j-1}$ for $1 \le j \le k$;

(b) $(\overline{\mathbf{w}_1}, \dots, \overline{\mathbf{w}_k})$ is a Jordan chain of $\mathbf{A}$ for $\overline{\lambda}$;

(c) the $2k$ vectors $\mathbf{u}_1, \mathbf{v}_1, \dots, \mathbf{u}_k, \mathbf{v}_k$ span, over $\mathbb{C}$, the same subspace of $\mathbb{C}^n$ as the $2k$ vectors $\mathbf{w}_1, \dots, \mathbf{w}_k, \overline{\mathbf{w}_1}, \dots, \overline{\mathbf{w}_k}$, and one of the two lists is linearly independent over $\mathbb{C}$ if and only if the other is;

(d) if the $2k$ vectors $\mathbf{u}_1, \mathbf{v}_1, \dots, \mathbf{u}_k, \mathbf{v}_k$ are linearly independent over $\mathbb{R}$, then $U = \operatorname{span}(\mathbf{u}_1, \mathbf{v}_1, \dots, \mathbf{u}_k, \mathbf{v}_k) \subseteq \mathbb{R}^n$ is invariant under $\mathbf{A}$, and the matrix of $T_{\mathbf{A}}|_U$ in the ordered basis $(\mathbf{u}_1, \mathbf{v}_1, \dots, \mathbf{u}_k, \mathbf{v}_k)$ is $\mathbf{C}_k(\lambda)$.

Idea. For (a), write the chain relation as $\mathbf{A}\mathbf{w}_j = \lambda\mathbf{w}_j + \mathbf{w}_{j-1}$ and compare real and imaginary parts; since $\mathbf{A}$ is real, $\mathbf{A}$ acts on the two parts separately, and the only mixing comes from multiplying by $a + bi$. The minus sign in $\mathbf{w}_j = \mathbf{u}_j - i\mathbf{v}_j$ is chosen so that the answer comes out with the signs of $\mathbf{\Lambda}(\lambda)$ rather than its transpose. Part (c) is bookkeeping: $(\mathbf{u}_j, \mathbf{v}_j)$ and $(\mathbf{w}_j, \overline{\mathbf{w}_j})$ are obtained from each other by an invertible 2×2 matrix of scalars. Part (d) just reads off the columns from (a).

Proof.

(a) Every $\mathbf{z} \in \mathbb{C}^n$ is uniquely $\mathbf{x} + i\mathbf{y}$ with $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$, by Definition 0.6.1 applied entry by entry; so $\mathbf{u}_j, \mathbf{v}_j$ are well defined. The chain relation says $\mathbf{A}\mathbf{w}_j = \lambda\mathbf{w}_j + \mathbf{w}_{j-1}$ for $1 \le j \le k$. Expanding both sides with $\mathbf{w}_j = \mathbf{u}_j - i\mathbf{v}_j$ and $\lambda = a + bi$,

$$\begin{aligned} \mathbf{A}\mathbf{u}_j - i\mathbf{A}\mathbf{v}_j &= (a+bi)(\mathbf{u}_j - i\mathbf{v}_j) + \mathbf{u}_{j-1} - i\mathbf{v}_{j-1} \\ &= \big(a\mathbf{u}_j + b\mathbf{v}_j + \mathbf{u}_{j-1}\big) + i\big(b\mathbf{u}_j - a\mathbf{v}_j - \mathbf{v}_{j-1}\big), \end{aligned}$$

where we used $i^2 = -1$ and, on the left, that $\mathbf{A}$ has real entries, so $\mathbf{A}(\mathbf{u}_j - i\mathbf{v}_j) = \mathbf{A}\mathbf{u}_j - i\mathbf{A}\mathbf{v}_j$ with $\mathbf{A}\mathbf{u}_j, \mathbf{A}\mathbf{v}_j \in \mathbb{R}^n$. Comparing real parts gives the first identity, and comparing imaginary parts gives $-\mathbf{A}\mathbf{v}_j = b\mathbf{u}_j - a\mathbf{v}_j - \mathbf{v}_{j-1}$, that is, the second.

(b) Conjugating the identity $(\mathbf{A} - \lambda\mathbf{I})\mathbf{w}_j = \mathbf{w}_{j-1}$ entry by entry and using that $\mathbf{A}$ is real, $\overline{\mathbf{A}\mathbf{z}} = \mathbf{A}\overline{\mathbf{z}}$ and $\overline{\lambda\mathbf{z}} = \overline{\lambda}\,\overline{\mathbf{z}}$ for every $\mathbf{z} \in \mathbb{C}^n$ (Theorem 0.6.2 (a), (b)). Hence $(\mathbf{A} - \overline{\lambda}\mathbf{I})\overline{\mathbf{w}_j} = \overline{\mathbf{w}_{j-1}}$ for $j \ge 2$ and $(\mathbf{A} - \overline{\lambda}\mathbf{I})\overline{\mathbf{w}_1} = \mathbf{0}$, which is the chain condition for $\overline{\lambda}$. (That $\overline{\mathbf{w}_1} \neq \mathbf{0}$ follows from $\mathbf{w}_1 \neq \mathbf{0}$.)

(c) Since $\mathbf{w}_j = \mathbf{u}_j - i\mathbf{v}_j$ and $\overline{\mathbf{w}_j} = \mathbf{u}_j + i\mathbf{v}_j$, we have

$$\mathbf{u}_j = \tfrac{1}{2}\big(\mathbf{w}_j + \overline{\mathbf{w}_j}\big), \qquad \mathbf{v}_j = \tfrac{i}{2}\big(\mathbf{w}_j - \overline{\mathbf{w}_j}\big).$$

So each vector of either list is a $\mathbb{C}$-combination of the other list, and the two spans agree (Theorem 1.4.2). The passage from $(\mathbf{w}_j, \overline{\mathbf{w}_j})$ to $(\mathbf{u}_j, \mathbf{v}_j)$ is given, for each j separately, by the matrix $\begin{pmatrix} 1/2 & 1/2 \\ i/2 & -i/2 \end{pmatrix}$ of determinant $-i/2 \neq 0$, which is invertible; so the change of lists is an invertible linear substitution of the coefficients, and a non-trivial vanishing combination of one list yields one of the other. Hence one list is independent if and only if the other is.

(d) By (a), every $\mathbf{A}\mathbf{u}_j$ and every $\mathbf{A}\mathbf{v}_j$ lies in U, so U is $\mathbf{A}$-invariant (Lemma 8.1.1). Order the basis as $(\mathbf{u}_1, \mathbf{v}_1, \dots, \mathbf{u}_k, \mathbf{v}_k)$ and read off the columns (Definition 3.6.1). By (a), the column of $\mathbf{u}_j$ has entry a at $\mathbf{u}_j$, b at $\mathbf{v}_j$, 1 at $\mathbf{u}_{j-1}$ and 0 elsewhere; the column of $\mathbf{v}_j$ has $-b$ at $\mathbf{u}_j$, a at $\mathbf{v}_j$, 1 at $\mathbf{v}_{j-1}$ and 0 elsewhere. Grouping the basis into the consecutive pairs $(\mathbf{u}_j, \mathbf{v}_j)$, the (j,j) block is $\begin{pmatrix} a & -b \\ b & a \end{pmatrix} = \mathbf{\Lambda}(\lambda)$, the $(j-1, j)$ block is $\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} = \mathbf{I}_2$, and all other blocks are zero. That is $\mathbf{C}_k(\lambda)$ (Definition 9.4.1).

■

Applying the lemma to the block itself tells us what a real Jordan block looks like over $\mathbb{C}$.

Corollary 9.4.2 — A Real Jordan Block Splits into Two Complex Ones

Let $\lambda \notin \mathbb{R}$ and $k \geq 1$. Then, as matrices over $\mathbb{C}$,

$$\mathbf{C}_k(\lambda) \sim \mathbf{J}_k(\lambda) \oplus \mathbf{J}_k(\overline{\lambda}).$$

In particular $p_{\mathbf{C}_k(\lambda)} = \big((x-\lambda)(x-\overline{\lambda})\big)^k$, the polynomial $\big((x-a)^2 + b^2\big)^k \in \mathbb{R}[x]$, and $m_{\mathbf{C}_k(\lambda)}$ is the same polynomial.

Proof. Put $\mathbf{A} = \mathbf{C}_k(\lambda) \in M_{2k}(\mathbb{R})$ and let $(\mathbf{u}_1, \mathbf{v}_1, \dots, \mathbf{u}_k, \mathbf{v}_k)$ be the standard basis of $\mathbb{R}^{2k}$ in this order. Reading the columns of $\mathbf{C}_k(\lambda)$ gives exactly the identities of Lemma 9.4.1 (a). Put $\mathbf{w}_j = \mathbf{u}_j - i\mathbf{v}_j$, so that $\mathbf{w}_1 = \mathbf{e}_1 - i\mathbf{e}_2 \neq \mathbf{0}$. Combining the two real identities,

$$\begin{aligned} \mathbf{A}\mathbf{w}_j = \mathbf{A}\mathbf{u}_j - i\mathbf{A}\mathbf{v}_j &= (a\mathbf{u}_j + b\mathbf{v}_j + \mathbf{u}_{j-1}) - i(-b\mathbf{u}_j + a\mathbf{v}_j + \mathbf{v}_{j-1}) \\ &= (a+bi)\mathbf{u}_j + (b-ai)\mathbf{v}_j + \mathbf{w}_{j-1} \\ &= \lambda\mathbf{w}_j + \mathbf{w}_{j-1}, \end{aligned}$$

since $\lambda(-i\mathbf{v}_j) = (b-ai)\mathbf{v}_j$. So $(\mathbf{w}_1, \dots, \mathbf{w}_k)$ is a Jordan chain of $\mathbf{A}$ for λ, and by (b) so is $(\overline{\mathbf{w}_1}, \dots, \overline{\mathbf{w}_k})$ for $\overline{\lambda}$. By (c), the $2k$ vectors $\mathbf{w}_1, \dots, \mathbf{w}_k, \overline{\mathbf{w}_1}, \dots, \overline{\mathbf{w}_k}$ are independent over $\mathbb{C}$, because the standard basis is; being $2k$ independent vectors in $\mathbb{C}^{2k}$, they form a basis (Theorem 1.6.4 (a)). On the span of one chain, $\mathbf{A} - \lambda\mathbf{I}$ has matrix $\mathbf{J}_k(0)$ by Lemma 9.2.2 (b), so $\mathbf{A}$ has matrix $\lambda\mathbf{I}_k + \mathbf{J}_k(0) = \mathbf{J}_k(\lambda)$ there, the matrix of a sum of operators being the sum of their matrices (Theorem 3.6.4, Definition 9.3.1); likewise $\mathbf{J}_k(\overline{\lambda})$ on the span of the conjugate chain. By Theorem 8.1.5 the matrix of $T_{\mathbf{A}}$ in the combined basis is

$\mathbf{J}_k(\lambda) \oplus \mathbf{J}_k(\overline{\lambda})$. Hence $\mathbf{C}_k(\lambda) \sim \mathbf{J}_k(\lambda) \oplus \mathbf{J}_k(\overline{\lambda})$ over $\mathbb{C}$ (Theorem 3.7.4).

The characteristic polynomial of $\mathbf{J}_k(\mu)$ is $(x-\mu)^k$ (Theorem 6.4.6), and similar matrices have the same characteristic polynomial (Theorem 6.10.3), so $p_{\mathbf{C}_k(\lambda)} = (x-\lambda)^k(x-\overline{\lambda})^k$. For the minimal polynomial, $m_{\mathbf{J}_k(\mu)} = (x-\mu)^k$ by Corollary 9.3.2 (c), a single Jordan block being a Jordan form of itself with one block, of size k; so $m_{\mathbf{C}_k(\lambda)} = \operatorname{lcm}\big((x-\lambda)^k, (x-\overline{\lambda})^k\big) = (x-\lambda)^k(x-\overline{\lambda})^k$ by Proposition 8.5.6 and Theorem 8.5.5, the factors being powers of distinct irreducibles.

■

Quick check. What are the complex eigenvalues of $\mathbf{C}_2(1+i)$, with their algebraic and geometric multiplicities?

Solution. By Corollary 9.4.2, $\mathbf{C}_2(1+i) \sim \mathbf{J}_2(1+i) \oplus \mathbf{J}_2(1-i)$ over $\mathbb{C}$. So the eigenvalues are $1 \pm i$, each with $a(\lambda) = 2$ (the total size of its blocks) and $g(\lambda) = 1$ (the number of its blocks), by Corollary 9.3.2 (a), (b).

9.4.2 The real Jordan form

Two facts about real matrices are needed before the theorem. The first is that a real matrix has the same kernel over $\mathbb{R}$ as over $\mathbb{C}$, in the sense that a real basis of the one is a complex basis of the other. Once one knows that $\tilde{U}$ is the complexification of U inside $\mathbb{C}^n = (\mathbb{R}^n)_{\mathbb{C}}$ (Definition 1.9.2, Example (The Complexification of $\mathbb{R}^n$ Is $\mathbb{C}^n$)), this is Theorem 1.9.3. It is worth proving directly, because the identification is itself part of what has to be checked, and because the statement is used both to find the real chains and to compare ranks.

Lemma 9.4.3 — Real and Complex Null Spaces of a Real Matrix

Let $\mathbf{M} \in M_n(\mathbb{R})$, let $U = \{\, \mathbf{x} \in \mathbb{R}^n : \mathbf{M}\mathbf{x} = \mathbf{0} \,\}$ be its null space over $\mathbb{R}$, and let $\tilde{U} = \{\, \mathbf{z} \in \mathbb{C}^n : \mathbf{M}\mathbf{z} = \mathbf{0} \,\}$ be its null space over $\mathbb{C}$. Then:

(a) for $\mathbf{z} = \mathbf{x} + i\mathbf{y}$ with $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$: $\mathbf{z} \in \tilde{U}$ if and only if $\mathbf{x} \in U$ and $\mathbf{y} \in U$;

(b) every basis of U over $\mathbb{R}$ is a basis of $\tilde{U}$ over $\mathbb{C}$; in particular $\dim_{\mathbb{R}} U = \dim_{\mathbb{C}} \tilde{U}$ and $\operatorname{rank}\mathbf{M}$ is the same computed over $\mathbb{R}$ and over $\mathbb{C}$.

Proof.

(a) Since $\mathbf{M}$ is real, $\mathbf{M}\mathbf{z} = \mathbf{M}\mathbf{x} + i\mathbf{M}\mathbf{y}$ with $\mathbf{M}\mathbf{x}, \mathbf{M}\mathbf{y} \in \mathbb{R}^n$. By the uniqueness of real and imaginary parts (Definition 0.6.1), $\mathbf{M}\mathbf{z} = \mathbf{0}$ if and only if $\mathbf{M}\mathbf{x} = \mathbf{0}$ and $\mathbf{M}\mathbf{y} = \mathbf{0}$.

(b) Let $(\mathbf{x}_1, \dots, \mathbf{x}_r)$ be a basis of U over $\mathbb{R}$. *Spanning.* Let $\mathbf{z} = \mathbf{x} + i\mathbf{y} \in \tilde{U}$. By (a), $\mathbf{x}, \mathbf{y} \in U$, so $\mathbf{x} = \sum_j c_j\mathbf{x}_j$ and $\mathbf{y} = \sum_j d_j\mathbf{x}_j$ with $c_j, d_j \in \mathbb{R}$; hence $\mathbf{z} = \sum_j (c_j + id_j)\mathbf{x}_j$. *Independence.* Let $\sum_j \alpha_j\mathbf{x}_j = \mathbf{0}$ with $\alpha_j = c_j + id_j \in \mathbb{C}$. Separating real and imaginary parts, which is legitimate because the $\mathbf{x}_j$ are real, gives $\sum_j c_j\mathbf{x}_j = \mathbf{0}$ and $\sum_j d_j\mathbf{x}_j = \mathbf{0}$; independence over $\mathbb{R}$ forces every $c_j = d_j = 0$. So $(\mathbf{x}_1, \dots, \mathbf{x}_r)$ is a basis of $\tilde{U}$ and $\dim_{\mathbb{C}} \tilde{U} = r = \dim_{\mathbb{R}} U$. The rank statement follows from Theorem 2.5.7 over each field.

■

Now the theorem. Read it as the Jordan form with one amendment: a conjugate pair of complex blocks of size k is replaced by a single real block of size $2k$.

Every real matrix is similar, over the reals, to a direct sum of Jordan blocks for its real eigenvalues and real Jordan blocks for its conjugate pairs, and that matrix is unique up to the order of its blocks.

Theorem 9.4.4 — Real Jordan Form

Let $\mathbf{A} \in M_n(\mathbb{R})$ with $n \geq 1$. List the eigenvalues of $\mathbf{A}$ in $\mathbb{C}$ as

$$\mu_1, \dots, \mu_p \in \mathbb{R} \quad \text{(the real ones, distinct)},$$
$$\lambda_1, \overline{\lambda_1}, \dots, \lambda_q, \overline{\lambda_q} \quad \text{(the conjugate pairs, with } \operatorname{Im}\lambda_t > 0\text{)}.$$

(a) **(Existence)** There is an invertible $\mathbf{P} \in M_n(\mathbb{R})$ such that $\mathbf{P}^{-1}\mathbf{A}\mathbf{P}$ is a real Jordan matrix (Definition 9.4.1), in which the blocks for a real eigenvalue μ_l are ordinary Jordan blocks $\mathbf{J}_k(\mu_l)$ and the blocks for a pair $\{\lambda_t, \overline{\lambda_t}\}$ are real Jordan blocks $\mathbf{C}_k(\lambda_t)$.

(b) **(Uniqueness)** In any such matrix, the number of blocks $\mathbf{J}_k(\mu)$ with $k \geq j$, for $\mu \in \mathbb{R}$, and the number of blocks $\mathbf{C}_k(\lambda)$ with $k \geq j$, for $\lambda \notin \mathbb{R}$, both equal

$$\operatorname{rank}(\mathbf{A} - \nu\mathbf{I})^{j-1} - \operatorname{rank}(\mathbf{A} - \nu\mathbf{I})^{j} \qquad (\nu = \mu \text{ resp. } \nu = \lambda),$$

the ranks being computed over $\mathbb{C}$ in the second case. Consequently the real Jordan matrix is determined by $\mathbf{A}$ up to the order of its blocks.

Idea. Work over $\mathbb{C}$, then come home. ① Split $\mathbb{C}^n = \bigoplus G_\nu(\mathbf{A})$ over all complex eigenvalues ν (Theorem 9.1.3). ② For a **real** eigenvalue, the generalized eigenspace is the complexification of a real subspace, by Lemma 9.4.3, and Section 2's structure theorem runs over $\mathbb{R}$ on that real subspace: nothing complex is needed. ③ For a **pair**, choose the chains in G_{λ_t} freely, and take their conjugates in $G_{\overline{\lambda_t}}$ — no choice there. ④ Replace each conjugate pair of chains by its real and imaginary parts; Lemma 9.4.1 says the new matrix is $\mathbf{C}_k(\lambda_t)$, and a count shows the real vectors collected are exactly n in number and independent. Uniqueness is the uniqueness of the complex Jordan form, since by Corollary 9.4.2 a real Jordan matrix has a known complex Jordan form.

Proof. Since $p_{\mathbf{A}} \in \mathbb{R}[x] \subseteq \mathbb{C}[x]$ has degree $n \geq 1$, it splits over $\mathbb{C}$ (Corollary 5.5.5), and its non-real roots come in conjugate pairs with equal multiplicities (Theorem 8.2.5 (a)); so the list of eigenvalues has the displayed shape. Write $a(\nu)$ for the algebraic multiplicity of ν in $p_{\mathbf{A}}$, so $a(\lambda_t) = a(\overline{\lambda_t})$ and

$$\sum_{l=1}^{p} a(\mu_l) + \sum_{t=1}^{q} 2a(\lambda_t) = n. \tag{$*$}$$

By Theorem 9.1.3 applied to $T_{\mathbf{A}}$ over $\mathbb{C}$,

$$\mathbb{C}^n = \bigoplus_{l=1}^{p} G_{\mu_l}(\mathbf{A}) \;\oplus\; \bigoplus_{t=1}^{q} \big(G_{\lambda_t}(\mathbf{A}) \oplus G_{\overline{\lambda_t}}(\mathbf{A})\big),$$

with $\dim_{\mathbb{C}} G_\nu(\mathbf{A}) = a(\nu)$ and $G_\nu(\mathbf{A}) = \ker(\mathbf{A} - \nu\mathbf{I})^n$ (Corollary 9.1.2 (a)).

Step 1. Real eigenvalues, handled entirely over $\mathbb{R}$. Fix a real eigenvalue $\mu = \mu_l$. The matrix $(\mathbf{A} - \mu\mathbf{I})^n$ is real, so by Lemma 9.4.3 its real null space

$$U_\mu := \{\, \mathbf{x} \in \mathbb{R}^n : (\mathbf{A} - \mu\mathbf{I})^n \mathbf{x} = \mathbf{0} \,\}$$

has a real basis which is a $\mathbb{C}$-basis of $G_\mu(\mathbf{A})$; in particular $\dim_{\mathbb{R}} U_\mu = a(\mu)$. The subspace U_μ is $\mathbf{A}$-invariant, since $(\mathbf{A} - \mu\mathbf{I})^n(\mathbf{A}\mathbf{x}) = \mathbf{A}(\mathbf{A} - \mu\mathbf{I})^n\mathbf{x} = \mathbf{0}$ for $\mathbf{x} \in U_\mu$ (Theorem 5.7.4 (b)), and $N_\mu := (\mathbf{A} - \mu\mathbf{I})|_{U_\mu}$ satisfies $N_\mu^n = 0$, so N_μ is nilpotent (Definition 9.2.1). By Theorem 9.2.3 there is a basis $\mathcal{B}_\mu$ of the **real** space U_μ, a concatenation of Jordan chains of N_μ, with $[N_\mu]_{\mathcal{B}_\mu} = \mathbf{J}_{k_1}(0) \oplus \cdots \oplus \mathbf{J}_{k_s}(0)$. Since $T_{\mathbf{A}}|_{U_\mu} = \mu\,\mathrm{id}_{U_\mu} + N_\mu$ and $[\mathrm{id}_{U_\mu}]_{\mathcal{B}_\mu} = \mathbf{I}_{k_1} \oplus \cdots \oplus \mathbf{I}_{k_s}$, adding the matrices (Theorem 3.6.4) blockwise (Theorem 7.1.4 (a), Definition 9.3.1) gives

$$[T_{\mathbf{A}}|_{U_\mu}]_{\mathcal{B}_\mu} = \mathbf{J}_{k_1}(\mu) \oplus \cdots \oplus \mathbf{J}_{k_s}(\mu),$$

a direct sum of ordinary Jordan blocks. Moreover $\mathcal{B}_\mu$, viewed in $\mathbb{C}^n$, is a Jordan basis of $G_\mu(\mathbf{A})$ for $T_{\mathbf{A}}$ over $\mathbb{C}$: the chain relations are the same equations, and $\mathcal{B}_\mu$ is a $\mathbb{C}$-basis of $G_\mu(\mathbf{A})$ by Lemma 9.4.3 (b).

Step 2. Conjugate pairs, chosen on one side. Fix t and write $\lambda = \lambda_t$, $G = G_\lambda(\mathbf{A})$, $\overline{G} = G_{\overline{\lambda}}(\mathbf{A})$. By Theorem 9.1.3 (d), $(\mathbf{A} - \lambda\mathbf{I})|_G$ is nilpotent, so Theorem 9.2.3 provides chains whose concatenation is a $\mathbb{C}$-basis of G; as in Step 1 these are Jordan chains of $\mathbf{A}$ for λ, of lengths $k_1, \ldots, k_m$ summing to $a(\lambda)$.

Claim: conjugating gives a Jordan basis of $\overline{G}$. Indeed, conjugation maps G onto $\overline{G}$: if $(\mathbf{A} - \lambda\mathbf{I})^n\mathbf{z} = \mathbf{0}$, then $(\mathbf{A} - \overline{\lambda}\mathbf{I})^n\overline{\mathbf{z}} = \mathbf{0}$ by the computation in Lemma 9.4.1 (b), and conjugating twice returns $\mathbf{z}$. If $(\mathbf{z}_1, \ldots, \mathbf{z}_d)$ is a $\mathbb{C}$-basis of G, then $(\overline{\mathbf{z}_1}, \ldots, \overline{\mathbf{z}_d})$ spans $\overline{G}$ — any $\mathbf{z} \in \overline{G}$ has $\overline{\mathbf{z}} \in G$, say $\overline{\mathbf{z}} = \sum_j c_j\mathbf{z}_j$, whence $\mathbf{z} = \sum_j \overline{c_j}\,\overline{\mathbf{z}_j}$ — and it has $d = \dim_{\mathbb{C}} \overline{G}$ entries, so it is a basis (Theorem 1.6.4 (b)). Applying this to the concatenated chains, and using Lemma 9.4.1 (b) chain by chain, the conjugated chains form a Jordan basis of $\overline{G}$ consisting of chains for $\overline{\lambda}$ of the same lengths $k_1, \ldots, k_m$.

Step 3. Realify each pair of conjugate chains. Keep t fixed and let $(\mathbf{w}_1, \ldots, \mathbf{w}_k)$ be one of the chains of Step 2, with $\mathbf{w}_j = \mathbf{u}_j - i\mathbf{v}_j$, $\mathbf{u}_j, \mathbf{v}_j \in \mathbb{R}^n$. By Lemma 9.4.1 (c), the $2k$ real vectors $\mathbf{u}_1, \mathbf{v}_1, \ldots, \mathbf{u}_k, \mathbf{v}_k$ have the same $\mathbb{C}$-span as the $2k$ chain vectors $\mathbf{w}_1, \ldots, \mathbf{w}_k, \overline{\mathbf{w}_1}, \ldots, \overline{\mathbf{w}_k}$. Do this for each of the m chains attached to λ_t, and for each t.

Step 4. The collected real vectors form a basis of $\mathbb{R}^n$. Let $\mathcal{B}$ be the list obtained by writing, one after another: the real Jordan bases $\mathcal{B}_{\mu_1}, \ldots, \mathcal{B}_{\mu_p}$ of Step 1, and then, for each t and each chain of Step 2, the block of $2k$ real vectors of Step 3. Its length is

$$\sum_{l=1}^{p} a(\mu_l) + \sum_{t=1}^{q} \sum_{\text{chains}} 2k = \sum_{l=1}^{p} a(\mu_l) + \sum_{t=1}^{q} 2a(\lambda_t) = n$$

by $(*)$, since the chain lengths for λ_t sum to $a(\lambda_t)$. Its $\mathbb{C}$-span contains a $\mathbb{C}$-basis of each $G_{\mu_l}(\mathbf{A})$ (Step 1) and, for each t, all the vectors $\mathbf{w}_j$ and $\overline{\mathbf{w}_j}$ (Step 3), which together form a $\mathbb{C}$-basis of $G_{\lambda_t}(\mathbf{A}) \oplus G_{\overline{\lambda_t}}(\mathbf{A})$ by Step 2. So the $\mathbb{C}$-span of $\mathcal{B}$ is all of $\mathbb{C}^n$, and $\mathcal{B}$ has exactly n entries, so $\mathcal{B}$ is a $\mathbb{C}$-basis of $\mathbb{C}^n$ (Theorem 1.6.4 (b)). In particular $\mathcal{B}$ is linearly independent over $\mathbb{C}$, hence over $\mathbb{R}$, and being a list of n independent vectors in $\mathbb{R}^n$ it is a basis of $\mathbb{R}^n$ (Theorem 1.6.4 (a)).

Step 5. The matrix. Each segment of $\mathcal{B}$ spans an $\mathbf{A}$-invariant real subspace: the spaces U_{μ_l} by Step 1, and the spaces U of Lemma 9.4.1 (d) by Step 3 and the independence just proved. Their direct sum is $\mathbb{R}^n$, since $\mathcal{B}$ is a basis. By Theorem 8.1.5, $[T_{\mathbf{A}}]_{\mathcal{B}}$ is block diagonal with the matrices of the restrictions as diagonal blocks, which are $\mathbf{J}_k(\mu_l)$'s by Step 1 and $\mathbf{C}_k(\lambda_t)$'s by Lemma 9.4.1 (d). Taking $\mathbf{P}$ to be the real matrix whose columns are the vectors of $\mathcal{B}$ gives $\mathbf{P}^{-1}\mathbf{A}\mathbf{P} = [T_{\mathbf{A}}]_{\mathcal{B}}$ (Theorem 3.7.4), which proves (a).

(b) Let $\mathbf{B} = \mathbf{P}^{-1}\mathbf{A}\mathbf{P}$ be any real Jordan matrix similar to $\mathbf{A}$ over $\mathbb{R}$, and regard the similarity over $\mathbb{C}$. By Corollary 9.4.2 and Theorem 7.1.4, replacing each block $\mathbf{C}_k(\lambda)$ of $\mathbf{B}$ by $\mathbf{J}_k(\lambda) \oplus \mathbf{J}_k(\overline{\lambda})$ produces a Jordan matrix similar to $\mathbf{B}$, hence to $\mathbf{A}$, over $\mathbb{C}$. By Theorem 9.3.1 (b), for every $\nu \in \mathbb{C}$ and $j \geq 1$ the number of blocks $\mathbf{J}_k(\nu)$ with $k \geq j$ in that Jordan matrix equals $\operatorname{rank}(\mathbf{A}-\nu\mathbf{I})^{j-1} - \operatorname{rank}(\mathbf{A}-\nu\mathbf{I})^{j}$, computed over $\mathbb{C}$. For a real μ, the blocks $\mathbf{J}_k(\mu)$ of the Jordan matrix are exactly the blocks $\mathbf{J}_k(\mu)$ of $\mathbf{B}$, since the replaced blocks contribute only non-real eigenvalues; and the ranks over $\mathbb{C}$ agree with the ranks over $\mathbb{R}$ by Lemma 9.4.3 (b), applied to the real matrix $(\mathbf{A} - \mu\mathbf{I})^j$. For $\lambda \notin \mathbb{R}$ with $\operatorname{Im}\lambda > 0$, the blocks $\mathbf{J}_k(\lambda)$ of the Jordan matrix come one each from the blocks $\mathbf{C}_k(\lambda)$ of $\mathbf{B}$: a block $\mathbf{C}_k(\lambda')$ of $\mathbf{B}$ with $\lambda' \neq \lambda$ contributes $\mathbf{J}_k(\lambda')$ and $\mathbf{J}_k(\overline{\lambda'})$, and $\overline{\lambda'} \neq \lambda$ because λ and λ' both have **positive** imaginary part (Definition 9.4.1). In both cases the count is determined by $\mathbf{A}$, so any two real Jordan matrices similar to $\mathbf{A}$ have the same blocks up to order.

■

So over $\mathbb{R}$ the dream of Chapter 3 comes true in the amended form: **every real square matrix is similar over $\mathbb{R}$ to a matrix that is block diagonal with blocks $\mathbf{J}_k(\mu)$ and $\mathbf{C}_k(\lambda)$**, and the only new feature is the 2×2 rotation-scaling block. Counting: a real eigenvalue μ contributes $a(\mu)$ to the size and $g(\mu)$ blocks; a pair $\{\lambda, \overline{\lambda}\}$ contributes $2a(\lambda)$ to the size and $g(\lambda)$ real blocks. For an operator T on a real vector space V the same statement holds, applied to $[T]_{\mathcal{C}}$ for any basis $\mathcal{C}$ of V: the theorem produces a real Jordan matrix similar to it, hence equal to $[T]_{\mathcal{B}}$ for another basis $\mathcal{B}$ of V (Theorem 3.7.4). The complexification $V_{\mathbb{C}}$ of Definition 1.9.2 is where the complex chains live; for $V = \mathbb{R}^n$ it is $\mathbb{C}^n$ (Example (The Complexification of $\mathbb{R}^n$ Is $\mathbb{C}^n$)), which is the case written out above.

Warning. **A real Jordan matrix is not triangular, and the real form is not obtained by "ignoring" the imaginary parts.** The real Jordan form of a matrix with a non-real eigenvalue **cannot** be triangular, since a triangular real matrix has its diagonal entries as eigenvalues, all real (Theorem 8.7.4). Nor is $\mathbf{\Lambda}(\lambda)$ a diagonal matrix in disguise: it has no real eigenvector. And the real basis is not the real part of the complex one: each complex chain vector $\mathbf{w}_j$ contributes **two** real vectors, $\operatorname{Re}\mathbf{w}_j$ and $-\operatorname{Im}\mathbf{w}_j$, and dropping either of them destroys the invariance.

Example. (The Real Jordan Form of a 4×4 Matrix)

Let

$$\mathbf{A} = \begin{pmatrix} 0 & -1 & 1 & 0 \\ 1 & 0 & 0 & 1 \\ -1 & 0 & 2 & -1 \\ 0 & -1 & 1 & 2 \end{pmatrix} \in M_4(\mathbb{R}), \qquad p_{\mathbf{A}} = (x^2 - 2x + 2)^2.$$

Find the real Jordan form of $\mathbf{A}$ (Theorem 9.4.4) and an invertible $\mathbf{P} \in M_4(\mathbb{R})$ with $\mathbf{P}^{-1}\mathbf{A}\mathbf{P}$ in that form.

Solution. The eigenvalues. $x^2 - 2x + 2 = (x-1)^2 + 1$ has roots $1 \pm i$, so over $\mathbb{C}$ the eigenvalues are $\lambda = 1+i$ and $\overline{\lambda} = 1-i$, each with $a(\lambda) = 2$. There is no real eigenvalue, so the real Jordan form consists of real blocks $\mathbf{C}_k(1+i)$ only, with sizes k summing to $a(\lambda) = 2$.

A chain for $\lambda = 1+i$. Put $\mathbf{M} = \mathbf{A} - (1+i)\mathbf{I}$, so that

$$\mathbf{M} = \begin{pmatrix} -1-i & -1 & 1 & 0 \\ 1 & -1-i & 0 & 1 \\ -1 & 0 & 1-i & -1 \\ 0 & -1 & 1 & 1-i \end{pmatrix}.$$

Solve $\mathbf{Mz} = \mathbf{0}$ using rows 2, 1 and 4 in that order. Row 2 gives $z_1 = (1+i)z_2 - z_4$; row 1 gives $z_3 = (1+i)z_1 + z_2$. Substituting the first into the second, and writing $s = z_2$, $u = z_4$,

$$z_1 = (1+i)s - u, \qquad z_3 = (1+i)\big((1+i)s - u\big) + s = (1+2i)s - (1+i)u,$$

using $(1+i)^2 = 2i$. Row 4 reads $-z_2 + z_3 + (1-i)z_4 = 0$, which becomes

$$-s + (1+2i)s - (1+i)u + (1-i)u = 2is - 2iu = 0,$$

so $s = u$. Row 3 is then automatic: with $s = u = 1$ we get $\mathbf{z} = (i, 1, i, 1)$, and row 3 gives $-i + (1-i)i - 1 = -i + i + 1 - 1 = 0$. So

$$\ker \mathbf{M} = \operatorname{span}\big((i, 1, i, 1)\big), \qquad g(\lambda) = 1.$$

Hence there is exactly one λ-block over $\mathbb{C}$ (Corollary 9.3.2 (b)), of size $a(\lambda) = 2$, and the real Jordan form is $\mathbf{C}_2(1+i)$. For the basis we need the chain: take $\mathbf{w}_1 = (i, 1, i, 1)$ and solve $\mathbf{M}\mathbf{w}_2 = \mathbf{w}_1$. Try $\mathbf{w}_2 = (0, 0, z_3, z_4)$, so that only columns 3 and 4 of $\mathbf{M}$ are used. Row 1 then reads $z_3 = i$ and row 2 reads $z_4 = 1$, so $\mathbf{w}_2 = (0, 0, i, 1)$ is the only candidate of this shape. Rows 3 and 4 confirm it:

$$(1-i)i - 1 = (i+1) - 1 = i \quad \text{and} \quad i + (1-i) = 1,$$

which are the third and fourth entries of $\mathbf{w}_1$. So $(\mathbf{w}_1, \mathbf{w}_2)$ is a Jordan chain of $\mathbf{A}$ for $1+i$.

Normalizing the chain. If $(\mathbf{w}_1, \mathbf{w}_2)$ is a chain, so is $(c\mathbf{w}_1, c\mathbf{w}_2)$ for any $c \neq 0$, since the chain relations are linear. Taking $c = -i$ clears the denominators of the realification:

$$\mathbf{w}_1' = -i(i, 1, i, 1) = (1, -i, 1, -i), \qquad \mathbf{w}_2' = -i(0, 0, i, 1) = (0, 0, 1, -i).$$

Now read off $\mathbf{w}_j' = \mathbf{u}_j - i\mathbf{v}_j$ with $\mathbf{u}_j, \mathbf{v}_j$ real, as Lemma 9.4.1 requires:

$$\mathbf{u}_1 = (1, 0, 1, 0), \quad \mathbf{v}_1 = (0, 1, 0, 1), \qquad \mathbf{u}_2 = (0, 0, 1, 0), \quad \mathbf{v}_2 = (0, 0, 0, 1).$$

The answer. With $\mathcal{B} = (\mathbf{u}_1, \mathbf{v}_1, \mathbf{u}_2, \mathbf{v}_2)$,

$$\mathbf{P} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 1 & 0 & 1 & 0 \\ 0 & 1 & 0 & 1 \end{pmatrix}, \qquad \mathbf{P}^{-1}\mathbf{A}\mathbf{P} = \mathbf{C}_2(1+i) = \begin{pmatrix} 1 & -1 & 1 & 0 \\ 1 & 1 & 0 & 1 \\ 0 & 0 & 1 & -1 \\ 0 & 0 & 1 & 1 \end{pmatrix}.$$

$\mathbf{P}$ is lower triangular with ones on the diagonal, so $\det \mathbf{P} = 1$ (Theorem 6.4.6) and $\mathbf{P}$ is invertible.

The check, column by column. Writing $\mathbf{c}_1, \dots, \mathbf{c}_4$ for the columns of $\mathbf{P}$, the identity $\mathbf{AP} = \mathbf{P}\,\mathbf{C}_2(1+i)$ says

$$\begin{aligned} \mathbf{A}\mathbf{c}_1 &= \mathbf{c}_1 + \mathbf{c}_2, \\ \mathbf{A}\mathbf{c}_2 &= -\mathbf{c}_1 + \mathbf{c}_2, \\ \mathbf{A}\mathbf{c}_3 &= \mathbf{c}_1 + \mathbf{c}_3 + \mathbf{c}_4, \\ \mathbf{A}\mathbf{c}_4 &= \mathbf{c}_2 - \mathbf{c}_3 + \mathbf{c}_4, \end{aligned}$$

read off the four columns of $\mathbf{C}_2(1+i)$; these are exactly the identities of Lemma 9.4.1 (a) with $a = b = 1$. Two of them in full:

$$\begin{aligned} \mathbf{A}\mathbf{c}_1 = \mathbf{A}(1,0,1,0) &= (0+1,\ 1+0,\ -1+2,\ 0+1) = (1,1,1,1) \\ &= (1,0,1,0) + (0,1,0,1) = \mathbf{c}_1 + \mathbf{c}_2, \end{aligned}$$

adding columns 1 and 3 of $\mathbf{A}$; and

$$\begin{aligned} \mathbf{A}\mathbf{c}_3 = \mathbf{A}(0,0,1,0) &= (1,0,2,1) = (1,0,1,0) + (0,0,1,0) + (0,0,0,1) \\ &= \mathbf{c}_1 + \mathbf{c}_3 + \mathbf{c}_4, \end{aligned}$$

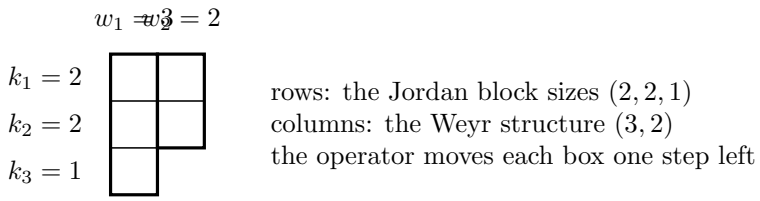
the third column of $\mathbf{A}$. The remaining two are the same kind of one-line computation.

Cross-checks. $\operatorname{tr}\mathbf{A} = 0+0+2+2 = 4$ and $\operatorname{tr}\mathbf{C}_2(1+i) = 4\cdot 1 = 4$. Over $\mathbb{C}$, Corollary 9.4.2 gives the complex Jordan form $\mathbf{J}_2(1+i) \oplus \mathbf{J}_2(1-i)$, whose characteristic polynomial is $\big((x-1)^2+1\big)^2 = p_{\mathbf{A}}$.

9.4.3 The Weyr form

The Jordan form of a nilpotent operator is the Young diagram of Section 2 read **by rows**: one row per chain, one block per row. The same diagram can be read **by columns**, and the columns are the jumps of the kernel chain (Definition 9.2.3 and the discussion after Theorem 9.2.4). Reordering a Jordan basis accordingly costs nothing and gives a second normal form, the Weyr form. It carries exactly the same information — a partition for each eigenvalue — but it wears it differently, and for one purpose it is strictly better: the matrices that commute with a Weyr matrix are block upper triangular, which is false for the Jordan form.

Here is the diagram for the partition $(2,2,1)$ of 5, whose dual partition is $(3,2)$:



The basis is the same; only its order changes. Instead of listing chain by chain, list the first column (a basis of the kernel), then the second column, and so on. Since the operator moves each box one step to the left, it maps the j-th group of basis vectors into the $(j-1)$-th, injectively, and the matrix becomes block upper triangular with a very rigid pattern of ones.

Definition 9.4.2 — Basic Weyr Matrix, Weyr Structure, Weyr Form

Let $\lambda \in F$ and let $w_1 \geq w_2 \geq \cdots \geq w_s \geq 1$ be a partition of an integer $m \geq 1$ (Definition 9.2.3). The **basic Weyr matrix** with eigenvalue λ and **Weyr structure** $(w_1, \ldots, w_s)$ is the matrix $\mathbf{W} \in M_m(F)$, partitioned into blocks according to $m = w_1 + \cdots + w_s$, whose blocks are

$$\mathbf{W}_{jj} = \lambda \mathbf{I}_{w_j}, \qquad \mathbf{W}_{j,j+1} = \begin{pmatrix} \mathbf{I}_{w_{j+1}} \\ 0 \end{pmatrix} \in M_{w_j \times w_{j+1}}(F), \qquad \mathbf{W}_{jl} = 0 \ \text{ otherwise.}$$

A **Weyr matrix** is a direct sum of basic Weyr matrices. A **Weyr form** of $T \in \mathcal{L}(V)$ is a Weyr matrix $\mathbf{W}$ with $[T]_{\mathcal{B}} = \mathbf{W}$ for some basis $\mathcal{B}$ of V; for $\mathbf{A} \in M_n(F)$, a Weyr form of $\mathbf{A}$ is a Weyr matrix similar to $\mathbf{A}$.

In words: the diagonal blocks are scalar, of the sizes given by the partition, and the only other non-zero blocks sit **immediately to the right** of the diagonal ones, each being an identity matrix stacked on top of a zero block — so $\mathbf{W}_{j,j+1}$ has full column rank w_{j+1}, which is possible exactly because $w_j \geq w_{j+1}$. The matrix is upper triangular, with λ repeated m times on the diagonal.

Examples.

- **One column.** If $s = 1$, then $\mathbf{W} = \lambda \mathbf{I}_{w_1}$: a scalar matrix. This is the diagonalizable case.
- **All parts equal to 1.** If $w_1 = \cdots = w_s = 1$, then $\mathbf{W} = \mathbf{J}_s(\lambda)$: a single Jordan block. So Jordan blocks are the basic Weyr matrices of the thinnest possible structure.
- **The structure $(3, 2)$ with $\lambda = 5$.** Here $m = 5$ and

$$\mathbf{W} = \begin{pmatrix} 5 & 0 & 0 & 1 & 0 \\ 0 & 5 & 0 & 0 & 1 \\ 0 & 0 & 5 & 0 & 0 \\ 0 & 0 & 0 & 5 & 0 \\ 0 & 0 & 0 & 0 & 5 \end{pmatrix},$$

  with the 3×2 block $\begin{pmatrix} \mathbf{I}_2 \\ 0 \end{pmatrix}$ in the upper right corner. As we will see, this is the Weyr form of $\mathbf{J}_2(5) \oplus \mathbf{J}_2(5) \oplus \mathbf{J}_1(5)$, the diagram drawn above.

Non-example by minimal change. Put the identity block in the **lower** part of $\mathbf{W}_{12}$ instead: with structure $(2, 1)$ and $\lambda = 0$, compare

$$\mathbf{W} = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} \qquad \text{and} \qquad \mathbf{W}' = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{pmatrix}.$$

Both are nilpotent of rank 1, and indeed $\mathbf{W} \sim \mathbf{W}'$ (Corollary 9.2.5): the shape is not an extra invariant, and the two matrices represent the same operator in different bases. But only $\mathbf{W}$ is a Weyr matrix. The clause that fails for $\mathbf{W}'$ is that the block $\mathbf{W}_{j,j+1}$ must be an identity matrix stacked **on top of** a zero block, not below it. The ordering is a normalization, and it is the one the commutant property below is proved with: there the block $\mathbf{W}_{j,j+1}$ is canceled on the left, which uses that its columns are the **first** w_{j+1} standard basis vectors, in order. Concretely, every matrix commuting with $\mathbf{W}$ turns out to be upper triangular, while the commutant of $\mathbf{W}'$ contains the matrix unit $\mathbf{E}_{21}$.

The existence and uniqueness of the form are now a repackaging of Section 3.

Theorem 9.4.5 — Weyr Form

Let V be a finite-dimensional vector space over F with $\dim V = n \geq 1$, and let $T \in \mathcal{L}(V)$.

(a) **(Existence)** T has a Weyr form if and only if p_T splits over F. One can be arranged with one basic Weyr block per eigenvalue.

(b) **(Uniqueness)** In any Weyr form of T with one basic block per eigenvalue, the block for λ has Weyr structure

$$w_j = \dim\ker(T - \lambda\,\mathrm{id}_V)^j - \dim\ker(T - \lambda\,\mathrm{id}_V)^{j-1} \qquad (j \geq 1),$$

the non-zero terms of this sequence; equivalently $(w_1, w_2, \dots)$ is the **dual partition** of the partition formed by the sizes of the λ-blocks of the Jordan form of T. So the Weyr form is determined by T up to the order of its basic blocks.

Idea. Both parts come from one observation: a Weyr basis is a Jordan basis in a different order. Arrange the λ-chains of a Jordan basis as the rows of the Young diagram, sorted by decreasing length, and read the diagram **column by column**. The operator $T-\lambda$ id moves each box one step to the left, so it carries the j-th column into the $(j-1)$-th, matching the i-th box of one with the i-th box of the other — which is exactly the block $\begin{pmatrix}\mathbf{I}\\0\end{pmatrix}$. For uniqueness, count the boxes: the first j columns of the diagram are a basis of $\ker(T-\lambda\ \mathrm{id})^j$, so the column lengths are the jumps of the kernel chain.

Proof. ($\Rightarrow$) A Weyr matrix is upper triangular, so if T has a Weyr form then T is triangularizable and p_T splits (Definition 8.7.1, Theorem 8.7.2).

($\Leftarrow$) Suppose p_T splits, and let λ be an eigenvalue. By Theorem 9.3.1 there is a Jordan basis; fix its part inside $G_\lambda(T)$, a concatenation of Jordan chains of $N = T - \lambda\,\mathrm{id}_V$ of lengths $k_1 \geq k_2 \geq \cdots \geq k_r \geq 1$ summing to $a(\lambda)$ (Theorem 9.2.3, after reindexing so that the lengths decrease). Write $\mathbf{b}_{i,1}, \dots, \mathbf{b}_{i,k_i}$ for the i-th chain in the order of Definition 9.2.2, so that

$$N\mathbf{b}_{i,1} = \mathbf{0}, \qquad N\mathbf{b}_{i,j} = \mathbf{b}_{i,j-1} \quad (2 \leq j \leq k_i).$$

Put $s = k_1$ and, for $1 \leq j \leq s$, let $w_j = \#\{\, i : k_i \geq j \,\}$, the length of the j-th column of the Young diagram; then $w_1 \geq \cdots \geq w_s \geq 1$ is the dual partition of $(k_1, \dots, k_r)$ (Definition 9.2.3), a partition of $a(\lambda)$. Because the k_i decrease, $\{\, i : k_i \geq j \,\} = \{1, 2, \dots, w_j\}$. Let

$$\mathcal{C}_j = \left(\mathbf{b}_{1,j}, \mathbf{b}_{2,j}, \dots, \mathbf{b}_{w_j,j}\right)$$

be the j-th column, and let $\mathcal{B}_\lambda$ be the list $\mathcal{C}_1, \mathcal{C}_2, \dots, \mathcal{C}_s$ written one after another: a reordering of the chosen basis of $G_\lambda(T)$, hence a basis of it.

Read the columns of $[T|_{G_\lambda}]_{\mathcal{B}_\lambda}$. For $j = 1$, $T\mathbf{b}_{i,1} = \lambda\mathbf{b}_{i,1}$. For $j \geq 2$, $T\mathbf{b}_{i,j} = \lambda\mathbf{b}_{i,j} + \mathbf{b}_{i,j-1}$, and $\mathbf{b}_{i,j-1}$ is the i-th entry of $\mathcal{C}_{j-1}$, which exists because $i \leq w_j \leq w_{j-1}$. In the block partition of $\mathcal{B}_\lambda$ by the groups $\mathcal{C}_1, \dots, \mathcal{C}_s$, this says: the (j,j) block is $\lambda\mathbf{I}_{w_j}$; the $(j-1, j)$ block sends the i-th basis vector of group j to the i-th of group $j-1$ for $i = 1, \dots, w_j$, so it is $\begin{pmatrix}\mathbf{I}_{w_j}\\0\end{pmatrix}$; and every other block is 0. That is the basic Weyr matrix with eigenvalue λ and

structure $(w_1, \dots, w_s)$ (Definition 9.4.2). Writing the lists $\mathcal{B}_\lambda$ for the distinct eigenvalues one after another and using $V = \bigoplus_\lambda G_\lambda(T)$ (Theorem 9.1.3) with Theorem 8.1.5, the resulting basis $\mathcal{B}$ makes $[T]_\mathcal{B}$ a direct sum of basic Weyr matrices, one per eigenvalue.

(b) Let $\mathbf{W}$ be a Weyr form of T with one basic block per eigenvalue, and fix λ with basic block of structure $(w_1, \dots, w_s)$ and size m. Let $\mathcal{B}$ be a basis with $[T]_\mathcal{B} = \mathbf{W}$, and name the basis vectors inside the λ-block $\mathbf{c}_{i,j}$, where j indexes the groups and $i = 1, \dots, w_j$ the entries within a group. The blocks of Definition 9.4.2 say precisely that

$$N\mathbf{c}_{i,1} = \mathbf{0}, \qquad N\mathbf{c}_{i,j} = \mathbf{c}_{i,j-1} \quad (j \geq 2), \qquad N = T - \lambda \operatorname{id}_V,$$

while on the span V' of the basis vectors belonging to the other basic blocks the operator N is invertible: V' is T-invariant and the matrix of $N|_{V'}$ is $\mathbf{W}' - \lambda\mathbf{I}$, where $\mathbf{W}'$ is a direct sum of basic Weyr matrices with eigenvalues $\mu \neq \lambda$, hence upper triangular with all diagonal entries $\mu - \lambda \neq 0$, so of non-zero determinant (Theorem 6.4.6, Theorem 6.5.2). Hence N^j kills $\mathbf{c}_{i,l}$ for $l \leq j$ and sends $\mathbf{c}_{i,l} \mapsto \mathbf{c}_{i,l-j}$ for $l > j$. Write $V = U \oplus V'$ with $U = \operatorname{span}(\mathbf{c}_{i,l})$; both summands are N-invariant, so $\ker N^j = (\ker N^j \cap U) \oplus (\ker N^j \cap V')$, and the second summand is $\{\mathbf{0}\}$ because $N^j|_{V'}$ is invertible. Inside U the displayed action gives

$$\ker N^j = \operatorname{span}\big(\mathbf{c}_{i,l} : l \leq j\big), \qquad \dim \ker N^j = w_1 + \cdots + w_j$$

for $0 \leq j \leq s$, the spanning vectors being members of the basis $\mathcal{B}$ and hence independent; and $\ker N^j = \ker N^s$ for $j \geq s$. Subtracting consecutive values gives $w_j = \dim \ker N^j - \dim \ker N^{j-1}$ as claimed, a number depending only on T and λ. By Corollary 9.3.2 (d) this is also $\#\{i : k_i \geq j\}$ for the λ-block sizes k_i of the Jordan form, that is, the dual partition. Since the structures are determined, so is $\mathbf{W}$ up to the order in which its basic blocks are listed.

■

Existence and uniqueness are thus free; what makes the form worth the trouble is the next property. Here $\mathbf{K} \in M_n(F)$ is called **block upper triangular** for a partition $n = n_1 + \cdots + n_s$, taken as both the row and the column partition (Definition 7.1.1), when every block $\mathbf{K}_{pq}$ with $p > q$ is zero; for $s = 2$ this is the shape of Chapter 7.

Proposition 9.4.6 — The Commutant of a Basic Weyr Matrix Is Block Triangular

Let $\mathbf{W} \in M_m(F)$ be a basic Weyr matrix with eigenvalue λ and Weyr structure $(w_1, \dots, w_s)$, and let $\mathbf{K} \in M_m(F)$ satisfy $\mathbf{WK} = \mathbf{KW}$. Then $\mathbf{K}$ is block upper triangular for the partition $m = w_1 + \cdots + w_s$: its blocks $\mathbf{K}_{pq}$ vanish for $p > q$.

Idea. Write both products blockwise. Because $\mathbf{W}$ has only one non-zero block in each block row, each block equation is short: $\mathbf{E}_p\mathbf{K}_{p+1,q} = \mathbf{K}_{p,q-1}\mathbf{E}_{q-1}$, where $\mathbf{E}_j = \begin{pmatrix} \mathbf{I}_{w_{j+1}} \\ 0 \end{pmatrix}$. Every $\mathbf{E}_j$ has full column rank, so it can be canceled on the left. Now sweep the block columns from left to right: the first block column forces $\mathbf{K}_{p1} = 0$ for $p > 1$, and each new column is forced by the previous one.

Proof. Put $\mathbf{N} = \mathbf{W} - \lambda \mathbf{I}_m$ and $\mathbf{E}_j = \begin{pmatrix} \mathbf{I}_{w_{j+1}} \\ 0 \end{pmatrix} \in M_{w_j \times w_{j+1}}(F)$ for $1 \le j \le s-1$, so that $\mathbf{N}$ has blocks $\mathbf{N}_{j,j+1} = \mathbf{E}_j$ and all other blocks zero (Definition 9.4.2). Since $\lambda \mathbf{I}_m$ commutes with everything, $\mathbf{WK} = \mathbf{KW}$ is equivalent to $\mathbf{NK} = \mathbf{KN}$. Comparing the (p,q) blocks with Theorem 7.1.1, and reading an undefined symbol as 0,

$$\mathbf{E}_p \, \mathbf{K}_{p+1,q} = (\mathbf{NK})_{pq} = (\mathbf{KN})_{pq} = \mathbf{K}_{p,q-1} \, \mathbf{E}_{q-1} \qquad \text{for all } 1 \le p, q \le s. \tag{$*$}$$

Each $\mathbf{E}_j$ is injective as a map $F^{w_{j+1}} \to F^{w_j}$, so $\mathbf{E}_j \mathbf{X} = 0$ forces $\mathbf{X} = 0$ for every matrix $\mathbf{X}$ with w_{j+1} rows.

We prove $\mathbf{K}_{pq} = 0$ for $p > q$ by induction on $q \ge 1$.

Case $q = 1$. Let $p > 1$. Taking the indices $(p-1, 1)$ in $(*)$, the right-hand side involves $\mathbf{K}_{p-1,0}$, which is undefined and therefore read as 0. So $\mathbf{E}_{p-1}\mathbf{K}_{p,1} = 0$, and $p - 1 \le s - 1$ makes $\mathbf{E}_{p-1}$ one of the listed blocks; injectivity gives $\mathbf{K}_{p,1} = 0$.

Induction step. Let $q \ge 2$ and assume $\mathbf{K}_{p'q'} = 0$ whenever $p' > q'$ and $q' < q$. Let $p > q$. Taking the indices $(p-1, q)$ in $(*)$,

$$\mathbf{E}_{p-1}\mathbf{K}_{pq} = \mathbf{K}_{p-1,q-1}\mathbf{E}_{q-1}.$$

Here $p - 1 > q - 1$ and $q - 1 < q$, so $\mathbf{K}_{p-1,q-1} = 0$ by the induction hypothesis, and the right-hand side is 0. Again $1 \le p - 1 \le s - 1$, so injectivity of $\mathbf{E}_{p-1}$ gives $\mathbf{K}_{pq} = 0$. This completes the induction and the proof.

■

Remark. The Jordan form has no such property, which is the reason the Weyr form exists at all. Take $\mathbf{J} = \mathbf{J}_2(0) \oplus \mathbf{J}_1(0)$ and $\mathbf{W}$ the Weyr matrix of the same operator, of structure $(2, 1)$:

$$\mathbf{J} = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \qquad \mathbf{W} = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}.$$

Solving $\mathbf{JK} = \mathbf{KJ}$ entry by entry gives the commutant $\left\{ \begin{pmatrix} a & b & c \\ 0 & a & 0 \\ 0 & h & i \end{pmatrix} \right\}$, which contains matrices with a non-zero entry **below** the diagonal, in position $(3, 2)$: the commutant of $\mathbf{J}$ is not contained in the upper triangular matrices, and in particular it is not block upper triangular for the Weyr partition $3 = 2 + 1$ of this operator. Solving $\mathbf{WK} = \mathbf{KW}$ gives $\left\{ \begin{pmatrix} a & b & c \\ 0 & e & f \\ 0 & 0 & a \end{pmatrix} \right\}$, every member of which is upper triangular, in agreement with Proposition 9.4.6. This is the property that makes the Weyr form the right one when two commuting operators must be brought to normal form at the same time.

Quick check. An operator T on a 7-dimensional complex space has one eigenvalue λ, with Jordan block sizes $(3, 2, 1, 1)$. What is the Weyr structure of its Weyr form, and what is $\dim \ker (T - \lambda \, \mathrm{id})^2$?

Solution. The Weyr structure is the dual partition: $w_1 = \#\{i : k_i \geq 1\} = 4$, $w_2 = \#\{i : k_i \geq 2\} = 2$, $w_3 = \#\{i : k_i \geq 3\} = 1$, so $(4, 2, 1)$, a partition of 7 as it must be. By Theorem 9.4.5 (b), $\dim \ker(T - \lambda \operatorname{id})^2 = w_1 + w_2 = 6$. (Equivalently, $\sum_i \min(k_i, 2) = 2 + 2 + 1 + 1 = 6$, by Corollary 9.3.2 (d).)

9.4.4 Exercises

9.4.4.1 A. Check your understanding

Exercise A1.

(a) Write down $\mathbf{\Lambda}(\lambda)$ for $\lambda = a + bi$ and $\mathbf{C}_2(\lambda)$, and say what their sizes are.

(b) State the Real Jordan Form Theorem.

(c) True or false: every matrix in $M_n(\mathbb{R})$ is similar over $\mathbb{R}$ to an upper triangular real matrix. Justify your answer.

(d) Let $\mathbf{A} \in M_6(\mathbb{R})$ have complex eigenvalues $2, 2, 1 + i, 1 - i, 1 + i, 1 - i$. What are the possible real Jordan forms?

(e) Define the Weyr structure of an eigenvalue and say how it is computed from T.

(f) What is the Weyr form of $\mathbf{J}_3(7)$? And of $7\mathbf{I}_3$?

Solution.

(a) $\mathbf{\Lambda}(\lambda) = \begin{pmatrix} a & -b \\ b & a \end{pmatrix} \in M_2(\mathbb{R})$ and $\mathbf{C}_2(\lambda) = \begin{pmatrix} \mathbf{\Lambda}(\lambda) & \mathbf{I}_2 \\ 0 & \mathbf{\Lambda}(\lambda) \end{pmatrix} \in M_4(\mathbb{R})$; the real Jordan block $\mathbf{C}_k(\lambda)$ has size $2k$ (Definition 9.4.1).

(b) Every $\mathbf{A} \in M_n(\mathbb{R})$ is similar, by a **real** invertible matrix, to a direct sum of blocks $\mathbf{J}_k(\mu)$ for the real eigenvalues μ and $\mathbf{C}_k(\lambda)$ for the conjugate pairs $\{\lambda, \overline{\lambda}\}$, and that matrix is unique up to the order of the blocks (Theorem 9.4.4).

(c) False. A triangular real matrix has real eigenvalues (Theorem 8.7.4), and similar matrices have the same characteristic polynomial (Theorem 6.10.3); so a real matrix with a non-real eigenvalue, such as the rotation by a right angle, is similar to no real triangular matrix.

(d) The real eigenvalue 2 has $a(2) = 2$, so its blocks are $\mathbf{J}_2(2)$ or $\mathbf{J}_1(2) \oplus \mathbf{J}_1(2)$. The pair $\{1 \pm i\}$ has $a(1+i) = 2$, so its real blocks are $\mathbf{C}_2(1+i)$ (size 4) or $\mathbf{C}_1(1+i) \oplus \mathbf{C}_1(1+i)$. That gives four possible real Jordan forms, of total size $2 + 4 = 6$ in each case.

(e) The Weyr structure of λ is the partition $(w_1, w_2, \dots)$ with $w_j = \dim \ker(T - \lambda \operatorname{id}_V)^j - \dim \ker(T - \lambda \operatorname{id}_V)^{j-1}$, that is, the dual partition of the λ-block sizes of the Jordan form (Theorem 9.4.5).

(f) $\mathbf{J}_3(7)$ has one 7-block of size 3, so the Weyr structure is $(1, 1, 1)$ and the Weyr form is $\mathbf{J}_3(7)$ itself. For $7\mathbf{I}_3$ the block sizes are $(1, 1, 1)$, the dual partition is (3), and the Weyr form is $7\mathbf{I}_3$.

9.4.4.2 B. Practice

Exercise B1: Real forms of two by two matrices.

For each real matrix, find the complex eigenvalues, the real Jordan form (Theorem 9.4.4), and an invertible $\mathbf{P} \in M_2(\mathbb{R})$ putting it in that form. Verify $\mathbf{AP} = \mathbf{P\Lambda}$ column by column.

(a) $\mathbf{A}_1 = \begin{pmatrix} 1 & 2 \\ -2 & 1 \end{pmatrix}$.

(b) $\mathbf{A}_2 = \begin{pmatrix} 3 & -5 \\ 1 & -1 \end{pmatrix}$.

Solution.

(a) $p_{\mathbf{A}_1} = x^2 - (\operatorname{tr}\mathbf{A}_1)x + \det\mathbf{A}_1 = x^2 - 2x + 5 = (x-1)^2 + 4$, so the eigenvalues are $1 \pm 2i$ and the real Jordan form is $\mathbf{\Lambda}(1+2i) = \begin{pmatrix} 1 & -2 \\ 2 & 1 \end{pmatrix}$. For $\lambda = 1+2i$, $\mathbf{A}_1 - \lambda\mathbf{I} = \begin{pmatrix} -2i & 2 \\ -2 & -2i \end{pmatrix}$, and the first row gives $z_2 = iz_1$; take $\mathbf{w} = (1, i)$. Then $\mathbf{w} = \mathbf{u} - i\mathbf{v}$ with $\mathbf{u} = (1, 0)$ and $\mathbf{v} = (0, -1)$, so

$$\mathbf{P} = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}, \qquad \mathbf{P}^{-1}\mathbf{A}_1\mathbf{P} = \begin{pmatrix} 1 & -2 \\ 2 & 1 \end{pmatrix}.$$

Check: $\mathbf{A}_1\mathbf{u} = (1, -2) = \mathbf{u} + 2\mathbf{v}$ and $\mathbf{A}_1\mathbf{v} = (-2, -1) = -2\mathbf{u} + \mathbf{v}$, which are the two columns of $\mathbf{\Lambda}(1+2i)$ as Lemma 9.4.1 (a) predicts with $a = 1, b = 2$.

(b) $p_{\mathbf{A}_2} = x^2 - 2x + (-3+5) = x^2 - 2x + 2$, with roots $1 \pm i$; the real Jordan form is $\mathbf{\Lambda}(1+i) = \begin{pmatrix} 1 & -1 \\ 1 & 1 \end{pmatrix}$. For $\lambda = 1+i$, the second row of $\mathbf{A}_2 - \lambda\mathbf{I} = \begin{pmatrix} 2-i & -5 \\ 1 & -2-i \end{pmatrix}$ gives $z_1 = (2+i)z_2$; take $\mathbf{w} = (2+i, 1)$. Then $\mathbf{u} = (2, 1)$ and $\mathbf{v} = -\operatorname{Im}\mathbf{w} = (-1, 0)$, so

$$\mathbf{P} = \begin{pmatrix} 2 & -1 \\ 1 & 0 \end{pmatrix}, \qquad \det\mathbf{P} = 1, \qquad \mathbf{P}^{-1}\mathbf{A}_2\mathbf{P} = \begin{pmatrix} 1 & -1 \\ 1 & 1 \end{pmatrix}.$$

Check: $\mathbf{A}_2\mathbf{u} = (6-5, 2-1) = (1, 1) = \mathbf{u} + \mathbf{v}$ and $\mathbf{A}_2\mathbf{v} = (-3, -1) = -\mathbf{u} + \mathbf{v}$.

Exercise B2: Weyr forms of Jordan matrices.

For each Jordan matrix, write down the block sizes, the Weyr structure of each eigenvalue, and the Weyr form (Theorem 9.4.5).

(a) $\mathbf{J}_3(0) \oplus \mathbf{J}_2(0) \oplus \mathbf{J}_1(0) \in M_6(F)$.

(b) $\mathbf{J}_2(4) \oplus \mathbf{J}_1(4) \oplus \mathbf{J}_1(9) \in M_4(F)$.

(c) $\mathbf{J}_2(0) \oplus \mathbf{J}_2(0) \in M_4(F)$.

Solution.

(a) Block sizes $(3, 2, 1)$, a partition of 6. Dual partition: $w_1 = 3$, $w_2 = 2$, $w_3 = 1$. So

the Weyr form is the basic Weyr matrix with $\lambda = 0$ and structure $(3, 2, 1)$,

$$\mathbf{W} = \begin{pmatrix} 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{pmatrix},$$

with the 3×2 block $\begin{pmatrix} \mathbf{I}_2 \\ 0 \end{pmatrix}$ and the 2×1 block $\begin{pmatrix} \mathbf{I}_1 \\ 0 \end{pmatrix}$ above the diagonal. As a check, $\operatorname{rank} \mathbf{W} = 3 = \operatorname{rank} \mathbf{J}$ and $\operatorname{rank} \mathbf{W}^2 = 1 = \operatorname{rank} \mathbf{J}^2$.

(b) For $\lambda = 4$: sizes $(2, 1)$, dual $(2, 1)$. For $\lambda = 9$: sizes (1), dual (1). The Weyr form is the direct sum of the basic blocks,

$$\begin{pmatrix} 4 & 0 & 1 \\ 0 & 4 & 0 \\ 0 & 0 & 4 \end{pmatrix} \oplus (9).$$

(c) Sizes $(2, 2)$, dual $w_1 = 2$, $w_2 = 2$. The basic Weyr matrix with $\lambda = 0$ and structure $(2, 2)$ is

$$\mathbf{W} = \begin{pmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix},$$

which is $\mathbf{J}_2(0) \oplus \mathbf{J}_2(0)$ with its basis reordered as $(\mathbf{e}_1, \mathbf{e}_3, \mathbf{e}_2, \mathbf{e}_4)$.

Exercise B3: Real forms of three by three matrices from the characteristic polynomial.

For each characteristic polynomial, list all possible real Jordan forms (Theorem 9.4.4) of a matrix $\mathbf{A} \in M_3(\mathbb{R})$ with that polynomial.

(a) $p_{\mathbf{A}} = (x - 2)(x^2 + 1)$.
(b) $p_{\mathbf{A}} = (x + 1)(x^2 - 2x + 5)$.
(c) $p_{\mathbf{A}} = (x - 1)^3$.
(d) $p_{\mathbf{A}} = (x^2 + 1)(x - 1)$ but with $\mathbf{A}$ required to be diagonalizable over $\mathbb{R}$. Is this possible?

Solution.

(a) The real eigenvalue 2 has $a(2) = 1$, giving the block $\mathbf{J}_1(2) = (2)$. The pair $\{i, -i\}$ has $a(i) = 1$, giving $\mathbf{C}_1(i) = \mathbf{\Lambda}(i) = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$. So the real Jordan form is $(2) \oplus \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$, the only possibility.

(b) $x^2 - 2x + 5$ has roots $1 \pm 2i$, so the form is $(-1) \oplus \mathbf{\Lambda}(1 + 2i) = (-1) \oplus \begin{pmatrix} 1 & -2 \\ 2 & 1 \end{pmatrix}$, again the only possibility.

(c) All eigenvalues are real, so the real Jordan form is an ordinary Jordan form: the 1-block sizes form a partition of 3, giving $\mathbf{J}_3(1)$, $\mathbf{J}_2(1) \oplus \mathbf{J}_1(1)$ or $\mathbf{I}_3$.

(d) No. A diagonalizable $\mathbf{A} \in M_3(\mathbb{R})$ is similar over $\mathbb{R}$ to a diagonal real matrix, whose characteristic polynomial splits over $\mathbb{R}$ (Theorem 6.4.6); but x^2+1 has no real root. In fact whenever $\mathbf{A}$ has a non-real eigenvalue its real Jordan form contains a block $\mathbf{\Lambda}(\lambda)$, which is not diagonal.

9.4.4.3 C. Going deeper

Exercise C1: The real form of a companion matrix.

Let $p = (x^2+1)^2 = x^4 + 2x^2 + 1 \in \mathbb{R}[x]$ and let $\mathbf{C} = \mathbf{C}(p) \in M_4(\mathbb{R})$ be its companion matrix, with 1 in each position just below the diagonal and last column $(-1, 0, -2, 0)$ (Exercise (C1: Companion matrices)).

(a) Write down $\mathbf{C}$, and explain why $p_\mathbf{C} = m_\mathbf{C} = p$.

(b) Determine the complex Jordan form of $\mathbf{C}$.

(c) Deduce the real Jordan form of $\mathbf{C}$.

(d) Verify your answer by comparing traces and characteristic polynomials.

Hint: for (b), the exponent of $x - i$ in $m_\mathbf{C}$ is the largest size of an i-block.

Solution.

(a) With $a_0 = 1$, $a_1 = 0$, $a_2 = 2$, $a_3 = 0$,

$$\mathbf{C} = \begin{pmatrix} 0 & 0 & 0 & -1 \\ 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & -2 \\ 0 & 0 & 1 & 0 \end{pmatrix}.$$

By Exercise (C1: Companion matrices) (b), $p_\mathbf{C} = p$, and by Exercise (B3: Companion matrices) (d), $m_\mathbf{C} = p$ as well.

(b) Over $\mathbb{C}$, $p = (x-i)^2(x+i)^2$, so $a(i) = a(-i) = 2$. By Corollary 9.3.2 (c), the exponent 2 of $x-i$ in $m_\mathbf{C}$ is the largest size of an i-block; the sizes form a partition of 2 with largest part 2, so there is one block $\mathbf{J}_2(i)$. Likewise one block $\mathbf{J}_2(-i)$. The complex Jordan form is $\mathbf{J}_2(i) \oplus \mathbf{J}_2(-i)$.

(c) By Theorem 9.4.4, the real Jordan form has no ordinary Jordan blocks (there is no real eigenvalue) and one real block per complex i-block, of the same size parameter. So it is

$$\mathbf{C}_2(i) = \begin{pmatrix} 0 & -1 & 1 & 0 \\ 1 & 0 & 0 & 1 \\ 0 & 0 & 0 & -1 \\ 0 & 0 & 1 & 0 \end{pmatrix}.$$

(Consistently, Corollary 9.4.2 turns $\mathbf{C}_2(i)$ back into $\mathbf{J}_2(i) \oplus \mathbf{J}_2(-i)$ over $\mathbb{C}$.)

(d) $\operatorname{tr}\mathbf{C} = 0 = \operatorname{tr}\mathbf{C}_2(i)$, and both matrices have characteristic polynomial $(x^2+1)^2$: for $\mathbf{C}$ by (a), and for $\mathbf{C}_2(i)$ by Corollary 9.4.2. Their minimal polynomials agree too, both being $(x^2+1)^2$.

Exercise C2: Commuting with a Weyr matrix, and with a Jordan matrix.

Let F be a field.

(a) Let $\mathbf{W} \in M_3(F)$ be the basic Weyr matrix with $\lambda = 0$ and structure $(2,1)$ (Definition 9.4.2). Find all $\mathbf{K} \in M_3(F)$ with $\mathbf{WK} = \mathbf{KW}$, and check that they are block upper triangular for the partition $3 = 2 + 1$.

(b) Let $\mathbf{J} = \mathbf{J}_2(0) \oplus \mathbf{J}_1(0)$. Find all $\mathbf{K} \in M_3(F)$ with $\mathbf{JK} = \mathbf{KJ}$, and exhibit one that is **not** upper triangular. Which partition of 3 does it violate?

(c) Compute the dimension of each of the two commutants, and explain why they are equal.

Solution.

(a) $\mathbf{W} = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}$. Write $\mathbf{K} = (k_{ij})$. Then $\mathbf{WK}$ has first row equal to the third row of $\mathbf{K}$ and other rows zero, while $\mathbf{KW}$ has third column equal to the first column of $\mathbf{K}$ and other columns zero. Equating,

$$(k_{31}, k_{32}, k_{33}) = (0, 0, k_{11}), \qquad k_{21} = k_{31} = 0.$$

So the commutant is

$$\left\{ \begin{pmatrix} a & b & c \\ 0 & e & f \\ 0 & 0 & a \end{pmatrix} : a, b, c, e, f \in F \right\},$$

of dimension 5. The lower-left 1×2 block is $(k_{31}, k_{32}) = (0, 0)$, so every such $\mathbf{K}$ is block upper triangular for $3 = 2 + 1$, as Proposition 9.4.6 asserts.

(b) $\mathbf{J} = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}$. Now $\mathbf{JK}$ has first row equal to the second row of $\mathbf{K}$ and other rows zero, while $\mathbf{KJ}$ has second column equal to the first column of $\mathbf{K}$ and other columns zero. Equating gives $k_{21} = 0$, $k_{22} = k_{11}$, $k_{23} = 0$ and $k_{31} = 0$, so the commutant is

$$\left\{ \begin{pmatrix} a & b & c \\ 0 & a & 0 \\ 0 & h & i \end{pmatrix} \right\},$$

also of dimension 5. Take $\mathbf{K}_0 = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix}$, which commutes with $\mathbf{J}$ (it is the case $a = b = c = i = 0$, $h = 1$). Its only non-zero entry sits in position $(3, 2)$, below the diagonal, so $\mathbf{K}_0$ is not upper triangular. The partition it violates is $3 = 2 + 1$, the Weyr partition of this operator: the lower-left 1×2 block of $\mathbf{K}_0$ is $(0, 1) \neq \mathbf{0}$. So the conclusion of Proposition 9.4.6 genuinely fails for the Jordan form, while (a) confirms it for the Weyr form (Theorem 9.4.5) of the same operator.

(c) Both have dimension 5. They must agree, because $\mathbf{J}$ and $\mathbf{W}$ are similar (both are nilpotent with rank $= 1$ and rank$^2 = 0$, so Corollary 9.2.5 applies): if $\mathbf{W} = \mathbf{P}^{-1}\mathbf{JP}$, then $\mathbf{K} \mapsto \mathbf{P}^{-1}\mathbf{KP}$ is a bijection from the commutant of $\mathbf{J}$ to that of $\mathbf{W}$, and it is linear and invertible, hence preserves dimension.

9.5 Cyclic Subspaces and Companion Matrices

The Jordan form of Section 3 exists only when the characteristic polynomial splits, because its building block $\mathbf{J}_k(\lambda)$ needs an eigenvalue λ in F. To build a normal form over **every** field we need a block that does not name a scalar. Look again at what a Jordan block really is: reading its columns, $\mathbf{J}_k(\lambda)$ is the matrix of T on the span of $\mathbf{u}, T\mathbf{u}, \dots, T^{k-1}\mathbf{u}$ for the top $\mathbf{u}$ of a chain. That description — *one vector and everything T can make of it* — mentions no eigenvalue at all. This section studies those subspaces, computes their dimension and their matrix, and decides when a single vector generates the whole space.

9.5.1 The subspace generated by one vector

Chapter 8 called a subspace U **invariant** when $T\mathbf{u} \in U$ for every $\mathbf{u} \in U$ (Definition 8.1.1). Given one vector $\mathbf{v}$, what is the smallest invariant subspace containing it? It must contain $\mathbf{v}$, hence $T\mathbf{v}$, hence $T^2\mathbf{v}$, and so on, hence every linear combination of these. That list is already closed under T, so nothing more is forced. So the answer is a span, and it deserves a name.

The cyclic subspace generated by a vector is everything that can be reached from it by applying the operator and taking combinations.

Definition 9.5.1 — Cyclic Subspace

Let V be a vector space over F, let $T \in \mathcal{L}(V)$ and let $\mathbf{v} \in V$. The **cyclic subspace generated by $\mathbf{v}$** is

$$Z(\mathbf{v}; T) \coloneqq \operatorname{span}\left(\mathbf{v},\ T\mathbf{v},\ T^2\mathbf{v},\ \dots\right) = \operatorname{span}\left(\{\, T^j\mathbf{v} : j \geq 0 \,\}\right),$$

where $T^0 = \mathrm{id}_V$. For $\mathbf{A} \in M_n(F)$ we write $Z(\mathbf{v}; \mathbf{A}) = Z(\mathbf{v}; T_{\mathbf{A}})$.

In words: we apply T to $\mathbf{v}$ over and over, collect all the vectors obtained, and take their span — so $Z(\mathbf{v}; T)$ is a subspace by Theorem 1.3.1, whatever $\mathbf{v}$ is. The spanning list may be infinite, but we shall see in a moment that in finite dimension its first few entries already suffice. Note $Z(\mathbf{0}; T) = \operatorname{span}(\emptyset) = \{\mathbf{0}\}$ and $\mathbf{v} \in Z(\mathbf{v}; T)$.

Proposition 9.5.1 — The Cyclic Subspace Is the Smallest Invariant Subspace Containing the Vector

Let V be a vector space over F, $T \in \mathcal{L}(V)$ and $\mathbf{v} \in V$. Then:

(a) $Z(\mathbf{v}; T) = \{\, p(T)\mathbf{v} : p \in F[x] \,\}$;
(b) $Z(\mathbf{v}; T)$ is T-invariant;
(c) if U is a T-invariant subspace of V with $\mathbf{v} \in U$, then $Z(\mathbf{v}; T) \subseteq U$.

Proof.

(a) A linear combination of the vectors $T^j\mathbf{v}$ is $\sum_j a_j T^j\mathbf{v} = p(T)\mathbf{v}$ with $p = \sum_j a_j x^j$, and conversely (Definition 3.4.2). By Definition 1.3.2, these combinations are exactly the elements of $Z(\mathbf{v};T)$.

(b) For $p \in F[x]$, $T\big(p(T)\mathbf{v}\big) = (xp)(T)\mathbf{v} \in Z(\mathbf{v};T)$ by Theorem 5.7.1 (b) and (a). (Or: T maps each spanning vector $T^j\mathbf{v}$ to $T^{j+1}\mathbf{v} \in Z(\mathbf{v};T)$, so Lemma 8.1.1 applies.)

(c) Let U be invariant with $\mathbf{v} \in U$. By induction on j, $T^j\mathbf{v} \in U$: this holds for $j = 0$, and if $T^j\mathbf{v} \in U$, then $T^{j+1}\mathbf{v} = T(T^j\mathbf{v}) \in U$ by invariance. So U contains the spanning list of $Z(\mathbf{v};T)$, and hence its span (Theorem 1.3.1, Proposition 1.3.4).

■

Examples. Throughout, V is finite-dimensional over F.

- **An eigenvector generates a line.** If $T\mathbf{v} = \lambda\mathbf{v}$ with $\mathbf{v} \neq \mathbf{0}$, then $T^j\mathbf{v} = \lambda^j\mathbf{v}$, so $Z(\mathbf{v};T) = \operatorname{span}(\mathbf{v})$, of dimension 1. The smallest invariant subspace containing an eigenvector is its own line (Proposition 8.1.2).
- **The top of a Jordan chain generates the block.** Let T have matrix $\mathbf{J}_k(\lambda)$ in the basis $\mathcal{B} = (\mathbf{b}_1, \dots, \mathbf{b}_k)$. Then $\mathbf{b}_k$ is the top of the chain (Definition 9.2.2), and $\mathbf{b}_{k-1} = (T - \lambda\,\mathrm{id}_V)\mathbf{b}_k = T\mathbf{b}_k - \lambda\mathbf{b}_k \in \operatorname{span}(\mathbf{b}_k, T\mathbf{b}_k)$; continuing downwards, every $\mathbf{b}_j$ lies in $\operatorname{span}(\mathbf{b}_k, T\mathbf{b}_k, \dots, T^{k-j}\mathbf{b}_k)$. So $Z(\mathbf{b}_k;T) = V$: a single Jordan block is one cyclic subspace.
- **Differentiation.** Let $D \in \mathcal{L}(\mathbb{R}[x]_{\leq 3})$ be differentiation. Then $Z(x^3;D) = \operatorname{span}(x^3, 3x^2, 6x, 6) = \mathbb{R}[x]_{\leq 3}$, everything; while $Z(x^2;D) = \operatorname{span}(x^2, 2x, 2) = \mathbb{R}[x]_{\leq 2}$, a proper subspace.
- **A companion matrix.** Let $\mathbf{A} \in M_n(F)$ have 1 in each position just below the diagonal, so that $\mathbf{A}\mathbf{e}_j = \mathbf{e}_{j+1}$ for $j \leq n-1$ (Exercise (C1: Companion matrices)). Then $\mathbf{A}^j\mathbf{e}_1 = \mathbf{e}_{j+1}$ for $j \leq n-1$, so $Z(\mathbf{e}_1;\mathbf{A})$ contains every standard basis vector and equals F^n.
- **The degenerate case.** $Z(\mathbf{0};T) = \{\mathbf{0}\}$, the smallest invariant subspace of all.

Non-example by minimal change. Truncate the spanning list: $\operatorname{span}(\mathbf{v}, T\mathbf{v})$ need **not** be invariant. For $\mathbf{A} = \begin{pmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix}$ and $\mathbf{v} = \mathbf{e}_1$ we get $\operatorname{span}(\mathbf{e}_1, \mathbf{A}\mathbf{e}_1) = \operatorname{span}(\mathbf{e}_1, \mathbf{e}_2)$, and $\mathbf{A}\mathbf{e}_2 = \mathbf{e}_3$ is outside it. What fails is closure: cutting the list short loses exactly the vectors that invariance demands. The correct statement is that the list may be cut short at the right place, which is the subject of the next subsection.

Warning. $Z(\mathbf{v};T)$ **depends on** T **as much as on** $\mathbf{v}$**, and the spanning list** $(\mathbf{v}, T\mathbf{v}, T^2\mathbf{v}, \dots)$ **is almost never independent.** For $\mathbf{v} = \mathbf{e}_1$ and $T = \mathrm{id}$ the list is $(\mathbf{e}_1, \mathbf{e}_1, \mathbf{e}_1, \dots)$ and the cyclic subspace is a line; for the same $\mathbf{v}$ and the companion matrix above it is all of F^3. In finite dimension the list must become dependent by step $\dim V$ at the latest (Theorem 1.6.3), and where it first does is the only thing that matters.

9.5.2 The annihilator of a vector

The examples suggest measuring $\mathbf{v}$ by the first dependence in the list $\mathbf{v}, T\mathbf{v}, T^2\mathbf{v}, \dots$. A dependence is a polynomial relation: $\sum_j a_j T^j\mathbf{v} = \mathbf{0}$ says that the polynomial $p = \sum_j a_j x^j$ kills $\mathbf{v}$, not necessarily all of V. Chapter 5 taught us what to do with such a set of polynomials.

The T-annihilator of $\mathbf{v}$ is the minimal polynomial of T as seen by the single vector $\mathbf{v}$.

Definition 9.5.2 — The T-Annihilator of a Vector

Let V be a **finite-dimensional** vector space over F, let $T \in \mathcal{L}(V)$ and let $\mathbf{v} \in V$. The set

$$I_{\mathbf{v}} := \{\, p \in F[x] : p(T)\mathbf{v} = \mathbf{0} \,\}$$

is a non-zero ideal of $F[x]$, and the **T-annihilator** of $\mathbf{v}$, written $m_{T,\mathbf{v}}$, is its unique **monic** generator:

$$I_{\mathbf{v}} = \langle m_{T,\mathbf{v}} \rangle.$$

Equivalently, $m_{T,\mathbf{v}}$ is the monic polynomial of **least degree** with $m_{T,\mathbf{v}}(T)\mathbf{v} = \mathbf{0}$. For $\mathbf{A} \in M_n(F)$ we write $m_{\mathbf{A},\mathbf{v}}$.

Well-definedness. Three checks. *Ideal:* if $p, q \in I_{\mathbf{v}}$, then $(p+q)(T)\mathbf{v} = p(T)\mathbf{v} + q(T)\mathbf{v} = \mathbf{0}$, and for any $h \in F[x]$, $(hp)(T)\mathbf{v} = h(T)\big(p(T)\mathbf{v}\big) = \mathbf{0}$, using Theorem 5.7.1 (a), (b); so $I_{\mathbf{v}}$ is an ideal (Definition 5.2.1). *Non-zero:* $m_T \in I_{\mathbf{v}}$, since $m_T(T) = 0$ as an operator (Definition 8.5.1), and $m_T \neq 0$. *Monic generator:* a non-zero ideal of $F[x]$ has exactly one monic generator, which is its non-zero element of least degree (Theorem 5.2.2). As with the minimal polynomial, the divisibility statement is the one we use:

$$p(T)\mathbf{v} = \mathbf{0} \iff m_{T,\mathbf{v}} \mid p. \tag{$*$}$$

In words: $m_{T,\mathbf{v}}$ records which polynomials in T kill this one vector. Two degenerate cases: $m_{T,\mathbf{0}} = 1$, because every polynomial kills $\mathbf{0}$; and if $\mathbf{v} \neq \mathbf{0}$, then $\deg m_{T,\mathbf{v}} \geq 1$, since the constant 1 does not kill $\mathbf{v}$. If $\mathbf{v}$ is an eigenvector for λ, then $m_{T,\mathbf{v}} = x - \lambda$.

Why this definition. The minimal polynomial m_T is the "annihilator of all of V at once": m_T kills every vector, so $m_{T,\mathbf{v}} \mid m_T$ for every $\mathbf{v}$ by $(*)$. The individual annihilators are finer, and they differ from vector to vector: for $\mathbf{J} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$ we have $m_{\mathbf{J},\mathbf{e}_1} = x - 1$ but $m_{\mathbf{J},\mathbf{e}_2} = (x-1)^2 = m_{\mathbf{J}}$. This spread is exactly what will let us split V into cyclic pieces in Section 6.

Now the payoff: the annihilator computes the dimension of the cyclic subspace, hands us a basis, and hands us the matrix.

Theorem 9.5.2 — Basis and Matrix of a Cyclic Subspace

Let V be a finite-dimensional vector space over F, let $T \in \mathcal{L}(V)$ and let $\mathbf{v} \in V$ with $\mathbf{v} \neq \mathbf{0}$. Write $Z = Z(\mathbf{v}; T)$ and

$$m_{T,\mathbf{v}} = x^k + a_{k-1}x^{k-1} + \cdots + a_1 x + a_0, \qquad k = \deg m_{T,\mathbf{v}} \geq 1.$$

Then:

(a) $\big(\mathbf{v},\ T\mathbf{v},\ \ldots,\ T^{k-1}\mathbf{v}\big)$ is a basis of Z; in particular $\dim Z = \deg m_{T,\mathbf{v}}$;

(b) $T^k\mathbf{v} = -\big(a_0\mathbf{v} + a_1 T\mathbf{v} + \cdots + a_{k-1}T^{k-1}\mathbf{v}\big)$, and the matrix of $T|_Z$ in the basis of (a) is the companion matrix of $m_{T,\mathbf{v}}$ (Exercise (C1: Companion matrices); the definition is repeated in full as Definition 9.5.3 below);

(c) $m_{T|_Z} = p_{T|_Z} = m_{T,\mathbf{v}}$;

(d) $m_{T,\mathbf{v}} \mid m_T$, and $\deg m_{T,\mathbf{v}} \leq \deg m_T \leq \dim V$.

Idea. For spanning, divide: any p is $q\,m_{T,\mathbf{v}} + r$ with $\deg r < k$, and the $q\,m_{T,\mathbf{v}}$ part dies on $\mathbf{v}$, so $p(T)\mathbf{v} = r(T)\mathbf{v}$ uses only the first k powers. For independence, a shorter dependence would be a non-zero polynomial of degree $< k$ in $I_{\mathbf{v}}$, and $m_{T,\mathbf{v}}$ has the least degree there. Part (b) is the definition of $m_{T,\mathbf{v}}$ rearranged, read as the last column of a matrix; (c) says that on Z the vector $\mathbf{v}$ already sees everything, so its annihilator is the minimal polynomial of the restriction, and a degree count makes it the characteristic polynomial too.

Proof.

(a) *Spanning.* Let $\mathbf{z} \in Z$, say $\mathbf{z} = p(T)\mathbf{v}$ with $p \in F[x]$ (Proposition 9.5.1 (a)). Divide by $m_{T,\mathbf{v}}$: there are $q, r \in F[x]$ with $p = q\,m_{T,\mathbf{v}} + r$ and $\deg r < k$ (Theorem 5.1.1). Then

$$\mathbf{z} = p(T)\mathbf{v} = q(T)\big(m_{T,\mathbf{v}}(T)\mathbf{v}\big) + r(T)\mathbf{v} = r(T)\mathbf{v},$$

by Theorem 5.7.1 (a), (b) and $m_{T,\mathbf{v}}(T)\mathbf{v} = \mathbf{0}$. As $\deg r < k$, the vector $r(T)\mathbf{v}$ is a combination of $\mathbf{v}, T\mathbf{v}, \dots, T^{k-1}\mathbf{v}$.
Independence. Suppose $c_0\mathbf{v} + c_1T\mathbf{v} + \cdots + c_{k-1}T^{k-1}\mathbf{v} = \mathbf{0}$ with the $c_j \in F$ not all zero. Then $q = \sum_{j<k} c_j x^j$ is a non-zero element of $I_{\mathbf{v}}$ of degree less than k, contradicting the fact that $m_{T,\mathbf{v}}$ has least degree among the non-zero elements of $I_{\mathbf{v}}$ (Theorem 5.2.2). So all $c_j = 0$.

(b) The identity $m_{T,\mathbf{v}}(T)\mathbf{v} = \mathbf{0}$ reads $T^k\mathbf{v} + a_{k-1}T^{k-1}\mathbf{v} + \cdots + a_0\mathbf{v} = \mathbf{0}$, which is the display. Write $\mathbf{z}_j = T^{j-1}\mathbf{v}$ for $j = 1, \dots, k$, the basis of (a). For $j \le k-1$, $T\mathbf{z}_j = T^j\mathbf{v} = \mathbf{z}_{j+1}$, so the j-th column of the matrix is $\mathbf{e}_{j+1}$; and $T\mathbf{z}_k = T^k\mathbf{v} = -a_0\mathbf{z}_1 - \cdots - a_{k-1}\mathbf{z}_k$, so the last column is $(-a_0, -a_1, \dots, -a_{k-1})$. That is exactly the companion matrix of $m_{T,\mathbf{v}}$ in the sense of Exercise (C1: Companion matrices), whose definition is recalled in full in the next subsection. For $k = 1$ the matrix is the 1×1 matrix $(-a_0)$.

(c) Let $p \in F[x]$. If $p(T)\mathbf{v} = \mathbf{0}$, then for every $q \in F[x]$,

$$p(T)\big(q(T)\mathbf{v}\big) = q(T)\big(p(T)\mathbf{v}\big) = \mathbf{0}$$

by Theorem 5.7.1 (c), so $p(T)$ kills all of Z by Proposition 9.5.1 (a), that is, $p(T|_Z) = 0$ (Exercise (C2: Minimal polynomials of the pieces) (a)). Conversely, if $p(T|_Z) = 0$, then in particular $p(T)\mathbf{v} = \mathbf{0}$, as $\mathbf{v} \in Z$. So the annihilating ideals of $\mathbf{v}$ and of $T|_Z$ coincide, and their monic generators agree: $m_{T|_Z} = m_{T,\mathbf{v}}$ (Definition 8.5.1, Theorem 5.2.2). Finally $m_{T|_Z} \mid p_{T|_Z}$ (Corollary 8.6.2), both are monic, and $\deg p_{T|_Z} = \dim Z = k = \deg m_{T|_Z}$ by (a) and Theorem 6.10.2; so they are equal (Proposition 5.1.2 (c), (d)).

(d) $m_T \in I_{\mathbf{v}}$ as noted after Definition 9.5.2, so $m_{T,\mathbf{v}} \mid m_T$ by $(*)$, and the degrees compare by Proposition 5.1.2 (c). And $\deg m_T \le \deg p_T = \dim V$ by Corollary 8.6.2 and Theorem 6.10.2.

■

Quick check. Let T be the operator on $\mathbb{Q}^2$ with matrix $\operatorname{diag}(2, 5)$, and let $\mathbf{v} = (1, 1)$. Find $m_{T,\mathbf{v}}$ and $Z(\mathbf{v}; T)$. Then do the same for $\mathbf{v} = \mathbf{e}_1$.

Solution. $(T - 2\,\mathrm{id})(T - 5\,\mathrm{id})\mathbf{v} = \mathbf{0}$, as one checks entry by entry, so $m_{T,\mathbf{v}} \mid (x-2)(x-5)$. Neither factor alone kills $\mathbf{v}$: $(T - 2\,\mathrm{id})\mathbf{v} = (0, 3) \neq \mathbf{0}$ and $(T - 5\,\mathrm{id})\mathbf{v} = (-3, 0) \neq \mathbf{0}$. So $m_{T,\mathbf{v}} = (x-2)(x-5)$, of degree 2, and $Z(\mathbf{v}; T) = \mathbb{Q}^2$ by Theorem 9.5.2 (a); the basis

it provides is $(\mathbf{v}, T\mathbf{v}) = \big((1,1),(2,5)\big)$. For $\mathbf{v} = \mathbf{e}_1$, an eigenvector, $m_{T,\mathbf{e}_1} = x - 2$ and $Z(\mathbf{e}_1; T) = \operatorname{span}(\mathbf{e}_1)$ is a line.

9.5.3 Companion matrices

The matrix in Theorem 9.5.2 (b) appeared in Chapter 6 as an exercise; it is the block we were looking for, and it deserves a definition of its own.

Definition 9.5.3 — Companion Matrix

Let $n \geq 1$ and let $p = x^n + a_{n-1}x^{n-1} + \cdots + a_1 x + a_0 \in F[x]$ be **monic** of degree n. The **companion matrix** of p is the matrix $\mathbf{C}(p) \in M_n(F)$ with 1 in each position $(j+1, j)$ just **below** the diagonal, last column $(-a_0, -a_1, \ldots, -a_{n-1})$, and 0 elsewhere:

$$\mathbf{C}(p) = \begin{pmatrix} 0 & 0 & \cdots & 0 & -a_0 \\ 1 & 0 & \cdots & 0 & -a_1 \\ 0 & 1 & \cdots & 0 & -a_2 \\ \vdots & & \ddots & & \vdots \\ 0 & 0 & \cdots & 1 & -a_{n-1} \end{pmatrix}.$$

For $n = 1$ and $p = x + a_0$ this reads $\mathbf{C}(p) = (-a_0)$.

This is the convention of Exercise (C1: Companion matrices), where the $n \geq 2$ case was introduced: the subdiagonal ones shift the standard basis forward, $\mathbf{C}(p)\mathbf{e}_j = \mathbf{e}_{j+1}$ for $j \leq n-1$, and the last column records the coefficients of p with their signs changed. Some books use the transpose, or put the coefficients in the last row; nothing changes but the bookkeeping, since a matrix and its transpose have the same characteristic polynomial (Exercise (B2: Transpose)).

Theorem 9.5.3 — The Companion Matrix Realizes Its Polynomial Twice

Let $p \in F[x]$ be monic of degree $n \geq 1$ and $\mathbf{C} = \mathbf{C}(p)$. Then

$$p_{\mathbf{C}} = m_{\mathbf{C}} = p,$$

and $\mathbf{e}_1$ satisfies $Z(\mathbf{e}_1; \mathbf{C}) = F^n$ with $m_{\mathbf{C},\mathbf{e}_1} = p$. Consequently every monic polynomial over F is both the characteristic and the minimal polynomial of some square matrix over F.

Proof. For $n = 1$ the matrix is $(-a_0)$, with $p_{\mathbf{C}} = m_{\mathbf{C}} = x + a_0 = p$. Let $n \geq 2$. Since $\mathbf{C}\mathbf{e}_j = \mathbf{e}_{j+1}$ for $j \leq n-1$, induction gives $\mathbf{C}^j\mathbf{e}_1 = \mathbf{e}_{j+1}$ for $0 \leq j \leq n-1$. Hence $Z(\mathbf{e}_1; \mathbf{C})$ contains $\mathbf{e}_1, \ldots, \mathbf{e}_n$, so $Z(\mathbf{e}_1; \mathbf{C}) = F^n$, and by Theorem 9.5.2 (a),

$$\deg m_{\mathbf{C},\mathbf{e}_1} = \dim Z(\mathbf{e}_1; \mathbf{C}) = n.$$

Applying Theorem 9.5.2 (c) with $Z = F^n$, so that $T_{\mathbf{C}}|_Z = T_{\mathbf{C}}$,

$$m_{\mathbf{C}} = m_{T_{\mathbf{C}}} = m_{\mathbf{C},\mathbf{e}_1} = p_{T_{\mathbf{C}}} = p_{\mathbf{C}},$$

where $m_{\mathbf{C}} = m_{T_{\mathbf{C}}}$ and $p_{T_{\mathbf{C}}} = p_{\mathbf{C}}$ hold by definition (Definition 8.5.1, Definition 6.10.2), the matrix of $T_{\mathbf{C}}$ in the standard basis being $\mathbf{C}$. Finally $p_{\mathbf{C}} = p$ by Exercise (C1: Companion matrices) (b). So $m_{\mathbf{C}} = p_{\mathbf{C}} = p$. The last sentence follows by taking $\mathbf{C}(p)$ for the given p.

■

So the companion matrix is the field-free analogue of a Jordan block: $\mathbf{J}_k(\lambda)$ and $\mathbf{C}\big((x-\lambda)^k\big)$ both have characteristic and minimal polynomial $(x-\lambda)^k$, and they are similar, as we will see in Section 6. The difference is that $\mathbf{C}(p)$ is available for **every** monic p, whether or not p has a root in F.

9.5.4 Cyclic operators

One block is one cyclic subspace. Before assembling many of them, we should know when a single one already fills the space.

Definition 9.5.4 — Cyclic Vector, Cyclic Operator

Let V be a finite-dimensional vector space over F with $\dim V = n \geq 1$, and let $T \in \mathcal{L}(V)$. A vector $\mathbf{v} \in V$ is a **cyclic vector** for T if

$$Z(\mathbf{v}; T) = V.$$

We call T **cyclic** if it has a cyclic vector, and $\mathbf{A} \in M_n(F)$ **cyclic** if $T_{\mathbf{A}}$ is.

By Theorem 9.5.2 (a), $\mathbf{v}$ is cyclic exactly when $\deg m_{T,\mathbf{v}} = n$, and then $(\mathbf{v}, T\mathbf{v}, \dots, T^{n-1}\mathbf{v})$ is a basis of V. That is the definition used in Exercise (C1: Cyclic vectors), so the two agree. Reading Theorem 9.5.2 (b) with $Z = V$: **in the basis generated by a cyclic vector, the matrix of T is a companion matrix.**

The key to the existence of cyclic vectors is a lemma about adding vectors whose annihilators have no common factor. It says that annihilators multiply, exactly as one hopes.

Lemma 9.5.4 — Annihilator of a Sum with Coprime Annihilators

Let V be finite-dimensional, $T \in \mathcal{L}(V)$, and $\mathbf{u}, \mathbf{w} \in V$ with $f = m_{T,\mathbf{u}}$ and $g = m_{T,\mathbf{w}}$ **coprime**. Then

$$m_{T,\mathbf{u}+\mathbf{w}} = fg.$$

More generally, if $\mathbf{v}_1, \dots, \mathbf{v}_k \in V$ have pairwise coprime T-annihilators $f_1, \dots, f_k$, then $m_{T,\mathbf{v}_1+\cdots+\mathbf{v}_k} = f_1 f_2 \cdots f_k$.

Idea. Write $h = m_{T,\mathbf{u}+\mathbf{w}}$. That h divides fg is immediate, since fg kills both summands. For the other direction, multiply the relation $h(T)(\mathbf{u}+\mathbf{w}) = \mathbf{0}$ by $g(T)$: the $\mathbf{w}$ part dies, leaving $(hg)(T)\mathbf{u} = \mathbf{0}$, so $f \mid hg$; and since f and g are coprime we may cancel g and conclude $f \mid h$. Symmetrically $g \mid h$, and two coprime divisors multiply.

Proof. Polynomials in T commute (Theorem 5.7.1 (c)). Hence

$$(fg)(T)(\mathbf{u}+\mathbf{w}) = g(T)\big(f(T)\mathbf{u}\big) + f(T)\big(g(T)\mathbf{w}\big) = \mathbf{0},$$

so $h \mid fg$, where $h = m_{T,\mathbf{u}+\mathbf{w}}$. Conversely, applying $g(T)$ to $h(T)(\mathbf{u}+\mathbf{w}) = \mathbf{0}$ and using $g(T)\mathbf{w} = \mathbf{0}$,

$$\mathbf{0} = g(T)h(T)(\mathbf{u}+\mathbf{w}) = (hg)(T)\mathbf{u} + h(T)\big(g(T)\mathbf{w}\big) = (hg)(T)\mathbf{u}.$$

Therefore $f \mid hg$, and since $\gcd(f,g) = 1$, Theorem 5.2.8 gives $f \mid h$. Swapping the roles of $\mathbf{u}$ and $\mathbf{w}$ gives $g \mid h$. As f and g are coprime and both divide h, their product divides h (Lemma 5.6.3 (b)). With $h \mid fg$, and all three polynomials monic, $h = fg$ (Proposition 5.1.2 (d)).

For k vectors, induct on k. The case $k = 1$ is trivial. Assume $m_{T,\mathbf{v}_1+\cdots+\mathbf{v}_{k-1}} = f_1 \cdots f_{k-1}$. Each f_i with $i \le k-1$ is coprime to f_k, so $f_1 \cdots f_{k-1}$ is coprime to f_k (Lemma 5.6.3 (a)), and the two-vector case applies to $\mathbf{u} = \mathbf{v}_1 + \cdots + \mathbf{v}_{k-1}$ and $\mathbf{w} = \mathbf{v}_k$.

■

Quick check. Let $\mathbf{A} = \operatorname{diag}(2,2,5)$ on $\mathbb{Q}^3$. Find $m_{\mathbf{A},\mathbf{e}_1}$, $m_{\mathbf{A},\mathbf{e}_3}$ and $m_{\mathbf{A},\mathbf{e}_1+\mathbf{e}_3}$. Is $\mathbf{e}_1+\mathbf{e}_3$ a cyclic vector for $\mathbf{A}$?

Solution. The vectors $\mathbf{e}_1$ and $\mathbf{e}_3$ are eigenvectors, for 2 and for 5, so $m_{\mathbf{A},\mathbf{e}_1} = x-2$ and $m_{\mathbf{A},\mathbf{e}_3} = x-5$. These are distinct monic linear polynomials, hence coprime, so Lemma 9.5.4 gives

$$m_{\mathbf{A},\mathbf{e}_1+\mathbf{e}_3} = (x-2)(x-5),$$

of degree 2. By Theorem 9.5.2 (a), $\dim Z(\mathbf{e}_1+\mathbf{e}_3;\mathbf{A}) = 2 < 3$, so $\mathbf{e}_1+\mathbf{e}_3$ is **not** cyclic; indeed $Z(\mathbf{e}_1+\mathbf{e}_3;\mathbf{A}) = \operatorname{span}(\mathbf{e}_1,\mathbf{e}_3)$. The lemma makes the annihilator as large as the two pieces allow, and here that is still not all of $\mathbb{Q}^3$ — the eigenvalue 2 is repeated, so $m_{\mathbf{A}} = (x-2)(x-5)$ has degree 2 and no vector can do better.

The lemma turns the primary decomposition into a supply of vectors with the largest possible annihilator.

Proposition 9.5.5 — Some Vector Has the Minimal Polynomial as Its Annihilator

Let $V \neq \{\mathbf{0}\}$ be a finite-dimensional vector space over F and $T \in \mathcal{L}(V)$. Then there is $\mathbf{v} \in V$ with

$$m_{T,\mathbf{v}} = m_T.$$

Idea. The minimal polynomial factors as $m_T = p_1^{e_1} \cdots p_k^{e_k}$, and the primary decomposition supplies an invariant piece V_i on which T has minimal polynomial exactly $p_i^{e_i}$. Inside V_i some vector must need the full exponent e_i, or $p_i^{e_i-1}$ would kill the whole piece. Then add up one such vector from each piece: the annihilators are powers of distinct irreducibles, hence pairwise coprime, so Lemma 9.5.4 multiplies them back into m_T.

Proof. Write $m_T = p_1^{e_1} \cdots p_k^{e_k}$ with $p_1, \dots, p_k$ distinct monic irreducibles and $e_i \ge 1$ (Theorem 5.3.5; $\deg m_T \ge 1$ because $V \neq \{\mathbf{0}\}$, by Theorem 8.5.1). By Theorem 8.8.1,

$V = V_1 \oplus \cdots \oplus V_k$ with $V_i = \ker p_i(T)^{e_i}$ invariant and $m_{T|_{V_i}} = p_i^{e_i}$.

Fix i. *Claim: some* $\mathbf{v}_i \in V_i$ *has* $m_{T,\mathbf{v}_i} = p_i^{e_i}$. For $\mathbf{v} \in V_i$ we have $p_i^{e_i}(T)\mathbf{v} = \mathbf{0}$ by the definition of V_i, so $m_{T,\mathbf{v}} \mid p_i^{e_i}$ and hence $m_{T,\mathbf{v}} = p_i^{f}$ with $0 \le f \le e_i$ (Lemma 8.5.2). Suppose no $\mathbf{v} \in V_i$ has $f = e_i$. Then $m_{T,\mathbf{v}} \mid p_i^{e_i-1}$ for every $\mathbf{v} \in V_i$, so $p_i^{e_i-1}(T)\mathbf{v} = \mathbf{0}$ for every $\mathbf{v} \in V_i$, that is, $p_i^{e_i-1}(T|_{V_i}) = 0$ (Exercise (C2: Minimal polynomials of the pieces) (a)). By Theorem 8.5.1 this forces $p_i^{e_i} = m_{T|_{V_i}}$ to divide $p_i^{e_i-1}$, which is false by degrees (Proposition 5.1.2 (c)). This proves the claim.

Pick such a $\mathbf{v}_i$ for each i and put $\mathbf{v} = \mathbf{v}_1 + \cdots + \mathbf{v}_k$. The polynomials $p_1^{e_1}, \dots, p_k^{e_k}$ are pairwise coprime: a monic common divisor of $p_i^{e_i}$ and $p_j^{e_j}$ with $i \neq j$ is both a power of p_i and a power of p_j (Lemma 8.5.2), hence is 1 by the uniqueness of factorization (Theorem 5.3.5 (b)). So Lemma 9.5.4 gives

$$m_{T,\mathbf{v}} = p_1^{e_1} \cdots p_k^{e_k} = m_T,$$

as claimed.

■

An operator is generated by one vector exactly when its minimal polynomial is as large as it can be.

Theorem 9.5.6 — Cyclic Operators

Let V be a finite-dimensional vector space over F with $\dim V = n \ge 1$, and let $T \in \mathcal{L}(V)$. The following are equivalent:

(a) T is cyclic, that is, T has a cyclic vector;
(b) $\deg m_T = n$;
(c) $m_T = p_T$.

In that case $\mathbf{v}$ is a cyclic vector if and only if $m_{T,\mathbf{v}} = m_T$, and in the basis $(\mathbf{v}, T\mathbf{v}, \dots, T^{n-1}\mathbf{v})$ the matrix of T is $\mathbf{C}(m_T)$. The same holds for $\mathbf{A} \in M_n(F)$.

Proof.

(b) $\Leftrightarrow$ (c). Always $m_T \mid p_T$ with both monic and $\deg p_T = n$ (Corollary 8.6.2, Theorem 6.10.2). So $\deg m_T = n$ if and only if $m_T = p_T$ (Proposition 5.1.2 (c), (d)).

(c) $\Rightarrow$ (b). Let $\mathbf{v}$ be cyclic. Then $\mathbf{v} \neq \mathbf{0}$, since $Z(\mathbf{0}; T) = \{\mathbf{0}\} \neq V$, and by Theorem 9.5.2 (a), (d),

$$n = \dim V = \dim Z(\mathbf{v}; T) = \deg m_{T,\mathbf{v}} \le \deg m_T \le n.$$

So all these numbers are equal; in particular $\deg m_T = n$ and $m_{T,\mathbf{v}} = m_T$, the two being monic with $m_{T,\mathbf{v}} \mid m_T$ of equal degree.

(d) $\Rightarrow$ (a). By Proposition 9.5.5 there is $\mathbf{v}$ with $m_{T,\mathbf{v}} = m_T$, and then $\dim Z(\mathbf{v}; T) = \deg m_T = n$ by Theorem 9.5.2 (a). A subspace of the same dimension as V is V (Theorem 1.6.8), so $Z(\mathbf{v}; T) = V$ and $\mathbf{v}$ is cyclic.

For the final statements, the computation in (a) $\Rightarrow$ (b) shows a cyclic vector has $m_{T,\mathbf{v}} =$

m_T; conversely if $m_{T,\mathbf{v}} = m_T$ and (b) holds, the argument of (b) $\Rightarrow$ (a) shows $\mathbf{v}$ is cyclic. The matrix is then $\mathbf{C}(m_{T,\mathbf{v}}) = \mathbf{C}(m_T)$ by Theorem 9.5.2 (b). For a matrix $\mathbf{A}$, apply all of this to $T_{\mathbf{A}}$, using $m_{\mathbf{A}} = m_{T_{\mathbf{A}}}$ and $p_{\mathbf{A}} = p_{T_{\mathbf{A}}}$.

■

The implication (a) $\Rightarrow$ (b) was Exercise (C1: Cyclic vectors) (a) in Chapter 8, where the converse was promised for this chapter; the promise is now paid off, and the proof shows what the missing vector is made of — one contribution from each primary piece, chosen to need the full exponent. Two consequences are worth naming. First, an operator with n distinct eigenvalues is cyclic, since then $m_T = p_T$ has n distinct roots (Theorem 8.8.2). Second, **a matrix is similar to a companion matrix if and only if $m_{\mathbf{A}} = p_{\mathbf{A}}$**: one direction is the last sentence of the theorem, and the other follows from Theorem 9.5.3 together with the fact that similar matrices share both polynomials. Section 6 makes this the first case of a general normal form.

Warning. **A cyclic vector need not exist, and when it exists it is far from unique.** For $T = \mathrm{id}$ on F^2 we have $m_T = x - 1$ of degree $1 < 2$, so no vector is cyclic: indeed $Z(\mathbf{v}; \mathrm{id}) = \mathrm{span}(\mathbf{v})$ is a line for every $\mathbf{v} \neq \mathbf{0}$. At the other extreme, if $\mathbf{v}$ is cyclic, then so is $c\mathbf{v}$ for every $c \neq 0$, and usually many more vectors are: for $\mathbf{J} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$ over $\mathbb{Q}$, a vector (s,t) is cyclic exactly when $t \neq 0$, since $\big((s,t),(s+t,t)\big)$ has determinant $-t^2$. So "the" cyclic vector is never a well-defined object; only the polynomial m_T is.

Example. (A Cyclic Subspace and a Cyclic Vector)

Let

$$\mathbf{A} = \begin{pmatrix} 1 & 1 & 0 \\ 0 & 1 & 0 \\ 1 & 0 & 2 \end{pmatrix} \in M_3(\mathbb{Q}).$$

(a) Find $p_{\mathbf{A}}$ and $m_{\mathbf{A}}$.

(b) Find $m_{\mathbf{A},\mathbf{e}_1}$, the subspace $Z(\mathbf{e}_1; \mathbf{A})$ and the matrix of $T_{\mathbf{A}}$ restricted to it.

(c) Find a cyclic vector for $\mathbf{A}$ and an invertible $\mathbf{P}$ with $\mathbf{P}^{-1}\mathbf{A}\mathbf{P}$ a companion matrix.

Solution.

(a) Expanding $\det(x\mathbf{I} - \mathbf{A})$ along the second row, whose only non-zero entry is $x - 1$ in position $(2,2)$ (Theorem 6.6.1),

$$p_{\mathbf{A}} = (x-1)\det\begin{pmatrix} x-1 & 0 \\ -1 & x-2 \end{pmatrix} = (x-1)^2(x-2).$$

For $m_{\mathbf{A}}$, the roots 1 and 2 must both occur (Theorem 8.5.3), so the first candidate is $(x-1)(x-2)$. With

$$\mathbf{A} - \mathbf{I} = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 0 \\ 1 & 0 & 1 \end{pmatrix}, \qquad \mathbf{A} - 2\mathbf{I} = \begin{pmatrix} -1 & 1 & 0 \\ 0 & -1 & 0 \\ 1 & 0 & 0 \end{pmatrix},$$

the product $(\mathbf{A} - \mathbf{I})(\mathbf{A} - 2\mathbf{I})$ has rows: row 1 of $\mathbf{A} - \mathbf{I}$ is $(0,1,0)$, which picks out row 2 of $\mathbf{A} - 2\mathbf{I}$, namely $(0,-1,0)$; row 2 is zero; row 3 is $(1,0,1)$, which gives row

1 plus row 3 of $\mathbf{A} - 2\mathbf{I}$, namely $(0, 1, 0)$. So

$$(\mathbf{A} - \mathbf{I})(\mathbf{A} - 2\mathbf{I}) = \begin{pmatrix} 0 & -1 & 0 \\ 0 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix} \neq 0,$$

and by Lemma 8.5.2 the only remaining candidate is $m_{\mathbf{A}} = (x-1)^2(x-2) = p_{\mathbf{A}}$. So $\mathbf{A}$ is cyclic by Theorem 9.5.6.

(b) $\mathbf{A}\mathbf{e}_1 = (1, 0, 1)$, the first column, and

$$\mathbf{A}^2\mathbf{e}_1 = \mathbf{A}(1, 0, 1) = (\text{column } 1) + (\text{column } 3) = (1, 0, 1) + (0, 0, 2) = (1, 0, 3).$$

Now $(1, 0, 3) = -2\mathbf{e}_1 + 3(1, 0, 1)$, so $(\mathbf{A}^2 - 3\mathbf{A} + 2\mathbf{I})\mathbf{e}_1 = \mathbf{0}$ and $m_{\mathbf{A},\mathbf{e}_1} \mid x^2 - 3x + 2 = (x-1)(x-2)$. Neither factor kills $\mathbf{e}_1$: $(\mathbf{A} - \mathbf{I})\mathbf{e}_1 = (0, 0, 1) \neq \mathbf{0}$ and $(\mathbf{A} - 2\mathbf{I})\mathbf{e}_1 = (-1, 0, 1) \neq \mathbf{0}$. Hence

$$m_{\mathbf{A},\mathbf{e}_1} = (x-1)(x-2) = x^2 - 3x + 2,$$

and by Theorem 9.5.2, $Z(\mathbf{e}_1; \mathbf{A}) = \operatorname{span}\big(\mathbf{e}_1, (1, 0, 1)\big) = \operatorname{span}(\mathbf{e}_1, \mathbf{e}_3)$, of dimension 2, with

$$\big[T_{\mathbf{A}}|_{Z(\mathbf{e}_1;\mathbf{A})}\big] = \mathbf{C}\big(x^2 - 3x + 2\big) = \begin{pmatrix} 0 & -2 \\ 1 & 3 \end{pmatrix}$$

in the basis $\big(\mathbf{e}_1, \mathbf{A}\mathbf{e}_1\big)$. In particular $\mathbf{e}_1$ is **not** cyclic for $\mathbf{A}$: its cyclic subspace is a plane, not $\mathbb{Q}^3$.

(c) Try $\mathbf{v} = \mathbf{e}_2$. Then

$$\mathbf{A}\mathbf{e}_2 = (1, 1, 0), \qquad \mathbf{A}^2\mathbf{e}_2 = \mathbf{A}(1, 1, 0) = (1, 0, 1) + (1, 1, 0) = (2, 1, 1).$$

The matrix with these three columns is

$$\mathbf{P} = \begin{pmatrix} 0 & 1 & 2 \\ 1 & 1 & 1 \\ 0 & 0 & 1 \end{pmatrix}, \qquad \det \mathbf{P} = -\det \begin{pmatrix} 1 & 2 \\ 0 & 1 \end{pmatrix} = -1 \neq 0,$$

expanding along the first column, whose only non-zero entry is the 1 in position $(2, 1)$. So $(\mathbf{e}_2, \mathbf{A}\mathbf{e}_2, \mathbf{A}^2\mathbf{e}_2)$ is a basis and $\mathbf{e}_2$ is a cyclic vector. By Theorem 9.5.6, $m_{\mathbf{A},\mathbf{e}_2} = m_{\mathbf{A}} = (x-1)^2(x-2) = x^3 - 4x^2 + 5x - 2$ and

$$\mathbf{P}^{-1}\mathbf{A}\mathbf{P} = \mathbf{C}(m_{\mathbf{A}}) = \begin{pmatrix} 0 & 0 & 2 \\ 1 & 0 & -5 \\ 0 & 1 & 4 \end{pmatrix}.$$

The check. The identity $\mathbf{A}\mathbf{P} = \mathbf{P}\,\mathbf{C}(m_{\mathbf{A}})$ reads, column by column, $\mathbf{A}\mathbf{e}_2 = \mathbf{A}\mathbf{e}_2$, $\mathbf{A}(\mathbf{A}\mathbf{e}_2) = \mathbf{A}^2\mathbf{e}_2$ — both true by construction — and

$$\mathbf{A}(\mathbf{A}^2\mathbf{e}_2) = 2\mathbf{e}_2 - 5\mathbf{A}\mathbf{e}_2 + 4\mathbf{A}^2\mathbf{e}_2,$$

which is the annihilator relation. Verifying it: $\mathbf{A}(2, 1, 1) = 2(1, 0, 1) + (1, 1, 0) + (0, 0, 2) = (3, 1, 4)$, while

$$2(0, 1, 0) - 5(1, 1, 0) + 4(2, 1, 1) = (0 - 5 + 8,\ 2 - 5 + 4,\ 4) = (3, 1, 4). \checkmark$$

9.5.5 Exercises

9.5.5.1 A. Check your understanding

Exercise A1.

(a) Define $Z(\mathbf{v};T)$ and the T-annihilator $m_{T,\mathbf{v}}$.

(b) State the formula for $\dim Z(\mathbf{v};T)$ and say which basis of $Z(\mathbf{v};T)$ the theorem provides.

(c) Write down $\mathbf{C}(p)$ for $p = x^3 - 2x + 5$, and say what $p_{\mathbf{C}(p)}$ and $m_{\mathbf{C}(p)}$ are.

(d) True or false: every operator on a space of dimension $n \geq 2$ has a cyclic vector. Justify your answer.

(e) What is $m_{T,\mathbf{v}}$ when $\mathbf{v}$ is an eigenvector of T for λ? What is $Z(\mathbf{v};T)$ then?

(f) True or false: if $m_{T,\mathbf{v}} = m_T$ for some $\mathbf{v}$, then $\mathbf{v}$ is a cyclic vector. Justify your answer.

Solution.

(a) $Z(\mathbf{v};T) = \operatorname{span}(\mathbf{v}, T\mathbf{v}, T^2\mathbf{v}, \dots) = \{p(T)\mathbf{v} : p \in F[x]\}$ (Definition 9.5.1, Proposition 9.5.1); $m_{T,\mathbf{v}}$ is the monic generator of the ideal $\{p : p(T)\mathbf{v} = \mathbf{0}\}$, equivalently the monic polynomial of least degree killing $\mathbf{v}$ (Definition 9.5.2).

(b) $\dim Z(\mathbf{v};T) = \deg m_{T,\mathbf{v}} = k$, with basis $(\mathbf{v}, T\mathbf{v}, \dots, T^{k-1}\mathbf{v})$ (Theorem 9.5.2 (a)).

(c) Here $a_0 = 5$, $a_1 = -2$, $a_2 = 0$, so

$$\mathbf{C}(p) = \begin{pmatrix} 0 & 0 & -5 \\ 1 & 0 & 2 \\ 0 & 1 & 0 \end{pmatrix},$$

and $p_{\mathbf{C}(p)} = m_{\mathbf{C}(p)} = x^3 - 2x + 5$ (Theorem 9.5.3).

(d) False. id_V has $m_T = x - 1$ of degree $1 < n$, so no cyclic vector (Theorem 9.5.6). More generally any T with $\deg m_T < n$ fails.

(e) $m_{T,\mathbf{v}} = x - \lambda$, and $Z(\mathbf{v};T) = \operatorname{span}(\mathbf{v})$ is the eigenline.

(f) False. By Theorem 9.5.2 (a), $\dim Z(\mathbf{v};T) = \deg m_{T,\mathbf{v}} = \deg m_T$, which need not be n. For $T = \mathrm{id}$ on F^2 and $\mathbf{v} = \mathbf{e}_1$ we have $m_{T,\mathbf{v}} = x - 1 = m_T$, yet $Z(\mathbf{v};T) = \operatorname{span}(\mathbf{e}_1)$ is a line. The statement is true when $\deg m_T = \dim V$ (Theorem 9.5.6).

9.5.5.2 B. Practice

Exercise B1: Annihilators of vectors.

Let

$$\mathbf{A} = \begin{pmatrix} 1 & 1 & 1 \\ 0 & 1 & 1 \\ 0 & 0 & 2 \end{pmatrix} \in M_3(\mathbb{Q}).$$

(a) Write down $p_{\mathbf{A}}$.

(b) Find $m_{\mathbf{A},\mathbf{e}_1}$, $m_{\mathbf{A},\mathbf{e}_2}$ and $m_{\mathbf{A},\mathbf{e}_3}$.

(c) For each of the three vectors, give $\dim Z(\mathbf{e}_j;\mathbf{A})$ and identify the subspace.

(d) Write down the matrix of $T_{\mathbf{A}}$ restricted to $Z(\mathbf{e}_2;\mathbf{A})$ in the basis $(\mathbf{e}_2, \mathbf{A}\mathbf{e}_2)$, and say which companion matrix it is.

Solution.

(a) $\mathbf{A}$ is upper triangular, so $p_{\mathbf{A}} = (x-1)^2(x-2)$ (Theorem 6.4.6).

(b) $\mathbf{A}\mathbf{e}_1 = \mathbf{e}_1$, so $\mathbf{e}_1$ is an eigenvector and $m_{\mathbf{A},\mathbf{e}_1} = x-1$.
$\mathbf{A}\mathbf{e}_2 = (1,1,0) = \mathbf{e}_1 + \mathbf{e}_2$, so $(\mathbf{A}-\mathbf{I})\mathbf{e}_2 = \mathbf{e}_1 \neq \mathbf{0}$ and $(\mathbf{A}-\mathbf{I})^2\mathbf{e}_2 = (\mathbf{A}-\mathbf{I})\mathbf{e}_1 = \mathbf{0}$. Hence $(x-1)^2$ kills $\mathbf{e}_2$ but $x-1$ does not, and $m_{\mathbf{A},\mathbf{e}_2} = (x-1)^2$ by Lemma 8.5.2.
$\mathbf{A}\mathbf{e}_3 = (1,1,2)$ and $\mathbf{A}^2\mathbf{e}_3 = \mathbf{A}(1,1,2) = (1,0,0) + (1,1,0) + 2(1,1,2) = (4,3,4)$. The matrix with columns $\mathbf{e}_3, (1,1,2), (4,3,4)$ is $\begin{pmatrix} 0 & 1 & 4 \\ 0 & 1 & 3 \\ 1 & 2 & 4 \end{pmatrix}$, of determinant $\det \begin{pmatrix} 1 & 4 \\ 1 & 3 \end{pmatrix} = -1 \neq 0$ by expansion along the first column. So the three vectors are independent, $\deg m_{\mathbf{A},\mathbf{e}_3} = 3$, and since $m_{\mathbf{A},\mathbf{e}_3} \mid m_{\mathbf{A}} \mid p_{\mathbf{A}}$ with $\deg p_{\mathbf{A}} = 3$ we get $m_{\mathbf{A},\mathbf{e}_3} = p_{\mathbf{A}} = (x-1)^2(x-2)$.

(c) $\dim Z(\mathbf{e}_1;\mathbf{A}) = 1$ and $Z(\mathbf{e}_1;\mathbf{A}) = \operatorname{span}(\mathbf{e}_1)$. $\dim Z(\mathbf{e}_2;\mathbf{A}) = 2$ and $Z(\mathbf{e}_2;\mathbf{A}) = \operatorname{span}(\mathbf{e}_2, \mathbf{e}_1+\mathbf{e}_2) = \operatorname{span}(\mathbf{e}_1, \mathbf{e}_2)$. $\dim Z(\mathbf{e}_3;\mathbf{A}) = 3$, so $Z(\mathbf{e}_3;\mathbf{A}) = \mathbb{Q}^3$ and $\mathbf{e}_3$ is a cyclic vector.

(d) $(x-1)^2 = x^2 - 2x + 1$, so by Theorem 9.5.2 (b) the matrix is

$$\mathbf{C}\big((x-1)^2\big) = \begin{pmatrix} 0 & -1 \\ 1 & 2 \end{pmatrix}.$$

Exercise B2: Cyclic or not?.

Determine whether each matrix is cyclic. For those that are, find a cyclic vector; for those that are not, say which condition fails.

(a) $\operatorname{diag}(1,2,3) \in M_3(\mathbb{Q})$.

(b) $\operatorname{diag}(1,1,2) \in M_3(\mathbb{Q})$.

(c) $\mathbf{B} = \begin{pmatrix} 2 & 1 & 0 \\ 0 & 2 & 0 \\ 1 & 1 & 1 \end{pmatrix} \in M_3(\mathbb{Q})$, for which $p_{\mathbf{B}} = m_{\mathbf{B}} = (x-2)^2(x-1)$. Check first that none of $\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3$ is cyclic.

(d) $\mathbf{J}_2(0) \oplus \mathbf{J}_1(0) \in M_3(\mathbb{Q})$.

Hint: for (c), compute the three annihilators $m_{\mathbf{B},\mathbf{e}_j}$ and use Lemma 9.5.4.

Solution.

(a) Cyclic. The three eigenvalues are distinct, so $m = (x-1)(x-2)(x-3) = p$ (Theorem 8.8.2), of degree 3. A cyclic vector is $\mathbf{v} = (1,1,1)$: the matrix with columns $\mathbf{v}, \mathbf{A}\mathbf{v} = (1,2,3), \mathbf{A}^2\mathbf{v} = (1,4,9)$ is a Vandermonde matrix with distinct nodes $1,2,3$, hence invertible (Corollary 6.8.2).

(b) Not cyclic. Here $m = (x-1)(x-2)$ has degree $2 < 3$, so condition (b) of Theorem 9.5.6 fails.

(c) *The standard basis vectors.* $\mathbf{B}\mathbf{e}_1 = (2,0,1)$ and $\mathbf{B}^2\mathbf{e}_1 = \mathbf{B}(2,0,1) = 2(2,0,1) + (0,0,1) = (4,0,3)$. Since $(4,0,3) = -2\mathbf{e}_1 + 3(2,0,1)$, the vector $\mathbf{e}_1$ is killed by

$x^2-3x+2=(x-1)(x-2)$, and by neither factor alone ($(\mathbf{B}-\mathbf{I})\mathbf{e}_1=(1,0,1)\neq\mathbf{0}$, $(\mathbf{B}-2\mathbf{I})\mathbf{e}_1=(0,0,1)\neq\mathbf{0}$); so $m_{\mathbf{B},\mathbf{e}_1}=(x-1)(x-2)$, of degree 2.
$\mathbf{B}\mathbf{e}_2=(1,2,1)$ and $\mathbf{B}^2\mathbf{e}_2=\mathbf{B}(1,2,1)=(2,0,1)+2(1,2,1)+(0,0,1)=(4,4,4)$. As $(4,4,4)=-4\mathbf{e}_2+4(1,2,1)$, the vector $\mathbf{e}_2$ is killed by $x^2-4x+4=(x-2)^2$, and not by $x-2$; so $m_{\mathbf{B},\mathbf{e}_2}=(x-2)^2$.
$\mathbf{B}\mathbf{e}_3=\mathbf{e}_3$, so $m_{\mathbf{B},\mathbf{e}_3}=x-1$.
All three degrees are less than 3, so none of $\mathbf{e}_1,\mathbf{e}_2,\mathbf{e}_3$ is cyclic (Theorem 9.5.2 (a)).
A cyclic vector. The annihilators $(x-2)^2$ of $\mathbf{e}_2$ and $x-1$ of $-\mathbf{e}_3$ — note $m_{T,-\mathbf{v}}=m_{T,\mathbf{v}}$, since $p(T)(-\mathbf{v})=-p(T)\mathbf{v}$ — are coprime, so Lemma 9.5.4 gives

$$m_{\mathbf{B},\mathbf{e}_2-\mathbf{e}_3}=(x-2)^2(x-1)=m_{\mathbf{B}}.$$

By Theorem 9.5.6, $\mathbf{v}=\mathbf{e}_2-\mathbf{e}_3=(0,1,-1)$ is a cyclic vector. As a check, $\mathbf{B}\mathbf{v}=(1,2,1)-(0,0,1)=(1,2,0)$ and $\mathbf{B}^2\mathbf{v}=\mathbf{B}(1,2,0)=(2,0,1)+2(1,2,1)=(4,4,3)$, and the matrix with columns $(0,1,-1),(1,2,0),(4,4,3)$ has determinant

$$-\det\begin{pmatrix}1&4\\-1&3\end{pmatrix}+4\det\begin{pmatrix}1&2\\-1&0\end{pmatrix}=-(3+4)+4\cdot 2=1\neq 0$$

by expansion along the first row.

(d) Not cyclic: $m=x^2$ (Proposition 8.5.6) has degree $2<3$.

Exercise B3: Cyclic subspaces for differentiation.

Let $V=\mathbb{R}[x]_{\leq 3}$ and let $D\in\mathcal{L}(V)$ be differentiation.

(a) Find $m_{D,q}$ for $q=1$, $q=x$, $q=x^2$ and $q=x^3$.
(b) Find $Z(x^2;D)$ and the matrix of D restricted to it in the basis (x^2,Dx^2,D^2x^2).
(c) Is x^3 a cyclic vector for D? What is m_D?

Solution.

(a) $D1=0$, so $m_{D,1}=x$. $Dx=1\neq 0$ and $D^2x=0$, so $m_{D,x}=x^2$. Likewise $D^2x^2=2\neq 0$ and $D^3x^2=0$, so $m_{D,x^2}=x^3$; and $D^3x^3=6\neq 0$ with $D^4x^3=0$, so $m_{D,x^3}=x^4$. (In each case the annihilator is a monic divisor of x^4, hence a power of x, by Lemma 8.5.2.)

(b) $Z(x^2;D)=\operatorname{span}(x^2,2x,2)=\mathbb{R}[x]_{\leq 2}$, of dimension $3=\deg m_{D,x^2}$. With $\mathbf{z}_1=x^2$, $\mathbf{z}_2=Dx^2=2x$, $\mathbf{z}_3=D^2x^2=2$ we have $D\mathbf{z}_1=\mathbf{z}_2$, $D\mathbf{z}_2=\mathbf{z}_3$, $D\mathbf{z}_3=0$, so the matrix is

$$\mathbf{C}(x^3)=\begin{pmatrix}0&0&0\\1&0&0\\0&1&0\end{pmatrix}=\mathbf{J}_3(0)^\top.$$

(c) Yes: $\dim Z(x^3;D)=\deg m_{D,x^3}=4=\dim V$. Hence $m_D=m_{D,x^3}=x^4=p_D$ by Theorem 9.5.6, which agrees with Example (Differentiation Is Nilpotent).

9.5.5.3 C. Going deeper

Exercise C1: What commutes with a cyclic operator.

Let V be finite-dimensional with $\dim V = n \geq 1$ and let $T \in \mathcal{L}(V)$ satisfy $m_T = p_T$.

(a) Prove that every $S \in \mathcal{L}(V)$ with $ST = TS$ is a polynomial in T, that is, $S = q(T)$ for some $q \in F[x]$.

(b) Deduce that the set $\{\, S \in \mathcal{L}(V) : ST = TS \,\}$ is a subspace of $\mathcal{L}(V)$ of dimension exactly n.

(c) Show that (a) fails without the hypothesis $m_T = p_T$, by taking $T = \mathrm{id}_V$ with $n \geq 2$.

Hint for (a): apply S to a cyclic vector.

Solution.

(a) By Theorem 9.5.6 there is a cyclic vector $\mathbf{v}$, and $\mathcal{B} = (\mathbf{v}, T\mathbf{v}, \dots, T^{n-1}\mathbf{v})$ is a basis of V. Since $\mathcal{B}$ spans V, there is $q \in F[x]$ with $S\mathbf{v} = q(T)\mathbf{v}$ (Proposition 9.5.1 (a)). For each $j \geq 0$, using $ST = TS$ and hence $ST^j = T^j S$ (induction on j), and that polynomials in T commute with T (Theorem 5.7.1 (c)),

$$S\big(T^j\mathbf{v}\big) = T^j\big(S\mathbf{v}\big) = T^j q(T)\mathbf{v} = q(T)\big(T^j\mathbf{v}\big).$$

So S and $q(T)$ agree on the basis $\mathcal{B}$, hence $S = q(T)$ (Theorem 3.1.5).

(b) The set is a subspace: it contains 0, and if $S_1T = TS_1$ and $S_2T = TS_2$, then $(S_1 + cS_2)T = T(S_1 + cS_2)$. By (a) it equals $\{q(T) : q \in F[x]\} = \mathrm{span}(\mathrm{id}_V, T, \dots, T^{n-1})$, where we used Theorem 5.1.1 to reduce q modulo m_T, whose degree is n. That spanning list is independent: a vanishing combination would give a non-zero polynomial of degree less than $n = \deg m_T$ annihilating T, contradicting Theorem 8.5.1. So the dimension is n.

(c) For $T = \mathrm{id}_V$ every S commutes with T, so the commutant is all of $\mathcal{L}(V)$, of dimension $n^2 \geq 4$. But the polynomials in id_V are just the scalar operators $c\,\mathrm{id}_V$, a subspace of dimension 1. Here $m_T = x - 1 \neq (x-1)^n = p_T$.

Exercise C2: How many cyclic vectors?.

Let V be finite-dimensional with $\dim V = n \geq 1$ and $T \in \mathcal{L}(V)$.

(a) Prove that $\mathbf{v}$ is a cyclic vector for T if and only if $\mathbf{v}$ lies in no T-invariant subspace U with $U \neq V$.

(b) Prove that if $\mathbf{v}$ is cyclic, then so is $c\mathbf{v}$ for every $c \in F$ with $c \neq 0$. Deduce that over an infinite field a cyclic operator has infinitely many cyclic vectors.

(c) Let $F = \mathbb{F}_2$ and $T = T_{\mathbf{J}}$ with $\mathbf{J} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$. Find **all** cyclic vectors of T.

(d) Deduce from (c) that the set of cyclic vectors, together with $\mathbf{0}$, need not be a subspace.

Solution.

(a) ($\Rightarrow$) Let $\mathbf{v}$ be cyclic and let U be T-invariant with $\mathbf{v} \in U$. By Proposition 9.5.1 (c), $V = Z(\mathbf{v}; T) \subseteq U$, so $U = V$. ($\Leftarrow$) If $\mathbf{v}$ is not cyclic, then $U = Z(\mathbf{v}; T)$ is itself a T-invariant subspace containing $\mathbf{v}$ with $U \neq V$ (Proposition 9.5.1 (b)).

(b) For $c \neq 0$, $p(T)(c\mathbf{v}) = cp(T)\mathbf{v}$, so $p(T)(c\mathbf{v}) = \mathbf{0}$ if and only if $p(T)\mathbf{v} = \mathbf{0}$ (as $c \neq 0$ and by Theorem 1.1.9). Hence $m_{T,c\mathbf{v}} = m_{T,\mathbf{v}}$, and Theorem 9.5.6 makes $c\mathbf{v}$ cyclic as well. Over an infinite field the vectors $c\mathbf{v}$, $c \neq 0$, are pairwise distinct (if $c\mathbf{v} = c'\mathbf{v}$ with $\mathbf{v} \neq \mathbf{0}$, then $c = c'$), so there are infinitely many.

(c) Write $\mathbf{v} = (s, t)$ with $s, t \in \mathbb{F}_2$. Then $\mathbf{J}\mathbf{v} = (s + t, t)$, and $(\mathbf{v}, \mathbf{J}\mathbf{v})$ is a basis of $\mathbb{F}_2^2$ if and only if

$$\det \begin{pmatrix} s & s+t \\ t & t \end{pmatrix} = st - t(s+t) = -t^2 = t^2 \neq 0,$$

that is, if and only if $t = 1$. So the cyclic vectors are exactly $(0, 1)$ and $(1, 1)$, two of the four vectors of $\mathbb{F}_2^2$.

(d) The set $\{\mathbf{0}, (0, 1), (1, 1)\}$ has 3 elements, and a subspace of $\mathbb{F}_2^2$ has 1, 2 or 4 elements. Concretely, $(0, 1)+(1, 1) = (1, 0)$, which is an eigenvector of $\mathbf{J}$ and hence not cyclic. So the set is not closed under addition.

9.6 The Rational Canonical Form

Everything so far has needed the characteristic polynomial to split. Section 5 removed that need from the building block: a companion matrix $\mathbf{C}(p)$ exists for every monic p, and it is the matrix of an operator on a cyclic subspace. What is left is to cut an arbitrary space into cyclic pieces. This section does that, over an **arbitrary field**, and the result is a genuine canonical form: a list of polynomials attached to T, from which the matrix is written down mechanically, and which two operators share exactly when they are similar. Along the way we learn that similarity does not change if the field is enlarged.

9.6.1 The plan

The goal, stated before its parts are named:

Every operator on a non-zero finite-dimensional space decomposes the space into cyclic subspaces $Z(\mathbf{v}_1; T), \ldots, Z(\mathbf{v}_r; T)$ whose annihilators form a divisibility chain $d_1 \mid d_2 \mid \cdots \mid d_r = m_T$, and that chain is determined by T.

In the adapted basis the matrix is then $\mathbf{C}(d_1) \oplus \cdots \oplus \mathbf{C}(d_r)$, by Theorem 9.5.2 (b) and Theorem 8.1.5. So the whole content is the decomposition, and it is the hardest theorem of the chapter. The route has three steps, and each one is a tool we already have.

- **Step 1 (one prime at a time).** Chapter 8's primary decomposition splits $V = V_1 \oplus \cdots \oplus V_k$, where $m_{T|_{V_i}} = p_i^{e_i}$ is a power of a single monic irreducible (Theorem 8.8.1). Nothing more is needed from the general theory.
- **Step 2 (inside one prime power).** On a piece with $m_T = p^e$, the operator $P = p(T)$ is nilpotent, and the structure theorem for nilpotent operators was proved by induction, with $\operatorname{im} N$ as the smaller space to which the hypothesis applies (Theorem 9.2.3). We run the same induction with P in place of N and cyclic subspaces $Z(\mathbf{u}; T)$ in place of the spans of chains. The outcome is a decomposition into cyclic pieces whose annihilators are powers $p^{e_1} \geq p^{e_2} \geq \ldots$ of the one prime.
- **Step 3 (regroup across primes).** A cyclic piece for p_1 and a cyclic piece for p_2 can be **merged**: the sum of their generators has annihilator the product, by Lemma 9.5.4. Merging the largest piece of every prime gives $d_r = m_T$, the next largest give d_{r-1}, and so

on; the divisibility chain is automatic because within one prime the exponents decrease.

Uniqueness is a count, exactly as for the nilpotent case: the dimensions $\dim \ker p(T)^k$ are visible in the decomposition and see nothing but the exponents.

9.6.2 One prime at a time

Here is Step 2. Compare it with Theorem 9.2.3, which is the special case $p = x$: there the pieces are spanned by Jordan chains $\mathbf{u}, N\mathbf{u}, \ldots$, and here by $\mathbf{u}, T\mathbf{u}, T^2\mathbf{u}, \ldots$.

Theorem 9.6.1 — Cyclic Decomposition for a Single Prime Power

Let $V \neq \{\mathbf{0}\}$ be a finite-dimensional vector space over F, let $T \in \mathcal{L}(V)$, and suppose

$$m_T = p^e, \qquad p \in F[x] \text{ monic irreducible of degree } d, \quad e \geq 1.$$

Then there are an integer $m \geq 1$, vectors $\mathbf{u}_1, \ldots, \mathbf{u}_m \in V$ and exponents

$$e = k_1 \geq k_2 \geq \cdots \geq k_m \geq 1$$

such that

$$V = Z(\mathbf{u}_1; T) \oplus Z(\mathbf{u}_2; T) \oplus \cdots \oplus Z(\mathbf{u}_m; T), \qquad m_{T,\mathbf{u}_i} = p^{k_i} \quad (1 \leq i \leq m).$$

In particular $\dim V = d(k_1 + \cdots + k_m)$.

Idea. Induction on $\dim V$, with the smaller object found inside: $W = \operatorname{im} p(T)$. It is T-invariant, the minimal polynomial of $T|_W$ is p^{e-1}, and $\dim W < \dim V$ because $p(T)$ is not injective. So W already breaks into cyclic pieces $Z(\mathbf{w}_i; T)$. Each is one step short of what we want: $\mathbf{w}_i = p(T)\mathbf{u}_i$ for some $\mathbf{u}_i \in V$, and $Z(\mathbf{u}_i; T)$ is a longer piece, with annihilator p times that of $\mathbf{w}_i$. What is still missing is counted by $U = \ker p(T)$, on which T has **irreducible** minimal polynomial p, so that U is a direct sum of cyclic pieces of dimension d each and no proper cyclic piece inside one of them exists (Chapter 8, Exercise (C2: Irreducible minimal polynomials)). The ends $p^{k_i-1}(T)\mathbf{u}_i$ of the lengthened pieces sit inside U; complete them to a decomposition of U, and the extra generators supply the pieces with annihilator p. Then Rank–Nullity makes the dimensions add up exactly, and directness is proved by applying $p(T)$ once, as in the nilpotent case.

Proof. We argue by induction on $n = \dim V \geq 1$, the statement being: for every field F, every monic irreducible $p \in F[x]$, every $e \geq 1$ and every T on a space of dimension n with $m_T = p^e$, a decomposition as described exists.

Write $P = p(T)$ and $U = \ker P$, and recall that $Z(\mathbf{v}; T|_{V'}) = Z(\mathbf{v}; T)$ whenever V' is a T-invariant subspace containing $\mathbf{v}$, since the two operators agree on $\mathbf{v}$ and on everything T produces from it.

The case $e = 1$. Then $m_T = p$ is irreducible, and Exercise (C2: Irreducible minimal polynomials) (d) gives $V = Z(\mathbf{u}_1; T) \oplus \cdots \oplus Z(\mathbf{u}_m; T)$ with every $\mathbf{u}_i \neq \mathbf{0}$ (the subspace called $W_{\mathbf{v}}$ there is $Z(\mathbf{v}; T)$, by Proposition 9.5.1 (a)). For $\mathbf{u} \neq \mathbf{0}$ we have $m_{T,\mathbf{u}} \mid m_T = p$ and $m_{T,\mathbf{u}} \neq 1$, so $m_{T,\mathbf{u}} = p$ and every $k_i = 1 = e$. This settles $e = 1$, and in particular the base case $n = 1$, where m_T is linear.

The case $e \geq 2$. Let $n \geq 2$ and assume the statement for all dimensions less than n.

Step 1. Cyclic pieces inside $\operatorname{im} P$. Put $W = \operatorname{im} P$. Since $e \geq 2$, the polynomial p does not annihilate T (else $m_T = p^e$ would divide p, Theorem 8.5.1), so $P \neq 0$ and $W \neq \{\mathbf{0}\}$. Also P is not injective: otherwise $P^e = m_T(T) = 0$ would be injective on $V \neq \{\mathbf{0}\}$ (Theorem 0.4.3), which is false. So $1 \leq \dim W < n$ by Theorem 3.3.1. The subspace W is T-invariant (Theorem 5.7.4 (b)), and

$$m_{T|_W} = p^{e-1}.$$

Indeed $p^{e-1}(T)$ kills W, because $p^{e-1}(T)P\mathbf{v} = m_T(T)\mathbf{v} = \mathbf{0}$ for every $\mathbf{v}$; and $p^{e-2}(T)$ does not, because $p^{e-2}(T)P \neq 0$ — that operator is $p^{e-1}(T)$, which is non-zero since $m_T = p^e \nmid p^{e-1}$ — so some $P\mathbf{v} \in W$ survives it. Hence $m_{T|_W}$ is a monic divisor of p^{e-1} but not of p^{e-2}, and Lemma 8.5.2 leaves only p^{e-1}. By the induction hypothesis applied to $T|_W$,

$$W = Z(\mathbf{w}_1; T) \oplus \cdots \oplus Z(\mathbf{w}_q; T), \qquad m_{T,\mathbf{w}_i} = p^{l_i}, \qquad e - 1 = l_1 \geq \cdots \geq l_q \geq 1.$$

Step 2. Lengthen each piece by one step. Each $\mathbf{w}_i$ lies in $W = \operatorname{im} P$, so we may choose $\mathbf{u}_i \in V$ with $P\mathbf{u}_i = \mathbf{w}_i$, for $i = 1, \ldots, q$. Put $k_i = l_i + 1$. Then $p^{k_i}(T)\mathbf{u}_i = p^{l_i}(T)\mathbf{w}_i = \mathbf{0}$, so $m_{T,\mathbf{u}_i} \mid p^{k_i}$; and $p^{l_i}(T)\mathbf{u}_i \neq \mathbf{0}$, since otherwise $p^{l_i-1}(T)\mathbf{w}_i = p^{l_i}(T)\mathbf{u}_i = \mathbf{0}$, contradicting $m_{T,\mathbf{w}_i} = p^{l_i}$. By Lemma 8.5.2,

$$m_{T,\mathbf{u}_i} = p^{k_i} = p^{l_i+1} \qquad (1 \leq i \leq q).$$

Step 3. Fill up $\ker P$. Put $\mathbf{z}_i = p^{l_i}(T)\mathbf{u}_i$ for $i \leq q$. Each is non-zero by Step 2, lies in $U = \ker P$ because $P\mathbf{z}_i = p^{k_i}(T)\mathbf{u}_i = \mathbf{0}$, and lies in $Z(\mathbf{w}_i; T)$, since $l_i \geq 1$ gives $\mathbf{z}_i = p^{l_i-1}(T)p(T)\mathbf{u}_i = p^{l_i-1}(T)\mathbf{w}_i$. Consequently $Z(\mathbf{z}_i; T) \subseteq Z(\mathbf{w}_i; T)$ (Proposition 9.5.1 (b), (c)), so the sum $Z(\mathbf{z}_1; T) + \cdots + Z(\mathbf{z}_q; T)$ is direct: a vanishing sum of vectors $\mathbf{c}_i \in Z(\mathbf{z}_i; T) \subseteq Z(\mathbf{w}_i; T)$ forces every $\mathbf{c}_i = \mathbf{0}$ by the directness of Step 1 (Theorem 1.7.5).

Now $U \neq \{\mathbf{0}\}$, U is T-invariant (Theorem 5.7.4 (b)), and $p(T|_U) = 0$ with p irreducible, so $m_{T|_U} = p$ as in the case $e = 1$. Among all lists $(\mathbf{z}_1, \ldots, \mathbf{z}_q, \mathbf{z}_{q+1}, \ldots, \mathbf{z}_s)$ of non-zero vectors of U extending $\mathbf{z}_1, \ldots, \mathbf{z}_q$ and with $Z(\mathbf{z}_1; T) + \cdots + Z(\mathbf{z}_s; T)$ direct, choose one with s as large as possible; this is possible because each summand has dimension d (Exercise (C2: Irreducible minimal polynomials) (b)), so $sd \leq \dim U$. Let S be that direct sum. If $S \neq U$, pick $\mathbf{y} \in U \setminus S$. The subspace $Z(\mathbf{y}; T) \cap S$ is T-invariant (Proposition 8.1.4), lies inside $Z(\mathbf{y}; T)$, and does not contain $\mathbf{y}$; by Exercise (C2: Irreducible minimal polynomials) (c), applied to $T|_U$, it is therefore $\{\mathbf{0}\}$. Then $S + Z(\mathbf{y}; T)$ is direct — a relation $\mathbf{c}_1 + \cdots + \mathbf{c}_s + \mathbf{c} = \mathbf{0}$ with $\mathbf{c}_j \in Z(\mathbf{z}_j; T)$ and $\mathbf{c} \in Z(\mathbf{y}; T)$ puts $\mathbf{c} \in Z(\mathbf{y}; T) \cap S = \{\mathbf{0}\}$, and directness of S kills the rest (Theorem 1.7.5) — contradicting the maximality of s. Hence

$$U = Z(\mathbf{z}_1; T) \oplus \cdots \oplus Z(\mathbf{z}_s; T), \qquad m_{T,\mathbf{z}_j} = p \ \text{ for every } j.$$

Put $m = s$, and for $q < i \leq m$ put $\mathbf{u}_i = \mathbf{z}_i$ and $k_i = 1$, so that $m_{T,\mathbf{u}_i} = p^{k_i}$ for those i as well.

Step 4. The pieces fill V. First count. By Theorem 9.5.2 (a), $\dim Z(\mathbf{u}_i; T) =$

$\deg p^{k_i} = dk_i$. Hence

$$\sum_{i=1}^{m} \dim Z(\mathbf{u}_i; T) = \sum_{i=1}^{q} d(l_i + 1) + (m - q)d$$
$$= \Big(\sum_{i=1}^{q} dl_i\Big) + md = \dim W + \dim U = n,$$

where $\sum_i dl_i = \sum_i \dim Z(\mathbf{w}_i; T) = \dim W$ by Step 1, $md = \sum_j \dim Z(\mathbf{z}_j; T) = \dim U$ by Step 3, and the last equality is Theorem 3.3.1.

Next, directness. Let $\mathbf{y}_1 + \cdots + \mathbf{y}_m = \mathbf{0}$ with $\mathbf{y}_i \in Z(\mathbf{u}_i; T)$, say $\mathbf{y}_i = f_i(T)\mathbf{u}_i$ (Proposition 9.5.1 (a)). Apply P. For $i > q$ we get $P\mathbf{y}_i = f_i(T)P\mathbf{u}_i = \mathbf{0}$, since $\mathbf{u}_i \in U$. For $i \le q$ we get $P\mathbf{y}_i = f_i(T)\mathbf{w}_i \in Z(\mathbf{w}_i; T)$. So

$$\sum_{i=1}^{q} f_i(T)\mathbf{w}_i = \mathbf{0},$$

and the directness of Step 1 forces $f_i(T)\mathbf{w}_i = \mathbf{0}$ for every $i \le q$, that is, $p^{l_i} \mid f_i$ (Definition 9.5.2). Write $f_i = p^{l_i} g_i$ for $i \le q$; then

$$\mathbf{y}_i = g_i(T)\, p^{l_i}(T)\mathbf{u}_i = g_i(T)\mathbf{z}_i \in Z(\mathbf{z}_i; T) \qquad (i \le q).$$

For $i > q$, $\mathbf{y}_i \in Z(\mathbf{u}_i; T) = Z(\mathbf{z}_i; T)$ by definition. So the relation $\mathbf{y}_1 + \cdots + \mathbf{y}_m = \mathbf{0}$ is a relation between vectors of the independent subspaces $Z(\mathbf{z}_1; T), \ldots, Z(\mathbf{z}_m; T)$ of Step 3, and every $\mathbf{y}_i = \mathbf{0}$. By Theorem 1.7.5 ((b) $\Rightarrow$ (a)) the sum $\sum_i Z(\mathbf{u}_i; T)$ is direct, and by the count its dimension is n, so it is all of V (Theorem 1.6.8).

Finally the exponents. We have $k_1 = l_1 + 1 = e$, the k_i with $i \le q$ decrease because the l_i do, and the remaining ones equal $1 \le k_q$; so after listing the pieces in this order, $e = k_1 \ge \cdots \ge k_m \ge 1$. The dimension formula $\dim V = d\sum_i k_i$ is the count above. This completes the induction.

■

Two sanity checks. For $p = x$, so that T is nilpotent with $m_T = x^e$, the theorem returns Theorem 9.2.3: $Z(\mathbf{u}; T) = \operatorname{span}(\mathbf{u}, T\mathbf{u}, \ldots, T^{k-1}\mathbf{u})$ is the span of a Jordan chain written backwards, and $d = 1$, so $\dim V = \sum_i k_i$. And for $e = 1$ it returns Exercise (C2: Irreducible minimal polynomials): all pieces have dimension d, so $d \mid \dim V$.

9.6.3 Invariant factors

Now Steps 1 and 3 of the plan. Merging pieces across different primes is where Lemma 9.5.4 earns its keep.

Theorem 9.6.2 — Cyclic Decomposition Theorem

Let $V \neq \{\mathbf{0}\}$ be a finite-dimensional vector space over F and let $T \in \mathcal{L}(V)$. Then there are an integer $r \ge 1$, vectors $\mathbf{v}_1, \ldots, \mathbf{v}_r \in V$ and monic **non-constant** polynomials

$d_1, \dots, d_r \in F[x]$ such that

$$V = Z(\mathbf{v}_1; T) \oplus \cdots \oplus Z(\mathbf{v}_r; T), \qquad m_{T,\mathbf{v}_j} = d_j,$$

and

(a) $d_1 \mid d_2 \mid \cdots \mid d_r$;
(b) $d_r = m_T$;
(c) $d_1 d_2 \cdots d_r = p_T$; in particular $\sum_j \deg d_j = \dim V$;
(d) there is a **finer** decomposition $V = \bigoplus_{i,j} Z(\mathbf{v}_{ij}; T)$ into cyclic subspaces whose annihilators $m_{T,\mathbf{v}_{ij}}$ are powers of monic irreducibles, and the list of these prime powers, with repetitions, consists exactly of the prime powers occurring in the factorizations of $d_1, \dots, d_r$.

Idea. Run the plan. Primary decomposition gives one piece per prime; Theorem 9.6.1 breaks each piece into cyclic subspaces with annihilators $p_i^{e_{i1}}, p_i^{e_{i2}}, \dots$, the exponents decreasing. Arrange these in an array, one row per prime, with the largest exponent of each prime in the **first** column. Multiplying down a column gives one member of the chain, and the columns are numbered **backwards**: the first column, which carries the largest exponent of every prime, gives $d_r = m_T$; the second gives d_{r-1}; the last gives d_1. The chain $d_1 \mid \cdots \mid d_r$ comes out for free, because the exponents in a row decrease from left to right. The generator for a column is the sum of the generators in it, whose annihilator is the product by Lemma 9.5.4.

Proof. **Step 1.** By Theorem 5.3.5, $m_T = p_1^{e_1} \cdots p_k^{e_k}$ with $p_1, \dots, p_k$ distinct monic irreducibles and $e_i \geq 1$; here $\deg m_T \geq 1$ since $V \neq \{\mathbf{0}\}$ (Theorem 8.5.1). By Theorem 8.8.1, $V = V_1 \oplus \cdots \oplus V_k$ with V_i non-zero and T-invariant and $m_{T|_{V_i}} = p_i^{e_i}$.

Step 2. Fix i and apply Theorem 9.6.1 to $T|_{V_i}$. Since $Z(\mathbf{v}; T|_{V_i}) = Z(\mathbf{v}; T)$ for $\mathbf{v} \in V_i$, it gives vectors $\mathbf{v}_{i1}, \dots, \mathbf{v}_{im_i} \in V_i$ and exponents $e_i = e_{i1} \geq \cdots \geq e_{im_i} \geq 1$ with

$$V_i = Z(\mathbf{v}_{i1}; T) \oplus \cdots \oplus Z(\mathbf{v}_{im_i}; T), \qquad m_{T,\mathbf{v}_{ij}} = p_i^{e_{ij}}.$$

Combining with Step 1, V is the direct sum of **all** the subspaces $Z(\mathbf{v}_{ij}; T)$: a basis of V is obtained by concatenating bases of the V_i, each of which is a concatenation of bases of its own pieces, so Theorem 1.7.5 ((d) $\Rightarrow$ (a)) applies.

Step 3. Let $r = \max_i m_i$ and, for $1 \leq j \leq r$, put $j' = r + 1 - j$ and

$$d_j = \prod_{i\,:\,m_i \geq j'} p_i^{e_{ij'}}, \qquad \mathbf{v}_j = \sum_{i\,:\,m_i \geq j'} \mathbf{v}_{ij'}.$$

So d_r collects the largest exponent of every prime and d_1 the smallest ones still present.

The divisibility chain. The exponent of p_i in d_j is $e_{ij'}$ if $m_i \geq j'$ and 0 otherwise. As j increases, j' decreases, so this exponent is non-decreasing in j (the exponents $e_{i1} \geq e_{i2} \geq \dots$ decrease in the second index, and a 0 is followed only by values ≥ 0). Hence $d_j \mid d_{j+1}$ for every j (Lemma 8.5.2), which is (a). Taking $j = r$, so $j' = 1$, gives $d_r = \prod_i p_i^{e_{i1}} = \prod_i p_i^{e_i} = m_T$, which is (b). Each d_j is non-constant: choosing i_0 with $m_{i_0} = r$, we have $m_{i_0} \geq j'$ for every j, so the factor $p_{i_0}^{e_{i_0 j'}}$ occurs in d_j, with exponent at least 1.

The annihilators and the pieces. For fixed j, the polynomials $p_i^{e_{ij'}}$ appearing in d_j are pairwise coprime, being powers of distinct monic irreducibles: a monic common divisor of p_i^a and $p_{i'}^b$ with $i \neq i'$ is a power of each, hence 1 by the uniqueness of factorization (Lemma 8.5.2, Theorem 5.3.5 (b)). So Lemma 9.5.4 gives $m_{T,\mathbf{v}_j} = d_j$. Moreover

$$Z(\mathbf{v}_j;T) = \bigoplus_{i\,:\,m_i \geq j'} Z(\mathbf{v}_{ij'};T)\,:$$

the left side is contained in the right, because the right side is a T-invariant subspace containing $\mathbf{v}_j$ (Proposition 8.1.4, Proposition 9.5.1 (c)), and the two have the same dimension,

$$\dim Z(\mathbf{v}_j;T) = \deg d_j = \sum_i \deg p_i^{e_{ij'}} = \sum_i \dim Z(\mathbf{v}_{ij'};T),$$

by Theorem 9.5.2 (a) and Theorem 1.7.5 ((a) $\Rightarrow$ (e)); so they are equal (Theorem 1.6.8).

The decomposition. Each subspace $Z(\mathbf{v}_{ij_0};T)$, with $1 \leq j_0 \leq m_i$, occurs in exactly one of the sums just displayed, namely the one with $j = r + 1 - j_0$; so every pair (i, j_0) is used exactly once and

$$\sum_{j=1}^{r} Z(\mathbf{v}_j;T) = \sum_{i,j} Z(\mathbf{v}_{ij};T) = V,$$

and $\sum_j \dim Z(\mathbf{v}_j;T) = \sum_{i,j} \dim Z(\mathbf{v}_{ij};T) = \dim V$. By Theorem 1.7.5 ((e) $\Rightarrow$ (a)) the sum over j is direct, and it equals V.

(c) Each $Z(\mathbf{v}_j;T)$ is T-invariant and non-zero, so by Theorem 8.1.5 there is a basis $\mathcal{B}$ of V with $[T]_{\mathcal{B}} = [T|_{Z(\mathbf{v}_1;T)}] \oplus \cdots \oplus [T|_{Z(\mathbf{v}_r;T)}]$. Then $x\mathbf{I} - [T]_{\mathcal{B}}$ is block diagonal with the blocks $x\mathbf{I} - [T|_{Z(\mathbf{v}_j;T)}]$, so Theorem 6.8.4, applied $r-1$ times, gives

$$p_T = \det\left(x\mathbf{I} - [T]_{\mathcal{B}}\right) = \prod_{j=1}^{r} p_{T|_{Z(\mathbf{v}_j;T)}}$$

(Definition 6.10.2). By Theorem 9.5.2 (c), $p_{T|_{Z(\mathbf{v}_j;T)}} = m_{T,\mathbf{v}_j} = d_j$. Hence $p_T = d_1 \cdots d_r$, and comparing degrees gives $\sum_j \deg d_j = \deg p_T = \dim V$ (Theorem 6.10.2).

(d) Step 2 already produced the finer decomposition $V = \bigoplus_{i,j} Z(\mathbf{v}_{ij};T)$, with $m_{T,\mathbf{v}_{ij}} = p_i^{e_{ij}}$ a prime power. By the definition of d_j in Step 3, the exponent of p_i in d_j is $e_{i,r+1-j}$ when $m_i \geq r+1-j$ and 0 otherwise, and each pair (i,j) with $1 \leq j \leq m_i$ is used exactly once. So the prime powers occurring in $d_1, \ldots, d_r$ are exactly the polynomials $p_i^{e_{ij}}$, with the same repetitions.

■

The polynomials in the chain, and the prime powers they are built from, are the data we are after — but first we must know that they do not depend on the decomposition we happened to construct. The count that settles this is the count of Section 2 in disguise: there the chain lengths were read off from the ranks of the powers of N, and here the exponents are read off from the dimensions of the kernels of the powers of $p(T)$. Write $v_p(f)$ for the exponent of a monic irreducible p in the factorization of a non-zero $f \in F[x]$, so that $v_p(f) \geq 1$ exactly when $p \mid f$.

Proposition 9.6.3 — Counting the Exponents

Let $V \neq \{\mathbf{0}\}$ be finite-dimensional over F, let $T \in \mathcal{L}(V)$, and suppose

$$V = Z(\mathbf{u}_1; T) \oplus \cdots \oplus Z(\mathbf{u}_N; T), \qquad m_{T,\mathbf{u}_i} = g_i,$$

with every g_i monic and non-constant. Then for every monic irreducible $p \in F[x]$:

(a) $\dim \ker p(T)^k = \deg p \cdot \sum_{i=1}^{N} \min\big(k, v_p(g_i)\big)$ for every integer $k \geq 0$;

(b) for every $k \geq 1$,

$$\#\{\, i : v_p(g_i) \geq k \,\} = \frac{\dim \ker p(T)^k - \dim \ker p(T)^{k-1}}{\deg p},$$

a number depending only on T, p and k.

Idea. Kernels respect the decomposition, so we may work inside one piece. There a vector is $h(T)\mathbf{u}$, and it is killed by $p(T)^k$ exactly when $g \mid p^k h$, which after canceling the common factor $\gcd(g, p^k)$ says that h is a multiple of $g/\gcd(g, p^k)$. The surviving vectors are therefore a cyclic subspace again, generated by that multiple of $\mathbf{u}$, and its annihilator is $\gcd(g, p^k) = p^{\min(k, v_p(g))}$. Summing over the pieces and taking differences in k then counts exponents.

Proof.

(a) Write $Z_i = Z(\mathbf{u}_i; T)$ and $S = p(T)^k$. Each Z_i is T-invariant, hence S-invariant (Theorem 5.7.4 (b)). If $\mathbf{v} = \mathbf{v}_1 + \cdots + \mathbf{v}_N$ with $\mathbf{v}_i \in Z_i$, then $S\mathbf{v} = S\mathbf{v}_1 + \cdots + S\mathbf{v}_N$ with $S\mathbf{v}_i \in Z_i$, so $S\mathbf{v} = \mathbf{0}$ if and only if every $S\mathbf{v}_i = \mathbf{0}$, by the uniqueness of the splitting (Theorem 1.7.5). Therefore

$$\ker S = (\ker S \cap Z_1) \oplus \cdots \oplus (\ker S \cap Z_N),$$

and it suffices to compute each $\dim(\ker S \cap Z_i)$. Fix i and write $\mathbf{u} = \mathbf{u}_i$, $g = g_i$, $Z = Z_i$. Put

$$c = \gcd(g, p^k) = p^{\min(k,\, v_p(g))} \qquad \text{and} \qquad t = g/c,$$

the formula for c holding because a monic common divisor of g and p^k is a power of p (Lemma 8.5.2) dividing both, and $p^s \mid g$ exactly when $s \leq v_p(g)$ (Theorem 5.3.5). Every element of Z is $h(T)\mathbf{u}$ for some $h \in F[x]$ (Proposition 9.5.1 (a)), and

$$p(T)^k h(T)\mathbf{u} = \mathbf{0} \iff g \mid p^k h \iff t \mid h,$$

where the second equivalence holds because $g = ct$ and $p^k = c\,(p^k/c)$ with $\gcd(t, p^k/c) = 1$: from $ct \mid c(p^k/c)h$ we get $t \mid (p^k/c)h$, hence $t \mid h$ (Theorem 5.2.8), and conversely $t \mid h$ gives $g = ct \mid c\,h \mid p^k h$ since $c \mid p^k$. So

$$\ker S \cap Z = \{\, h(T)\mathbf{u} : t \mid h \,\} = \{\, s(T)\big(t(T)\mathbf{u}\big) : s \in F[x] \,\} = Z\big(t(T)\mathbf{u};\, T\big).$$

Its generator has annihilator c: for $s \in F[x]$, $s(T)t(T)\mathbf{u} = \mathbf{0}$ if and only if $g \mid st$, that is, $c \mid s$, because $g = ct$. Taking $s = 1$ shows that $t(T)\mathbf{u} \neq \mathbf{0}$ unless $c = 1$, so

Theorem 9.5.2 (a) applies whenever $c \neq 1$ and gives

$$\dim(\ker S \cap Z_i) = \deg c = \min\big(k, v_p(g_i)\big)\deg p,$$

where for $c = 1$ the cyclic subspace is $\{\mathbf{0}\}$ of dimension 0, in agreement. Adding over i gives (a).

(b) Subtract the values of (a) at k and $k-1$. Each term $\min(k, v_p(g_i)) - \min(k-1, v_p(g_i))$ equals 1 if $v_p(g_i) \geq k$ and 0 otherwise, so the difference is $\deg p$ times the number of indices i with $v_p(g_i) \geq k$. The left-hand side is defined from T, p and k alone.

■

Corollary 9.6.4 — Uniqueness of the Chain and of the Prime Powers

Let $V \neq \{\mathbf{0}\}$ be finite-dimensional over F and $T \in \mathcal{L}(V)$.

(a) Any two decompositions as in Theorem 9.6.2 give the **same** ordered list $d_1 \mid \cdots \mid d_r$.

(b) Any decomposition $V = Z(\mathbf{u}_1; T) \oplus \cdots \oplus Z(\mathbf{u}_N; T)$ whose annihilators $m_{T,\mathbf{u}_i}$ are powers of monic irreducibles gives the same list of annihilators, up to order, namely the prime powers occurring in $d_1, \ldots, d_r$.

(c) Explicitly, writing

$$c_p(k) = \frac{\dim\ker p(T)^k - \dim\ker p(T)^{k-1}}{\deg p} \qquad (p \text{ monic irreducible},\ k \geq 1),$$

the list is recovered by $r = \max_p c_p(1)$ and

$$v_p(d_j) = \#\{\, k \geq 1 : c_p(k) \geq r + 1 - j \,\} \qquad (1 \leq j \leq r).$$

In particular the invariant factors of T are determined by the numbers $\dim\ker p(T)^k$ alone.

Idea. Divisibility puts the zeros first: in the list $v_p(d_1) \leq \cdots \leq v_p(d_r)$, the indices where p actually occurs are a block at the **right** end. So a count of how many d_j are divisible by p^k pins down *which* ones they are, and therefore each individual exponent. The counts are supplied by Proposition 9.6.3, which sees only T.

Proof.

(a) and (c). Let $V = \bigoplus_{j=1}^{r} Z(\mathbf{v}_j; T)$ be such a decomposition, with annihilators $d_1 \mid \cdots \mid d_r$, all monic and non-constant. Fix a monic irreducible p. By Proposition 9.6.3 (b), applied to this decomposition,

$$c_p(k) = \#\{\, j : v_p(d_j) \geq k \,\} \qquad (k \geq 1),$$

so the left-hand side, which is defined from T, p and k alone, computes the right-hand side. Divisibility makes the exponents non-decreasing, $v_p(d_1) \leq \cdots \leq v_p(d_r)$,

so for each k the set $\{\, j : v_p(d_j) \geq k \,\}$ is the set of the **last** $c_p(k)$ indices:

$$v_p(d_j) \geq k \iff j \geq r + 1 - c_p(k) \iff c_p(k) \geq r + 1 - j. \qquad (*)$$

First, r is determined. Each d_j is non-constant, so $v_p(d_1) \geq 1$ for some monic irreducible p; for that p, $(*)$ with $k = 1$ and $j = 1$ gives $c_p(1) \geq r$, while $c_p(1) \leq r$ always. Hence $r = \max_p c_p(1)$. Next, for each p and each j, counting the $k \geq 1$ for which $(*)$ holds gives

$$v_p(d_j) = \#\{\, k \geq 1 : c_p(k) \geq r + 1 - j \,\},$$

a finite number, since $c_p(k) = 0$ for $k > \deg m_T$. This proves (c). Finally each d_j is monic with determined exponents $v_p(d_j)$ for every p, so d_j is determined (Theorem 5.3.5), which proves (a).

(b) Let $V = \bigoplus_i Z(\mathbf{u}_i; T)$ with $m_{T,\mathbf{u}_i} = q_i^{f_i}$, q_i monic irreducible and $f_i \geq 1$. For a monic irreducible p we have $v_p(q_i^{f_i}) = f_i$ if $q_i = p$ and 0 otherwise. Applying Proposition 9.6.3 (b) to this decomposition and to the one in (a) gives, for every p and every $k \geq 1$,

$$\#\{\, i : q_i = p,\ f_i \geq k \,\} = c_p(k) = \#\{\, j : v_p(d_j) \geq k \,\}.$$

Hence, for each p, the exponents f_i with $q_i = p$ and the positive exponents $v_p(d_j)$ form the same multiset. So the list $(q_i^{f_i})_i$ is exactly the list of prime powers occurring in $d_1, \ldots, d_r$, with the same repetitions. By Theorem 9.6.2 (d) such a decomposition exists, so both lists are non-empty and agree.

■

Definition 9.6.1 — Invariant Factors, Elementary Divisors

Let $V \neq \{\mathbf{0}\}$ be finite-dimensional over F and $T \in \mathcal{L}(V)$. The **invariant factors** of T are the monic non-constant polynomials

$$d_1 \mid d_2 \mid \cdots \mid d_r$$

of Theorem 9.6.2, which by Corollary 9.6.4 (a) do not depend on the decomposition. The **elementary divisors** of T are the prime powers occurring in the factorizations of $d_1, \ldots, d_r$, listed with repetition; by Corollary 9.6.4 (b) they are the annihilators of the pieces in any decomposition of V into cyclic subspaces with prime-power annihilators. For $\mathbf{A} \in M_n(F)$ the invariant factors and elementary divisors are those of $T_{\mathbf{A}}$.

In words: the invariant factors are the annihilators of the cyclic pieces, ordered so that each divides the next; the largest is m_T, and their product is p_T. The elementary divisors are the same information cut along the primes. Each list determines the other: one by factoring, the other by the regrouping recipe of Step 3 in the proof of Theorem 9.6.2, which Corollary 9.6.4 (c) shows to be forced.

Non-example by minimal change. Drop the divisibility clause and keep only the product. For an operator on a $\mathbb{Q}$-space of dimension 3 with $p_T = (x-1)(x-2)^2$, the pair

$$d_1 = x - 1, \qquad d_2 = (x-2)^2$$

multiplies to p_T and consists of monic non-constant polynomials of the right total degree. It is still not a list of invariant factors of anything, because $d_1 \nmid d_2$. The clause that fails is (a) of Theorem 9.6.2, and with it (b): the largest member of the list has to be m_T, and $m_T(T)$ kills every vector of V, so m_T is a multiple of the annihilator of every piece (Theorem 9.5.2 (d)). The genuine lists here are $\big((x-1)(x-2)^2\big)$ and $\big(x-2,\ (x-1)(x-2)\big)$.

> *Quick check.* Let T be an operator on a $\mathbb{Q}$-vector space with $p_T = (x^2+1)^2$. How many possibilities are there for the list of elementary divisors, and what are the corresponding invariant factors?

> *Solution.* The product of the elementary divisors is p_T (by Theorem 9.6.2 (c) and Definition 9.6.1), and x^2+1 is irreducible over $\mathbb{Q}$ (no rational root, Theorem 5.3.1 (b)). So the elementary divisors are powers of x^2+1 with exponents forming a partition of 2: either $(x^2+1)^2$ alone, or x^2+1 twice. The invariant factors are $d_1 = (x^2+1)^2$ in the first case (one piece, $r=1$) and $d_1 = d_2 = x^2+1$ in the second. The two are told apart by m_T, which is d_r: $(x^2+1)^2$ against x^2+1.

9.6.4 The rational canonical form

Everything is now assembled. Writing the matrix down is Theorem 9.5.2 (b), one piece at a time.

Every operator over every field has a block diagonal matrix whose blocks are companion matrices of a divisibility chain, and the chain is unique.

Theorem 9.6.5 — Rational Canonical Form

Let $V \neq \{\mathbf{0}\}$ be a finite-dimensional vector space over **any** field F, and let $T \in \mathcal{L}(V)$ have invariant factors $d_1 \mid d_2 \mid \cdots \mid d_r$. Then there is a basis $\mathcal{B}$ of V with

$$[T]_{\mathcal{B}} = \mathbf{C}(d_1) \oplus \mathbf{C}(d_2) \oplus \cdots \oplus \mathbf{C}(d_r),$$

and this matrix is determined by T. It is called the **rational canonical form** of T. Equivalently, every $\mathbf{A} \in M_n(F)$ with $n \geq 1$ is similar to exactly one matrix of the form $\mathbf{C}(d_1) \oplus \cdots \oplus \mathbf{C}(d_r)$ with $d_1 \mid \cdots \mid d_r$ monic and non-constant.

> *Proof.* By Theorem 9.6.2, $V = Z(\mathbf{v}_1;T) \oplus \cdots \oplus Z(\mathbf{v}_r;T)$ with $m_{T,\mathbf{v}_j} = d_j$. Each piece is T-invariant and non-zero, and by Theorem 9.5.2 (a), (b) the list $\mathcal{B}_j = (\mathbf{v}_j, T\mathbf{v}_j, \ldots, T^{\deg d_j - 1}\mathbf{v}_j)$ is a basis of $Z(\mathbf{v}_j;T)$ in which the matrix of the restriction is $\mathbf{C}(d_j)$. Let $\mathcal{B}$ be $\mathcal{B}_1, \ldots, \mathcal{B}_r$ written one after another; by Theorem 8.1.5, $\mathcal{B}$ is a basis of V and $[T]_{\mathcal{B}} = \mathbf{C}(d_1) \oplus \cdots \oplus \mathbf{C}(d_r)$. The blocks are determined by T, since the d_j are (Corollary 9.6.4 (a)).
>
> For a matrix $\mathbf{A} \in M_n(F)$, apply this to $T_{\mathbf{A}}$ and use Theorem 3.7.4. For the uniqueness in the matrix form, suppose $\mathbf{A} \sim \mathbf{C}(f_1) \oplus \cdots \oplus \mathbf{C}(f_s)$ with $f_1 \mid \cdots \mid f_s$ monic and non-constant. By Theorem 3.7.4 there is a basis $\mathcal{C}$ of F^n with $[T_{\mathbf{A}}]_{\mathcal{C}} = \mathbf{C}(f_1) \oplus \cdots \oplus \mathbf{C}(f_s)$. Let U_j be the span of the segment of $\mathcal{C}$ belonging to the j-th block; then $F^n = U_1 \oplus \cdots \oplus U_s$ with each U_j invariant and $[T_{\mathbf{A}}|_{U_j}] = \mathbf{C}(f_j)$ (Theorem 8.1.5). By Theorem 9.5.3, Theorem 8.5.5 and Definition 6.10.2, $m_{T_{\mathbf{A}}|_{U_j}} = p_{T_{\mathbf{A}}|_{U_j}} = f_j$, so $T_{\mathbf{A}}|_{U_j}$ is cyclic (Theorem 9.5.6) and $U_j = Z(\mathbf{u}_j;T_{\mathbf{A}})$ for some $\mathbf{u}_j$ with $m_{T_{\mathbf{A}},\mathbf{u}_j} = f_j$ (Theorem 9.5.2 (c)). This is a decomposition as in Theorem 9.6.2, so $(f_1, \ldots, f_s) = (d_1, \ldots, d_r)$ by Corollary 9.6.4 (a).

Hence the matrix is the rational canonical form of $\mathbf{A}$.

■

This pays off the promise made in Section 3: **there is a canonical form over every field.** No hypothesis on F was used, and none is needed. The form is canonical in the strong sense: the blocks come in a prescribed order, dictated by divisibility, so two operators have the *same* form, not merely similar forms.

Corollary 9.6.6 — Similarity via the Invariant Factors

Let $\mathbf{A}, \mathbf{B} \in M_n(F)$ with $n \geq 1$. The following are equivalent:

(a) $\mathbf{A} \sim \mathbf{B}$;
(b) $\mathbf{A}$ and $\mathbf{B}$ have the same invariant factors;
(c) $\mathbf{A}$ and $\mathbf{B}$ have the same elementary divisors, up to order;
(d) $\dim\ker p(\mathbf{A})^k = \dim\ker p(\mathbf{B})^k$ for every monic irreducible $p \in F[x]$ and every $k \geq 1$.

Proof.

(a) $\Rightarrow$ (d). If $\mathbf{B} = \mathbf{P}^{-1}\mathbf{A}\mathbf{P}$, then $p(\mathbf{B})^k = \mathbf{P}^{-1}p(\mathbf{A})^k\mathbf{P}$ (Proposition 3.7.6 (c)), so the two have the same rank (Proposition 3.7.6 (a)) and hence the same nullity (Theorem 2.5.7).

(b) $\Rightarrow$ (b). By Corollary 9.6.4 (c), the invariant factors of a matrix are computed from the numbers $\dim\ker p(\cdot)^k$ alone: those numbers give the counts $c_p(k)$, which give the length r and the exponents $v_p(d_j)$. Equal numbers therefore give equal invariant factors.

(c) $\Leftrightarrow$ (c). The elementary divisors are the prime powers in the factorizations of the invariant factors (Definition 9.6.1), so (b) $\Rightarrow$ (c). Conversely, $c_p(k)$ is the number of elementary divisors of the form p^f with $f \geq k$ (Corollary 9.6.4 (b) and (c)), so the list of elementary divisors determines every $c_p(k)$, hence the invariant factors by Corollary 9.6.4 (c); so (c) $\Rightarrow$ (b).

(d) $\Rightarrow$ (a). Both matrices are similar to $\mathbf{C}(d_1) \oplus \cdots \oplus \mathbf{C}(d_r)$ (Theorem 9.6.5), and similarity is an equivalence relation (Example (Similarity)).

■

So the invariant factors are a **complete set of similarity invariants over every field**, which is the promise of Chapter 6 kept in full; Corollary 9.3.3 was the special case in which $p_{\mathbf{A}}$ splits. Counting similarity classes becomes counting divisibility chains: over any field, the classes of $n \times n$ matrices with a given characteristic polynomial p correspond to the ways of writing $p = d_1 \cdots d_r$ with $d_1 \mid \cdots \mid d_r$ monic and non-constant.

Warning. **The invariant factors are not the factors of $p_{\mathbf{A}}$ in any naive sense, and $m_{\mathbf{A}}$ alone is only the last of them.** For $\mathbf{A} = \operatorname{diag}(1, 1, 2)$ over $\mathbb{Q}$ the invariant factors are $d_1 = x - 1$ and $d_2 = (x-1)(x-2) = m_{\mathbf{A}}$, and $d_1 d_2 = (x-1)^2(x-2) = p_{\mathbf{A}}$; the factorization of $p_{\mathbf{A}}$ into linear factors plays no role in the chain. Nor does the chain have length $\deg p_{\mathbf{A}}$: here $r = 2$ for a 3×3 matrix, and $r = 1$ exactly when $\mathbf{A}$ is cyclic

(Theorem 9.5.6).

9.6.5 Elementary divisors, and the way back to Jordan

Cutting the pieces as finely as possible gives a second form, usually with more and smaller blocks.

Theorem 9.6.7 — Elementary Divisor Form

Let $V \neq \{\mathbf{0}\}$ be finite-dimensional over F, let $T \in \mathcal{L}(V)$, and let $q_1, \dots, q_N$ be the elementary divisors of T. Then there is a basis $\mathcal{B}$ of V with

$$[T]_{\mathcal{B}} = \mathbf{C}(q_1) \oplus \mathbf{C}(q_2) \oplus \cdots \oplus \mathbf{C}(q_N),$$

and the blocks are determined by T up to their order.

Proof. By Theorem 9.6.2 (d) there is a decomposition $V = \bigoplus_{i,j} Z(\mathbf{v}_{ij}; T)$ into cyclic subspaces whose annihilators are prime powers, and by Corollary 9.6.4 (b) those annihilators are exactly the elementary divisors $q_1, \dots, q_N$ of T, up to order. Take the basis of Theorem 9.5.2 (a) in each piece and concatenate; Theorem 9.5.2 (b) and Theorem 8.1.5 give the displayed matrix. The list of blocks depends on T alone, again by Corollary 9.6.4 (b).

■

When the characteristic polynomial splits, this is the Jordan form in disguise, because a companion block for a power of a linear polynomial is a Jordan block.

Corollary 9.6.8 — Companion Blocks of Linear Powers Are Jordan Blocks

Let $\lambda \in F$ and $k \geq 1$. Then

$$\mathbf{C}\big((x-\lambda)^k\big) \sim \mathbf{J}_k(\lambda).$$

Consequently, if p_T splits over F, then the elementary divisors of T are the polynomials $(x-\lambda)^k$ for the Jordan blocks $\mathbf{J}_k(\lambda)$ of T, and the elementary divisor form of Theorem 9.6.7 and the Jordan form of T are obtained from one another by replacing each block $\mathbf{C}\big((x-\lambda)^k\big)$ by $\mathbf{J}_k(\lambda)$ and conversely.

Proof. Put $\mathbf{J} = \mathbf{J}_k(\lambda)$. Then $\mathbf{J} - \lambda\mathbf{I} = \mathbf{J}_k(0)$ satisfies $\mathbf{J}_k(0)^k = 0 \neq \mathbf{J}_k(0)^{k-1}$, so $(x-\lambda)^k$ annihilates $\mathbf{J}$ and no smaller power does; by Lemma 8.5.2 and Theorem 8.5.1, $m_{\mathbf{J}} = (x-\lambda)^k$. Also $p_{\mathbf{J}} = (x-\lambda)^k$ (Theorem 6.4.6), so $m_{\mathbf{J}} = p_{\mathbf{J}}$ and $\mathbf{J}$ is cyclic (Theorem 9.5.6). By the last sentence of that theorem, $\mathbf{J}$ is similar to $\mathbf{C}(m_{\mathbf{J}}) = \mathbf{C}\big((x-\lambda)^k\big)$.

Now suppose p_T splits and let $\mathcal{B}$ be a Jordan basis, with $[T]_{\mathcal{B}} = \mathbf{J}_{k_1}(\mu_1) \oplus \cdots \oplus \mathbf{J}_{k_m}(\mu_m)$ (Theorem 9.3.1). Each block corresponds to a T-invariant subspace U_l, spanned by the segment of $\mathcal{B}$ belonging to it, with $V = U_1 \oplus \cdots \oplus U_m$ and $[T|_{U_l}] = \mathbf{J}_{k_l}(\mu_l)$. By the

first paragraph, $m_{T|_{U_l}} = p_{T|_{U_l}} = (x-\mu_l)^{k_l}$, so $T|_{U_l}$ is cyclic: there is $\mathbf{v}_l \in U_l$ with $U_l = Z(\mathbf{v}_l; T)$ and $m_{T,\mathbf{v}_l} = (x-\mu_l)^{k_l}$ (Theorem 9.5.6, Theorem 9.5.2 (c)). Since $x-\mu_l$ is irreducible, being of degree 1, this exhibits V as a direct sum of cyclic subspaces with prime-power annihilators, so by Corollary 9.6.4 (b) the elementary divisors of T are exactly the polynomials $(x-\mu_l)^{k_l}$. Replacing each Jordan block by the similar companion block, or conversely, therefore turns one form into the other.

■

Remark. The two forms carry the same information in different shapes, and each is better for something. The rational canonical form of Theorem 9.6.5 has the fewest blocks and reads off $m_T = d_r$ at a glance; the elementary divisor form has the most blocks and reads off the primes, and over a splitting field it is the Jordan form. The rational form is also called the **Frobenius normal form**. The word *rational* refers to the field: the form is computed by rational operations in F, with no root extraction, which is exactly why it exists over every field.

9.6.6 Similarity does not depend on the field

Here is a striking consequence, and one that would be hard to guess. Two rational matrices might conceivably be conjugate by a complex matrix and by no rational one. They cannot be.

Lemma 9.6.9 — Rank Does Not Change with the Field

Let K be a subfield of a field L and let $\mathbf{M} \in M_{m\times n}(K)$. Then the rank of $\mathbf{M}$ computed over K equals its rank computed over L.

Proof. If $\mathbf{M} = 0$, both ranks are 0. Otherwise, by Theorem 6.7.1 (a), each rank is the largest k such that some $k \times k$ minor of $\mathbf{M}$ is non-zero. The minors are determinants of submatrices of $\mathbf{M}$, computed by the Leibniz formula from the entries of $\mathbf{M}$ (Definition 6.4.1), so they are the **same elements of** K whichever field we regard $\mathbf{M}$ in. And an element of K is zero in K if and only if it is zero in L. So the two largest such k agree.

■

Corollary 9.6.10 — Similarity Is Independent of the Field

Let K be a subfield of L and let $\mathbf{A}, \mathbf{B} \in M_n(K)$, $n \geq 1$. If $\mathbf{A}$ and $\mathbf{B}$ are similar over L, then they are similar over K:

$$\mathbf{A} = \mathbf{Q}^{-1}\mathbf{B}\mathbf{Q} \text{ for some invertible } \mathbf{Q} \in M_n(L)$$
$$\Longrightarrow \mathbf{A} = \mathbf{P}^{-1}\mathbf{B}\mathbf{P} \text{ for some invertible } \mathbf{P} \in M_n(K).$$

Idea. Similarity over K is decided by the numbers $\dim\ker p(\mathbf{A})^k$ for the monic irreducibles p of $K[x]$ (Corollary 9.6.6). Each such number is a nullity of a matrix with entries in K, and nullities do not notice a larger field. Similarity over L makes the

numbers agree when computed over L, hence over K.

Proof. Let $p \in K[x]$ be monic irreducible and $k \geq 1$. The matrices $p(\mathbf{A})^k$ and $p(\mathbf{B})^k$ have entries in K. Since $\mathbf{A}$ and $\mathbf{B}$ are similar over L, say $\mathbf{A} = \mathbf{Q}^{-1}\mathbf{B}\mathbf{Q}$, we have $p(\mathbf{A})^k = \mathbf{Q}^{-1}p(\mathbf{B})^k\mathbf{Q}$ (Proposition 3.7.6 (c)), so these two matrices have the same rank over L (Proposition 3.7.6 (a)). By Lemma 9.6.9 their ranks over K are the same numbers, hence

$$\dim\ker p(\mathbf{A})^k = n - \operatorname{rank} p(\mathbf{A})^k = n - \operatorname{rank} p(\mathbf{B})^k = \dim\ker p(\mathbf{B})^k$$

over K, by Theorem 2.5.7. As p and k were arbitrary, Corollary 9.6.6 ((d) $\Rightarrow$ (a)) gives $\mathbf{A} \sim \mathbf{B}$ over K.

■

The invariant factors are computed in $K[x]$ and never need a root; that is the whole reason. Note what the corollary does **not** say: the invariant factors themselves do change with the field, since the irreducible polynomials do. Over $\mathbb{Q}$ the matrix $\mathbf{C}\big((x^2+1)^2\big)$ has the single invariant factor $(x^2+1)^2$ and the single elementary divisor $(x^2+1)^2$; over $\mathbb{C}$ its invariant factor is unchanged, but its elementary divisors are $(x-i)^2$ and $(x+i)^2$, and its Jordan form is $\mathbf{J}_2(i)\oplus\mathbf{J}_2(-i)$. What is field-independent is the **answer to the similarity question**, not the bookkeeping.

9.6.7 Computing the forms

Algorithm. **Invariant factors, elementary divisors and the two forms of $\mathbf{A} \in M_n(F)$.**

1. Compute $p_{\mathbf{A}}$ and factor it into monic irreducibles over F: $p_{\mathbf{A}} = p_1^{a_1}\cdots p_k^{a_k}$.
2. For each i and each $k \geq 1$, compute $\dim\ker p_i(\mathbf{A})^k$ until it stops growing, and read off the exponents of the elementary divisors for p_i from Proposition 9.6.3, subtracting twice for exact counts. (Equivalently: find $m_{\mathbf{A}}$ and, in small cases, use $\sum_{i,j} e_{ij}\deg p_i = n$ with $\max_j e_{ij}$ = the exponent of p_i in $m_{\mathbf{A}}$.)
3. Group the exponents of each prime into a row, in decreasing order, and multiply down the columns, numbering them backwards: the first column gives $d_r = m_{\mathbf{A}}$, the second d_{r-1}, the last d_1.
4. Write $\mathbf{C}(d_1)\oplus\cdots\oplus\mathbf{C}(d_r)$, or $\bigoplus_{i,j}\mathbf{C}(p_i^{e_{ij}})$.
5. For a basis: find a cyclic generator for each piece, as in Section 5.

Example. (Invariant Factors from Polynomial Data)

Let T be an operator on a 6-dimensional $\mathbb{Q}$-vector space with

$$p_T = (x-1)^2(x^2+1)^2, \qquad m_T = (x-1)(x^2+1)^2.$$

Find the elementary divisors, the invariant factors, the rational canonical form (Theorem 9.6.5) and the elementary divisor form (Theorem 9.6.7).

Solution. The primes. $x-1$ and x^2+1 are monic irreducible over $\mathbb{Q}$ (the second has no rational root, Theorem 5.3.1 (b)), and $\deg p_T = 2+4 = 6$ as it must be.

The exponents. The elementary divisors are powers $(x-1)^a$ and $(x^2+1)^b$. For each prime, the largest exponent occurring is its exponent in $m_T = d_r$ (Theorem 9.6.2 (b), Definition 9.6.1), and the exponents weighted by the degrees sum to $\deg p_T$ (Theorem 9.6.2 (c)). For $x-1$: the largest exponent is 1 and the total contribution is 2, so there are two elementary divisors $x-1$. For x^2+1: the largest exponent is 2 and the total contribution is $4 = 2 \cdot 2$, so there is exactly one elementary divisor $(x^2+1)^2$. Hence the elementary divisors are

$$x-1, \qquad x-1, \qquad (x^2+1)^2.$$

The invariant factors. Arrange the exponents by prime in decreasing order:

$$x-1: \ 1,1; \qquad x^2+1: \ 2.$$

So $r = \max(2,1) = 2$, and multiplying down the columns, the first giving d_2 and the second d_1,

$$d_2 = (x-1)(x^2+1)^2 = m_T, \qquad d_1 = x-1.$$

Check: $d_1 \mid d_2$ and $d_1 d_2 = (x-1)^2(x^2+1)^2 = p_T$.

The forms. With $d_2 = (x-1)(x^2+1)^2 = (x-1)(x^4+2x^2+1) = x^5-x^4+2x^3-2x^2+x-1$,

$$\mathbf{C}(d_1) \oplus \mathbf{C}(d_2) = (1) \oplus \begin{pmatrix} 0 & 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 & -1 \\ 0 & 1 & 0 & 0 & 2 \\ 0 & 0 & 1 & 0 & -2 \\ 0 & 0 & 0 & 1 & 1 \end{pmatrix},$$

of total size $1+5=6$. The elementary divisor form is smaller-blocked:

$$\mathbf{C}(x-1) \oplus \mathbf{C}(x-1) \oplus \mathbf{C}\big((x^2+1)^2\big) = (1) \oplus (1) \oplus \begin{pmatrix} 0 & 0 & 0 & -1 \\ 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & -2 \\ 0 & 0 & 1 & 0 \end{pmatrix},$$

of total size $1+1+4=6$. Read as a complex matrix, the second form splits further: over $\mathbb{C}$ we have $x^2+1 = (x-i)(x+i)$, so the elementary divisors become $x-1, x-1, (x-i)^2, (x+i)^2$ — the invariant factors d_1, d_2 are unchanged — and Corollary 9.6.8 turns the elementary divisor form into the Jordan form $(1) \oplus (1) \oplus \mathbf{J}_2(i) \oplus \mathbf{J}_2(-i)$. Over $\mathbb{Q}$ no further splitting is possible, since x^2+1 is irreducible there.

Example. (The Rational Canonical Form of a Matrix over the Rationals)

Let

$$\mathbf{A} = \begin{pmatrix} 0 & -1 & 1 & 0 \\ 1 & 0 & 0 & 1 \\ 0 & 0 & 0 & -1 \\ 0 & 0 & 1 & 0 \end{pmatrix} \in M_4(\mathbb{Q}), \qquad p_{\mathbf{A}} = (x^2+1)^2.$$

Find the invariant factors of $\mathbf{A}$, its rational canonical form (Theorem 9.6.5), and an invertible $\mathbf{P} \in M_4(\mathbb{Q})$ realizing it.

Solution. The characteristic polynomial. In 2×2 blocks, $\mathbf{A} = \begin{pmatrix} \mathbf{R} & \mathbf{I}_2 \\ 0 & \mathbf{R} \end{pmatrix}$ with $\mathbf{R} =$

$\begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$, so $x\mathbf{I} - \mathbf{A}$ is block upper triangular and $p_{\mathbf{A}} = (\det(x\mathbf{I}_2 - \mathbf{R}))^2 = (x^2+1)^2$ (Theorem 6.8.4), as stated.

The minimal polynomial. By Theorem 8.5.1 and Lemma 8.5.2, $m_{\mathbf{A}}$ is x^2+1 or $(x^2+1)^2$. Compute $\mathbf{A}^2$: its columns are $\mathbf{A}$ applied to the columns of $\mathbf{A}$. With $\mathbf{c}_1, \dots, \mathbf{c}_4$ the columns of $\mathbf{A}$,

$$\mathbf{A}\mathbf{c}_1 = \mathbf{A}(0,1,0,0) = (-1,0,0,0), \qquad \mathbf{A}\mathbf{c}_2 = \mathbf{A}(-1,0,0,0) = (0,-1,0,0),$$

$$\mathbf{A}\mathbf{c}_3 = \mathbf{A}(1,0,0,1) = (0,1,0,0) + (0,1,-1,0) = (0,2,-1,0),$$
$$\mathbf{A}\mathbf{c}_4 = \mathbf{A}(0,1,-1,0) = (-1,0,0,0) + (-1,0,0,-1) = (-2,0,0,-1).$$

So

$$\mathbf{A}^2 = \begin{pmatrix} -1 & 0 & 0 & -2 \\ 0 & -1 & 2 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & -1 \end{pmatrix}, \qquad \mathbf{A}^2 + \mathbf{I} = \begin{pmatrix} 0 & 0 & 0 & -2 \\ 0 & 0 & 2 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} \neq 0.$$

Hence $m_{\mathbf{A}} = (x^2+1)^2 = p_{\mathbf{A}}$, and $\mathbf{A}$ is cyclic (Theorem 9.5.6). So $r = 1$, the single invariant factor is $d_1 = (x^2+1)^2 = x^4 + 2x^2 + 1$, and the rational canonical form is

$$\mathbf{C}(d_1) = \begin{pmatrix} 0 & 0 & 0 & -1 \\ 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & -2 \\ 0 & 0 & 1 & 0 \end{pmatrix}.$$

The elementary divisor form (Theorem 9.6.7) is the same matrix, since x^2+1 is irreducible over $\mathbb{Q}$ and d_1 is already a prime power.

A cyclic vector. By Theorem 9.5.6 we need $\mathbf{v}$ with $m_{\mathbf{A},\mathbf{v}} = m_{\mathbf{A}}$; since $\mathbf{A}^2 + \mathbf{I} \neq 0$, pick $\mathbf{v}$ with $(\mathbf{A}^2 + \mathbf{I})\mathbf{v} \neq \mathbf{0}$. The third column of $\mathbf{A}^2 + \mathbf{I}$ is non-zero, so $\mathbf{v} = \mathbf{e}_3$ works: then $(\mathbf{A}^2 + \mathbf{I})\mathbf{v} \neq \mathbf{0}$, so $m_{\mathbf{A},\mathbf{v}} \nmid x^2+1$, and as $m_{\mathbf{A},\mathbf{v}}$ divides $(x^2+1)^2$ it must equal $(x^2+1)^2$ (Lemma 8.5.2). Its chain is

$$\mathbf{v} = (0,0,1,0), \quad \mathbf{A}\mathbf{v} = (1,0,0,1), \quad \mathbf{A}^2\mathbf{v} = (0,2,-1,0),$$
$$\mathbf{A}^3\mathbf{v} = \mathbf{A}(0,2,-1,0) = (-2,0,0,0) + (-1,0,0,-1) = (-3,0,0,-1),$$

reading columns of $\mathbf{A}$ as before. Hence

$$\mathbf{P} = \begin{pmatrix} 0 & 1 & 0 & -3 \\ 0 & 0 & 2 & 0 \\ 1 & 0 & -1 & 0 \\ 0 & 1 & 0 & -1 \end{pmatrix}, \qquad \mathbf{P}^{-1}\mathbf{A}\mathbf{P} = \mathbf{C}\big((x^2+1)^2\big).$$

Invertibility of $\mathbf{P}$. Expanding $\det \mathbf{P}$ along the third row, whose entries are $(1,0,-1,0)$ (Theorem 6.6.1), and then each 3×3 determinant along its own first column,

$$\det \mathbf{P} = 1 \cdot \det \begin{pmatrix} 1 & 0 & -3 \\ 0 & 2 & 0 \\ 1 & 0 & -1 \end{pmatrix} + (-1)(-1)^{3+3} \det \begin{pmatrix} 0 & 1 & -3 \\ 0 & 0 & 0 \\ 0 & 1 & -1 \end{pmatrix}$$
$$= 1 \cdot \big(2(-1+3)\big) - 0 = 4 \neq 0,$$

the second determinant vanishing because it has a zero row, and the first being $2\det\begin{pmatrix}1 & -3\\ 1 & -1\end{pmatrix} = 2\cdot 2 = 4$ by expansion along its second row.

The check. The identity $\mathbf{AP} = \mathbf{P}\,\mathbf{C}(d_1)$ reads column by column as $\mathbf{Av} = \mathbf{Av}$, $\mathbf{A}(\mathbf{Av}) = \mathbf{A}^2\mathbf{v}$, $\mathbf{A}(\mathbf{A}^2\mathbf{v}) = \mathbf{A}^3\mathbf{v}$ — true by construction — and

$$\mathbf{A}(\mathbf{A}^3\mathbf{v}) = -\mathbf{v} - 2\mathbf{A}^2\mathbf{v},$$

which is the annihilator relation $\mathbf{A}^4 + 2\mathbf{A}^2 + \mathbf{I} = 0$ applied to $\mathbf{v}$. Verifying it directly: $\mathbf{A}(-3,0,0,-1) = -3(0,1,0,0) - (0,1,-1,0) = (0,-4,1,0)$, while

$$-\mathbf{v} - 2\mathbf{A}^2\mathbf{v} = -(0,0,1,0) - 2(0,2,-1,0) = (0,-4,2-1,0) = (0,-4,1,0).\checkmark$$

9.6.8 Exercises

9.6.8.1 A. Check your understanding

Exercise A1.

(a) State the Cyclic Decomposition Theorem, including the divisibility chain and what d_r and $\prod_j d_j$ are.

(b) Define the invariant factors and the elementary divisors of T.

(c) What is the rational canonical form of T, and over which fields does it exist?

(d) True or false: two matrices in $M_n(\mathbb{Q})$ that are similar over $\mathbb{C}$ are similar over $\mathbb{Q}$. Justify your answer.

(e) An operator on a 5-dimensional $\mathbb{Q}$-space has $p_T = (x-3)^5$ and $m_T = (x-3)^2$. What are its elementary divisors and invariant factors?

(f) True or false: $r = 1$ if and only if T is cyclic. Justify your answer.

Solution.

(a) For $V \neq \{\mathbf{0}\}$ finite-dimensional and $T \in \mathcal{L}(V)$, there are $\mathbf{v}_1, \dots, \mathbf{v}_r$ with $V = Z(\mathbf{v}_1;T) \oplus \cdots \oplus Z(\mathbf{v}_r;T)$ and $m_{T,\mathbf{v}_j} = d_j$, where $d_1 \mid d_2 \mid \cdots \mid d_r$ are monic and non-constant, $d_r = m_T$ and $d_1 \cdots d_r = p_T$ (Theorem 9.6.2).

(b) The invariant factors are the polynomials $d_1 \mid \cdots \mid d_r$ of that theorem; the elementary divisors are the prime powers occurring in their factorizations, listed with repetition (Definition 9.6.1). Both are determined by T (Corollary 9.6.4).

(c) The matrix $\mathbf{C}(d_1) \oplus \cdots \oplus \mathbf{C}(d_r)$, which is $[T]_{\mathcal{B}}$ for a suitable basis; it exists over **every** field (Theorem 9.6.5).

(d) True, by Corollary 9.6.10 with $K = \mathbb{Q}$ and $L = \mathbb{C}$.

(e) Elementary divisors are powers of $x-3$ with largest exponent 2 and exponents summing to 5: so $(x-3)^2, (x-3)^2, x-3$. The exponents, in decreasing order, are $2, 2, 1$; numbering the columns backwards gives $d_3 = (x-3)^2 = m_T$, $d_2 = (x-3)^2$ and $d_1 = x-3$.

(f) True. $r = 1$ means $V = Z(\mathbf{v}_1;T)$, that is, $\mathbf{v}_1$ is a cyclic vector; conversely if $\mathbf{v}$ is cyclic, then $d_1 = m_{T,\mathbf{v}} = m_T = p_T$ is the only invariant factor, by Theorem 9.5.6 and the uniqueness in Corollary 9.6.4.

9.6.8.2 B. Practice

Exercise B1: Invariant factors from given data.

In each case T is an operator on a $\mathbb{Q}$-vector space with the stated characteristic and minimal polynomials. Find the elementary divisors, the invariant factors, and the rational canonical form (Theorem 9.6.5).

(a) $p_T = (x-2)^4$, $m_T = (x-2)^2$.
(b) $p_T = (x^2-2)^3$, $m_T = (x^2-2)^2$.
(c) $p_T = (x-1)^2(x+1)^2$, $m_T = (x-1)(x+1)$.

Solution.

(a) Powers of $x-2$ with largest exponent 2 and exponents summing to 4: either $2,2$ or $2,1,1$. So the data do **not** determine the answer; both

$$\text{elementary divisors } (x-2)^2, (x-2)^2 \quad \text{and} \quad (x-2)^2, x-2, x-2$$

are possible, with invariant factors $\big((x-2)^2, (x-2)^2\big)$ and $\big(x-2, x-2, (x-2)^2\big)$ and rational forms

$$\mathbf{C}\big((x-2)^2\big) \oplus \mathbf{C}\big((x-2)^2\big), \qquad (2) \oplus (2) \oplus \mathbf{C}\big((x-2)^2\big),$$

where $\mathbf{C}\big((x-2)^2\big) = \mathbf{C}(x^2-4x+4) = \begin{pmatrix} 0 & -4 \\ 1 & 4 \end{pmatrix}$. (The extra datum that decides is $\dim\ker(T-2\,\mathrm{id})$, which is 2 in the first case and 3 in the second, by Proposition 9.6.3.)

(b) x^2-2 is irreducible over $\mathbb{Q}$, since $\sqrt{2} \notin \mathbb{Q}$ (Theorem 0.2.3, Theorem 5.3.1 (b)). The exponents are powers of x^2-2 with largest 2 summing to 3: only $2,1$. So the elementary divisors are $(x^2-2)^2$ and x^2-2, the invariant factors are $d_1 = x^2-2$ and $d_2 = (x^2-2)^2 = x^4-4x^2+4$, and the rational form is

$$\mathbf{C}(x^2-2) \oplus \mathbf{C}\big((x^2-2)^2\big) = \begin{pmatrix} 0 & 2 \\ 1 & 0 \end{pmatrix} \oplus \begin{pmatrix} 0 & 0 & 0 & -4 \\ 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 4 \\ 0 & 0 & 1 & 0 \end{pmatrix},$$

of size $2+4 = 6 = \deg p_T$.

(c) Both primes have largest exponent 1 and total contribution 2, so the elementary divisors are $x-1, x-1, x+1, x+1$. Arranging by prime, $x-1 : 1,1$ and $x+1 : 1,1$, so $r = 2$ and $d_2 = (x-1)(x+1) = m_T$, $d_1 = (x-1)(x+1)$. The rational form is

$$\mathbf{C}(x^2-1) \oplus \mathbf{C}(x^2-1) = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} \oplus \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}.$$

(This operator is diagonalizable, with $\mathrm{diag}(1,1,-1,-1)$ as its Jordan form; the rational form is a different matrix representing the same operator.)

Exercise B2: Rational forms of matrices.

For each matrix, find $p_{\mathbf{A}}$, $m_{\mathbf{A}}$, the invariant factors, the rational canonical form (Theo-

rem 9.6.5) and the elementary divisor form (Theorem 9.6.7).

(a) $\mathbf{A}_1 = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 0 & 0 \end{pmatrix} \in M_3(\mathbb{Q})$.

(b) $\mathbf{A}_2 = \operatorname{diag}(1, 1, 2) \in M_3(\mathbb{Q})$.

(c) $\mathbf{A}_3 = \begin{pmatrix} 0 & -1 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & -1 \\ 0 & 0 & 1 & 0 \end{pmatrix} \in M_4(\mathbb{Q})$.

Solution.

(a) Reading the columns, $\mathbf{A}_1\mathbf{e}_1 = \mathbf{e}_3$, $\mathbf{A}_1\mathbf{e}_3 = \mathbf{e}_2$ and $\mathbf{A}_1\mathbf{e}_2 = \mathbf{e}_1$, so $\mathbf{A}_1^3 = \mathbf{I}$ and the polynomial $x^3 - 1$ annihilates $\mathbf{A}_1$. Also $\mathbf{A}_1^2\mathbf{e}_1 = \mathbf{A}_1\mathbf{e}_3 = \mathbf{e}_2$, so $(\mathbf{e}_1, \mathbf{A}_1\mathbf{e}_1, \mathbf{A}_1^2\mathbf{e}_1) = (\mathbf{e}_1, \mathbf{e}_3, \mathbf{e}_2)$ is a basis of $\mathbb{Q}^3$ and $\mathbf{e}_1$ is a cyclic vector. Hence $\deg m_{\mathbf{A}_1} = 3$ (Theorem 9.5.6), and since $m_{\mathbf{A}_1}$ is monic of degree 3 dividing $x^3 - 1$, we get $m_{\mathbf{A}_1} = p_{\mathbf{A}_1} = x^3 - 1$. The single invariant factor is $d_1 = x^3 - 1$, and the rational canonical form is

$$\mathbf{C}(x^3 - 1) = \begin{pmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix}.$$

Over $\mathbb{Q}$, $x^3 - 1 = (x - 1)(x^2 + x + 1)$ with both factors irreducible (the quadratic has no rational root). So the elementary divisors are $x - 1$ and $x^2 + x + 1$, and the elementary divisor form is

$$(1) \oplus \mathbf{C}(x^2 + x + 1) = (1) \oplus \begin{pmatrix} 0 & -1 \\ 1 & -1 \end{pmatrix}.$$

(b) $p_{\mathbf{A}_2} = (x - 1)^2(x - 2)$ and $m_{\mathbf{A}_2} = (x - 1)(x - 2)$ (Proposition 8.5.6). Elementary divisors: $x - 1, x - 1, x - 2$. Invariant factors: $d_2 = (x - 1)(x - 2) = m_{\mathbf{A}_2}$ and $d_1 = x - 1$. Rational form

$$(1) \oplus \mathbf{C}\big((x - 1)(x - 2)\big) = (1) \oplus \begin{pmatrix} 0 & -2 \\ 1 & 3 \end{pmatrix},$$

elementary divisor form $(1) \oplus (1) \oplus (2) = \operatorname{diag}(1, 1, 2) = \mathbf{A}_2$ itself.

(c) $\mathbf{A}_3 = \mathbf{R} \oplus \mathbf{R}$ with $\mathbf{R} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$, and $p_{\mathbf{R}} = x^2 + 1$, $m_{\mathbf{R}} = x^2 + 1$, so $p_{\mathbf{A}_3} = (x^2 + 1)^2$ (Theorem 6.8.4 applied to $x\mathbf{I} - \mathbf{A}_3$, which is block diagonal over $\mathbb{Q}[x]$) and $m_{\mathbf{A}_3} = \operatorname{lcm}(x^2 + 1, x^2 + 1) = x^2 + 1$ (Proposition 8.5.6). Since $x^2 + 1$ is irreducible over $\mathbb{Q}$, the elementary divisors are $x^2 + 1$ and $x^2 + 1$; $r = 2$ and $d_1 = d_2 = x^2 + 1$. Both forms are

$$\mathbf{C}(x^2 + 1) \oplus \mathbf{C}(x^2 + 1) = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} \oplus \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} = \mathbf{A}_3.$$

Compare Example (The Rational Canonical Form of a Matrix over the Rationals): that matrix has the same characteristic polynomial but a different minimal polynomial, so the two are **not** similar.

Exercise B3: Counting similarity classes over a finite field.

Work over $F = \mathbb{F}_2$. For each polynomial p, find the number of similarity classes of matrices $\mathbf{A} \in M_3(\mathbb{F}_2)$ with $p_{\mathbf{A}} = p$, and list the invariant factors of each class.

(a) $p = (x+1)^3$.
(b) $p = x(x+1)^2$.
(c) $p = x^3 + x + 1$.

Hint: by Corollary 9.6.6, a class is a way of writing $p = d_1 \cdots d_r$ with $d_1 \mid \cdots \mid d_r$.

Solution.

(a) The only prime involved is $x+1$, so the elementary divisors are powers $(x+1)^a$ with exponents forming a partition of 3. The three partitions (3), (2, 1), (1, 1, 1) give

$$\big((x+1)^3\big), \qquad \big(x+1,\ (x+1)^2\big), \qquad \big(x+1,\ x+1,\ x+1\big)$$

as lists of invariant factors. So there are 3 classes, with representatives $\mathbf{C}\big((x+1)^3\big)$, $(1) \oplus \mathbf{C}\big((x+1)^2\big)$ and $\mathbf{I}_3$ (note $-1 = 1$ in $\mathbb{F}_2$).

(b) Now two primes, x with total exponent 1 and $x+1$ with total exponent 2. For x the only option is the single elementary divisor x; for $x+1$ the options are $(x+1)^2$ or $x+1, x+1$. So there are 2 classes, with invariant factors

$$\big(x(x+1)^2\big) \qquad \text{and} \qquad \big(x+1,\ x(x+1)\big).$$

In the first case $r = 1$ and the matrix is cyclic; in the second $r = 2$.

(c) $x^3 + x + 1$ has no root in $\mathbb{F}_2$ (its values at 0 and 1 are 1 and 1), so it is irreducible (Theorem 5.3.1 (b)). A prime of degree 3 in a characteristic polynomial of degree 3 can occur only with exponent 1, so the only possible list of elementary divisors is $(x^3 + x + 1)$ itself: 1 class, represented by $\mathbf{C}(x^3 + x + 1)$.

9.6.8.3 C. Going deeper

Exercise C1: Which matrices are companion matrices.

Let $\mathbf{A} \in M_n(F)$ with $n \geq 1$.

(a) Prove that $\mathbf{A}$ is similar to a companion matrix if and only if $m_{\mathbf{A}} = p_{\mathbf{A}}$, and that the companion matrix is then $\mathbf{C}(p_{\mathbf{A}})$.
(b) Deduce that $\mathbf{A}$ is similar to a companion matrix if and only if its rational canonical form has exactly one block.
(c) Give an example of a matrix in $M_2(F)$ that is not similar to any companion matrix.

Solution.

(a) ($\Leftarrow$) If $m_{\mathbf{A}} = p_{\mathbf{A}}$, then $\mathbf{A}$ is cyclic (Theorem 9.5.6) and, in the basis generated by a cyclic vector, its matrix is $\mathbf{C}(m_{\mathbf{A}}) = \mathbf{C}(p_{\mathbf{A}})$; so $\mathbf{A} \sim \mathbf{C}(p_{\mathbf{A}})$ (Theorem 3.7.4). ($\Rightarrow$) Suppose $\mathbf{A} \sim \mathbf{C}(q)$ for some monic q. By Theorem 9.5.3, $m_{\mathbf{C}(q)} = p_{\mathbf{C}(q)} = q$. Similar matrices share both polynomials (Theorem 6.10.3, Theorem 8.5.5), so

$m_{\mathbf{A}} = p_{\mathbf{A}} = q$, and the companion matrix is $\mathbf{C}(p_{\mathbf{A}})$.

(b) By Theorem 9.6.5 the form has one block exactly when $r = 1$, that is, when $d_1 = m_{\mathbf{A}} = p_{\mathbf{A}}$ (Theorem 9.6.2 (b), (c)). Now apply (a).

(c) $\mathbf{I}_2$: here $m = x - 1 \neq (x-1)^2 = p$. Concretely, $\mathbf{I}_2$ is similar only to itself, and no companion matrix of a monic quadratic is $\mathbf{I}_2$, since the $(2,1)$ entry of $\mathbf{C}(q)$ is $1 \neq 0$.

Exercise C2: All similarity classes of two by two matrices over the smallest field.

Work over $F = \mathbb{F}_2$, so that $M_2(\mathbb{F}_2)$ has 16 elements.

(a) List the four monic polynomials of degree 2 over $\mathbb{F}_2$ and factor each into irreducibles.

(b) For each, list the possible lists of invariant factors of a matrix $\mathbf{A} \in M_2(\mathbb{F}_2)$ with that characteristic polynomial.

(c) Conclude the total number of similarity classes in $M_2(\mathbb{F}_2)$, and give a representative of each.

(d) Check your count against the orbit sizes: $|\mathrm{GL}_2(\mathbb{F}_2)| = 6$, and the class of $\mathbf{A}$ has $6/|\{\mathbf{P} : \mathbf{P}^{-1}\mathbf{A}\mathbf{P} = \mathbf{A}\}|$ elements.

Solution.

(a) x^2; $x^2 + 1 = (x+1)^2$; $x^2 + x = x(x+1)$; and $x^2 + x + 1$, which has no root in $\mathbb{F}_2$ and is therefore irreducible (Theorem 5.3.1 (b)).

(b) For $p = x^2$: elementary divisors x^2 (invariant factors (x^2)) or x, x (invariant factors (x, x)) — two options. For $p = (x+1)^2$: likewise two, $\big((x+1)^2\big)$ and $(x+1, x+1)$. For $p = x(x+1)$: each prime occurs once, so the elementary divisors are $x, x+1$ and there is a single list of invariant factors, $\big(x(x+1)\big)$. For the irreducible $p = x^2+x+1$: one option, $(x^2 + x + 1)$.

(c) Total $2 + 2 + 1 + 1 = 6$ classes, with representatives

$$\mathbf{C}(x^2) = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix}, \quad 0, \quad \mathbf{C}\big((x+1)^2\big) = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix},$$
$$\mathbf{I}_2, \quad \mathrm{diag}(0,1), \quad \mathbf{C}(x^2+x+1) = \begin{pmatrix} 0 & 1 \\ 1 & 1 \end{pmatrix},$$

using $-1 = 1$ in $\mathbb{F}_2$. (For $(x+1)^2 = x^2 + 1$ the coefficients are $a_0 = 1, a_1 = 0$, so $\mathbf{C} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$, the coordinate swap.)

(d) The two scalar matrices 0 and $\mathbf{I}_2$ commute with everything, so their classes have $6/6 = 1$ element each. For $\mathrm{diag}(0,1)$, a matrix commutes with it exactly when it is diagonal (compare entries), and the invertible diagonal matrices over $\mathbb{F}_2$ are only $\mathbf{I}_2$, so the class has 6 elements. For $\mathbf{C}(x^2)$ and $\mathbf{C}(x^2+1)$ the commutant inside GL_2 has 2 elements — by Exercise (C1: What commutes with a cyclic operator) the commutant of a cyclic matrix is $\{a\mathbf{I} + b\mathbf{A}\}$, which here has 4 elements, of which 2 are invertible — so each class has 3 elements. For $\mathbf{C}(x^2+x+1)$, whose order is 3 in $\mathrm{GL}_2(\mathbb{F}_2)$, the commutant is $\{a\mathbf{I} + b\mathbf{A}\}$ again, with 3 invertible elements, so

the class has 2 elements. Total:

$$1+1+6+3+3+2=16=|M_2(\mathbb{F}_2)|.\checkmark$$

Exercise C3: A matrix over the rationals is similar to its transpose.

(a) Let $\mathbf{A},\mathbf{B}\in M_n(\mathbb{Q})$ have the same Jordan form over $\mathbb{C}$. Prove that $\mathbf{A}$ and $\mathbf{B}$ are similar over $\mathbb{Q}$.

(b) Deduce that $\mathbf{A}\sim\mathbf{A}^\top$ over $\mathbb{Q}$ for every $\mathbf{A}\in M_n(\mathbb{Q})$.

(c) Which step of (b) would fail for a general field K in place of $\mathbb{Q}$?

Hint for (b): Exercise (C1: A matrix is similar to its transpose).

Solution.

(a) A matrix in $M_n(\mathbb{Q})$ is also a matrix in $M_n(\mathbb{C})$, and $p_{\mathbf{A}}$ splits over $\mathbb{C}$ (Corollary 5.5.5), so both have Jordan forms there. Having the same Jordan form, they are similar over $\mathbb{C}$ (Corollary 9.3.3). By Corollary 9.6.10 with $K=\mathbb{Q}$ and $L=\mathbb{C}$, they are similar over $\mathbb{Q}$.

(b) Let $\mathbf{A}\in M_n(\mathbb{Q})$. Over $\mathbb{C}$, $p_{\mathbf{A}}$ splits, so Exercise (C1: A matrix is similar to its transpose) (c) gives $\mathbf{A}\sim\mathbf{A}^\top$ over $\mathbb{C}$. Both matrices lie in $M_n(\mathbb{Q})$, so Corollary 9.6.10 gives $\mathbf{A}\sim\mathbf{A}^\top$ over $\mathbb{Q}$.

(c) The step that fails is the splitting: over a general field K there is no reason for $p_{\mathbf{A}}$ to split, and we have not constructed a larger field where it does. (The conclusion is nevertheless true over every field; Section 7 proves it without any splitting, using the Smith normal form of $x\mathbf{I}-\mathbf{A}$.) Note that Corollary 9.6.10 itself needs no hypothesis on K — only the existence of a suitable L does.

9.7 Polynomial Matrices and the Smith Normal Form

The rational canonical form of the previous section is a complete answer to the similarity problem, but the proof did not tell us how to *find* the invariant factors of a given matrix. This section supplies the missing algorithm, and it comes from an unexpected place: instead of working with $\mathbf{A}$, we work with the single polynomial matrix $x\mathbf{I}-\mathbf{A}$, and we reduce it by row and column operations whose scalars are allowed to be polynomials. The reduced form is diagonal, its non-constant diagonal entries are the invariant factors, and two matrices are similar exactly when their reduced forms agree. On the way we finally pay off a promise from Chapter 3: every square matrix is similar to its transpose, over every field.

9.7.1 The space as a module over the polynomials

Everything in this chapter is built by applying **polynomials** in T to vectors: the T-annihilator of a vector, the cyclic subspace $Z(\mathbf{v};T)$, the kernels $\ker p(T)$. Name that structure once. For V

a vector space over F and $T \in \mathcal{L}(V)$, the product

$$F[x] \times V \to V, \qquad p \cdot \mathbf{v} \coloneqq p(T)\,\mathbf{v}$$

satisfies, by Theorem 5.7.1, exactly the vector space axioms with F replaced by $F[x]$: it is additive in each factor, $(pq)\cdot\mathbf{v} = p\cdot(q\cdot\mathbf{v})$, and $1\cdot\mathbf{v} = \mathbf{v}$. A set with an addition and a product by the elements of a commutative ring R obeying these rules is an **R-module**, so the pair (V, T) is the same thing as an $F[x]$-module that is finite-dimensional over the constants F. We develop no general theory of modules; the point is the dictionary:

$F[x]$-module language	operator language
submodule of V	T-invariant subspace (Definition 8.1.1)
submodule generated by $\mathbf{v}$, that is $F[x]\cdot\mathbf{v}$	cyclic subspace $Z(\mathbf{v};T)$ (Definition 9.5.1)
the annihilator of $\mathbf{v}$ in $F[x]$	the T-annihilator of $\mathbf{v}$
V is generated by one element	T has a cyclic vector

A subspace closed under multiplication by x is closed under multiplication by every polynomial, which is why the first two lines match.

Where does $x\mathbf{I}-\mathbf{A}$ come from here? Fix $\mathcal{B} = (\mathbf{b}_1,\dots,\mathbf{b}_n)$ with $\mathbf{A} = [T]_{\mathcal{B}}$. As an $F[x]$-module, V is generated by $\mathbf{b}_1,\dots,\mathbf{b}_n$, subject to the n relations $x\cdot\mathbf{b}_j = \sum_i a_{ij}\mathbf{b}_i$, whose coefficient vectors are the columns of $x\mathbf{I}-\mathbf{A}$. So $x\mathbf{I}-\mathbf{A}$ is the **matrix of relations**, and changing generators or replacing one relation by a combination of relations should not change V. That is the intuition behind the operations we now allow; the proofs below are matrix proofs and do not rely on it.

9.7.2 Row and column operations with polynomial multipliers

A matrix in $M_n(F[x])$ will be called a **polynomial matrix**. Over a field we reduced a matrix by three kinds of row operation (Definition 2.2.1). Over $F[x]$ we must be careful with one of them: multiplying a row by x cannot be undone, because x has no inverse in $F[x]$. So the scaling operation keeps its scalar in F, while the operation that adds a multiple of one row to another may use any polynomial multiplier.

Definition 9.7.1 — Elementary Operations over $F[x]$

Let $\mathbf{M} \in M_n(F[x])$. An **elementary row operation over** $F[x]$ on $\mathbf{M}$ is one of:

(E1) interchanging two rows;

(E2) multiplying one row by a **non-zero scalar** $c \in F$;

(E3) adding h times one row to a **different** row, where $h \in F[x]$ is **any** polynomial.

Elementary column operations over $F[x]$ are defined the same way with "column" in place of "row".

In words: (E1) and (E3) are as over a field, except that (E3) now permits a polynomial multiplier; (E2) is restricted, because only the non-zero constants have inverses in $F[x]$. Each of the three

is reversible by an operation of the same kind: swap back, scale by c^{-1}, add $-h$ times the row back.

Two polynomial matrices reachable from one another by such operations should count as the same. As over a field (Definition 3.8.1), the clean way to say this is with invertible matrices on both sides — but "invertible" must now mean invertible *inside* $M_n(F[x])$.

Proposition 9.7.1 — Invertible Polynomial Matrices

Let $\mathbf{U} \in M_n(F[x])$. Then $\mathbf{U}$ has an inverse in $M_n(F[x])$ if and only if $\det \mathbf{U}$ is a **non-zero constant**.

Proof. ($\Rightarrow$) Suppose $\mathbf{UW} = \mathbf{I}$ with $\mathbf{W} \in M_n(F[x])$. Taking determinants and using multiplicativity over the commutative ring $F[x]$ (Theorem 6.5.4 and the remark on commutative rings after it), $\det \mathbf{U} \cdot \det \mathbf{W} = 1$. By Theorem 0.8.3, $\deg(\det \mathbf{U}) + \deg(\det \mathbf{W}) = \deg 1 = 0$, and degrees of non-zero polynomials are ≥ 0, so $\deg(\det \mathbf{U}) = 0$; that is, $\det \mathbf{U} \in F \setminus \{0\}$.

($\Leftarrow$) Suppose $\det \mathbf{U} = c \in F \setminus \{0\}$. The adjugate identity

$$\mathbf{U} \operatorname{adj} \mathbf{U} = \operatorname{adj} \mathbf{U}\ \mathbf{U} = (\det \mathbf{U})\, \mathbf{I}$$

holds over any commutative ring (Theorem 6.6.2 and the remark on commutative rings following it), and $\operatorname{adj} \mathbf{U} \in M_n(F[x])$, since its entries are minors of $\mathbf{U}$. So $\mathbf{W} = c^{-1} \operatorname{adj} \mathbf{U} \in M_n(F[x])$ satisfies $\mathbf{UW} = \mathbf{WU} = \mathbf{I}$.

■

Definition 9.7.2 — Equivalence over $F[x]$

Let $\mathbf{M}, \mathbf{M}' \in M_n(F[x])$. We say $\mathbf{M}$ and $\mathbf{M}'$ are **equivalent over** $F[x]$, written $\mathbf{M} \approx \mathbf{M}'$, if there are $\mathbf{U}, \mathbf{V} \in M_n(F[x])$, **each invertible in** $M_n(F[x])$, with

$$\mathbf{M}' = \mathbf{UMV}.$$

Proposition 9.7.2 — Operations and Equivalence

Let $\mathbf{M}, \mathbf{M}' \in M_n(F[x])$.

(a) $\approx$ is an equivalence relation on $M_n(F[x])$.

(b) If $\mathbf{M}'$ is obtained from $\mathbf{M}$ by a finite sequence of elementary row and column operations over $F[x]$, then $\mathbf{M} \approx \mathbf{M}'$.

Proof.

(a) Take $\mathbf{U} = \mathbf{V} = \mathbf{I}$ for reflexivity. If $\mathbf{M}' = \mathbf{UMV}$, then $\mathbf{M} = \mathbf{U}^{-1}\mathbf{M}'\mathbf{V}^{-1}$, and $\mathbf{U}^{-1}, \mathbf{V}^{-1}$ are invertible in $M_n(F[x])$; this gives symmetry. If $\mathbf{M}' = \mathbf{UMV}$ and $\mathbf{M}'' = \mathbf{U}'\mathbf{M}'\mathbf{V}'$, then $\mathbf{M}'' = (\mathbf{U}'\mathbf{U})\mathbf{M}(\mathbf{VV}')$, and a product of invertible matrices is invertible, which gives transitivity.

(b) Each elementary row operation over $F[x]$ is left multiplication by the matrix obtained by performing that operation on $\mathbf{I}_n$, exactly as over a field (Theorem 2.4.1, whose proof uses only the ring operations). Those three matrices are $\mathbf{P}_{ij}$, $\mathbf{D}_i(c)$ and $\mathbf{I} + h\mathbf{E}_{ij}$ with $i \neq j$, of determinants -1, $c \neq 0$ and 1 respectively (Theorem 6.4.6 and Theorem 6.5.1, valid over a commutative ring), hence invertible in $M_n(F[x])$ by Proposition 9.7.1. Column operations are right multiplication by the same matrices. Now use (a).

■

Warning. **Multiplying a row by a non-constant polynomial is not an allowed operation.** It changes the answer. The matrix $\mathbf{M} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$ becomes $\begin{pmatrix} x & 0 \\ 0 & 1 \end{pmatrix}$ after "multiplying row 1 by x", and the two are not equivalent: their determinants are 1 and x, and by Proposition 9.7.1 the first is invertible over $F[x]$ while the second is not. The rule to remember is that only the **units** of $F[x]$ — the non-zero constants — may be used as scaling factors.

9.7.3 The Smith normal form

Every polynomial matrix can be brought to a diagonal form whose diagonal entries divide one another in turn, and that form is unique.

The existence proof is Euclidean division, run on whichever non-zero entry has the smallest degree: if that entry fails to divide one of its neighbors in the same row or column, the remainder gives a non-zero entry of strictly smaller degree, and degrees cannot decrease forever.

Theorem 9.7.3 — Smith Normal Form

Let F be a field, $n \geq 1$ and $\mathbf{M} \in M_n(F[x])$. Then:

(a) **(Existence)** $\mathbf{M}$ is equivalent over $F[x]$, by a finite sequence of elementary row and column operations, to a diagonal matrix

$$\mathbf{D} = \operatorname{diag}(d_1, d_2, \ldots, d_n)$$

in which every d_i is **monic or zero** and $d_i \mid d_{i+1}$ for $i = 1, \ldots, n-1$.

(b) **(Uniqueness)** The list $(d_1, \ldots, d_n)$ is determined by $\mathbf{M}$: if $\mathbf{M} \approx \operatorname{diag}(d_1, \ldots, d_n) \approx \operatorname{diag}(e_1, \ldots, e_n)$ with both lists as in (a), then $d_i = e_i$ for every i.

The matrix $\mathbf{D}$ is called the **Smith normal form** of $\mathbf{M}$, and $d_1, \ldots, d_n$ its **invariant divisors**.

Since $0 \mid f$ holds only for $f = 0$, the divisibility chain forces the zero entries, if any, to be the last ones.

Idea. **Step roadmap for existence.** ① Among all matrices reachable from $\mathbf{M}$ by operations, pick one whose smallest non-zero entry degree is least, and move that entry to the corner. ② That corner entry f must divide every other entry of its row and column: otherwise divide with remainder and produce an entry of smaller degree, contradicting

the choice in ①. ③ Clear the first row and column with f; the same remainder trick, after adding a row to the first one, shows f divides every entry of what is left. ④ Induct on the size. The divisibility $d_1 \mid d_2$ survives the induction because operations replace entries by $F[x]$-combinations of entries.

For uniqueness, find a quantity that can be read off both $\mathbf{M}$ and $\mathbf{D}$. The greatest common divisor of all $k \times k$ minors is such a quantity: minors of a product are $F[x]$-combinations of minors of the factors (Cauchy–Binet), so the gcd cannot change under equivalence, and for a diagonal matrix with a divisibility chain it is simply $d_1 d_2 \cdots d_k$.

Proof.

(a) If $\mathbf{M} = 0$, it is already of the stated form. So assume $\mathbf{M} \neq 0$.
For a non-zero $\mathbf{N} \in M_n(F[x])$ put

$$\delta(\mathbf{N}) := \min\{\, \deg n_{ij} : n_{ij} \neq 0 \,\} \in \mathbb{N},$$

the least degree of a non-zero entry. Let $\mathcal{S}$ be the set of all non-zero matrices obtainable from $\mathbf{M}$ by finite sequences of elementary row and column operations over $F[x]$; it contains $\mathbf{M}$. The set $\{\delta(\mathbf{N}) : \mathbf{N} \in \mathcal{S}\}$ is a non-empty subset of $\mathbb{N}$, so it has a least element; **fix $\mathbf{N} \in \mathcal{S}$ with $\delta(\mathbf{N})$ least**.
Step 1. Put a least-degree entry in the corner, monic. Choose (i, j) with $n_{ij} \neq 0$ and $\deg n_{ij} = \delta(\mathbf{N})$. Swapping row i with row 1 and column j with column 1 (operations (E1)), and then scaling the new first row by the inverse of the leading coefficient of the corner entry (operation (E2)), we obtain a matrix in $\mathcal{S}$ whose $(1,1)$-entry f is **monic** of degree $\delta(\mathbf{N})$. These operations permute the entries and rescale some of them, so the new matrix still has least non-zero entry degree $\delta(\mathbf{N})$. Rename it $\mathbf{N}$.
Step 2. f divides every entry of the first row and the first column. Suppose $f \nmid n_{1j}$ for some $j \geq 2$. By Theorem 5.1.1, $n_{1j} = qf + r$ with $r \neq 0$ and $\deg r < \deg f$. Adding $-q$ times column 1 to column j (operation (E3)) produces a matrix $\mathbf{N}' \in \mathcal{S}$ whose $(1,j)$-entry is $r \neq 0$ with $\deg r < \deg f = \delta(\mathbf{N})$. Then $\delta(\mathbf{N}') < \delta(\mathbf{N})$, contradicting the minimality of $\delta(\mathbf{N})$. Hence $f \mid n_{1j}$ for every j, and the same argument with rows in place of columns gives $f \mid n_{i1}$ for every i.
Step 3. Clear the first row and column. For $j \geq 2$ add $-(n_{1j}/f)$ times column 1 to column j; the multipliers are polynomials by Step 2, and after these operations the first row is $(f, 0, \ldots, 0)$ while the first column is unchanged. Then for $i \geq 2$ add $-(n_{i1}/f)$ times row 1 to row i; since the first row is now $(f, 0, \ldots, 0)$, this clears the first column and changes nothing else. The result is

$$\begin{pmatrix} f & 0 \\ 0 & \mathbf{M}' \end{pmatrix} \in \mathcal{S}, \qquad \mathbf{M}' \in M_{n-1}(F[x]),$$

and its least non-zero entry degree is still $\delta(\mathbf{N})$: it is $\geq \delta(\mathbf{N})$ by minimality, and f is an entry of degree $\delta(\mathbf{N})$.
Step 4. f divides every entry of $\mathbf{M}'$. Suppose $f \nmid (\mathbf{M}')_{kl}$ for some k, l. Add row $k+1$ to row 1. The new first row is $\big(f, (\mathbf{M}')_{k1}, \ldots, (\mathbf{M}')_{k,n-1}\big)$, so the $(1, l+1)$-entry of the resulting matrix $\mathbf{N}'' \in \mathcal{S}$ is $(\mathbf{M}')_{kl}$, which is not divisible by f, while the $(1,1)$-entry is still f, monic of degree $\delta(\mathbf{N})$. By minimality $\delta(\mathbf{N}'') = \delta(\mathbf{N})$, so Step 2 applies to $\mathbf{N}''$ and says that f divides every entry of the first row of $\mathbf{N}''$ — a contradiction.

Step 5. Induct on n. We prove (a) by induction on n. For $n = 1$, scale the single entry to be monic (or leave it 0). For $n \geq 2$, Steps 1–4 give a sequence of operations taking $\mathbf{M}$ to $f \oplus \mathbf{M}'$ with f monic and f dividing every entry of $\mathbf{M}'$. By the induction hypothesis there are operations taking $\mathbf{M}'$ to $\mathbf{D}' = \operatorname{diag}(d_2, \dots, d_n)$ with every d_i monic or zero and $d_2 \mid \cdots \mid d_n$; performing the corresponding operations on rows and columns $2, \dots, n$ of $f \oplus \mathbf{M}'$ takes it to $f \oplus \mathbf{D}' = \operatorname{diag}(f, d_2, \dots, d_n)$. It remains to see that $f \mid d_2$. By Proposition 9.7.2, $\mathbf{D}' = \mathbf{U}'\mathbf{M}'\mathbf{V}'$ for some $\mathbf{U}', \mathbf{V}' \in M_{n-1}(F[x])$, so every entry of $\mathbf{D}'$ is a sum of products $u'_{ik}(\mathbf{M}')_{kl}v'_{lj}$ (Definition 0.9.9) and is therefore divisible by f, since every $(\mathbf{M}')_{kl}$ is. In particular $f \mid d_2$. Setting $d_1 = f$ finishes the induction.

(b) Call a set $I \subseteq [n]$ with $|I| = k$ a k-**set**. For $\mathbf{M} \in M_n(F[x])$ and $1 \leq k \leq n$ define the k-th **determinantal divisor**

$$\Delta_k(\mathbf{M}) \coloneqq \text{the monic generator of the ideal } \left\langle \det \mathbf{M}_{I,J} : I, J \ k\text{-sets} \right\rangle \subseteq F[x],$$

and $\Delta_k(\mathbf{M}) \coloneqq 0$ if all the $k \times k$ minors of $\mathbf{M}$ vanish. This is well defined by Proposition 5.2.1 and Theorem 5.2.2: the ideal generated by the finitely many $k \times k$ minors is $\langle \Delta_k(\mathbf{M}) \rangle$ for exactly one monic $\Delta_k(\mathbf{M})$ unless the ideal is $\{0\}$. Equivalently, $\Delta_k(\mathbf{M})$ is the monic greatest common divisor of the $k \times k$ minors: it divides each of them, and every common divisor of them divides it (Theorem 5.2.3, extended from two polynomials to finitely many by the same ideal argument).

Claim 1. $\mathbf{M} \approx \mathbf{M}'$ implies $\Delta_k(\mathbf{M}) = \Delta_k(\mathbf{M}')$ for every k.

Proof. Let $\mathbf{M}' = \mathbf{U}\mathbf{M}\mathbf{V}$ with $\mathbf{U}, \mathbf{V}$ invertible over $F[x]$, and let I, J be k-sets. The submatrix of a product on rows I and columns J is the product of the submatrix of the left factor on rows I and all columns with the submatrix of the right factor on all rows and columns J (Definition 0.9.9, read off entry by entry). Applying this twice and then Theorem 6.7.2 over the commutative ring $F[x]$ — legitimate by the remark after that theorem — to the $k \times n$ times $n \times k$ products involved,

$$\det \mathbf{M}'_{I,J} = \sum_S \det \mathbf{U}_{I,S} \det(\mathbf{M}\mathbf{V})_{S,J} = \sum_S \sum_R \det \mathbf{U}_{I,S} \det \mathbf{M}_{S,R} \det \mathbf{V}_{R,J},$$

with S and R running over the k-sets. So every $k \times k$ minor of $\mathbf{M}'$ is an $F[x]$-combination of $k \times k$ minors of $\mathbf{M}$, hence lies in $\langle \det \mathbf{M}_{S,R} \rangle$. Therefore $\Delta_k(\mathbf{M})$ divides every $k \times k$ minor of $\mathbf{M}'$, and so $\Delta_k(\mathbf{M}) \mid \Delta_k(\mathbf{M}')$. Exchanging the roles of $\mathbf{M}$ and $\mathbf{M}'$ using $\mathbf{M} = \mathbf{U}^{-1}\mathbf{M}'\mathbf{V}^{-1}$ gives $\Delta_k(\mathbf{M}') \mid \Delta_k(\mathbf{M})$. Two monic polynomials dividing each other are equal (Proposition 5.1.2), and if one is 0 so is the other.

■

Claim 2. If $\mathbf{D} = \operatorname{diag}(d_1, \dots, d_n)$ with $d_1 \mid d_2 \mid \cdots \mid d_n$, then $\Delta_k(\mathbf{D}) = d_1 d_2 \cdots d_k$.

Proof. Let I, J be k-sets. If $I \neq J$, pick $i \in I \setminus J$; row i of $\mathbf{D}$ has its only possibly non-zero entry in column $i \notin J$, so the submatrix $\mathbf{D}_{I,J}$ has a zero row and $\det \mathbf{D}_{I,J} = 0$. If $I = J = \{i_1 < \cdots < i_k\}$, then $\mathbf{D}_{I,I} = \operatorname{diag}(d_{i_1}, \ldots, d_{i_k})$ and $\det \mathbf{D}_{I,I} = d_{i_1} \cdots d_{i_k}$ (Theorem 6.4.6, valid over the commutative ring $F[x]$ by the remark after it). Since $i_j \geq j$, the chain gives $d_j \mid d_{i_j}$ for each j, hence

$$d_1 d_2 \cdots d_k \mid d_{i_1} d_{i_2} \cdots d_{i_k}.$$

So $d_1 \cdots d_k$ divides every $k \times k$ minor of $\mathbf{D}$, and it is itself the minor for $I = J = \{1, \ldots, k\}$. Hence the ideal generated by the $k \times k$ minors is $\langle d_1 \cdots d_k \rangle$. If $d_1 \cdots d_k \neq 0$ it is monic, being a product of monic polynomials, and equals $\Delta_k(\mathbf{D})$. If $d_1 \cdots d_k = 0$, say $d_m = 0$ with $m \leq k$, then for every k-set I we have $i_k \geq k \geq m$, so $d_m \mid d_{i_k}$ forces $d_{i_k} = 0$ and the minor vanishes; thus $\Delta_k(\mathbf{D}) = 0 = d_1 \cdots d_k$.

■

Now let $\mathbf{M} \approx \operatorname{diag}(d_1, \ldots, d_n)$ with the d_i as in (a). By Claims 1 and 2,

$$\Delta_k(\mathbf{M}) = d_1 d_2 \cdots d_k \qquad (k = 1, \ldots, n),$$

a quantity depending only on $\mathbf{M}$. Reading this backwards recovers the d_i: first $d_1 = \Delta_1(\mathbf{M})$; and for $k \geq 2$, if $\Delta_{k-1}(\mathbf{M}) \neq 0$ then $d_k = \Delta_k(\mathbf{M})/\Delta_{k-1}(\mathbf{M})$, while if $\Delta_{k-1}(\mathbf{M}) = 0$ then $d_1 \cdots d_{k-1} = 0$, so some $d_m = 0$ with $m \leq k-1$, and the chain forces $d_k = 0$. Hence any second list $(e_1, \ldots, e_n)$ as in (a) satisfies the same recipe and equals $(d_1, \ldots, d_n)$. This proves the theorem.

■

The proof is an algorithm, and it is the one to use by hand: hunt for the entry of least degree, divide, and repeat.

Algorithm. **Smith normal form of $\mathbf{M} \in M_n(F[x])$.**

1. If $\mathbf{M} = 0$, stop. Otherwise find a non-zero entry of least degree and move it to position $(1,1)$ by a row and a column swap; scale row 1 so that the entry is monic. Call it f.
2. For each other entry g in row 1 or column 1 with $f \nmid g$, replace g by its remainder on division by f (subtract a multiple of column 1, resp. row 1), move the remainder to the corner, and go back to step 1.
3. When f divides all of row 1 and column 1, clear them. If some entry g of the remaining block is not divisible by f, add its row to row 1 and go back to step 2.
4. Repeat on the remaining $(n-1) \times (n-1)$ block.
5. Check the answer: Δ_k must equal $d_1 \cdots d_k$. In particular $d_1 \cdots d_n$ is $\det \mathbf{M}$ rescaled by a non-zero constant to be monic, and d_1 is the monic gcd of the entries.

Quick check. Two polynomial matrices in $M_2(F[x])$ have determinants x^2 and x^2, and in both the greatest common divisor of the four entries is 1. Are they equivalent over $F[x]$?

Solution. Yes. Here $\Delta_1 = 1$ (the gcd of the 1×1 minors, that is, of the entries) and Δ_2 is the determinant rescaled to be monic, so $\Delta_2 = x^2$ for both. By Theorem 9.7.3 both have Smith normal form $\operatorname{diag}(1, x^2)$, and since $\approx$ is an equivalence relation (Proposition 9.7.2 (a)) they are equivalent to each other. For 2×2 matrices the pair (Δ_1, Δ_2) is therefore a complete invariant.

Example. (A Smith Normal Form Computed by Hand)

Let

$$\mathbf{A} = \begin{pmatrix} 2 & 1 & -2 \\ 1 & 2 & -2 \\ 1 & 1 & -1 \end{pmatrix} \in M_3(\mathbb{Q}).$$

Find the Smith normal form of $x\mathbf{I} - \mathbf{A}$ over $\mathbb{Q}[x]$, naming every operation, and check the answer with determinantal divisors.

Solution. We have

$$x\mathbf{I} - \mathbf{A} = \begin{pmatrix} x-2 & -1 & 2 \\ -1 & x-2 & 2 \\ -1 & -1 & x+1 \end{pmatrix}.$$

Find the corner. The entries of least degree are the three entries equal to -1. Swap columns 1 and 2, then multiply the first row by -1:

$$\begin{pmatrix} -1 & x-2 & 2 \\ x-2 & -1 & 2 \\ -1 & -1 & x+1 \end{pmatrix} \longrightarrow \begin{pmatrix} 1 & -(x-2) & -2 \\ x-2 & -1 & 2 \\ -1 & -1 & x+1 \end{pmatrix}.$$

The corner is now 1, which divides everything, so no division step is needed.

Clear the first column. Add $-(x-2)$ times row 1 to row 2, and add row 1 to row 3. In row 2 this gives entries $-1 + (x-2)^2 = (x-1)(x-3)$ and $2 + 2(x-2) = 2(x-1)$; in row 3 it gives $-1 - (x-2) = -(x-1)$ and $x + 1 - 2 = x - 1$:

$$\begin{pmatrix} 1 & -(x-2) & -2 \\ 0 & (x-1)(x-3) & 2(x-1) \\ 0 & -(x-1) & x-1 \end{pmatrix}.$$

Clear the first row. Add $(x-2)$ times column 1 to column 2, and 2 times column 1 to column 3. Since the first column below the corner is zero, nothing else changes:

$$\begin{pmatrix} 1 & 0 & 0 \\ 0 & (x-1)(x-3) & 2(x-1) \\ 0 & -(x-1) & x-1 \end{pmatrix} = \operatorname{diag}(1) \oplus \begin{pmatrix} (x-1)(x-3) & 2(x-1) \\ -(x-1) & x-1 \end{pmatrix}.$$

Every entry of the 2×2 block is divisible by 1, so we move on to the block.

The block. Its entries of least degree are the three of degree 1. Swap rows 2 and 3 and scale the new row 2 by -1, putting the monic $x - 1$ in the corner of the block:

$$\begin{pmatrix} 1 & 0 & 0 \\ 0 & x-1 & -(x-1) \\ 0 & (x-1)(x-3) & 2(x-1) \end{pmatrix}.$$

Now $x-1$ divides every entry of its row and column. Add column 2 to column 3, which clears the block's first row and turns the $(3,3)$-entry into $2(x-1)+(x-1)(x-3) = (x-1)(x-1)$:

$$\begin{pmatrix} 1 & 0 & 0 \\ 0 & x-1 & 0 \\ 0 & (x-1)(x-3) & (x-1)^2 \end{pmatrix}.$$

Add $-(x-3)$ times row 2 to row 3 to clear the block's first column:

$$\mathbf{D} = \operatorname{diag}\big(1,\ x-1,\ (x-1)^2\big),$$

and $1 \mid x-1 \mid (x-1)^2$, so this is the Smith normal form.

The check. The matrix $x\mathbf{I}-\mathbf{A}$ has an entry -1, so $\Delta_1 = 1$. Its determinant is $p_{\mathbf{A}} = (x-1)^3$ — expanding along the first row,

$$\begin{aligned}(x-2)\big[(x-2)(x+1)+2\big] + \big[-(x+1)+2\big] + 2\big[1+(x-2)\big] \\ = (x-2)(x^2-x) + (1-x) + 2(x-1),\end{aligned}$$

which is $(x-2)x(x-1)+(x-1) = (x-1)(x^2-2x+1) = (x-1)^3$ — so $\Delta_3 = (x-1)^3$. For Δ_2, the minor on rows $\{2,3\}$ and columns $\{1,2\}$ is $\det\begin{pmatrix} -1 & x-2 \\ -1 & -1 \end{pmatrix} = 1+(x-2) = x-1$, so $\Delta_2 \mid x-1$; and every 2×2 minor is divisible by $x-1$, as Claim 2 predicts from $\mathbf{D}$. Hence $\Delta_2 = x-1$, and

$$(d_1,d_2,d_3) = \Big(\Delta_1,\ \tfrac{\Delta_2}{\Delta_1},\ \tfrac{\Delta_3}{\Delta_2}\Big) = \big(1,\ x-1,\ (x-1)^2\big),$$

in agreement. As a sanity check on $\mathbf{A}$ itself: $\mathbf{A}-\mathbf{I}$ has rank 1, so $g_{\mathbf{A}}(1) = 2$ and the Jordan form of $\mathbf{A}$ is $\mathbf{J}_2(1)\oplus\mathbf{J}_1(1)$ (Corollary 9.3.2).

9.7.4 Similarity read off from a polynomial matrix

We can now state the theorem that makes all of this useful. It converts a question about $\mathbf{A}$ and $\mathbf{B}$ — is there an invertible $\mathbf{P}\in M_n(F)$ with $\mathbf{B} = \mathbf{P}^{-1}\mathbf{A}\mathbf{P}$? — into a question about the two polynomial matrices $x\mathbf{I}-\mathbf{A}$ and $x\mathbf{I}-\mathbf{B}$, which the Smith algorithm answers by computation.

One direction is immediate. The other needs a tool: polynomial matrices can be divided by $x\mathbf{I}-\mathbf{A}$, with a **constant** remainder.

Lemma 9.7.4 — Division of a Polynomial Matrix by $x\mathbf{I}-\mathbf{A}$

Let $\mathbf{A}\in M_n(F)$ and $\mathbf{M}\in M_n(F[x])$. Then there are $\mathbf{Q}\in M_n(F[x])$ and $\mathbf{R}\in M_n(F)$ with

$$\mathbf{M} = (x\mathbf{I}-\mathbf{A})\,\mathbf{Q} + \mathbf{R}.$$

Idea. Write $\mathbf{M}$ as a polynomial $\sum_k \mathbf{M}_k x^k$ with **constant matrix** coefficients. The scalar identity $x^k - a^k = (x-a)(x^{k-1}+\cdots+a^{k-1})$ has a matrix version $x^k\mathbf{I}-\mathbf{A}^k = (x\mathbf{I}-\mathbf{A})\mathbf{S}_k$, in which the second factor is a polynomial in x and $\mathbf{A}$ and so commutes with $x\mathbf{I}-\mathbf{A}$. Replacing each $x^k\mathbf{I}$ by $(x^k\mathbf{I}-\mathbf{A}^k)+\mathbf{A}^k$ puts a factor $x\mathbf{I}-\mathbf{A}$ in front of everything except a constant matrix.

Proof. Collecting the coefficients of each power of x in the entries of $\mathbf{M}$, write $\mathbf{M} = \sum_{k=0}^{m} x^k \mathbf{M}_k$ with $\mathbf{M}_0, \dots, \mathbf{M}_m \in M_n(F)$; note that x^k is a scalar polynomial, so $x^k \mathbf{M}_k = \mathbf{M}_k x^k$. For $k \geq 1$ put

$$\mathbf{S}_k := \sum_{j=0}^{k-1} x^{\,k-1-j} \mathbf{A}^{\,j} \in M_n(F[x]), \qquad \mathbf{S}_0 := 0.$$

Expanding the product and telescoping,

$$(x\mathbf{I} - \mathbf{A})\mathbf{S}_k = \sum_{j=0}^{k-1} x^{\,k-j} \mathbf{A}^{\,j} - \sum_{j=0}^{k-1} x^{\,k-1-j} \mathbf{A}^{\,j+1} = x^k \mathbf{I} - \mathbf{A}^k$$

for every $k \geq 0$. Therefore

$$\begin{aligned} \mathbf{M} &= \sum_{k=0}^{m} (x^k \mathbf{I}) \mathbf{M}_k = \sum_{k=0}^{m} (x^k \mathbf{I} - \mathbf{A}^k) \mathbf{M}_k + \sum_{k=0}^{m} \mathbf{A}^k \mathbf{M}_k \\ &= (x\mathbf{I} - \mathbf{A}) \underbrace{\sum_{k=0}^{m} \mathbf{S}_k \mathbf{M}_k}_{=\mathbf{Q}} + \underbrace{\sum_{k=0}^{m} \mathbf{A}^k \mathbf{M}_k}_{=\mathbf{R}}, \end{aligned}$$

with $\mathbf{Q} \in M_n(F[x])$ and $\mathbf{R} \in M_n(F)$, as claimed.

■

Theorem 9.7.5 — Similarity as Equivalence of $x\mathbf{I} - \mathbf{A}$ and $x\mathbf{I} - \mathbf{B}$

Let F be a field, $n \geq 1$ and $\mathbf{A}, \mathbf{B} \in M_n(F)$. Then

$$\mathbf{A} \sim \mathbf{B} \quad \text{over } F \qquad \Longleftrightarrow \qquad x\mathbf{I} - \mathbf{A} \approx x\mathbf{I} - \mathbf{B} \quad \text{over } F[x].$$

Idea. ($\Rightarrow$) is a one-line computation: a constant invertible $\mathbf{P}$ is also an invertible polynomial matrix.

($\Leftarrow$) is the substance, and the whole difficulty is that the matrices $\mathbf{U}, \mathbf{V}$ witnessing the equivalence have polynomial entries, while we must produce a **constant** $\mathbf{P}$. The trick is to divide $\mathbf{U}$ by $x\mathbf{I} - \mathbf{B}$ and keep only the constant remainder $\mathbf{P}$. Comparing degrees in the resulting identity shows that $\mathbf{P}$ alone already conjugates: $\mathbf{P}(x\mathbf{I} - \mathbf{A}) = (x\mathbf{I} - \mathbf{B})\mathbf{P}$, that is, $\mathbf{PA} = \mathbf{BP}$. Running the same argument on the inverted relation produces a second constant $\mathbf{P}'$ with $\mathbf{P}'\mathbf{B} = \mathbf{AP}'$, and multiplying the two expressions for $\mathbf{V}^{-1}$ and $\mathbf{V}$ shows $\mathbf{PP}' = \mathbf{I}$, so $\mathbf{P}$ is invertible.

Proof. ($\Rightarrow$) Suppose $\mathbf{B} = \mathbf{P}^{-1}\mathbf{AP}$ with $\mathbf{P} \in M_n(F)$ invertible. Then, inside $M_n(F[x])$,

$$x\mathbf{I} - \mathbf{B} = \mathbf{P}^{-1}(x\mathbf{I})\mathbf{P} - \mathbf{P}^{-1}\mathbf{AP} = \mathbf{P}^{-1}(x\mathbf{I} - \mathbf{A})\mathbf{P},$$

and $\mathbf{P}^{-1}, \mathbf{P} \in M_n(F) \subseteq M_n(F[x])$ have non-zero constant determinants, hence are invertible over $F[x]$ (Proposition 9.7.1). So $x\mathbf{I} - \mathbf{A} \approx x\mathbf{I} - \mathbf{B}$.

($\Leftarrow$) Suppose

$$x\mathbf{I} - \mathbf{B} = \mathbf{U}(x\mathbf{I} - \mathbf{A})\mathbf{V} \tag{$*$}$$

with $\mathbf{U}, \mathbf{V} \in M_n(F[x])$ invertible over $F[x]$.

Step 1. Divide U by $x\mathbf{I}-\mathbf{B}$. By Lemma 9.7.4 there are $\mathbf{Q} \in M_n(F[x])$ and $\mathbf{P} \in M_n(F)$ with $\mathbf{U} = (x\mathbf{I} - \mathbf{B})\mathbf{Q} + \mathbf{P}$. Substituting into $(*)$,

$$x\mathbf{I} - \mathbf{B} = (x\mathbf{I} - \mathbf{B})\,\mathbf{Q}(x\mathbf{I} - \mathbf{A})\mathbf{V} + \mathbf{P}(x\mathbf{I} - \mathbf{A})\mathbf{V},$$

so $\mathbf{P}(x\mathbf{I} - \mathbf{A})\mathbf{V} = (x\mathbf{I} - \mathbf{B})\big[\mathbf{I} - \mathbf{Q}(x\mathbf{I} - \mathbf{A})\mathbf{V}\big]$. Multiplying on the right by $\mathbf{V}^{-1}$ and putting

$$\mathbf{S} := \mathbf{V}^{-1} - \mathbf{Q}(x\mathbf{I} - \mathbf{A}) \in M_n(F[x]),$$

we get

$$\mathbf{P}(x\mathbf{I} - \mathbf{A}) = (x\mathbf{I} - \mathbf{B})\,\mathbf{S}. \tag{1}$$

Step 2. S is a constant matrix, and PA = BP. Suppose $\mathbf{S} \neq 0$ and write $\mathbf{S} = \sum_{k=0}^{d} x^k \mathbf{S}_k$ with $\mathbf{S}_k \in M_n(F)$ and $\mathbf{S}_d \neq 0$. The coefficient of x^{d+1} in $(x\mathbf{I} - \mathbf{B})\mathbf{S}$ is $\mathbf{S}_d \neq 0$, while the left-hand side of (1) is $x\mathbf{P} - \mathbf{PA}$, whose coefficients vanish beyond x^1. Hence $d+1 \leq 1$, that is $d = 0$. So in every case $\mathbf{S} \in M_n(F)$. Comparing the coefficients of x^1 in (1) gives $\mathbf{P} = \mathbf{S}$, and comparing the constant terms gives $-\mathbf{PA} = -\mathbf{BP}$. Therefore

$$\mathbf{PA} = \mathbf{BP}, \qquad \text{equivalently} \qquad \mathbf{P}(x\mathbf{I} - \mathbf{A}) = (x\mathbf{I} - \mathbf{B})\mathbf{P}, \tag{2}$$

the second form because $\mathbf{P}(x\mathbf{I} - \mathbf{A}) = x\mathbf{P} - \mathbf{PA} = x\mathbf{P} - \mathbf{BP} = (x\mathbf{I} - \mathbf{B})\mathbf{P}$. Moreover $\mathbf{S} = \mathbf{P}$ turns the definition of $\mathbf{S}$ into

$$\mathbf{V}^{-1} = \mathbf{P} + \mathbf{Q}(x\mathbf{I} - \mathbf{A}). \tag{3}$$

Step 3. The same argument, inverted. From $(*)$, $x\mathbf{I}-\mathbf{A} = \mathbf{U}^{-1}(x\mathbf{I}-\mathbf{B})\mathbf{V}^{-1}$, which is $(*)$ with $\mathbf{A}, \mathbf{B}$ interchanged and $\mathbf{U}, \mathbf{V}$ replaced by the invertible polynomial matrices $\mathbf{U}^{-1}, \mathbf{V}^{-1}$. So Steps 1 and 2 apply and give $\mathbf{Q}' \in M_n(F[x])$ and $\mathbf{P}' \in M_n(F)$ with

$$\mathbf{P}'(x\mathbf{I} - \mathbf{B}) = (x\mathbf{I} - \mathbf{A})\mathbf{P}' \qquad \text{and} \qquad \mathbf{V} = \mathbf{P}' + \mathbf{Q}'(x\mathbf{I} - \mathbf{B}). \tag{4}$$

Step 4. P is invertible. Multiplying (3) by (4),

$$\begin{aligned} \mathbf{I} = \mathbf{V}^{-1}\mathbf{V} &= \big[\mathbf{P} + \mathbf{Q}(x\mathbf{I} - \mathbf{A})\big]\big[\mathbf{P}' + \mathbf{Q}'(x\mathbf{I} - \mathbf{B})\big] \\ &= \mathbf{PP}' + \mathbf{PQ}'(x\mathbf{I} - \mathbf{B}) + \mathbf{Q}(x\mathbf{I} - \mathbf{A})\mathbf{P}' \\ &\quad + \mathbf{Q}(x\mathbf{I} - \mathbf{A})\mathbf{Q}'(x\mathbf{I} - \mathbf{B}). \end{aligned}$$

By the first identity in (4), $(x\mathbf{I}-\mathbf{A})\mathbf{P}' = \mathbf{P}'(x\mathbf{I}-\mathbf{B})$, so the third summand is $\mathbf{QP}'(x\mathbf{I}-\mathbf{B})$ and

$$\mathbf{I} - \mathbf{PP}' = \mathbf{Y}(x\mathbf{I} - \mathbf{B}), \qquad \mathbf{Y} := \mathbf{PQ}' + \mathbf{QP}' + \mathbf{Q}(x\mathbf{I} - \mathbf{A})\mathbf{Q}' \in M_n(F[x]).$$

If $\mathbf{Y} \neq 0$, write $\mathbf{Y} = \sum_{k=0}^{e} x^k \mathbf{Y}_k$ with $\mathbf{Y}_e \neq 0$; the coefficient of x^{e+1} on the right is $\mathbf{Y}_e \neq 0$, while the left-hand side is constant. Hence $\mathbf{Y} = 0$ and $\mathbf{PP}' = \mathbf{I}$. By Theorem 2.4.5, $\mathbf{P}$ is invertible with $\mathbf{P}^{-1} = \mathbf{P}'$.

Step 5. Conclude. By (2), $\mathbf{PA} = \mathbf{BP}$, so $\mathbf{B} = \mathbf{PAP}^{-1}$ and $\mathbf{A} \sim \mathbf{B}$. This proves the theorem.

■

Two by-products are worth recording. Whenever $x\mathbf{I}-\mathbf{B} = \mathbf{U}(x\mathbf{I}-\mathbf{A})\mathbf{V}$ with $\mathbf{U}, \mathbf{V}$ invertible over $F[x]$, taking determinants gives $p_{\mathbf{B}} = (\det \mathbf{U})(\det \mathbf{V})\, p_{\mathbf{A}}$ with $\det \mathbf{U}, \det \mathbf{V}$ non-zero constants (Proposition 9.7.1); both $p_{\mathbf{A}}$ and $p_{\mathbf{B}}$ are monic of degree n, so

$$p_{\mathbf{A}} = p_{\mathbf{B}} \qquad \text{and} \qquad (\det \mathbf{U})(\det \mathbf{V}) = 1,$$

which recovers the invariance of the characteristic polynomial. And, by Theorem 9.7.3, the test is now decidable by a finite computation in $F[x]$: reduce $x\mathbf{I} - \mathbf{A}$ and $x\mathbf{I} - \mathbf{B}$ to Smith normal form and compare.

Corollary 9.7.6 — The Smith Form of $x\mathbf{I} - \mathbf{A}$ Carries the Invariant Factors

Let $\mathbf{A} \in M_n(F)$ with invariant factors $d_1 \mid d_2 \mid \cdots \mid d_r$ as in Theorem 9.6.5. Then the Smith normal form of $x\mathbf{I} - \mathbf{A}$ is

$$\operatorname{diag}\big(\underbrace{1, \ldots, 1}_{n-r},\, d_1,\, d_2,\, \ldots,\, d_r\big).$$

In particular the invariant factors of $\mathbf{A}$ are exactly the non-constant diagonal entries of the Smith normal form of $x\mathbf{I} - \mathbf{A}$, read from the top down, and two matrices in $M_n(F)$ are similar if and only if $x\mathbf{I} - \mathbf{A}$ and $x\mathbf{I} - \mathbf{B}$ have the same Smith normal form.

Proof. By Theorem 9.6.5, $\mathbf{A} \sim \mathbf{C}(d_1) \oplus \cdots \oplus \mathbf{C}(d_r)$ with d_i monic, $\deg d_i = k_i \geq 1$ and $\sum k_i = n$. By the ($\Rightarrow$) direction of Theorem 9.7.5 it is enough to find the Smith normal form of

$$x\mathbf{I}_n - \big(\mathbf{C}(d_1) \oplus \cdots \oplus \mathbf{C}(d_r)\big) = \big(x\mathbf{I}_{k_1} - \mathbf{C}(d_1)\big) \oplus \cdots \oplus \big(x\mathbf{I}_{k_r} - \mathbf{C}(d_r)\big),$$

the equality by Theorem 7.1.4 (a).

One block. Let d be monic of degree $k \geq 1$. By Definition 9.5.3, the only non-zero entries of $x\mathbf{I}_k - \mathbf{C}(d)$ are x on the diagonal (with $x + a_{k-1}$ in the corner), -1 in each position $(i+1, i)$, and the entries of the last column. Delete row 1 and column k. In the remaining $(k-1) \times (k-1)$ matrix, the entry in position (p, q) is the $(p+1, q)$-entry of $x\mathbf{I}_k - \mathbf{C}(d)$: it is -1 when $q = p$, it is x when $q = p+1$, and it is 0 when $q < p$. So that matrix is upper triangular with every diagonal entry -1, and its determinant is $(-1)^{k-1} \neq 0$ by Theorem 6.4.6, again over $F[x]$. Hence $\Delta_{k-1}(x\mathbf{I}_k - \mathbf{C}(d)) = 1$. By Claim 2 in the proof of Theorem 9.7.3, the determinantal divisors of any matrix are the partial products $d_1 \cdots d_j$ of its Smith diagonal, so $\Delta_j \mid \Delta_{k-1} = 1$ and therefore $\Delta_j = 1$ for every $j \leq k-1$. Also $\Delta_k = \det(x\mathbf{I}_k - \mathbf{C}(d)) = p_{\mathbf{C}(d)} = d$ by Theorem 9.5.3. By the uniqueness part of Theorem 9.7.3, the Smith normal form of $x\mathbf{I}_k - \mathbf{C}(d)$ is $\operatorname{diag}(1, \ldots, 1, d)$. (For $k = 1$ read this as $\operatorname{diag}(d)$.)

Assembling. If $\mathbf{M}_i \approx \mathbf{M}_i'$ with witnesses $\mathbf{U}_i, \mathbf{V}_i$, then $\bigoplus_i \mathbf{M}_i \approx \bigoplus_i \mathbf{M}_i'$ with witnesses $\bigoplus_i \mathbf{U}_i$ and $\bigoplus_i \mathbf{V}_i$, which are invertible with inverses $\bigoplus_i \mathbf{U}_i^{-1}$, $\bigoplus_i \mathbf{V}_i^{-1}$ (Theorem 7.1.4 (a), (c)). So $x\mathbf{I}_n - \mathbf{A}$ is equivalent to the direct sum of the matrices $\operatorname{diag}(1, \ldots, 1, d_i)$, a diagonal matrix whose diagonal entries are $n - r$ ones and the polynomials $d_1, \ldots, d_r$. Simultaneous row and column swaps — each a pair of elementary operations — reorder these entries at will, so $x\mathbf{I}_n - \mathbf{A}$ is equivalent to

$$\operatorname{diag}(1, \ldots, 1, d_1, d_2, \ldots, d_r),$$

and this is already in the shape required by Theorem 9.7.3 (a), because $1 \mid d_1 \mid d_2 \mid \cdots \mid d_r$

and all the entries are monic. By uniqueness it *is* the Smith normal form of $x\mathbf{I} - \mathbf{A}$. The final claim combines this with Theorem 9.7.5 and the uniqueness in Theorem 9.7.3.

■

So the determinantal divisors of $x\mathbf{I} - \mathbf{A}$ compute the invariant factors of $\mathbf{A}$ without any factorization of polynomials: Δ_k is a gcd, obtained from the Euclidean algorithm alone. Moreover $\Delta_n(x\mathbf{I} - \mathbf{A}) = p_{\mathbf{A}}$ and $\Delta_n/\Delta_{n-1} = d_r = m_{\mathbf{A}}$.

9.7.5 Every matrix is similar to its transpose

Chapter 3 asked whether $\mathbf{A}$ and $\mathbf{A}^{\top}$ are always similar and postponed the answer; Exercise (C1: A matrix is similar to its transpose) settled it whenever $p_{\mathbf{A}}$ splits. The Smith form removes that hypothesis, because transposing a matrix does not change its minors.

Corollary 9.7.7 — A Matrix Is Similar to Its Transpose

Let F be any field and $\mathbf{A} \in M_n(F)$. Then $\mathbf{A} \sim \mathbf{A}^{\top}$.

Proof. Let $\mathbf{M} = x\mathbf{I} - \mathbf{A}$, so that $\mathbf{M}^{\top} = x\mathbf{I} - \mathbf{A}^{\top}$. For k-sets I, J we have $(\mathbf{M}^{\top})_{I,J} = (\mathbf{M}_{J,I})^{\top}$ by Definition 0.9.10, so $\det(\mathbf{M}^{\top})_{I,J} = \det \mathbf{M}_{J,I}$ by Theorem 6.4.5, valid over the commutative ring $F[x]$. Hence the $k \times k$ minors of $\mathbf{M}^{\top}$ are exactly the $k \times k$ minors of $\mathbf{M}$, listed in a different order, and

$$\Delta_k(x\mathbf{I} - \mathbf{A}^{\top}) = \Delta_k(x\mathbf{I} - \mathbf{A}) \qquad (k = 1, \dots, n).$$

By Theorem 9.7.3, each of $x\mathbf{I} - \mathbf{A}$ and $x\mathbf{I} - \mathbf{A}^{\top}$ is equivalent over $F[x]$ to the diagonal matrix built from its own determinantal divisors, and these two diagonal matrices coincide. Since $\approx$ is an equivalence relation (Proposition 9.7.2 (a)), $x\mathbf{I} - \mathbf{A} \approx x\mathbf{I} - \mathbf{A}^{\top}$. By Theorem 9.7.5, $\mathbf{A} \sim \mathbf{A}^{\top}$.

■

Two sentences of consequence. An operator and its dual have the same invariants: by Theorem 4.4.2 the matrix of T' in the dual basis is $[T]_{\mathcal{B}}^{\top}$, so T and T' share their characteristic polynomial, their minimal polynomial and their invariant factors. And a matrix and its transpose always have the same Jordan form when one exists, which says that the *rows* of $\mathbf{A} - \lambda\mathbf{I}$ are exactly as informative as its columns.

Warning. **Similar is not the same as "equivalent over $F[x]$" for the matrices themselves.** The theorem compares $x\mathbf{I} - \mathbf{A}$ with $x\mathbf{I} - \mathbf{B}$, not $\mathbf{A}$ with $\mathbf{B}$. As polynomial matrices, any two invertible $\mathbf{A}, \mathbf{B} \in M_n(F)$ are equivalent over $F[x]$ — take $\mathbf{U} = \mathbf{A}^{-1}$, $\mathbf{V} = \mathbf{B}$ — whether or not they are similar. The whole content of Theorem 9.7.5 is that inserting the variable x on the diagonal remembers the conjugation.

9.7.6 Exercises

9.7.6.1 A. Check your understanding

Exercise A1.

(a) List the three elementary operations over $F[x]$, and say which one differs from its counterpart over a field and why.

(b) State a criterion for a matrix $\mathbf{U} \in M_n(F[x])$ to be invertible in $M_n(F[x])$.

(c) State the Smith Normal Form theorem, including the uniqueness clause.

(d) Define the k-th determinantal divisor of a polynomial matrix, and say why it is unchanged by equivalence.

(e) True or false: if $\det(x\mathbf{I} - \mathbf{A}) = \det(x\mathbf{I} - \mathbf{B})$, then $x\mathbf{I} - \mathbf{A} \approx x\mathbf{I} - \mathbf{B}$. Justify your answer.

(f) How do you read $m_{\mathbf{A}}$ off the Smith normal form of $x\mathbf{I} - \mathbf{A}$?

Solution.

(a) Swap two rows; multiply a row by a non-zero **scalar** of F; add a **polynomial** multiple of one row to a different row (Definition 9.7.1). The scaling operation is restricted, because only the non-zero constants are invertible in $F[x]$; multiplying a row by x is not reversible.

(b) $\mathbf{U}$ is invertible over $F[x]$ if and only if $\det \mathbf{U}$ is a non-zero constant (Proposition 9.7.1).

(c) Every $\mathbf{M} \in M_n(F[x])$ is equivalent over $F[x]$, by elementary operations, to a diagonal $\operatorname{diag}(d_1, \dots, d_n)$ with each d_i monic or zero and $d_i \mid d_{i+1}$; this diagonal is unique (Theorem 9.7.3).

(d) $\Delta_k(\mathbf{M})$ is the monic generator of the ideal generated by all $k \times k$ minors of $\mathbf{M}$, equivalently their monic gcd. It is unchanged by equivalence because every $k \times k$ minor of $\mathbf{UMV}$ is an $F[x]$-combination of $k \times k$ minors of $\mathbf{M}$, by the Cauchy–Binet formula (Claim 1 in the proof of Theorem 9.7.3).

(e) False. Equality of determinants says only $\Delta_n(x\mathbf{I} - \mathbf{A}) = \Delta_n(x\mathbf{I} - \mathbf{B})$; the lower determinantal divisors can differ. For $\mathbf{A} = \mathbf{J}_2(0) \oplus \mathbf{J}_2(0)$ and $\mathbf{B} = \mathbf{J}_3(0) \oplus \mathbf{J}_1(0)$ in $M_4(F)$, both determinants are x^4, but the Smith normal forms are $\operatorname{diag}(1, 1, x^2, x^2)$ and $\operatorname{diag}(1, 1, x, x^3)$. (Equivalently, the matrices are not similar, by Corollary 9.3.3.)

(f) $m_{\mathbf{A}}$ is the **last** diagonal entry of the Smith normal form of $x\mathbf{I} - \mathbf{A}$, that is $\Delta_n/\Delta_{n-1} = p_{\mathbf{A}}/\Delta_{n-1}$ (Corollary 9.7.6, since the last diagonal entry is $d_r = m_{\mathbf{A}}$ in the notation there).

9.7.6.2 B. Practice

Exercise B1: Smith normal forms.

Find the Smith normal form over $\mathbb{Q}[x]$ of each of the following, naming the operations you use.

(a) $\mathbf{M}_1 = \begin{pmatrix} x & x+1 \\ x-1 & x \end{pmatrix}$.

(b) $\mathbf{M}_2 = \begin{pmatrix} x^2-1 & 0 \\ 0 & x^2-x \end{pmatrix}$.

(c) $\mathbf{M}_3 = \begin{pmatrix} x & 0 & 1 \\ -1 & x & 0 \\ 0 & -1 & x \end{pmatrix}$.

Solution.

(a) $\det \mathbf{M}_1 = x^2-(x+1)(x-1) = 1$, so $\mathbf{M}_1$ is invertible over $\mathbb{Q}[x]$ (Proposition 9.7.1) and $\Delta_1 = \Delta_2 = 1$. The Smith normal form is $\operatorname{diag}(1,1) = \mathbf{I}_2$. (Concretely: subtract column 1 from column 2 to get $\begin{pmatrix} x & 1 \\ x-1 & 1 \end{pmatrix}$, then subtract row 1 from row 2, swap columns, and clear.)

(b) Here $\Delta_1 = \gcd(x^2-1, x^2-x) = \gcd\big((x-1)(x+1), x(x-1)\big) = x-1$ and $\Delta_2 = \det \mathbf{M}_2 = x(x-1)^2(x+1)$. So the Smith normal form is

$$\operatorname{diag}\left(x-1,\ \tfrac{x(x-1)^2(x+1)}{x-1}\right) = \operatorname{diag}\big(x-1,\ x(x-1)(x+1)\big),$$

and indeed $x-1$ divides $x(x-1)(x+1)$. By operations: add column 2 to column 1, giving first column (x^2-1, x^2-x); subtract row 1 from row 2 to get $(x^2-1, 1-x)$ in column 1; the entry $1-x$ has least degree, so swap it into the corner, scale by -1, and continue.

(c) The 2×2 minor on rows $\{2,3\}$ and columns $\{1,2\}$ is $\det \begin{pmatrix} -1 & x \\ 0 & -1 \end{pmatrix} = 1$, so $\Delta_2 = 1$, and then $\Delta_1 = 1$ as well (it divides Δ_2). Expanding $\det \mathbf{M}_3$ along the first row, $x(x^2-0) + 1\cdot(1-0) = x^3+1$, so $\Delta_3 = x^3+1$ and the Smith normal form is $\operatorname{diag}(1,1,x^3+1)$. Note $\mathbf{M}_3 = x\mathbf{I} - \mathbf{C}$ with $\mathbf{C} = \begin{pmatrix} 0 & 0 & -1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix} = \mathbf{C}(x^3+1)$, and Corollary 9.7.6 predicts exactly this, since a companion matrix has the single invariant factor x^3+1.

Exercise B2: Invariant factors from determinantal divisors.

For each matrix $\mathbf{A}$, compute $\Delta_1, \dots, \Delta_n$ of $x\mathbf{I} - \mathbf{A}$, write down the Smith normal form, and read off the invariant factors, $m_{\mathbf{A}}$ and the Jordan form.

(a) $\mathbf{A} = \mathbf{J}_2(0) \oplus \mathbf{J}_2(0) \in M_4(\mathbb{Q})$.

(b) $\mathbf{A} = \mathbf{J}_3(0) \oplus \mathbf{J}_1(0) \in M_4(\mathbb{Q})$.

(c) $\mathbf{A} = \begin{pmatrix} 3 & 1 \\ 0 & 3 \end{pmatrix} \in M_2(\mathbb{Q})$.

Solution. One remark makes the minors easy. If $\mathbf{M} = \mathbf{M}_1 \oplus \mathbf{M}_2$ with square blocks, and I, J are k-sets, split $I = I_1 \cup I_2$ and $J = J_1 \cup J_2$ according to the blocks. If $|I_1| \neq |J_1|$, then $\mathbf{M}_{I,J}$ has a zero row or a zero column and $\det \mathbf{M}_{I,J} = 0$; if $|I_1| = |J_1|$, then $\mathbf{M}_{I,J} = (\mathbf{M}_1)_{I_1,J_1} \oplus (\mathbf{M}_2)_{I_2,J_2}$ and the determinant is the product of the two, by Theorem 6.8.4, whose proof uses only sums and products of entries and so applies over $F[x]$ (the remark after that theorem). So **the minors of a block diagonal matrix are the products of matching-size minors of the blocks.** Here $x\mathbf{I} - \mathbf{A}$ is the direct

sum of the blocks $x\mathbf{I}_k - \mathbf{J}_k(0)$, each upper triangular with x on the diagonal and -1 on the superdiagonal.

(a) $x\mathbf{I} - \mathbf{A} = \mathbf{N} \oplus \mathbf{N}$ with $\mathbf{N} = \begin{pmatrix} x & -1 \\ 0 & x \end{pmatrix}$, whose minors are the entries $x, -1, 0$ for $k = 1$ and x^2 for $k = 2$. By the remark, the minors of $\mathbf{N} \oplus \mathbf{N}$ are $\{x, -1, 0\}$ for $k = 1$; the products of two 1×1 minors together with x^2 for $k = 2$; x^2 times a 1×1 minor for $k = 3$; and x^4 for $k = 4$. Hence

$$\Delta_1 = 1, \qquad \Delta_2 = 1 \ \ (\text{from } (-1)(-1) = 1), \qquad \Delta_3 = x^2, \qquad \Delta_4 = x^4,$$

so the Smith normal form is $\operatorname{diag}(1, 1, x^2, x^2)$, the invariant factors are $x^2 \mid x^2$, $m_{\mathbf{A}} = x^2$ is the last of them, and the Jordan form is $\mathbf{J}_2(0) \oplus \mathbf{J}_2(0)$.

(b) Now $x\mathbf{I} - \mathbf{A} = \mathbf{N}_3 \oplus (x)$ with $\mathbf{N}_3 = \begin{pmatrix} x & -1 & 0 \\ 0 & x & -1 \\ 0 & 0 & x \end{pmatrix}$. The minors of $\mathbf{N}_3$ are $\{x, -1, 0\}$ for $k = 1$; $\{x^2, -x, 1, 0\}$ for $k = 2$, the value 1 coming from rows $\{1, 2\}$ and columns $\{2, 3\}$; and x^3 for $k = 3$. By the remark, the $k \times k$ minors of $x\mathbf{I} - \mathbf{A}$ are those of $\mathbf{N}_3$ together with x times its $(k-1) \times (k-1)$ minors, so

$$\begin{aligned} \Delta_1 &= 1, \\ \Delta_2 &= \gcd(x^2, -x, 1, x \cdot x, -x) = 1, \\ \Delta_3 &= \gcd(x^3,\ x \cdot x^2,\ -x \cdot x,\ x \cdot 1) = x, \\ \Delta_4 &= x^4. \end{aligned}$$

The Smith normal form is $\operatorname{diag}(1, 1, x, x^3)$: the invariant factors are $x \mid x^3$, $m_{\mathbf{A}} = x^3$ is the last of them, and the Jordan form is $\mathbf{J}_3(0) \oplus \mathbf{J}_1(0)$. Compared with (a) the determinants agree but Δ_3 does not, which is exactly why the two matrices are not similar.

(c) $x\mathbf{I} - \mathbf{A} = \begin{pmatrix} x-3 & -1 \\ 0 & x-3 \end{pmatrix}$. Then $\Delta_1 = 1$ and $\Delta_2 = (x-3)^2$, so the Smith normal form is $\operatorname{diag}(1, (x-3)^2)$, the only invariant factor is $(x-3)^2 = m_{\mathbf{A}} = p_{\mathbf{A}}$, and the Jordan form is $\mathbf{J}_2(3)$. Consistently, $\mathbf{A}$ is a companion matrix up to similarity, since $m_{\mathbf{A}} = p_{\mathbf{A}}$ (Theorem 9.5.6).

Exercise B3: Deciding similarity.

Determine whether each pair is similar over the stated field. Justify your answer using Theorem 9.7.5.

(a) $\mathbf{A} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$ and $\mathbf{B} = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}$ over $\mathbb{Q}$.

(b) $\mathbf{A} = \begin{pmatrix} 2 & 1 & -2 \\ 1 & 2 & -2 \\ 1 & 1 & -1 \end{pmatrix}$ and $\mathbf{B} = \mathbf{J}_2(1) \oplus \mathbf{J}_1(1)$ over $\mathbb{Q}$.

(c) $\mathbf{A} = \begin{pmatrix} 0 & -2 \\ 1 & 0 \end{pmatrix}$ and $\mathbf{B} = \begin{pmatrix} 0 & -1 \\ 2 & 0 \end{pmatrix}$ over $\mathbb{Q}$.

Solution.

(a) Similar. Here $\mathbf{B} = \mathbf{A}^\top$, so Corollary 9.7.7 applies. (Explicitly, $\Delta_1 = 1$ and $\Delta_2 = x^2 + 1$ for both, so both Smith normal forms are $\operatorname{diag}(1, x^2+1)$.)

(b) Similar. By Example (A Smith Normal Form Computed by Hand) the Smith normal form of $x\mathbf{I}-\mathbf{A}$ is $\operatorname{diag}(1, x-1, (x-1)^2)$. For $\mathbf{B}$, $x\mathbf{I}-\mathbf{B} = \begin{pmatrix} x-1 & -1 \\ 0 & x-1 \end{pmatrix} \oplus (x-1)$. Its entry -1 gives $\Delta_1 = 1$. By the block-minor rule in the solution to Exercise (B2: Invariant factors from determinantal divisors), the 2×2 minors are $(x-1)^2$, from the 2×2 block, together with the products of a 1×1 minor of each block, that is $(x-1)^2, -(x-1)$ and 0; so $\Delta_2 = x-1$. Finally $\Delta_3 = \det(x\mathbf{I}-\mathbf{B}) = (x-1)^3$. The Smith normal forms agree, so $x\mathbf{I}-\mathbf{A} \approx x\mathbf{I}-\mathbf{B}$ and $\mathbf{A} \sim \mathbf{B}$.

(c) Similar. Here

$$x\mathbf{I}-\mathbf{A} = \begin{pmatrix} x & 2 \\ -1 & x \end{pmatrix}, \qquad x\mathbf{I}-\mathbf{B} = \begin{pmatrix} x & 1 \\ -2 & x \end{pmatrix},$$

and each has an entry that is a non-zero constant, so $\Delta_1 = 1$ in both cases; and $\Delta_2 = \det(x\mathbf{I}-\mathbf{A}) = x^2+2 = \det(x\mathbf{I}-\mathbf{B})$. So both Smith normal forms are $\operatorname{diag}(1, x^2+2)$, hence $x\mathbf{I}-\mathbf{A} \approx x\mathbf{I}-\mathbf{B}$ and $\mathbf{A} \sim \mathbf{B}$ by Theorem 9.7.5. Note that x^2+2 is irreducible over $\mathbb{Q}$, so no Jordan form exists over $\mathbb{Q}$ and Exercise (C1: A matrix is similar to its transpose) would not have decided this pair. (Here $\mathbf{B} \neq \mathbf{A}^\top$, so Corollary 9.7.7 does not apply directly; the Smith forms settle it anyway.)

9.7.6.3 C. Going deeper

Exercise C1: The same algorithm over the integers.

The proof of Theorem 9.7.3 used only one property of $F[x]$: division with remainder, where the "size" of a non-zero element is its degree. The integers $\mathbb{Z}$ have the same property, with $|a|$ in place of deg.

(a) State the version of Theorem 9.7.3 for $\mathbf{M} \in M_n(\mathbb{Z})$ that the same proof gives, saying what replaces "monic".

(b) Compute the Smith normal form over $\mathbb{Z}$ of $\mathbf{M} = \begin{pmatrix} 2 & 4 \\ 6 & 4 \end{pmatrix}$, naming the operations.

(c) Every finite abelian group G with n generators is $\mathbb{Z}^n$ modulo the column span of some $\mathbf{M} \in M_n(\mathbb{Z})$, the matrix of relations, exactly as V was $F[x]^n$ modulo the columns of $x\mathbf{I}-\mathbf{A}$. Using (b), identify the group with relation matrix $\mathbf{M}$ as a product of cyclic groups.

Hint: for (c), a diagonal relation matrix $\operatorname{diag}(d_1, \dots, d_n)$ *presents the product of the cyclic groups* $\mathbb{Z}/d_i\mathbb{Z}$.

Solution.

(a) Every $\mathbf{M} \in M_n(\mathbb{Z})$ can be brought by integer elementary operations — swap two rows or columns, multiply a row or column by ± 1 (the units of $\mathbb{Z}$), add an **integer** multiple of one row or column to another — to a diagonal matrix $\operatorname{diag}(d_1, \dots, d_n)$ with every $d_i \geq 0$ and $d_i \mid d_{i+1}$, and this diagonal is unique. "Monic" is replaced by "non-negative", which is the normalization available because the units of $\mathbb{Z}$

are ± 1. Uniqueness again follows from the determinantal divisors Δ_k, now non-negative integer gcds of the $k \times k$ minors, using the Cauchy–Binet formula over the commutative ring $\mathbb{Z}$.

(b) The least absolute value among the entries is 2, already in the corner. It divides 4 and 6. Subtract 2 times column 1 from column 2, and 3 times row 1 from row 2:

$$\begin{pmatrix} 2 & 4 \\ 6 & 4 \end{pmatrix} \longrightarrow \begin{pmatrix} 2 & 0 \\ 6 & -8 \end{pmatrix} \longrightarrow \begin{pmatrix} 2 & 0 \\ 0 & -8 \end{pmatrix} \longrightarrow \begin{pmatrix} 2 & 0 \\ 0 & 8 \end{pmatrix},$$

the last step multiplying row 2 by -1. Since $2 \mid 8$, the Smith normal form is $\operatorname{diag}(2, 8)$. Check: $\Delta_1 = \gcd(2, 4, 6, 4) = 2$ and $\Delta_2 = |\det \mathbf{M}| = |8 - 24| = 16 = 2 \cdot 8$.

(c) By (b) and the hint, the group is $\mathbb{Z}/2\mathbb{Z} \times \mathbb{Z}/8\mathbb{Z}$, of order $16 = |\det \mathbf{M}|$. This is the structure theorem for finite abelian groups in miniature: the invariant divisors $d_1 \mid \cdots \mid d_n$ of the relation matrix are the orders of the cyclic factors.

Exercise C2: Uniqueness by hand in the smallest case.

Let $\mathbf{M} \in M_2(F[x])$ be non-zero.

(a) Prove directly, without using determinantal divisors, that $\Delta_1(\mathbf{M})$ — the monic gcd of the four entries of $\mathbf{M}$ — is unchanged by each of the six elementary operations of Definition 9.7.1.

(b) Prove that $\det(\mathbf{UMV}) = c \det \mathbf{M}$ for a non-zero constant c whenever $\mathbf{U}, \mathbf{V}$ are invertible over $F[x]$.

(c) Deduce that if $\operatorname{diag}(d_1, d_2) \approx \operatorname{diag}(e_1, e_2)$ with all four entries monic or zero, $d_1 \mid d_2$ and $e_1 \mid e_2$, then $d_1 = e_1$ and $d_2 = e_2$.

Solution.

(a) Write $d = \Delta_1(\mathbf{M})$, the monic gcd of the entries, that is, the monic generator of the ideal $\langle m_{11}, m_{12}, m_{21}, m_{22} \rangle$ (Theorem 5.2.2). A swap permutes the entries, so the ideal is unchanged. Scaling a row by $c \in F \setminus \{0\}$ replaces two generators g by cg, and $\langle cg \rangle = \langle g \rangle$ since c is a unit, so the ideal is unchanged. Adding h times row 1 to row 2 replaces m_{2j} by $m_{2j} + h m_{1j}$, which lies in the old ideal; so the new ideal is contained in the old one, and the operation is reversed by adding $-h$ times row 1 to row 2, which gives the reverse containment. The same three arguments apply to columns. Hence d is unchanged.

(b) By multiplicativity of the determinant over the commutative ring $F[x]$ (Theorem 6.5.4 and the remark on commutative rings), $\det(\mathbf{UMV}) = \det \mathbf{U} \cdot \det \mathbf{M} \cdot \det \mathbf{V}$, and $\det \mathbf{U}, \det \mathbf{V}$ are non-zero constants by Proposition 9.7.1. Take $c = \det \mathbf{U} \det \mathbf{V}$.

(c) By Proposition 9.7.2 and (a), Δ_1 is an invariant of equivalence as far as elementary operations go; and for a general equivalence $\mathbf{M}' = \mathbf{UMV}$ the argument of (a) applies verbatim with the generators of the ideal replaced using $m'_{ij} = \sum_{k,l} u_{ik} m_{kl} v_{lj} \in \langle m_{kl} \rangle$, and symmetrically. For the two diagonal matrices, $\Delta_1(\operatorname{diag}(d_1, d_2)) = \gcd(d_1, d_2) = d_1$ since $d_1 \mid d_2$ and d_1 is monic (or $d_1 = d_2 = 0$); likewise $\Delta_1(\operatorname{diag}(e_1, e_2)) = e_1$. Hence $d_1 = e_1$. By (b), $d_1 d_2 = c\, e_1 e_2$ for some non-zero constant c; if $d_1 = e_1 \neq 0$ then $d_2 = c\, e_2$, and two monic polynomials (or two zeros) differing by a constant factor are equal, so $d_2 = e_2$. If $d_1 = e_1 = 0$, then

$d_2 = e_2 = 0$ by the divisibility chain.

9.8 Semisimple Operators and the Jordan–Chevalley Decomposition

The Jordan canonical form says that an operator whose characteristic polynomial splits is "a diagonal matrix plus a nilpotent one" — but only after a basis has been chosen. This section turns that sentence into a statement about the operator itself: $T = S + N$ with S diagonalizable, N nilpotent and, crucially, $SN = NS$; and there is exactly one such pair. Before that we need a name for the operators that deserve to be called diagonalizable even when the field is too small to see it.

9.8.1 Diagonalizable once the field is big enough

Two operators fail to be diagonalizable for completely different reasons. The rotation $\mathbf{R} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} \in M_2(\mathbb{R})$ has $p_{\mathbf{R}} = m_{\mathbf{R}} = x^2 + 1$, with no real root, so it has no eigenvectors at all (Example (A Real Matrix with Non-Real Eigenvalues)). Yet over $\mathbb{C}$ it becomes $\operatorname{diag}(i, -i)$: the operator was fine, the field was too small. The shear $\mathbf{J}_2(0)$ has $m = x^2$ and is not diagonalizable over **any** field, however large: its single eigenvalue 0 has $a = 2$ and $g = 1$, and enlarging the field changes neither.

What separates the two cases is visible in the minimal polynomial. For $\mathbf{R}$ it is $x^2 + 1$, irreducible over $\mathbb{R}$ and appearing to the first power. For $\mathbf{J}_2(0)$ it is x^2, the **square** of the irreducible x. Chapter 8 proved that T is diagonalizable exactly when m_T is a product of **distinct linear** factors (Theorem 8.8.2). Deleting the word "linear" from that criterion gives the notion we want.

A semisimple operator is one whose minimal polynomial is squarefree: no irreducible factor is repeated.

Definition 9.8.1 — Semisimple Operator

Let V be a finite-dimensional vector space over F with $\dim V \geq 1$, and let $T \in \mathcal{L}(V)$. We say T is **semisimple** if

$$m_T = p_1 p_2 \cdots p_k$$

for **distinct** monic irreducible $p_1, \ldots, p_k \in F[x]$; equivalently, if **no** irreducible polynomial $p \in F[x]$ satisfies $p^2 \mid m_T$. A matrix $\mathbf{A} \in M_n(F)$ is **semisimple over** F if $T_{\mathbf{A}}$ is.

In words: factor m_T into irreducibles over F (Theorem 5.3.5). Semisimplicity says every exponent in that factorization is 1. The two descriptions agree: the exponents are all 1 exactly when no p^2 divides m_T, by uniqueness of factorization. Note the dependence on the field, which is built into the word "irreducible over F".

Examples.

- **Diagonalizable operators.** If T is diagonalizable, m_T is a product of distinct linear factors (Theorem 8.8.2), and linear polynomials are irreducible (Definition 5.3.1). So T is semisimple.
- **The rotation.** $\mathbf{R} \in M_2(\mathbb{R})$ above has $m_{\mathbf{R}} = x^2 + 1$, irreducible over $\mathbb{R}$ since it has no real root (Theorem 5.3.1). One factor, exponent 1: semisimple over $\mathbb{R}$, though not diagonalizable over $\mathbb{R}$.
- **Any operator with irreducible minimal polynomial**, for the same reason. In particular the companion matrix $\mathbf{C}(p)$ of an irreducible p is semisimple, since $m_{\mathbf{C}(p)} = p$ (Theorem 9.5.3).
- **The degenerate case.** On a space of dimension 1, $T = \lambda\,\mathrm{id}_V$ has $m_T = x - \lambda$: semisimple. So is id_V on any V, with $m = x - 1$.

Non-example by minimal change. Over $\mathbb{R}$, replace $m = x^2 + 1$ by $m = (x^2 + 1)^2$: the companion matrix $\mathbf{C}\big((x^2+1)^2\big) \in M_4(\mathbb{R})$ has $m = (x^2+1)^2$ (Theorem 9.5.3), so the irreducible $x^2 + 1$ is repeated and the matrix is **not** semisimple. The clause that fails is "distinct": there is one irreducible factor, but it occurs twice.

Why this definition. The word *simple* names the case in which V has no T-invariant subspace except $\{\mathbf{0}\}$ and V. That happens exactly when m_T is irreducible **and** $\dim V = \deg m_T$, for then every non-zero $\mathbf{v}$ has T-annihilator m_T and so $Z(\mathbf{v}; T) = V$ (Theorem 9.5.2). *Semisimple* then means "a direct sum of simple pieces", which is what Theorem 8.8.1 followed by a cyclic decomposition (Theorem 9.6.2) delivers. The definition is the right one because it is exactly diagonalizability after the field has been enlarged enough to split m_T — provided the field is not pathological. Making that precise needs one small fact: the minimal polynomial does not change when the field grows.

Lemma 9.8.1 — The Minimal Polynomial Does Not Notice a Larger Field

Let $K \subseteq L$ be fields and $\mathbf{A} \in M_n(K)$, $n \geq 1$. Then the minimal polynomial of $\mathbf{A}$ computed in $K[x]$ equals the minimal polynomial of $\mathbf{A}$ computed in $L[x]$.

Idea. The degree of $m_{\mathbf{A}}$ is the position of the first linear dependence in the list $\mathbf{I}, \mathbf{A}, \mathbf{A}^2, \ldots$ (Proposition 8.5.4). Whether a list of matrices with entries in K is dependent is decided by row reducing one matrix with entries in K, and row reduction does not care that a bigger field is available.

Proof. Write m^K and m^L for the two minimal polynomials, and $d = \deg m^K$, $e = \deg m^L$.

Since $m^K \in K[x] \subseteq L[x]$ annihilates $\mathbf{A}$, Theorem 8.5.1 gives $m^L \mid m^K$, so $e \leq d$.

For the reverse inequality, list the entries of $\mathbf{I}, \mathbf{A}, \ldots, \mathbf{A}^e$ as the columns of a matrix $\mathbf{B} \in M_{n^2 \times (e+1)}(K)$, one column per power. A linear combination $\sum_{i=0}^{e} c_i \mathbf{A}^i$ is the zero matrix exactly when $\mathbf{Bc} = \mathbf{0}$ for $\mathbf{c} = (c_0, \ldots, c_e)$. By Proposition 8.5.4 applied over L, the list $(\mathbf{I}, \mathbf{A}, \ldots, \mathbf{A}^e)$ is dependent over L, so $\mathbf{Bc} = \mathbf{0}$ has a non-trivial solution in L^{e+1}, and hence $\mathrm{rank}_L\, \mathbf{B} < e + 1$ (Theorem 2.5.7). Now reduce $\mathbf{B}$ to reduced row echelon form by row operations performed inside K (Theorem 2.2.3); the resulting matrix $\mathbf{R}$ has entries in K, and the definition of reduced row echelon form (Definition 2.2.4) makes no reference to the field, so $\mathbf{R}$ is also **the** reduced row echelon form of $\mathbf{B}$ over L, by the uniqueness in Theorem 2.3.4. The rank is the number of pivots of $\mathbf{R}$ (Corollary 2.5.6),

a number read off $\mathbf{R}$ alone. Hence

$$\operatorname{rank}_K \mathbf{B} = \operatorname{rank}_L \mathbf{B} < e + 1,$$

so $\mathbf{Bc} = \mathbf{0}$ has a non-trivial solution in K^{e+1} as well. That solution gives a non-zero $f \in K[x]$ of degree at most e with $f(\mathbf{A}) = 0$, whence $d = \deg m^K \leq e$ by Theorem 8.5.1 and Proposition 5.1.2.

So $d = e$, and $m^L \mid m^K$ with both monic of the same degree forces $m^L = m^K$.

■

Proposition 9.8.2 — Semisimple Means Diagonalizable After Enlarging the Field

Let K be a field of characteristic 0, let $\mathbf{A} \in M_n(K)$ with $n \geq 1$, and let $L \supseteq K$ be a field over which $m_{\mathbf{A}}$ splits. Then

$$\mathbf{A} \text{ is semisimple over } K \iff \mathbf{A} \text{ is diagonalizable over } L.$$

Proof. By Lemma 9.8.1 the minimal polynomial is the same polynomial $m = m_{\mathbf{A}}$ whether computed over K or over L. By Theorem 8.8.2, $\mathbf{A}$ is diagonalizable over L if and only if m is a product of distinct linear factors in $L[x]$, that is, if and only if m splits over L — which it does by hypothesis — with **no repeated root**.

($\Leftarrow$) Suppose m has no repeated root in L. If some irreducible $p \in K[x]$ satisfied $m = p^2 h$, then $p \mid m$ and m splits over L, so p has a root $\lambda \in L$; by Theorem 5.4.2, $\operatorname{mult}_\lambda(m) \geq 2 \operatorname{mult}_\lambda(p) \geq 2$, and λ would be a repeated root of m. So no such p exists and $\mathbf{A}$ is semisimple over K.

($\Rightarrow$) Suppose $m = p_1 \cdots p_k$ with $p_1, \ldots, p_k \in K[x]$ distinct monic irreducibles. The formal derivative is computed from the coefficients (Definition 5.4.3), so each p_i' is the same polynomial whether read in $K[x]$ or in $L[x]$.

No p_i has a repeated root in L. Since K has characteristic 0 and $\deg p_i \geq 1$, the derivative p_i' is non-zero of degree $\deg p_i - 1$, so $p_i \nmid p_i'$; as p_i is irreducible, Lemma 5.3.2 gives $\gcd(p_i, p_i') = 1$, and by Corollary 5.2.4 there are $a, b \in K[x]$ with $a p_i + b p_i' = 1$. If $\lambda \in L$ were a repeated root of p_i, then $p_i(\lambda) = p_i'(\lambda) = 0$ by Theorem 5.4.5 (a), applied in $L[x]$; evaluating the identity at λ would give $1 = 0$.

No two p_i share a root in L. For $i \neq j$, a monic divisor of the irreducible p_j is 1 or p_j, so $p_i \nmid p_j$, and Lemma 5.3.2 gives $\gcd(p_i, p_j) = 1$. Again by Corollary 5.2.4, $a p_i + b p_j = 1$ for some $a, b \in K[x]$, and a common root in L would give $1 = 0$.

Therefore, by Theorem 5.4.2, every root of m in L has multiplicity 1: it is a root of exactly one p_i, and a simple one. So m is a product of distinct linear factors over L, and $\mathbf{A}$ is diagonalizable over L.

■

Remark. A field over which every irreducible polynomial has distinct roots in a splitting field is called **perfect**. The proof above shows that every field of characteristic 0 is perfect, and every finite field is perfect as well, although that needs an argument we do

not give here. Over a non-perfect field Proposition 9.8.2 can fail: in characteristic p there are irreducible polynomials of the form $q(x^p)$, whose derivative vanishes identically and which acquire repeated roots in a splitting field. Everything in the rest of this section takes place over a field where p_T splits, so this subtlety will not arise again.

Quick check. Over $\mathbb{Q}$, which of $\mathbf{A} = \mathbf{C}(x^2+1) \oplus \mathbf{C}(x^2+1) \in M_4(\mathbb{Q})$ and $\mathbf{B} = \mathbf{C}\big((x^2+1)^2\big) \in M_4(\mathbb{Q})$ is semisimple? Is either diagonalizable over $\mathbb{Q}$?

Solution. $\mathbf{A}$ is semisimple. Each block has minimal polynomial x^2+1 (Theorem 9.5.3), so $m_{\mathbf{A}} = \operatorname{lcm}(x^2+1, x^2+1) = x^2+1$ (Proposition 8.5.6), an irreducible polynomial to the first power. $\mathbf{B}$ is not: $m_{\mathbf{B}} = (x^2+1)^2$ repeats the irreducible x^2+1. Neither is diagonalizable over $\mathbb{Q}$, since x^2+1 has no rational root, so neither minimal polynomial is a product of linear factors. Over $\mathbb{C}$, however, $\mathbf{A}$ becomes $\operatorname{diag}(i,-i,i,-i)$, while $\mathbf{B}$ becomes $\mathbf{J}_2(i) \oplus \mathbf{J}_2(-i)$, which is not diagonal.

9.8.2 Splitting an operator in two

Here is the goal. **When p_T splits, T is the sum of a diagonalizable operator and a nilpotent operator that commute, in exactly one way, and both summands are polynomials in T.** The Jordan form already shows *a* splitting: in a Jordan basis, $\mathbf{J} = \mathbf{D} + \mathbf{M}$ where $\mathbf{D}$ is the diagonal of $\mathbf{J}$ and $\mathbf{M}$ carries the superdiagonal ones, and these commute because $\mathbf{D}$ is constant on each block. What the theorem adds is that the two pieces do not depend on which Jordan basis was used, and that they can be written down without finding one.

Theorem 9.8.3 — Jordan–Chevalley Decomposition

Let V be a finite-dimensional vector space over F with $\dim V = n \geq 1$, and let $T \in \mathcal{L}(V)$ with p_T split over F. Then:

(a) **(Existence)** There are $S, N \in \mathcal{L}(V)$ with

$$T = S + N, \qquad S \text{ diagonalizable}, \qquad N \text{ nilpotent}, \qquad SN = NS;$$

moreover $S = g(T)$ and $N = h(T)$ for some $g, h \in F[x]$.

(b) **(Uniqueness)** If $T = S' + N'$ with S' diagonalizable, N' nilpotent and $S'N' = N'S'$, then $S' = S$ and $N' = N$.

We call S the **semisimple part** and N the **nilpotent part** of T.

Idea. **Existence.** The generalized eigenspace decomposition already puts the answer in front of us: on G_λ the operator is $\lambda\,\mathrm{id}$ +nilpotent. Declare S to be $\lambda\,\mathrm{id}$ on G_λ for each λ and let N be the rest. Then S is diagonalizable because a basis assembled from bases of the G_λ consists of eigenvectors of S, and N is nilpotent because it is nilpotent on each piece. That S and N are polynomials in T is the extra information carried by the primary decomposition: its projections are $h_i(T)$.

Uniqueness. A second decomposition $S' + N'$ has S' commuting with T, hence with

every polynomial in T, hence with S and with N; the same for N'. Then $S-S' = N'-N$ is simultaneously diagonalizable and nilpotent, and the only such operator is 0.

Proof.

(a) Let $\lambda_1, \dots, \lambda_k$ be the distinct eigenvalues of T and write

$$m_T = (x-\lambda_1)^{s_1} \cdots (x-\lambda_k)^{s_k}, \qquad G_i = G_{\lambda_i}(T),$$

as in Theorem 9.1.3, so that $V = G_1 \oplus \cdots \oplus G_k$ with $G_i = \ker(T-\lambda_i \operatorname{id}_V)^{s_i}$. The factors $(x-\lambda_i)^{s_i}$ are exactly the primary factors of m_T, since $x-\lambda_i$ is irreducible, so G_i is the i-th primary component of Theorem 8.8.1. By part (d) of that theorem there are $h_1, \dots, h_k \in F[x]$ such that

$$\pi_i \coloneqq h_i(T) \in \mathcal{L}(V)$$

is the projection onto G_i along $\bigoplus_{j\neq i} G_j$. Put

$$g \coloneqq \sum_{i=1}^{k} \lambda_i h_i \in F[x],$$

$$S \coloneqq g(T) = \sum_{i=1}^{k} \lambda_i \pi_i,$$

$$N \coloneqq T - S = h(T) \text{ with } h = x - g.$$

S is diagonalizable. Fix i and $\mathbf{v} \in G_i$. Then $\pi_i \mathbf{v} = \mathbf{v}$ and $\pi_j \mathbf{v} = \mathbf{0}$ for $j \neq i$ (Theorem 3.10.1), so $S\mathbf{v} = \lambda_i \mathbf{v}$. Choose a basis of each G_i and let $\mathcal{B}$ be the concatenation, a basis of V because $V = \bigoplus_i G_i$. Every vector of $\mathcal{B}$ is an eigenvector of S, so $[S]_{\mathcal{B}}$ is diagonal and S is diagonalizable (Theorem 8.4.1).
N is nilpotent. Fix i and $\mathbf{v} \in G_i$. Then $N\mathbf{v} = T\mathbf{v} - \lambda_i \mathbf{v} = (T-\lambda_i \operatorname{id}_V)\mathbf{v}$, which lies in G_i because G_i is T-invariant, so by induction $N^j \mathbf{v} = (T-\lambda_i \operatorname{id}_V)^j \mathbf{v}$ for every $j \geq 0$. With $s = \max_i s_i$ we get $N^s \mathbf{v} = (T-\lambda_i \operatorname{id}_V)^s \mathbf{v} = \mathbf{0}$, since $(T-\lambda_i \operatorname{id}_V)^{s_i}\mathbf{v} = \mathbf{0}$ and $s \geq s_i$. As every $\mathbf{v} \in V$ is a sum of such vectors, $N^s = 0$ and N is nilpotent (Definition 9.2.1).
They commute. Both $S = g(T)$ and $N = h(T)$ are polynomials in T, and any two polynomials in T commute (Theorem 5.7.1 (c)). This proves (a).

(b) Suppose $T = S' + N'$ as stated. First, S' commutes with T:

$$S'T = S'(S'+N') = S'S' + S'N' = S'S' + N'S' = (S'+N')S' = TS',$$

where the middle equality is the hypothesis $S'N' = N'S'$. Hence S' commutes with every power of T and so with every polynomial in T, in particular with $S = g(T)$ and $N = h(T)$. The same computation gives $N'T = TN'$, so N' too commutes with S and N.

Now set $X \coloneqq S - S'$. From $S + N = T = S' + N'$ we get

$$X = S - S' = N' - N.$$

The operators S and S' are diagonalizable and commute, so they are simultaneously diagonalizable (Theorem 8.9.5): there is a basis $\mathcal{C}$ in which $[S]_{\mathcal{C}}$ and $[S']_{\mathcal{C}}$ are both diagonal. Then $[X]_{\mathcal{C}} = [S]_{\mathcal{C}} - [S']_{\mathcal{C}}$ is diagonal, so X is diagonalizable. On the other hand N and

N' are nilpotent and commute, hence so do N' and $-N$, and $X = N' + (-N)$ is nilpotent by Exercise (C2: Commuting nilpotent matrices) (b), whose binomial argument uses only that the two summands commute and so applies verbatim to operators.

So X is diagonalizable and nilpotent. Being nilpotent, $\operatorname{spec}(X) = \{0\}$ (Proposition 9.2.1 (c)); being diagonalizable, $[X]_{\mathcal{D}}$ is diagonal with the eigenvalues of X on the diagonal for some basis $\mathcal{D}$ (Theorem 8.4.1), so $[X]_{\mathcal{D}} = 0$ and $X = 0$. Hence $S' = S$ and, subtracting from T, $N' = N$. This proves the theorem.

■

Warning. **Splitting a matrix into its diagonal part and its off-diagonal part is *not* the Jordan–Chevalley decomposition.** For $\mathbf{A} = \begin{pmatrix} 1 & 1 \\ 0 & 2 \end{pmatrix}$, the "obvious" split is $\mathbf{D} = \operatorname{diag}(1, 2)$ plus $\mathbf{E} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$. Here $\mathbf{D}$ is diagonal and $\mathbf{E}$ is nilpotent, but

$$\mathbf{DE} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} \neq \begin{pmatrix} 0 & 2 \\ 0 & 0 \end{pmatrix} = \mathbf{ED},$$

so the commuting requirement fails, and the split is not the one the theorem produces. Indeed $\mathbf{A}$ has distinct eigenvalues, so it is diagonalizable (Corollary 8.4.2) and its actual decomposition is $\mathbf{S} = \mathbf{A}$, $\mathbf{N} = 0$. The off-diagonal part of a matrix is a feature of the basis; the nilpotent part is a feature of the operator.

The formulas in the proof are also the recipe: build the projections π_i onto the generalized eigenspaces — by Bézout, as in Example (A Primary Decomposition with an Irreducible Quadratic) — and set $S = \sum_i \lambda_i \pi_i$.

Example. (The Semisimple and Nilpotent Parts of a 3×3 Matrix)

Let

$$\mathbf{A} = \begin{pmatrix} 2 & 2 & -1 \\ -1 & 3 & -1 \\ -1 & -1 & 2 \end{pmatrix} \in M_3(\mathbb{Q}), \qquad p_{\mathbf{A}} = (x-2)^2(x-3).$$

Find the Jordan–Chevalley decomposition $\mathbf{A} = \mathbf{S} + \mathbf{N}$, and exhibit $\mathbf{S}$ and $\mathbf{N}$ as polynomials in $\mathbf{A}$.

Solution. The minimal polynomial. Put $\mathbf{B} = \mathbf{A} - 2\mathbf{I} = \begin{pmatrix} 0 & 2 & -1 \\ -1 & 1 & -1 \\ -1 & -1 & 0 \end{pmatrix}$. Then

$$\mathbf{B}(\mathbf{A} - 3\mathbf{I}) = \begin{pmatrix} 0 & 2 & -1 \\ -1 & 1 & -1 \\ -1 & -1 & 0 \end{pmatrix} \begin{pmatrix} -1 & 2 & -1 \\ -1 & 0 & -1 \\ -1 & -1 & -1 \end{pmatrix} = \begin{pmatrix} -1 & 1 & -1 \\ 1 & -1 & 1 \\ 2 & -2 & 2 \end{pmatrix} \neq 0,$$

so $m_{\mathbf{A}} \neq (x-2)(x-3)$; since $m_{\mathbf{A}} \mid p_{\mathbf{A}}$ and $m_{\mathbf{A}}$ has both 2 and 3 as roots (Theorem 8.5.3), $m_{\mathbf{A}} = (x-2)^2(x-3)$. The primary factors are $(x-2)^2$ and $x-3$.

Bézout. Dividing, $(x-2)^2 = x^2 - 4x + 4 = (x-3)(x-1) + 1$, so

$$1 \cdot (x-2)^2 - (x-1)(x-3) = 1.$$

Following Theorem 5.7.5 with $p = (x-2)^2$ and $q = x-3$: the projection onto $\ker q(\mathbf{A}) = G_3(\mathbf{A})$ along $\ker p(\mathbf{A}) = G_2(\mathbf{A})$ is $\pi_3 = (\mathbf{A} - 2\mathbf{I})^2 = \mathbf{B}^2$, and $\pi_2 = \mathbf{I} - \mathbf{B}^2$.

Compute. Squaring,

$$\mathbf{B}^2 = \begin{pmatrix} -1 & 3 & -2 \\ 0 & 0 & 0 \\ 1 & -3 & 2 \end{pmatrix}, \qquad \text{and } \mathbf{B}^3 = \mathbf{B}^2 \text{ (as } \mathbf{B}^2(\mathbf{B} - \mathbf{I}) = 0).$$

Hence

$$\mathbf{S} = 2\pi_2 + 3\pi_3 = 2\mathbf{I} + \mathbf{B}^2 = \begin{pmatrix} 1 & 3 & -2 \\ 0 & 2 & 0 \\ 1 & -3 & 4 \end{pmatrix},$$
$$\mathbf{N} = \mathbf{A} - \mathbf{S} = \mathbf{B} - \mathbf{B}^2 = \begin{pmatrix} 1 & -1 & 1 \\ -1 & 1 & -1 \\ -2 & 2 & -2 \end{pmatrix}.$$

The checks. First $\mathbf{S} + \mathbf{N} = \mathbf{A}$ by construction. Next $\mathbf{N}^2 = 0$: reading the rows of $\mathbf{N}$ as multiples of $(1, -1, 1)$ shows that $\mathbf{N} = \mathbf{u}\mathbf{w}^\top$ with $\mathbf{u} = (1, -1, -2)$ and $\mathbf{w} = (1, -1, 1)$, and $\mathbf{w}^\top\mathbf{u} = 1 + 1 - 2 = 0$, so $\mathbf{N}^2 = \mathbf{u}(\mathbf{w}^\top\mathbf{u})\mathbf{w}^\top = 0$. Next $\mathbf{S}$ is diagonalizable: $(\mathbf{S} - 2\mathbf{I})(\mathbf{S} - 3\mathbf{I}) = \mathbf{B}^2(\mathbf{B}^2 - \mathbf{I}) = \mathbf{B}^4 - \mathbf{B}^2 = 0$, because $\mathbf{B}^3 = \mathbf{B}^2$ gives $\mathbf{B}^4 = \mathbf{B}^2$; so $m_{\mathbf{S}}$ divides a product of distinct linear factors and $\mathbf{S}$ is diagonalizable (Theorem 8.8.2). Finally $\mathbf{S}\mathbf{N} = \mathbf{N}\mathbf{S}$, since both are polynomials in $\mathbf{A}$: explicitly $\mathbf{S} = 2\mathbf{I} + (\mathbf{A} - 2\mathbf{I})^2$ and $\mathbf{N} = (\mathbf{A} - 2\mathbf{I}) - (\mathbf{A} - 2\mathbf{I})^2$, that is,

$$\mathbf{S} = g(\mathbf{A}) \text{ with } g = x^2 - 4x + 6,$$
$$\mathbf{N} = h(\mathbf{A}) \text{ with } h = -x^2 + 5x - 6 = -(x-2)(x-3).$$

As a cross-check, $g + h = x$, so $g(\mathbf{A}) + h(\mathbf{A}) = \mathbf{A}$; and $\operatorname{tr}\mathbf{S} = 1 + 2 + 4 = 7 = 2 + 2 + 3$ is the sum of the eigenvalues of $\mathbf{A}$, while $\operatorname{tr}\mathbf{N} = 1 + 1 - 2 = 0$, as it must be for a nilpotent matrix (Proposition 9.2.1 (c) and Theorem 8.3.3).

Two consequences are worth naming now. Because S and N are polynomials in T, **every operator commuting with T automatically commutes with S and with N.** And the decomposition is exactly what makes functions of matrices computable in the next section: any reasonable function f will satisfy $f(T) = f(S + N)$ with the two parts handled separately, S by its eigenvalues and N by finitely many terms, since its powers stop.

Remark. The splitting exists in greater generality. Over a perfect field, every T can be written uniquely as $T = S + N$ with S **semisimple** in the sense of Definition 9.8.1, N nilpotent and $SN = NS$; the proof runs through the primary decomposition of m_T into powers of general irreducibles instead of linear ones. We prove only the split case, which is all we use.

9.8.3 Exercises

9.8.3.1 A. Check your understanding

Exercise A1.

(a) Define a semisimple operator, and say how the definition specializes to Chapter 8's criterion for diagonalizability.

(b) State the Jordan–Chevalley Decomposition Theorem, including all three conditions on S and N and the uniqueness clause.

(c) True or false: $\begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} \in M_2(\mathbb{R})$ is semisimple. Justify your answer.

(d) True or false: if $\mathbf{A} = \mathbf{D} + \mathbf{E}$ with $\mathbf{D}$ the diagonal part of $\mathbf{A}$ and $\mathbf{E}$ the off-diagonal part, then $\mathbf{D}$ is the semisimple part of $\mathbf{A}$. Justify your answer.

(e) Which hypothesis of the uniqueness clause does the pair $(\mathbf{D}, \mathbf{E})$ of part (d) typically violate?

(f) Why does every operator commuting with T commute with the semisimple part of T?

Solution.

(a) T is semisimple if m_T is a product of **distinct monic irreducible** polynomials over F (Definition 9.8.1). Requiring those irreducibles to be **linear** gives Theorem 8.8.2, the criterion for diagonalizability. So diagonalizable $\Rightarrow$ semisimple, and the converse holds when m_T splits.

(b) If p_T splits, then $T = S + N$ with S diagonalizable, N nilpotent and $SN = NS$; such S and N are unique, and both are polynomials in T (Theorem 9.8.3).

(c) True. Its minimal polynomial is $x^2 + 1$, which has no real root and so is irreducible over $\mathbb{R}$ (Theorem 5.3.1); one irreducible factor, exponent 1.

(d) False. For $\mathbf{A} = \begin{pmatrix} 1 & 1 \\ 0 & 2 \end{pmatrix}$ the semisimple part is $\mathbf{A}$ itself, since $\mathbf{A}$ is diagonalizable, whereas $\mathbf{D} = \operatorname{diag}(1, 2) \neq \mathbf{A}$.

(e) The commuting condition $\mathbf{DE} = \mathbf{ED}$; see the warning after Theorem 9.8.3.

(f) Because $S = g(T)$ for some polynomial g (Theorem 9.8.3 (a)), and an operator commuting with T commutes with every power of T, hence with every polynomial in T.

9.8.3.2 B. Practice

Exercise B1: Semisimple and nilpotent parts.

For each matrix over $\mathbb{Q}$, find the Jordan–Chevalley decomposition $\mathbf{A} = \mathbf{S} + \mathbf{N}$ and express $\mathbf{S}$ as a polynomial in $\mathbf{A}$.

(a) $\mathbf{A}_1 = \begin{pmatrix} 3 & 1 \\ 0 & 3 \end{pmatrix}$.

(b) $\mathbf{A}_2 = \begin{pmatrix} 1 & 2 \\ 0 & 3 \end{pmatrix}$.

(c) $\mathbf{A}_3 = \begin{pmatrix} 2 & 1 & 3 \\ 0 & 2 & 0 \\ 0 & 0 & 5 \end{pmatrix}$.

Solution.

(a) $m_{\mathbf{A}_1} = (x-3)^2$, so there is one eigenvalue and $G_3 = \mathbb{Q}^2$; the projection onto it is $\mathbf{I}$. Hence $\mathbf{S} = 3\mathbf{I}$ and $\mathbf{N} = \mathbf{A}_1 - 3\mathbf{I} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$, with $\mathbf{N}^2 = 0$. As a polynomial, $\mathbf{S} = 3\mathbf{I} = g(\mathbf{A}_1)$ with $g = 3$ the constant polynomial. (Every scalar multiple of $\mathbf{I}$ is diagonalizable, and $\mathbf{S}$ commutes with everything.)

(b) $\mathbf{A}_2$ has the distinct eigenvalues 1 and 3, so it is diagonalizable (Corollary 8.4.2). By uniqueness, $\mathbf{S} = \mathbf{A}_2$ and $\mathbf{N} = 0$; here $g = x$. The naive split into $\operatorname{diag}(1,3)$ and $\begin{pmatrix} 0 & 2 \\ 0 & 0 \end{pmatrix}$ is **not** the Jordan–Chevalley decomposition.

(c) $p_{\mathbf{A}_3} = (x-2)^2(x-5)$. Put $\mathbf{M} = \mathbf{A}_3 - 2\mathbf{I} = \begin{pmatrix} 0 & 1 & 3 \\ 0 & 0 & 0 \\ 0 & 0 & 3 \end{pmatrix}$. Then $\mathbf{M}(\mathbf{A}_3 - 5\mathbf{I})$ has $(1,2)$-entry $-3 \neq 0$, so $m_{\mathbf{A}_3} = (x-2)^2(x-5)$. Bézout: $(x-2)^2 = (x-5)(x+1)+9$, so $\frac{1}{9}(x-2)^2 - \frac{1}{9}(x+1)(x-5) = 1$, and by Theorem 5.7.5 the projection onto G_5 along G_2 is $\pi_5 = \frac{1}{9}\mathbf{M}^2$. Computing $\mathbf{M}^2 = \begin{pmatrix} 0 & 0 & 9 \\ 0 & 0 & 0 \\ 0 & 0 & 9 \end{pmatrix}$,

$$\mathbf{S} = 2\mathbf{I} + 3\pi_5 = 2\mathbf{I} + \tfrac{1}{3}\mathbf{M}^2 = \begin{pmatrix} 2 & 0 & 3 \\ 0 & 2 & 0 \\ 0 & 0 & 5 \end{pmatrix}, \qquad \mathbf{N} = \mathbf{A}_3 - \mathbf{S} = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}.$$

Checks: $\mathbf{N}^2 = 0$; $\mathbf{S} - 2\mathbf{I}$ has rank 1, so $g_{\mathbf{S}}(2) = 2 = a_{\mathbf{S}}(2)$ and $\mathbf{S}$ is diagonalizable (Theorem 8.4.1); and $\mathbf{SN} = \begin{pmatrix} 0 & 2 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} = \mathbf{NS}$. As a polynomial, $\mathbf{S} = 2\mathbf{I} + \frac{1}{3}(\mathbf{A}_3 - 2\mathbf{I})^2 = g(\mathbf{A}_3)$ with $g = \frac{1}{3}x^2 - \frac{4}{3}x + \frac{10}{3}$. Note that $\mathbf{S}$ keeps the entry 3 in position $(1,3)$: the diagonal part of $\mathbf{A}_3$ is the wrong answer, and it does not commute with the rest, since $\operatorname{diag}(2,2,5)(\mathbf{A}_3 - \operatorname{diag}(2,2,5))$ and the reverse product differ in position $(1,3)$ by -9.

Exercise B2: When is the nilpotent part zero?.

Let V be finite-dimensional with $\dim V \geq 1$ and let $T \in \mathcal{L}(V)$ with p_T split, with Jordan–Chevalley decomposition $T = S + N$. Prove that $N = 0$ if and only if T is diagonalizable, and that $S = 0$ if and only if T is nilpotent.

Solution. If $N = 0$, then $T = S$ is diagonalizable. Conversely, if T is diagonalizable, then $T = T + 0$ is a decomposition into a diagonalizable and a nilpotent part that commute ($T \cdot 0 = 0 = 0 \cdot T$), so by the uniqueness in Theorem 9.8.3, $S = T$ and $N = 0$.

If $S = 0$, then $T = N$ is nilpotent. Conversely, if T is nilpotent, then $T = 0 + T$ is such a decomposition, since the zero operator is diagonalizable and commutes with T; uniqueness gives $S = 0$ and $N = T$.

Exercise B3: Block diagonal matrices.

Let $\mathbf{A}_1 \in M_p(F)$ and $\mathbf{A}_2 \in M_q(F)$ have split characteristic polynomials, with Jordan–Chevalley decompositions $\mathbf{A}_i = \mathbf{S}_i + \mathbf{N}_i$. Prove that the Jordan–Chevalley decomposi-

tion of $\mathbf{A}_1 \oplus \mathbf{A}_2$ is

$$\mathbf{A}_1 \oplus \mathbf{A}_2 = (\mathbf{S}_1 \oplus \mathbf{S}_2) + (\mathbf{N}_1 \oplus \mathbf{N}_2).$$

Solution. Write $\mathbf{S} = \mathbf{S}_1 \oplus \mathbf{S}_2$ and $\mathbf{N} = \mathbf{N}_1 \oplus \mathbf{N}_2$. By Theorem 7.1.4 (a), $\mathbf{S} + \mathbf{N} = (\mathbf{S}_1 + \mathbf{N}_1) \oplus (\mathbf{S}_2 + \mathbf{N}_2) = \mathbf{A}_1 \oplus \mathbf{A}_2$. Also $p_{\mathbf{A}_1 \oplus \mathbf{A}_2} = p_{\mathbf{A}_1} p_{\mathbf{A}_2}$ splits (Theorem 6.8.4, applied over $F[x]$ as the remark after it allows), so Theorem 9.8.3 applies to $\mathbf{A}_1 \oplus \mathbf{A}_2$ and it suffices, by uniqueness, to check the three conditions.

$\mathbf{S}$ *is diagonalizable.* Pick invertible $\mathbf{P}_i$ with $\mathbf{P}_i^{-1}\mathbf{S}_i\mathbf{P}_i$ diagonal. Then $\mathbf{P} = \mathbf{P}_1 \oplus \mathbf{P}_2$ is invertible with $\mathbf{P}^{-1} = \mathbf{P}_1^{-1} \oplus \mathbf{P}_2^{-1}$, and $\mathbf{P}^{-1}\mathbf{S}\mathbf{P} = (\mathbf{P}_1^{-1}\mathbf{S}_1\mathbf{P}_1) \oplus (\mathbf{P}_2^{-1}\mathbf{S}_2\mathbf{P}_2)$ is diagonal (Theorem 7.1.4 (a), (c)).

$\mathbf{N}$ *is nilpotent.* If $\mathbf{N}_1^a = 0$ and $\mathbf{N}_2^b = 0$, then $\mathbf{N}^{\max(a,b)} = \mathbf{N}_1^{\max(a,b)} \oplus \mathbf{N}_2^{\max(a,b)} = 0$ by Theorem 7.1.4 (b).

They commute. $\mathbf{S}\mathbf{N} = (\mathbf{S}_1\mathbf{N}_1) \oplus (\mathbf{S}_2\mathbf{N}_2) = (\mathbf{N}_1\mathbf{S}_1) \oplus (\mathbf{N}_2\mathbf{S}_2) = \mathbf{N}\mathbf{S}$, again by Theorem 7.1.4 (a).

By the uniqueness in Theorem 9.8.3, $\mathbf{S}$ and $\mathbf{N}$ are the semisimple and nilpotent parts of $\mathbf{A}_1 \oplus \mathbf{A}_2$.

9.8.3.3 C. Going deeper

Exercise C1: The multiplicative version.

Call $U \in \mathcal{L}(V)$ **unipotent** if $U - \mathrm{id}_V$ is nilpotent. Let $T \in \mathcal{L}(V)$ be **invertible** with p_T split, and let $T = S + N$ be its Jordan–Chevalley decomposition.

(a) Prove that S is invertible.

(b) Prove that S^{-1} commutes with N, and that $S^{-1}N$ is nilpotent.

(c) Deduce that $T = SU$ with S diagonalizable, U unipotent and $SU = US$.

(d) Prove that this multiplicative decomposition is unique: if $T = S'U'$ with S' diagonalizable, U' unipotent and $S'U' = U'S'$, then $S' = S$ and $U' = U$.

Hint: for (d), turn the multiplicative statement into an additive one by writing $T = S' + S'(U' - \mathrm{id}_V)$.

Solution.

(a) By the proof of Theorem 9.8.3, $S\mathbf{v} = \lambda_i\mathbf{v}$ for every $\mathbf{v} \in G_{\lambda_i}(T)$, so $\mathrm{spec}(S) = \mathrm{spec}(T)$ — a basis of eigenvectors of S with these eigenvalues was exhibited there. Since T is invertible, $0 \notin \mathrm{spec}(T)$ (Theorem 8.2.6), so $0 \notin \mathrm{spec}(S)$ and S is invertible.

(b) From $SN = NS$, multiply on both sides by S^{-1}: $S^{-1}(SN)S^{-1} = S^{-1}(NS)S^{-1}$ gives $NS^{-1} = S^{-1}N$. Hence $(S^{-1}N)^j = S^{-j}N^j$ for every $j \geq 1$, by induction using $NS^{-1} = S^{-1}N$. With $N^s = 0$ we get $(S^{-1}N)^s = 0$.

(c) Put $U = \mathrm{id}_V + S^{-1}N$. Then $SU = S + N = T$, and $U - \mathrm{id}_V = S^{-1}N$ is nilpotent by (b), so U is unipotent. They commute: $SU = S + N = US$, since $S(S^{-1}N) = N = (S^{-1}N)S$ by (b).

(d) Suppose $T = S'U'$ with S' diagonalizable, U' unipotent and $S'U' = U'S'$. Put

$N' = S'(U' - \mathrm{id}_V)$, so that $T = S' + N'$. Then N' is nilpotent: S' commutes with U', hence with $U' - \mathrm{id}_V$, so $(N')^j = (S')^j(U' - \mathrm{id}_V)^j = 0$ once j is large. And $S'N' = S'S'(U' - \mathrm{id}_V) = S'(U' - \mathrm{id}_V)S' = N'S'$. So $T = S' + N'$ satisfies the hypotheses of Theorem 9.8.3 (b), giving $S' = S$ and $N' = N$. Then $U' - \mathrm{id}_V = (S')^{-1}N' = S^{-1}N = U - \mathrm{id}_V$, so $U' = U$.

Exercise C2: The parts inherit every symmetry.

Let V be finite-dimensional with $\dim V \geq 1$, let $T \in \mathcal{L}(V)$ with p_T split, and let $T = S + N$ be its Jordan–Chevalley decomposition.

(a) Prove that if $X \in \mathcal{L}(V)$ satisfies $XT = TX$, then $XS = SX$ and $XN = NX$.

(b) Deduce that every T-invariant subspace is S-invariant and N-invariant, and that S and N map each $G_\lambda(T)$ into itself.

(c) Give an example of a diagonalizable S and a nilpotent N with $SN \neq NS$ for which $S + N$ is **not** the operator whose semisimple part is S. (So the commuting hypothesis cannot be dropped from the uniqueness statement.)

Solution.

(a) By Theorem 9.8.3 (a), $S = g(T)$ and $N = h(T)$ for some $g, h \in F[x]$. From $XT = TX$ we get $XT^j = T^jX$ for all $j \geq 0$ by induction, hence $Xf(T) = f(T)X$ for every $f \in F[x]$ by taking linear combinations. Applying this to $f = g$ and $f = h$ gives $XS = SX$ and $XN = NX$.

(b) Let $U \subseteq V$ be T-invariant. Then U is T^j-invariant for every j, hence $f(T)$-invariant for every $f \in F[x]$ (a sum of vectors of U lies in U); taking $f = g, h$ gives that U is S- and N-invariant. In particular $G_\lambda(T) = \ker(T - \lambda\,\mathrm{id}_V)^n$ is T-invariant (Corollary 9.1.2 (b)), so S and N map it into itself.

(c) Take $\mathbf{S} = \mathrm{diag}(1, 2)$ and $\mathbf{N} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$ in $M_2(\mathbb{Q})$. Then $\mathbf{S}$ is diagonal, $\mathbf{N}^2 = 0$, and $\mathbf{SN} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} \neq \begin{pmatrix} 0 & 2 \\ 0 & 0 \end{pmatrix} = \mathbf{NS}$. Their sum $\mathbf{A} = \begin{pmatrix} 1 & 1 \\ 0 & 2 \end{pmatrix}$ has distinct eigenvalues, so it is diagonalizable, and its semisimple part is $\mathbf{A}$ itself, not $\mathbf{S}$, with nilpotent part 0, not $\mathbf{N}$ (Exercise (B2: When is the nilpotent part zero?)). Without the commuting hypothesis, an operator can be written as "diagonalizable plus nilpotent" in many ways: for any $c \in \mathbb{Q}$, $\mathbf{A} = \begin{pmatrix} 1 & c \\ 0 & 2 \end{pmatrix} + \begin{pmatrix} 0 & 1-c \\ 0 & 0 \end{pmatrix}$ is such a splitting, the first summand being diagonalizable because its eigenvalues $1, 2$ are distinct.

9.9 Functions of Matrices, the Exponential and Linear Differential Equations

We have known since Chapter 3 what $p(\mathbf{A})$ means for a polynomial p. This section gives a meaning to $f(\mathbf{A})$ for a much larger class of functions — square roots, logarithms, sines, and above all $e^{\mathbf{A}}$ — and the Jordan form is what makes it possible. The definition needs a well-

definedness proof, which turns out to be Hermite interpolation from Chapter 5: whatever f is, $f(\mathbf{A})$ is really $p(\mathbf{A})$ for a polynomial p that agrees with f to the right order at each eigenvalue. With $e^{t\mathbf{A}}$ in hand, every linear system of differential equations with constant coefficients is solved in one formula.

Throughout this section $F = \mathbb{C}$ (or $\mathbb{R}$, when we say so), so that every characteristic polynomial splits (Corollary 5.5.5) and Jordan forms exist.

9.9.1 What a polynomial does to a Jordan block

Start with what we already have. A Jordan block is a scalar plus a nilpotent matrix whose powers stop, and a polynomial applied to it can be read off from a Taylor expansion.

Lemma 9.9.1 — A Polynomial of a Jordan Block

Let F have characteristic 0, let $k \geq 1$, $\lambda \in F$ and $p \in F[x]$. Then $p(\mathbf{J}_k(\lambda))$ is the upper triangular matrix whose $(r, r+j)$-entry is

$$\big(p(\mathbf{J}_k(\lambda))\big)_{r,r+j} = \frac{p^{(j)}(\lambda)}{j!} \qquad (0 \leq j \leq k-1,\ 1 \leq r \leq k-j),$$

with all entries below the diagonal equal to 0. In particular the value $p(\lambda)$ fills the diagonal, $p'(\lambda)$ the superdiagonal, and only the first k derivatives of p at λ are involved.

Proof. Write $\mathbf{J} = \mathbf{J}_k(\lambda) = \lambda \mathbf{I}_k + \mathbf{M}$ with $\mathbf{M} = \mathbf{J}_k(0)$ (Definition 9.3.1). Reading off the columns of $\mathbf{M}$, we have $\mathbf{M}\mathbf{e}_1 = \mathbf{0}$ and $\mathbf{M}\mathbf{e}_r = \mathbf{e}_{r-1}$ for $r \geq 2$, so by induction $\mathbf{M}^j \mathbf{e}_r = \mathbf{e}_{r-j}$ when $r > j$ and $\mathbf{M}^j \mathbf{e}_r = \mathbf{0}$ when $r \leq j$. Hence, for $0 \leq j \leq k-1$, the matrix $\mathbf{M}^j$ has 1 in each position $(r, r+j)$ and 0 elsewhere, and $\mathbf{M}^k = 0$. Let $d = \deg p$. By Theorem 5.4.7 (b), applied with $c = \lambda$ and $n = d$,

$$p(x) = \sum_{j=0}^{d} \frac{p^{(j)}(\lambda)}{j!}\,(x-\lambda)^j.$$

Substituting $\mathbf{J}$ for x — legitimate because evaluation at $\mathbf{J}$ is a ring homomorphism (Theorem 5.7.1) — and using $\mathbf{J} - \lambda \mathbf{I}_k = \mathbf{M}$,

$$p(\mathbf{J}) = \sum_{j=0}^{d} \frac{p^{(j)}(\lambda)}{j!}\,\mathbf{M}^j = \sum_{j=0}^{\min(d,\,k-1)} \frac{p^{(j)}(\lambda)}{j!}\,\mathbf{M}^j,$$

since $\mathbf{M}^j = 0$ for $j \geq k$. Each $\mathbf{M}^j$ contributes its coefficient to every position $(r, r+j)$ and to no other position, which is the claim. ∎

For $p = x^m$ this reads $p^{(j)}(\lambda)/j! = \binom{m}{j}\lambda^{m-j}$, so

$$\big(\mathbf{J}_k(\lambda)^m\big)_{r,\,r+j} = \binom{m}{j}\lambda^{\,m-j},$$

which is the formula behind everything that follows, here and in the next section.

9.9.2 Functions of a matrix

Reading Lemma 9.9.1 backwards suggests the definition. The formula for $p(\mathbf{J}_k(\lambda))$ uses nothing about p except the numbers $p(\lambda), p'(\lambda), \dots, p^{(k-1)}(\lambda)$. Any function that has those derivatives can be inserted instead.

To apply f to a matrix, apply it to each Jordan block, putting $f^{(j)}(\lambda)/j!$ on the j-th superdiagonal.

Definition 9.9.1 — Function of a Matrix

Let $\mathbf{A} \in M_n(\mathbb{C})$ with Jordan form $\mathbf{J} = \mathbf{J}_{k_1}(\lambda_1) \oplus \cdots \oplus \mathbf{J}_{k_m}(\lambda_m)$ and $\mathbf{A} = \mathbf{P}\mathbf{J}\mathbf{P}^{-1}$. Let f be a complex-valued function that is defined and **at least $k_i - 1$ times differentiable at λ_i** for every i — for instance, a function given by a convergent power series on a disc around each eigenvalue. Define

$$f\big(\mathbf{J}_k(\lambda)\big) \coloneqq \begin{pmatrix} f(\lambda) & f'(\lambda) & \frac{f''(\lambda)}{2!} & \cdots & \frac{f^{(k-1)}(\lambda)}{(k-1)!} \\ & f(\lambda) & f'(\lambda) & \ddots & \vdots \\ & & \ddots & \ddots & \frac{f''(\lambda)}{2!} \\ & & & f(\lambda) & f'(\lambda) \\ & & & & f(\lambda) \end{pmatrix} \in M_k(\mathbb{C}),$$

the upper triangular matrix with $f^{(j)}(\lambda)/j!$ in every position $(r, r+j)$, and

$$f(\mathbf{A}) \coloneqq \mathbf{P}\left(f\big(\mathbf{J}_{k_1}(\lambda_1)\big) \oplus \cdots \oplus f\big(\mathbf{J}_{k_m}(\lambda_m)\big)\right)\mathbf{P}^{-1}.$$

In words: the diagonal of $f(\mathbf{J})$ records the values $f(\lambda_i)$, and each further superdiagonal records the next derivative, divided by a factorial. For a diagonalizable $\mathbf{A}$ every block has size 1, no derivatives are needed, and the definition says the familiar thing: $f(\mathbf{A}) = \mathbf{P}\,\mathrm{diag}(f(\lambda_1), \dots, f(\lambda_n))\mathbf{P}^{-1}$.

Well-definedness. Two choices were made: the invertible $\mathbf{P}$ and the order of the blocks. The Jordan form itself is unique only up to the order of the blocks (Theorem 9.3.1), and even for a fixed $\mathbf{J}$ there are many $\mathbf{P}$ with $\mathbf{A} = \mathbf{P}\mathbf{J}\mathbf{P}^{-1}$. The next theorem removes both worries at once, by identifying $f(\mathbf{A})$ with $p(\mathbf{A})$ for a suitable **polynomial** p, an expression in which no choice appears.

Theorem 9.9.2 — Functions of a Matrix Are Polynomials in It

Let $\mathbf{A} \in M_n(\mathbb{C})$ with distinct eigenvalues $\mu_1, \dots, \mu_d$, and write

$$m_{\mathbf{A}} = (x - \mu_1)^{s_1} \cdots (x - \mu_d)^{s_d},$$

so that s_l is the largest size of a μ_l-block of the Jordan form of $\mathbf{A}$ (Corollary 9.3.2 (c)). Let f be as in Definition 9.9.1. Then:

(a) there is a polynomial $p \in \mathbb{C}[x]$ with $\deg p < \deg m_{\mathbf{A}}$ and

$$p^{(j)}(\mu_l) = f^{(j)}(\mu_l) \qquad \text{for all } l = 1, \dots, d \text{ and } j = 0, \dots, s_l - 1,$$

and p is the **only** such polynomial of degree less than $\deg m_{\mathbf{A}}$;

(b) for **every** polynomial $q \in \mathbb{C}[x]$ satisfying those $\deg m_{\mathbf{A}}$ equations, $q(\mathbf{A}) = p(\mathbf{A})$;
(c) $f(\mathbf{A}) = p(\mathbf{A})$. In particular $f(\mathbf{A})$ does not depend on the choice of $\mathbf{P}$ or on the order of the blocks, and $f(\mathbf{A})$ is determined by the finitely many numbers $f^{(j)}(\mu_l)$.

The polynomial p of (a) is the **Hermite interpolating polynomial** of f on the spectrum of $\mathbf{A}$.

Idea. The list of conditions "match f and its first $s_l - 1$ derivatives at μ_l" is exactly a congruence modulo $(x-\mu_l)^{s_l}$, by the Taylor expansion; and the moduli $(x-\mu_l)^{s_l}$ are pairwise coprime. So the Chinese Remainder Theorem produces p and shows it is unique below the degree of the product $m_{\mathbf{A}}$ — this is Example (Values and Slopes by CRT) with more nodes and higher orders. Once p exists, Lemma 9.9.1 says that p and f do the same thing to every Jordan block of $\mathbf{A}$, because a μ_l-block has size at most s_l and only derivatives up to order $s_l - 1$ are consulted.

Proof.

(a) For each l let $r_l := \sum_{j=0}^{s_l-1} \frac{f^{(j)}(\mu_l)}{j!}(x-\mu_l)^j \in \mathbb{C}[x]$. For $g \in \mathbb{C}[x]$, the Taylor expansion of Theorem 5.4.7 (b) at μ_l, together with the uniqueness of the remainder on division by $(x-\mu_l)^{s_l}$ (Theorem 5.1.1), gives

$$g \equiv r_l \pmod{(x-\mu_l)^{s_l}} \qquad \Longleftrightarrow \qquad g^{(j)}(\mu_l) = f^{(j)}(\mu_l) \text{ for } j = 0, \dots, s_l - 1,$$

exactly as in Example (Values and Slopes by CRT) (a) for $s_l = 2$: the remainder of g on division by $(x-\mu_l)^{s_l}$ is $\sum_{j<s_l} \frac{g^{(j)}(\mu_l)}{j!}(x-\mu_l)^j$, and two polynomials of degree less than s_l are equal precisely when their coefficients in the basis $\big(1, x-\mu_l, \dots, (x-\mu_l)^{s_l-1}\big)$ agree (Theorem 5.4.7 (a)).
The moduli $(x-\mu_1)^{s_1}, \dots, (x-\mu_d)^{s_d}$ are pairwise coprime: for $l \neq l'$, any common divisor divides both, and a monic common divisor would be a power of $x-\mu_l$ and a power of $x-\mu_{l'}$ with $\mu_l \neq \mu_{l'}$, hence 1 (Lemma 8.5.2, Theorem 5.3.5). Their product is $m_{\mathbf{A}}$. So Theorem 5.6.4 (c) provides exactly one p with $\deg p < \deg m_{\mathbf{A}}$ and $p \equiv r_l \pmod{(x-\mu_l)^{s_l}}$ for every l, which by the displayed equivalence is (a).

(b) Let q satisfy the same equations. By the equivalence again, $q \equiv r_l \equiv p \pmod{(x-\mu_l)^{s_l}}$ for every l, so Theorem 5.6.4 (b) gives $m_{\mathbf{A}} \mid q - p$. Writing $q - p = m_{\mathbf{A}} h$ and evaluating at $\mathbf{A}$, $q(\mathbf{A}) - p(\mathbf{A}) = m_{\mathbf{A}}(\mathbf{A})h(\mathbf{A}) = 0$ since $m_{\mathbf{A}}(\mathbf{A}) = 0$ (Definition 8.5.1). Hence $q(\mathbf{A}) = p(\mathbf{A})$.

(c) Let $\mathbf{J} = \mathbf{J}_{k_1}(\lambda_1) \oplus \cdots \oplus \mathbf{J}_{k_m}(\lambda_m)$ be any Jordan form of $\mathbf{A}$ and $\mathbf{A} = \mathbf{P}\mathbf{J}\mathbf{P}^{-1}$. Fix i and let l be the index with $\lambda_i = \mu_l$. By Corollary 9.3.2 (c), $k_i \le s_l$, so Lemma 9.9.1 and the equations in (a) give

$$\big(p(\mathbf{J}_{k_i}(\lambda_i))\big)_{r,r+j} = \frac{p^{(j)}(\lambda_i)}{j!} = \frac{f^{(j)}(\lambda_i)}{j!} = \big(f(\mathbf{J}_{k_i}(\lambda_i))\big)_{r,r+j} \qquad (0 \le j \le k_i - 1),$$

the derivatives involved having order at most $k_i - 1 \le s_l - 1$. So $p(\mathbf{J}_{k_i}(\lambda_i)) = f(\mathbf{J}_{k_i}(\lambda_i))$ for every i. Since evaluating a polynomial blockwise gives the polynomial of the block diagonal matrix (Theorem 7.1.4 (a), (b)),

$$\begin{aligned} p(\mathbf{A}) = p(\mathbf{P}\mathbf{J}\mathbf{P}^{-1}) = \mathbf{P}\,p(\mathbf{J})\,\mathbf{P}^{-1} &= \mathbf{P}\Big(\bigoplus_i p\big(\mathbf{J}_{k_i}(\lambda_i)\big)\Big)\mathbf{P}^{-1} \\ &= \mathbf{P}\Big(\bigoplus_i f\big(\mathbf{J}_{k_i}(\lambda_i)\big)\Big)\mathbf{P}^{-1} = f(\mathbf{A}), \end{aligned}$$

the second equality by Proposition 3.7.6 (c). The left-hand side mentions neither $\mathbf{P}$ nor the order of the blocks, so neither does the right-hand side. This proves the theorem.

■

So the definition is consistent with the old one: if f happens to be a polynomial, then f itself satisfies the interpolation conditions, and (b) gives $f(\mathbf{A})$ in the new sense $= f(\mathbf{A})$ in the old sense.

Warning. **$f(\mathbf{A})$ is not f applied to the entries of $\mathbf{A}$.** Even for $f(x) = x^2$ this fails: with $\mathbf{A} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$, squaring each entry gives $\begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$, while $\mathbf{A}^2 = \begin{pmatrix} 1 & 2 \\ 0 & 1 \end{pmatrix}$. The definition is designed so that $f(\mathbf{A})$ is a polynomial in $\mathbf{A}$, and entrywise application is not.

Example. (Square Roots of Two Matrices)

Using Definition 9.9.1 with $f(x) = \sqrt{x}$, the branch with $\sqrt{4} = 2$ and $\sqrt{9} = 3$, compute a square root of

(a) $\mathbf{A} = \begin{pmatrix} 5 & 4 \\ 4 & 5 \end{pmatrix}$;

(b) $\mathbf{B} = \begin{pmatrix} 4 & 1 \\ 0 & 4 \end{pmatrix}$.

Solution.

(a) $p_{\mathbf{A}} = (x-5)^2 - 16 = x^2 - 10x + 9 = (x-1)(x-9)$, so the eigenvalues are 1 and 9, distinct, and $\mathbf{A}$ is diagonalizable. Solving $(\mathbf{A} - \mathbf{I})\mathbf{x} = \mathbf{0}$ gives $\operatorname{span}((1,-1))$ and $(\mathbf{A} - 9\mathbf{I})\mathbf{x} = \mathbf{0}$ gives $\operatorname{span}((1,1))$. With $\mathbf{P} = \begin{pmatrix} 1 & 1 \\ -1 & 1 \end{pmatrix}$, $\det \mathbf{P} = 2$ and $\mathbf{P}^{-1} = \frac{1}{2}\begin{pmatrix} 1 & -1 \\ 1 & 1 \end{pmatrix}$, we have $\mathbf{P}^{-1}\mathbf{A}\mathbf{P} = \operatorname{diag}(1,9)$ and

$$f(\mathbf{A}) = \mathbf{P}\operatorname{diag}(1,3)\mathbf{P}^{-1} = \tfrac{1}{2}\begin{pmatrix} 1 & 3 \\ -1 & 3 \end{pmatrix}\begin{pmatrix} 1 & -1 \\ 1 & 1 \end{pmatrix} = \tfrac{1}{2}\begin{pmatrix} 4 & 2 \\ 2 & 4 \end{pmatrix} = \begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix}.$$

Check. $\begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix}^2 = \begin{pmatrix} 5 & 4 \\ 4 & 5 \end{pmatrix} = \mathbf{A}$.

(b) $\mathbf{B} = \mathbf{J}_2(4)$ is its own Jordan form, with $\mathbf{P} = \mathbf{I}$. Here $f(4) = 2$ and $f'(x) = \frac{1}{2\sqrt{x}}$, so $f'(4) = \frac{1}{4}$, and Definition 9.9.1 gives

$$f(\mathbf{B}) = \begin{pmatrix} 2 & \frac{1}{4} \\ 0 & 2 \end{pmatrix}.$$

Check. $\begin{pmatrix} 2 & 1/4 \\ 0 & 2 \end{pmatrix}^2 = \begin{pmatrix} 4 & 2\cdot\frac{1}{4} + \frac{1}{4}\cdot 2 \\ 0 & 4 \end{pmatrix} = \begin{pmatrix} 4 & 1 \\ 0 & 4 \end{pmatrix} = \mathbf{B}$.

The Hermite polynomial. For (b), $m_{\mathbf{B}} = (x-4)^2$, and the interpolating polynomial of

degree < 2 with $p(4) = 2$, $p'(4) = \frac{1}{4}$ is $p = 2 + \frac{1}{4}(x-4) = \frac{1}{4}x + 1$. Indeed $p(\mathbf{B}) = \frac{1}{4}\mathbf{B} + \mathbf{I} = \begin{pmatrix} 2 & 1/4 \\ 0 & 2 \end{pmatrix}$, as Theorem 9.9.2 (c) predicts.

Quick check. A matrix $\mathbf{A} \in M_5(\mathbb{C})$ has Jordan form $\mathbf{J}_3(2) \oplus \mathbf{J}_1(2) \oplus \mathbf{J}_1(7)$. Which values of f and its derivatives does $f(\mathbf{A})$ depend on?

Solution. On $f(2), f'(2), f''(2)$ and $f(7)$: four numbers. Indeed $m_{\mathbf{A}} = (x-2)^3(x-7)$ by Corollary 9.3.2 (c), so $s_1 = 3$ for $\mu_1 = 2$ and $s_2 = 1$ for $\mu_2 = 7$, and Theorem 9.9.2 lists the derivatives of order $0, 1, 2$ at 2 and order 0 at 7. Note $\deg m_{\mathbf{A}} = 4$, matching the number of conditions and the degree bound on the interpolating polynomial. Nothing about f away from $\{2, 7\}$ matters, and no third derivative is consulted even though $\dim = 5$.

9.9.3 The matrix exponential

The most important function of a matrix is the exponential, and it has a second description, as the sum of a series. We check that the series converges, and that its sum is the matrix $\exp(\mathbf{A})$ that Definition 9.9.1 produces. Convergence is meant **entrywise**, as in Chapter 8: a sequence $\mathbf{M}_1, \mathbf{M}_2, \ldots$ in $M_n(\mathbb{C})$ converges to $\mathbf{M}$ if for each position (r, s) the number sequence $(\mathbf{M}_m)_{rs}$ converges to $\mathbf{M}_{rs}$, and a series of matrices converges if its sequence of partial sums does. No notion of length of a matrix is used anywhere in this section.

Remark. **What we assume from analysis.** Everything below uses exactly the following facts about real and complex numbers, and nothing else. Chapter 15 will develop the tools that make such statements routine; here they are quoted.

(A1) **The scalar exponential.** For every $z \in \mathbb{C}$ the series $\sum_{i \geq 0} z^i/i!$ converges; its sum is written e^z. It satisfies $e^{z+w} = e^z e^w$, $e^0 = 1$, and $e^{i\theta} = \cos\theta + i\sin\theta$ for real θ. For real $s \geq 0$, $e^s \geq 1$.

(A2) **Termwise differentiation.** If a power series $\sum_{m \geq 0} c_m t^m$ with $c_m \in \mathbb{C}$ converges for **every** real t, then the function $t \mapsto \sum_m c_m t^m$ is differentiable on $\mathbb{R}$ with derivative $\sum_{m \geq 1} m c_m t^{m-1}$.

(A3) **Limits and products.** Limits of convergent sequences of complex numbers respect sums, scalar multiples and products. The derivative of a product of two differentiable functions $\mathbb{R} \to \mathbb{C}$ obeys the product rule, and differentiation is linear.

(A4) **Zero derivative.** A differentiable function $\mathbb{R} \to \mathbb{C}$ whose derivative vanishes everywhere is constant.

(A5) **Decay.** For every integer $j \geq 0$ and every real $c < 0$, $t^j e^{ct} \to 0$ as $t \to \infty$.

Fact (A5) is used only in the last exercise of this section. Nothing else about exp, cos or sin is assumed: the derivative $\frac{d}{dt} e^{zt} = z\, e^{zt}$ for $z \in \mathbb{C}$ is the 1×1 case of Theorem 9.9.4 (b) below, proved from (A2), and the derivatives of cos and sin used in the examples follow from it through Euler's formula in (A1).

Definition 9.9.2 — Matrix Exponential

Let $\mathbf{A} \in M_n(\mathbb{C})$. The **matrix exponential** of $\mathbf{A}$ is

$$e^{\mathbf{A}} := \sum_{m=0}^{\infty} \frac{\mathbf{A}^m}{m!} = \lim_{\mathbf{M}\to\infty} \sum_{m=0}^{\mathbf{M}} \frac{\mathbf{A}^m}{m!},$$

the limit taken entrywise, provided it exists; $\mathbf{A}^0 = \mathbf{I}$.

That the limit does exist, and what it is, is the content of the next theorem. The Jordan form reduces the question to a single block, where the series can be summed exactly.

Theorem 9.9.3 — The Exponential Series Converges to the Jordan Definition

Let $\mathbf{A} \in M_n(\mathbb{C})$. Then the series $\sum_m \mathbf{A}^m/m!$ converges entrywise, and its sum is the matrix $\exp(\mathbf{A})$ given by Definition 9.9.1 for the function $f = \exp$. In particular, for a single Jordan block,

$$e^{\mathbf{J}_k(\lambda)} = e^{\lambda} \begin{pmatrix} 1 & 1 & \frac{1}{2!} & \cdots & \frac{1}{(k-1)!} \\ & 1 & 1 & \ddots & \vdots \\ & & \ddots & \ddots & \frac{1}{2!} \\ & & & 1 & 1 \\ & & & & 1 \end{pmatrix},$$

the upper triangular matrix with $e^{\lambda}/j!$ in every position $(r, r+j)$.

Idea. For one block the entries of the partial sums are themselves partial sums of a scalar series, and that series can be recognized: the terms $\binom{m}{j}\lambda^{m-j}/m!$ simplify to $\lambda^{m-j}/(j!\,(m-j)!)$, which is $1/j!$ times the $(m-j)$-th term of the series for e^{λ}. For general $\mathbf{A}$, conjugation by a fixed $\mathbf{P}$ turns each entry of a partial sum into a fixed finite linear combination of entries of the block partial sums, and limits pass through finite linear combinations.

Proof. **Step 1. One block.** Fix $k \geq 1$, $\lambda \in \mathbb{C}$ and a position $(r, r+j)$ with $0 \leq j \leq k-1$. By Lemma 9.9.1 applied to $p = x^m$,

$$\left(\frac{\mathbf{J}_k(\lambda)^m}{m!}\right)_{r,\,r+j} = \frac{1}{m!}\binom{m}{j}\lambda^{\,m-j} = \begin{cases} \dfrac{\lambda^{\,m-j}}{j!\,(m-j)!}, & m \geq j, \\ 0, & m < j, \end{cases}$$

using $\binom{m}{j}/m! = 1/(j!\,(m-j)!)$ for $m \geq j$ and $\binom{m}{j} = 0$ for $m < j$. Hence the partial sums satisfy

$$\sum_{m=0}^{\mathbf{M}} \left(\frac{\mathbf{J}_k(\lambda)^m}{m!}\right)_{r,\,r+j} = \frac{1}{j!} \sum_{i=0}^{\mathbf{M}-j} \frac{\lambda^i}{i!} \qquad (\mathbf{M} \geq j),$$

after the substitution $i = m - j$. By (A1) the right-hand side converges to $e^{\lambda}/j!$ as $\mathbf{M} \to \infty$. Entries with $j < 0$, that is entries below the diagonal, are 0 in every term. So

the series converges entrywise and

$$e^{\mathbf{J}_k(\lambda)} = \Big(\text{upper triangular with } \tfrac{e^\lambda}{j!} \text{ on the } j\text{-th superdiagonal}\Big) = \exp\big(\mathbf{J}_k(\lambda)\big),$$

the last equality being Definition 9.9.1 for $f = \exp$, whose derivatives are $f^{(j)} = \exp$, so $f^{(j)}(\lambda)/j! = e^\lambda/j!$.

Step 2. A Jordan matrix. If $\mathbf{J} = \mathbf{J}_{k_1}(\lambda_1) \oplus \cdots \oplus \mathbf{J}_{k_m}(\lambda_m)$, then $\mathbf{J}^m/m!$ is the direct sum of the corresponding blocks (Theorem 7.1.4 (b)), so each entry of a partial sum of $\sum_m \mathbf{J}^m/m!$ is either identically 0 or an entry of a partial sum from one block. By Step 1 all of them converge, and $e^{\mathbf{J}} = \bigoplus_i e^{\mathbf{J}_{k_i}(\lambda_i)}$.

Step 3. General A. By Theorem 9.3.1 there are a Jordan matrix $\mathbf{J}$ and an invertible $\mathbf{P}$ with $\mathbf{A} = \mathbf{P}\mathbf{J}\mathbf{P}^{-1}$. Then $\mathbf{A}^m = \mathbf{P}\mathbf{J}^m\mathbf{P}^{-1}$ (Proposition 3.7.6 (c)), so

$$\sum_{m=0}^{\mathbf{M}} \frac{\mathbf{A}^m}{m!} = \mathbf{P}\Big(\sum_{m=0}^{\mathbf{M}} \frac{\mathbf{J}^m}{m!}\Big)\mathbf{P}^{-1}.$$

Each entry of the left-hand side is a fixed finite linear combination — with coefficients built from the entries of $\mathbf{P}$ and $\mathbf{P}^{-1}$, independent of $\mathbf{M}$ — of the entries of the middle partial sum. By Step 2 those entries converge, so by (A3) the left-hand side converges entrywise, with

$$e^{\mathbf{A}} = \mathbf{P}\, e^{\mathbf{J}}\, \mathbf{P}^{-1} = \mathbf{P}\Big(\bigoplus_i e^{\mathbf{J}_{k_i}(\lambda_i)}\Big)\mathbf{P}^{-1} = \exp(\mathbf{A}),$$

the last equality by Definition 9.9.1. This proves the theorem.

■

From now on we write $e^{\mathbf{A}}$ for this matrix and use both descriptions freely. Note one consequence of Theorem 9.9.2: $e^{\mathbf{A}}$ is a **polynomial** in $\mathbf{A}$, namely $p(\mathbf{A})$ for the Hermite interpolant of exp on $\operatorname{spec}(\mathbf{A})$. Everything that commutes with $\mathbf{A}$ therefore commutes with $e^{\mathbf{A}}$.

Theorem 9.9.4 — Properties of the Matrix Exponential

Let $\mathbf{A}, \mathbf{B} \in M_n(\mathbb{C})$ and let $\mathbf{P} \in M_n(\mathbb{C})$ be invertible.

(a) $e^{\mathbf{0}} = \mathbf{I}$ and $e^{\mathbf{P}^{-1}\mathbf{A}\mathbf{P}} = \mathbf{P}^{-1}e^{\mathbf{A}}\mathbf{P}$.

(b) The function $\mathbb{R} \to M_n(\mathbb{C})$, $t \mapsto e^{t\mathbf{A}}$, is differentiable entrywise, with

$$\frac{d}{dt}\, e^{t\mathbf{A}} = \mathbf{A}e^{t\mathbf{A}} = e^{t\mathbf{A}}\mathbf{A}.$$

(c) $e^{\mathbf{A}}$ is invertible, with $(e^{\mathbf{A}})^{-1} = e^{-\mathbf{A}}$.

(d) If $\mathbf{A}\mathbf{B} = \mathbf{B}\mathbf{A}$, then $e^{\mathbf{A}+\mathbf{B}} = e^{\mathbf{A}}e^{\mathbf{B}}$.

(e) $\det e^{\mathbf{A}} = e^{\operatorname{tr}\mathbf{A}}$.

Idea. Part (b) is termwise differentiation, entry by entry. Everything after it is the same two-line trick: to prove $\mathbf{X}(t) = \mathbf{Y}(t)$ for two matrix functions, show that $\mathbf{Z}(t) = e^{-t\mathbf{C}}\mathbf{X}(t)$ has derivative 0 for a suitable $\mathbf{C}$, so $\mathbf{Z}$ is constant and equals $\mathbf{Z}(0)$. That is why (c) and

(d) come after (b), even though the series would also give them. Part (e) is read off the Jordan form: $e^{\mathbf{J}}$ is triangular with e^{λ_i} on the diagonal.

Proof.

(a) $0^m = 0$ for $m \geq 1$ and $0^0 = \mathbf{I}$, so the series is $\mathbf{I}$. For the second claim, Step 3 of the previous proof applies verbatim with $\mathbf{J}$ replaced by $\mathbf{P}^{-1}\mathbf{A}\mathbf{P}$: the partial sums of $\sum_m (\mathbf{P}^{-1}\mathbf{A}\mathbf{P})^m/m!$ are $\mathbf{P}^{-1}\big(\sum_m \mathbf{A}^m/m!\big)\mathbf{P}$, and (A3) lets the limit pass through.

(b) Fix a position (r,s). By Theorem 9.9.3 the series $\sum_m t^m(\mathbf{A}^m)_{rs}/m!$ converges for every real t, since $(t\mathbf{A})^m = t^m\mathbf{A}^m$. So (A2) applies with $c_m = (\mathbf{A}^m)_{rs}/m!$ and gives

$$\frac{d}{dt}\left(e^{t\mathbf{A}}\right)_{rs} = \sum_{m\geq 1} \frac{m\,t^{m-1}}{m!}(\mathbf{A}^m)_{rs} = \sum_{m\geq 1} \frac{t^{m-1}}{(m-1)!}\big(\mathbf{A}\cdot\mathbf{A}^{m-1}\big)_{rs}$$
$$= \Big(\mathbf{A}\sum_{l\geq 0}\frac{t^l\mathbf{A}^l}{l!}\Big)_{rs},$$

where the last step moves the constant matrix $\mathbf{A}$ outside the limit: each entry of $\mathbf{A}\big(\sum_{l\leq L} t^l\mathbf{A}^l/l!\big)$ is a fixed linear combination of entries of the partial sum, so (A3) applies. Hence $\frac{d}{dt}e^{t\mathbf{A}} = \mathbf{A}e^{t\mathbf{A}}$. The same computation with $\mathbf{A}^m = \mathbf{A}^{m-1}\mathbf{A}$ gives $e^{t\mathbf{A}}\mathbf{A}$.

(c) Put $\mathbf{H}(t) = e^{t\mathbf{A}}e^{-t\mathbf{A}}$ for $t \in \mathbb{R}$. Each entry of $\mathbf{H}$ is a finite sum of products of differentiable functions, so by (A3) and (b),

$$\mathbf{H}'(t) = \big(\mathbf{A}e^{t\mathbf{A}}\big)e^{-t\mathbf{A}} + e^{t\mathbf{A}}\big(-\mathbf{A}e^{-t\mathbf{A}}\big) = \mathbf{A}e^{t\mathbf{A}}e^{-t\mathbf{A}} - \mathbf{A}e^{t\mathbf{A}}e^{-t\mathbf{A}} = 0,$$

where the second equality uses $e^{t\mathbf{A}}\mathbf{A} = \mathbf{A}e^{t\mathbf{A}}$ from (b). By (A4) every entry of $\mathbf{H}$ is constant, so $\mathbf{H}(t) = \mathbf{H}(0) = e^0e^0 = \mathbf{I}$ for all t. At $t = 1$, $e^{\mathbf{A}}e^{-\mathbf{A}} = \mathbf{I}$, and Theorem 2.4.5 finishes it.

(d) Suppose $\mathbf{A}\mathbf{B} = \mathbf{B}\mathbf{A}$. Then $\mathbf{B}$ commutes with every partial sum of $\sum_m t^m\mathbf{A}^m/m!$, so by (A3) it commutes with the limit: $\mathbf{B}e^{t\mathbf{A}} = e^{t\mathbf{A}}\mathbf{B}$ for every t. Put

$$\mathbf{G}(t) = e^{-t(\mathbf{A}+\mathbf{B})}e^{t\mathbf{A}}e^{t\mathbf{B}}.$$

Differentiating entrywise with the product rule (A3) and (b),

$$\mathbf{G}'(t) = -(\mathbf{A}+\mathbf{B})e^{-t(\mathbf{A}+\mathbf{B})}e^{t\mathbf{A}}e^{t\mathbf{B}} + e^{-t(\mathbf{A}+\mathbf{B})}\mathbf{A}e^{t\mathbf{A}}e^{t\mathbf{B}} + e^{-t(\mathbf{A}+\mathbf{B})}e^{t\mathbf{A}}\mathbf{B}e^{t\mathbf{B}}.$$

In the third term replace $e^{t\mathbf{A}}\mathbf{B}$ by $\mathbf{B}e^{t\mathbf{A}}$; in the first, use $(\mathbf{A}+\mathbf{B})e^{-t(\mathbf{A}+\mathbf{B})} = e^{-t(\mathbf{A}+\mathbf{B})}(\mathbf{A}+\mathbf{B})$ from (b). The three terms become

$$e^{-t(\mathbf{A}+\mathbf{B})}\big(-(\mathbf{A}+\mathbf{B}) + \mathbf{A} + \mathbf{B}\big)e^{t\mathbf{A}}e^{t\mathbf{B}} = 0.$$

By (A4), $\mathbf{G}$ is constant, so $\mathbf{G}(t) = \mathbf{G}(0) = \mathbf{I}$. Multiplying on the left by $e^{t(\mathbf{A}+\mathbf{B})}$ and using (c), $e^{t\mathbf{A}}e^{t\mathbf{B}} = e^{t(\mathbf{A}+\mathbf{B})}$; put $t = 1$.

(e) Write $\mathbf{A} = \mathbf{P}\mathbf{J}\mathbf{P}^{-1}$ with $\mathbf{J} = \bigoplus_i \mathbf{J}_{k_i}(\lambda_i)$ a Jordan matrix. By (a) and Theorem 9.9.3,

$$\det e^{\mathbf{A}} = \det\big(\mathbf{P}e^{\mathbf{J}}\mathbf{P}^{-1}\big) = \det e^{\mathbf{J}}$$

(Corollary 6.5.7), and $e^{\mathbf{J}} = \bigoplus_i e^{\mathbf{J}_{k_i}(\lambda_i)}$ is upper triangular with e^{λ_i} repeated k_i times along the diagonal. By Theorem 6.4.6 and (A1),

$$\det e^{\mathbf{J}} = \prod_i \left(e^{\lambda_i}\right)^{k_i} = e^{\sum_i k_i \lambda_i} = e^{\operatorname{tr} \mathbf{J}} = e^{\operatorname{tr} \mathbf{A}},$$

the last equality because similar matrices have equal traces (Theorem 3.7.5). This proves the theorem.

■

Part (e) says something striking: $\det e^{\mathbf{A}} \neq 0$ always, which re-proves (c), and if $\operatorname{tr} \mathbf{A} = 0$ then $e^{\mathbf{A}} \in \mathrm{SL}_n(\mathbb{C})$.

The following corollary is the formula actually used in computations. Note that $t\mathbf{J}_k(\lambda)$ is **not** a Jordan block for $k \geq 2$ and $t \neq 1$, since its superdiagonal entries are t; the commuting law does the work instead.

Corollary 9.9.5 — Exponential of a Jordan Block, with a Parameter

Let $k \geq 1$, $\lambda \in \mathbb{C}$ and $t \in \mathbb{R}$. Then $e^{t\mathbf{J}_k(\lambda)}$ is the upper triangular matrix with

$$\left(e^{t\mathbf{J}_k(\lambda)}\right)_{r,\,r+j} = \frac{t^j e^{\lambda t}}{j!} \qquad (0 \leq j \leq k-1)$$

and zeros below the diagonal. Consequently, if $\mathbf{A} = \mathbf{P}\mathbf{J}\mathbf{P}^{-1}$ with $\mathbf{J} = \mathbf{J}_{k_1}(\lambda_1) \oplus \cdots \oplus \mathbf{J}_{k_m}(\lambda_m)$, then

$$e^{t\mathbf{A}} = \mathbf{P}\left(e^{t\mathbf{J}_{k_1}(\lambda_1)} \oplus \cdots \oplus e^{t\mathbf{J}_{k_m}(\lambda_m)}\right)\mathbf{P}^{-1}.$$

In particular, for a diagonal $\mathbf{D} = \operatorname{diag}(d_1, \dots, d_n)$, $e^{t\mathbf{D}} = \operatorname{diag}(e^{td_1}, \dots, e^{td_n})$.

Proof. Write $t\mathbf{J}_k(\lambda) = (t\lambda)\mathbf{I}_k + t\mathbf{M}$ with $\mathbf{M} = \mathbf{J}_k(0)$. The two summands commute, since $\mathbf{I}_k$ commutes with everything, so Theorem 9.9.4 (d) gives $e^{t\mathbf{J}_k(\lambda)} = e^{(t\lambda)\mathbf{I}_k} e^{t\mathbf{M}}$. For the first factor, $\left((t\lambda)\mathbf{I}_k\right)^m = (t\lambda)^m \mathbf{I}_k$, so the partial sums are $\left(\sum_{m \leq \mathbf{M}} (t\lambda)^m/m!\right)\mathbf{I}_k$ and $e^{(t\lambda)\mathbf{I}_k} = e^{\lambda t}\mathbf{I}_k$ by (A1). For the second, $\mathbf{M}^j = 0$ for $j \geq k$, so the series terminates:

$$e^{t\mathbf{M}} = \sum_{j=0}^{k-1} \frac{t^j}{j!}\mathbf{M}^j,$$

and $\mathbf{M}^j$ has 1 in each position $(r, r+j)$, as computed in the proof of Lemma 9.9.1. Multiplying by the scalar $e^{\lambda t}$ gives the entry formula. The second display follows from $t\mathbf{A} = \mathbf{P}(t\mathbf{J})\mathbf{P}^{-1}$ with Theorem 9.9.4 (a) and Theorem 7.1.4 (b), exactly as in Step 2 of the proof of Theorem 9.9.3. The diagonal case is the case in which every block has size 1.

■

Warning. $e^{\mathbf{A}+\mathbf{B}} = e^{\mathbf{A}}e^{\mathbf{B}}$ **fails when $\mathbf{A}$ and $\mathbf{B}$ do not commute.** Take

$$\mathbf{A} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}, \qquad \mathbf{B} = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix}.$$

Both square to 0, so the series stop after two terms: $e^{\mathbf{A}} = \mathbf{I} + \mathbf{A} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$ and $e^{\mathbf{B}} = \mathbf{I} + \mathbf{B} = \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix}$. Then

$$e^{\mathbf{A}}e^{\mathbf{B}} = \begin{pmatrix} 2 & 1 \\ 1 & 1 \end{pmatrix} \neq \begin{pmatrix} 1 & 1 \\ 1 & 2 \end{pmatrix} = e^{\mathbf{B}}e^{\mathbf{A}}.$$

Since $\mathbf{A}+\mathbf{B} = \mathbf{B}+\mathbf{A}$, at most one of the two products can equal $e^{\mathbf{A}+\mathbf{B}}$, so the identity must fail for one of the pairs $(\mathbf{A},\mathbf{B})$, $(\mathbf{B},\mathbf{A})$. (In fact it fails for both: $(\mathbf{A}+\mathbf{B})^2 = \mathbf{I}$, so $e^{\mathbf{A}+\mathbf{B}}$ has all four entries non-zero and none of them equal to 2.) The moral: check $\mathbf{AB} = \mathbf{BA}$ before splitting an exponential.

9.9.4 Linear systems of differential equations

A system of n linear differential equations with constant coefficients,

$$x_1' = a_{11}x_1 + \cdots + a_{1n}x_n, \quad \ldots, \quad x_n' = a_{n1}x_1 + \cdots + a_{nn}x_n,$$

is the single equation $\mathbf{x}' = \mathbf{A}\mathbf{x}$ for a vector-valued function $\mathbf{x}\colon \mathbb{R} \to \mathbb{C}^n$, differentiated entrywise. In one dimension the answer is $x(t) = e^{ta}x_0$; the matrix exponential makes the general answer look exactly the same.

Theorem 9.9.6 — Solution of a Linear System

Let $\mathbf{A} \in M_n(\mathbb{C})$ and $\mathbf{x}_0 \in \mathbb{C}^n$. Then the function

$$\mathbf{x}(t) = e^{t\mathbf{A}}\mathbf{x}_0 \qquad (t \in \mathbb{R})$$

is differentiable and satisfies $\mathbf{x}'(t) = \mathbf{A}\mathbf{x}(t)$ for all t and $\mathbf{x}(0) = \mathbf{x}_0$; and it is the **only** differentiable function $\mathbb{R} \to \mathbb{C}^n$ with these two properties.

Idea. Existence is Theorem 9.9.4 (b) applied to a fixed vector. For uniqueness, take any solution $\mathbf{y}$ and multiply it by $e^{-t\mathbf{A}}$, the one factor that can undo the growth: the product has derivative 0, hence is constant. This is the same move as in the proofs of parts (c) and (d) above.

Proof. Existence. Each entry of $\mathbf{x}(t) = e^{t\mathbf{A}}\mathbf{x}_0$ is a linear combination of entries of $e^{t\mathbf{A}}$ with constant coefficients, so $\mathbf{x}$ is differentiable with $\mathbf{x}'(t) = \left(\frac{d}{dt}e^{t\mathbf{A}}\right)\mathbf{x}_0$ by the linearity of differentiation (A3). By Theorem 9.9.4 (b), $\mathbf{x}'(t) = \mathbf{A}e^{t\mathbf{A}}\mathbf{x}_0 = \mathbf{A}\mathbf{x}(t)$. And $\mathbf{x}(0) = e^{0}\mathbf{x}_0 = \mathbf{x}_0$ by Theorem 9.9.4 (a).

Uniqueness. Let $\mathbf{y}\colon \mathbb{R} \to \mathbb{C}^n$ be differentiable with $\mathbf{y}' = \mathbf{A}\mathbf{y}$ and $\mathbf{y}(0) = \mathbf{x}_0$. Put

$\mathbf{z}(t) = e^{-t\mathbf{A}}\mathbf{y}(t)$. By the product rule (A3) and Theorem 9.9.4 (b) applied to $-\mathbf{A}$,

$$\mathbf{z}'(t) = \big(-\mathbf{A}e^{-t\mathbf{A}}\big)\mathbf{y}(t) + e^{-t\mathbf{A}}\mathbf{y}'(t) = -\mathbf{A}e^{-t\mathbf{A}}\mathbf{y}(t) + e^{-t\mathbf{A}}\mathbf{A}\mathbf{y}(t) = \mathbf{0},$$

where the last step uses $e^{-t\mathbf{A}}\mathbf{A} = \mathbf{A}e^{-t\mathbf{A}}$ from Theorem 9.9.4 (b). By (A4) each entry of $\mathbf{z}$ is constant, so $\mathbf{z}(t) = \mathbf{z}(0) = \mathbf{x}_0$ for all t. Multiplying by $e^{t\mathbf{A}}$ and using Theorem 9.9.4 (c),

$$\mathbf{y}(t) = e^{t\mathbf{A}}\mathbf{z}(t) = e^{t\mathbf{A}}\mathbf{x}_0 = \mathbf{x}(t).$$

This proves the theorem.

■

The formula is only as useful as our ability to compute $e^{t\mathbf{A}}$, and the Jordan form does that. Two shapes of answer occur, and they are worth seeing side by side.

Example. (Two Two-Dimensional Systems)

Solve $\mathbf{x}' = \mathbf{A}\mathbf{x}$ with $\mathbf{x}(0) = (1, 0)$ for

(a) $\mathbf{A} = \begin{pmatrix} 1 & -2 \\ 2 & 1 \end{pmatrix}$ (complex eigenvalues);

(b) $\mathbf{A} = \begin{pmatrix} 2 & 1 \\ 0 & 2 \end{pmatrix}$ (one eigenvalue, one block of size 2).

Solution.

(a) $p_{\mathbf{A}} = (x-1)^2 + 4$, with roots $\lambda = 1 \pm 2i$, distinct, so $\mathbf{A}$ is diagonalizable over $\mathbb{C}$ and every block has size 1. Solving $(\mathbf{A} - (1+2i)\mathbf{I})\mathbf{x} = \mathbf{0}$: the first row reads $-2ix_1 - 2x_2 = 0$, so $x_2 = -ix_1$ and $(1, -i)$ is an eigenvector; $(1, i)$ is one for $1 - 2i$. With $\mathbf{P} = \begin{pmatrix} 1 & 1 \\ -i & i \end{pmatrix}$ we get $\det \mathbf{P} = 2i$ and $\mathbf{P}^{-1} = \frac{1}{2i}\begin{pmatrix} i & -1 \\ i & 1 \end{pmatrix} = \frac{1}{2}\begin{pmatrix} 1 & i \\ 1 & -i \end{pmatrix}$, so $\mathbf{P}^{-1}\mathbf{A}\mathbf{P} = \operatorname{diag}(1+2i, 1-2i)$. By Corollary 9.9.5,

$$\begin{aligned} e^{t\mathbf{A}} &= \mathbf{P}\operatorname{diag}\big(e^{(1+2i)t},\, e^{(1-2i)t}\big)\mathbf{P}^{-1} \\ &= \tfrac{1}{2}\begin{pmatrix} e^{(1+2i)t} + e^{(1-2i)t} & i\big(e^{(1+2i)t} - e^{(1-2i)t}\big) \\ -i\big(e^{(1+2i)t} - e^{(1-2i)t}\big) & e^{(1+2i)t} + e^{(1-2i)t} \end{pmatrix}. \end{aligned}$$

By (A1), $e^{(1\pm 2i)t} = e^t(\cos 2t \pm i \sin 2t)$, so $e^{(1+2i)t} + e^{(1-2i)t} = 2e^t \cos 2t$ and $e^{(1+2i)t} - e^{(1-2i)t} = 2ie^t \sin 2t$. Substituting, and using $i \cdot 2i = -2$,

$$e^{t\mathbf{A}} = e^t\begin{pmatrix} \cos 2t & -\sin 2t \\ \sin 2t & \cos 2t \end{pmatrix}, \qquad \mathbf{x}(t) = e^{t\mathbf{A}}\begin{pmatrix} 1 \\ 0 \end{pmatrix} = e^t\begin{pmatrix} \cos 2t \\ \sin 2t \end{pmatrix}.$$

The solution spirals outwards: rotation at angular speed 2, growth at rate 1. The entries are real, as they must be for a real $\mathbf{A}$ and a real $\mathbf{x}_0$.
Check. $\mathbf{x}'(t) = e^t(\cos 2t - 2\sin 2t,\ \sin 2t + 2\cos 2t)$, and $\mathbf{A}\mathbf{x}(t) = e^t(\cos 2t - 2\sin 2t,\ 2\cos 2t + \sin 2t)$. They agree, and $\mathbf{x}(0) = (1, 0)$.

(b) $\mathbf{A} = \mathbf{J}_2(2)$ is its own Jordan form. Writing $\mathbf{A} = 2\mathbf{I} + \mathbf{M}$ with $\mathbf{M} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$, the

two summands commute and $\mathbf{M}^2 = 0$, so Corollary 9.9.5 with $k = 2$ gives

$$e^{t\mathbf{A}} = e^{2t}(\mathbf{I} + t\mathbf{M}) = e^{2t}\begin{pmatrix} 1 & t \\ 0 & 1 \end{pmatrix}.$$

So $\mathbf{x}(t) = e^{2t}(1, 0)$. A different initial vector shows the new phenomenon: $\mathbf{x}(0) = (0, 1)$ gives $\mathbf{x}(t) = e^{2t}(t, 1)$, whose first entry is te^{2t}. **A repeated eigenvalue with a block of size k produces solutions containing $t^j e^{\lambda t}$ for $j < k$.** This is the same $t^j \lambda^m$ pattern that Chapter 8 met for recurrences with repeated roots, now in continuous time.

A scalar equation of higher order is a system in disguise, and the translation is the companion matrix of Section 5.

Example. (A Second-Order Equation with a Repeated Root)

Solve $y'' - 4y' + 4y = 0$ with $y(0) = 1$ and $y'(0) = 3$.

Solution. Make it a system. Put $\mathbf{u} = (y, y')$. Then $\mathbf{u}' = (y', y'') = (y', 4y' - 4y)$, so $\mathbf{u}' = \mathbf{M}\mathbf{u}$ with

$$\mathbf{M} = \begin{pmatrix} 0 & 1 \\ -4 & 4 \end{pmatrix}, \qquad \mathbf{u}(0) = (1, 3).$$

Note that $p_{\mathbf{M}} = x(x - 4) + 4 = x^2 - 4x + 4$ is the polynomial of the equation, and that $\mathbf{M} = \mathbf{C}(p_{\mathbf{M}})^\top$ for the companion matrix $\mathbf{C}(p_{\mathbf{M}}) = \begin{pmatrix} 0 & -4 \\ 1 & 4 \end{pmatrix}$ of Definition 9.5.3; by Corollary 9.7.7 the two are similar, so which of them one uses is immaterial.

Exponentiate. $p_{\mathbf{M}} = (x-2)^2$. Put $\mathbf{N} = \mathbf{M} - 2\mathbf{I} = \begin{pmatrix} -2 & 1 \\ -4 & 2 \end{pmatrix}$; then $\mathbf{N}^2 = \begin{pmatrix} 4-4 & -2+2 \\ 8-8 & -4+4 \end{pmatrix} = 0$, so $2\mathbf{I}$ and $\mathbf{N}$ commute and Theorem 9.9.4 (d) gives, as in the previous example,

$$e^{t\mathbf{M}} = e^{2t}(\mathbf{I} + t\mathbf{N}) = e^{2t}\begin{pmatrix} 1 - 2t & t \\ -4t & 1 + 2t \end{pmatrix}.$$

(No basis change was needed: $\mathbf{M}$ is a scalar plus a nilpotent matrix on the nose.)

Read off the answer.

$$\mathbf{u}(t) = e^{t\mathbf{M}}\begin{pmatrix} 1 \\ 3 \end{pmatrix} = e^{2t}\begin{pmatrix} (1 - 2t) + 3t \\ -4t + 3(1 + 2t) \end{pmatrix} = e^{2t}\begin{pmatrix} 1 + t \\ 3 + 2t \end{pmatrix},$$

so $y(t) = (1 + t)e^{2t}$.

Check. $y' = e^{2t} + 2(1 + t)e^{2t} = (3 + 2t)e^{2t}$, which is the second entry of $\mathbf{u}$, as it should be, and $y'(0) = 3$. Then $y'' = 2e^{2t} + 2(3 + 2t)e^{2t} = (8 + 4t)e^{2t}$, and

$$y'' - 4y' + 4y = \big[(8 + 4t) - 4(3 + 2t) + 4(1 + t)\big]e^{2t} = 0.$$

The repeated root 2 produces the term te^{2t}, exactly as the size-2 block predicts.

Chapter 15 will return to $e^{\mathbf{A}}$ with norms available, which give quantitative bounds instead of exact formulas. The next section stays with exact formulas and asks the discrete-time question: what happens to $\mathbf{A}^m$?

9.9.5 Exercises

9.9.5.1 A. Check your understanding

Exercise A1.

(a) State the formula for $p(\mathbf{J}_k(\lambda))$ and say where the factorials come from.

(b) Define $f(\mathbf{A})$ for $\mathbf{A} \in M_n(\mathbb{C})$ with a given Jordan form, and list the two choices whose irrelevance has to be checked.

(c) Which values of f and its derivatives does $f(\mathbf{A})$ depend on? How many numbers is that?

(d) State the five properties of $e^{\mathbf{A}}$ proved in Theorem 9.9.4, with their hypotheses.

(e) True or false: $e^{\mathbf{A}+\mathbf{B}} = e^{\mathbf{A}}e^{\mathbf{B}}$ for all $\mathbf{A}, \mathbf{B} \in M_n(\mathbb{C})$. Justify your answer.

(f) True or false: $e^{\mathbf{A}}$ can be singular. Justify your answer.

Solution.

(a) $p(\mathbf{J}_k(\lambda))$ is upper triangular with $p^{(j)}(\lambda)/j!$ in every position $(r, r+j)$ (Lemma 9.9.1). The factorials come from the Taylor expansion $p = \sum_j \frac{p^{(j)}(\lambda)}{j!}(x-\lambda)^j$ (Theorem 5.4.7), whose j-th term contributes $\mathbf{J}_k(0)^j$, the matrix with ones on the j-th superdiagonal.

(b) $f(\mathbf{A}) = \mathbf{P}\big(\bigoplus_i f(\mathbf{J}_{k_i}(\lambda_i))\big)\mathbf{P}^{-1}$ with $f(\mathbf{J}_k(\lambda))$ as in (a) (Definition 9.9.1). The choices are the matrix $\mathbf{P}$ and the order in which the blocks are listed; both are irrelevant because $f(\mathbf{A}) = p(\mathbf{A})$ for the Hermite interpolating polynomial p (Theorem 9.9.2).

(c) On $f^{(j)}(\mu)$ for each eigenvalue μ and each $j < s_\mu$, where s_μ is the exponent of $x-\mu$ in $m_{\mathbf{A}}$, that is, the largest μ-block size. The total number is $\sum_\mu s_\mu = \deg m_{\mathbf{A}}$ (Theorem 9.9.2).

(d) $e^{\mathbf{P}^{-1}\mathbf{A}\mathbf{P}} = \mathbf{P}^{-1}e^{\mathbf{A}}\mathbf{P}$ for invertible $\mathbf{P}$; $\frac{d}{dt}e^{t\mathbf{A}} = \mathbf{A}e^{t\mathbf{A}} = e^{t\mathbf{A}}\mathbf{A}$; $(e^{\mathbf{A}})^{-1} = e^{-\mathbf{A}}$; $e^{\mathbf{A}+\mathbf{B}} = e^{\mathbf{A}}e^{\mathbf{B}}$ **provided** $\mathbf{AB} = \mathbf{BA}$; and $\det e^{\mathbf{A}} = e^{\operatorname{tr}\mathbf{A}}$ with no hypothesis.

(e) False. With $\mathbf{A} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$ and $\mathbf{B} = \mathbf{A}^{\top}$, the matrices $e^{\mathbf{A}}e^{\mathbf{B}}$ and $e^{\mathbf{B}}e^{\mathbf{A}}$ differ, so the identity cannot hold for both orders; see the warning after Theorem 9.9.4.

(f) False. $\det e^{\mathbf{A}} = e^{\operatorname{tr}\mathbf{A}} \neq 0$ by Theorem 9.9.4 (e) and (A1), so $e^{\mathbf{A}}$ is always invertible (Theorem 6.5.2).

9.9.5.2 B. Practice

Exercise B1: Computing exponentials.

Compute $e^{t\mathbf{A}}$ for each of the following.

(a) $\mathbf{A} = \begin{pmatrix} 1 & 3 \\ 3 & 1 \end{pmatrix}$.

(b) $\mathbf{A} = \begin{pmatrix} 5 & 1 \\ 0 & 5 \end{pmatrix}$.

(c) $\mathbf{A} = \begin{pmatrix} 3 & 1 & 0 \\ 0 & 3 & 1 \\ 0 & 0 & 3 \end{pmatrix} = \mathbf{J}_3(3)$.

Solution.

(a) $p_{\mathbf{A}} = (x-1)^2 - 9$, with roots 4 and -2. Eigenvectors: $(\mathbf{A} - 4\mathbf{I})\mathbf{x} = \mathbf{0}$ gives $\operatorname{span}((1,1))$; $(\mathbf{A} + 2\mathbf{I})\mathbf{x} = \mathbf{0}$ gives $\operatorname{span}((1,-1))$. With $\mathbf{P} = \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}$ we have $\det \mathbf{P} = -2$, $\mathbf{P}^{-1} = \frac{1}{2}\begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}$ and $\mathbf{P}^{-1}\mathbf{A}\mathbf{P} = \operatorname{diag}(4,-2)$, so by Corollary 9.9.5

$$e^{t\mathbf{A}} = \mathbf{P}\operatorname{diag}(e^{4t}, e^{-2t})\mathbf{P}^{-1} = \frac{1}{2}\begin{pmatrix} e^{4t}+e^{-2t} & e^{4t}-e^{-2t} \\ e^{4t}-e^{-2t} & e^{4t}+e^{-2t} \end{pmatrix}.$$

Check at $t = 0$: both diagonal entries give 1 and both off-diagonal ones 0, so $e^{0} = \mathbf{I}$.

(b) $\mathbf{A} = \mathbf{J}_2(5)$, so Corollary 9.9.5 with $k = 2$ gives

$$e^{t\mathbf{A}} = e^{5t}(\mathbf{I} + t\mathbf{M}) = e^{5t}\begin{pmatrix} 1 & t \\ 0 & 1 \end{pmatrix}.$$

(c) By Corollary 9.9.5 with $k = 3$ and $\lambda = 3$, or directly from $\mathbf{A} = 3\mathbf{I} + \mathbf{M}$ with $\mathbf{M} = \mathbf{J}_3(0)$ and $\mathbf{M}^3 = 0$, giving $e^{t\mathbf{A}} = e^{3t}\bigl(\mathbf{I} + t\mathbf{M} + \frac{t^2}{2}\mathbf{M}^2\bigr)$:

$$e^{t\mathbf{A}} = e^{3t}\begin{pmatrix} 1 & t & \frac{t^2}{2} \\ 0 & 1 & t \\ 0 & 0 & 1 \end{pmatrix}.$$

This is Definition 9.9.1 for $f(x) = e^{tx}$: the j-th superdiagonal carries $f^{(j)}(3)/j! = t^j e^{3t}/j!$.

Exercise B2: Solving systems.

Solve each initial value problem, and verify your answer by differentiating.

(a) $x' = x + 3y$, $y' = 3x + y$, with $x(0) = 2$, $y(0) = 0$.

(b) $\mathbf{x}' = \begin{pmatrix} 0 & -3 \\ 3 & 0 \end{pmatrix}\mathbf{x}$ with $\mathbf{x}(0) = (0,1)$.

(c) $y''' = 0$ with $y(0) = 1$, $y'(0) = 0$, $y''(0) = 2$, by turning it into a system.

Solution.

(a) This is $\mathbf{x}' = \mathbf{A}\mathbf{x}$ for the matrix of Exercise (B1: Computing exponentials) (a). By Theorem 9.9.6,

$$\mathbf{x}(t) = e^{t\mathbf{A}}\begin{pmatrix} 2 \\ 0 \end{pmatrix} = \begin{pmatrix} e^{4t}+e^{-2t} \\ e^{4t}-e^{-2t} \end{pmatrix},$$

that is, $x = e^{4t} + e^{-2t}$ and $y = e^{4t} - e^{-2t}$. *Check.* $x' = 4e^{4t} - 2e^{-2t}$ and $x + 3y = e^{4t} + e^{-2t} + 3e^{4t} - 3e^{-2t} = 4e^{4t} - 2e^{-2t}$; similarly for y'. And $x(0) = 2$, $y(0) = 0$.

(b) Write $\mathbf{A} = 3\mathbf{R}$ with $\mathbf{R} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$, whose eigenvalues are $\pm i$ (Example (A Real Matrix with Non-Real Eigenvalues)), so those of $\mathbf{A}$ are $\pm 3i$, distinct. Repeating the computation of Example (Two Two-Dimensional Systems) (a) with $1 \pm 2i$ replaced by $\pm 3i$ — eigenvectors $(1, -i)$ for $3i$ and $(1, i)$ for $-3i$ — gives

$$e^{t\mathbf{A}} = \begin{pmatrix} \cos 3t & -\sin 3t \\ \sin 3t & \cos 3t \end{pmatrix}, \qquad \mathbf{x}(t) = \begin{pmatrix} -\sin 3t \\ \cos 3t \end{pmatrix}.$$

Check. $\mathbf{x}'(t) = (-3\cos 3t, -3\sin 3t)$ and $\mathbf{A}\mathbf{x}(t) = (-3\cos 3t, -3\sin 3t)$; and $\mathbf{x}(0) = (0, 1)$. The solution runs around the unit circle: no growth, since the eigenvalues are purely imaginary.

(c) Put $\mathbf{u} = (y, y', y'')$. Then $\mathbf{u}' = (y', y'', 0) = \mathbf{M}\mathbf{u}$ with $\mathbf{M} = \mathbf{J}_3(0)$, and $\mathbf{u}(0) = (1, 0, 2)$. By Corollary 9.9.5 with $\lambda = 0$ and $k = 3$,

$$e^{t\mathbf{M}} = \begin{pmatrix} 1 & t & t^2/2 \\ 0 & 1 & t \\ 0 & 0 & 1 \end{pmatrix}, \qquad \mathbf{u}(t) = e^{t\mathbf{M}} \begin{pmatrix} 1 \\ 0 \\ 2 \end{pmatrix} = \begin{pmatrix} 1 + t^2 \\ 2t \\ 2 \end{pmatrix}.$$

So $y(t) = 1 + t^2$. *Check.* $y' = 2t$, $y'' = 2$, $y''' = 0$, and the three initial values are $1, 0, 2$. The eigenvalue 0 with one block of size 3 gives polynomial solutions $t^j e^{0t} = t^j$ for $j < 3$.

Exercise B3: A square root and a logarithm.

(a) Let $\mathbf{A} = \begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix}$. Compute $f(\mathbf{A})$ for $f(x) = \sqrt{x}$ (positive branch) and verify that $f(\mathbf{A})^2 = \mathbf{A}$.

(b) Let $\mathbf{B} = \begin{pmatrix} 1 & 2 \\ 0 & 1 \end{pmatrix}$. Compute $f(\mathbf{B})$ for $f(x) = \log x$ with $\log 1 = 0$, and verify that $e^{f(\mathbf{B})} = \mathbf{B}$.

(c) Explain why the same method produces **no** square root of $\begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$.

Solution.

(a) $p_{\mathbf{A}} = (x-2)^2 - 1 = (x-1)(x-3)$, eigenvalues $1, 3$. Eigenvectors $(1, -1)$ for 1 and $(1, 1)$ for 3. With $\mathbf{P} = \begin{pmatrix} 1 & 1 \\ -1 & 1 \end{pmatrix}$ and $\mathbf{P}^{-1} = \frac{1}{2}\begin{pmatrix} 1 & -1 \\ 1 & 1 \end{pmatrix}$,

$$f(\mathbf{A}) = \mathbf{P}\,\mathrm{diag}(1, \sqrt{3})\mathbf{P}^{-1} = \tfrac{1}{2}\begin{pmatrix} 1+\sqrt{3} & -1+\sqrt{3} \\ -1+\sqrt{3} & 1+\sqrt{3} \end{pmatrix}.$$

Squaring, the diagonal entry is $\frac{1}{4}\left[(1+\sqrt{3})^2 + (\sqrt{3}-1)^2\right] = \frac{1}{4}(4 + 2\sqrt{3} + 4 - 2\sqrt{3}) = 2$, and the off-diagonal entry is $\frac{1}{4} \cdot 2(1+\sqrt{3})(\sqrt{3}-1) = \frac{1}{2}(3-1) = 1$. So $f(\mathbf{A})^2 = \mathbf{A}$.

(b) Here $m_{\mathbf{B}} = (x-1)^2$, since $(\mathbf{B} - \mathbf{I})^2 = 0 \neq \mathbf{B} - \mathbf{I}$, so by Theorem 9.9.2 the answer is $p(\mathbf{B})$ for the polynomial of degree < 2 with $p(1) = f(1) = 0$ and $p'(1) = f'(1) = 1$,

namely $p = x - 1$. Hence

$$f(\mathbf{B}) = \mathbf{B} - \mathbf{I} = \begin{pmatrix} 0 & 2 \\ 0 & 0 \end{pmatrix}.$$

Its square is 0, so $e^{f(\mathbf{B})} = \mathbf{I} + f(\mathbf{B}) = \begin{pmatrix} 1 & 2 \\ 0 & 1 \end{pmatrix} = \mathbf{B}$. The Jordan route gives the same thing: with $\mathbf{Q} = \operatorname{diag}(2, 1)$ we get $\mathbf{Q}^{-1}\mathbf{B}\mathbf{Q} = \mathbf{J}_2(1)$, and $f(\mathbf{J}_2(1)) = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$, so $f(\mathbf{B}) = \mathbf{Q} f(\mathbf{J}_2(1))\mathbf{Q}^{-1} = \begin{pmatrix} 0 & 2 \\ 0 & 0 \end{pmatrix}$.

(c) The matrix is $\mathbf{J}_2(0)$, with the single eigenvalue 0 and a block of size 2. Definition 9.9.1 needs f and f' at 0, and $f(x) = \sqrt{x}$ is not differentiable at 0 — the entry $f'(0)$ does not exist. In fact $\mathbf{J}_2(0)$ has no square root at all: if $\mathbf{X}^2 = \mathbf{J}_2(0)$, then $\mathbf{X}^4 = \mathbf{J}_2(0)^2 = 0$, so $\mathbf{X}$ is nilpotent, so $\mathbf{X}^2 = 0$ by Proposition 9.2.1 (a) with $n = 2$, contradicting $\mathbf{X}^2 = \mathbf{J}_2(0) \neq 0$.

9.9.5.3 C. Going deeper

Exercise C1: How badly the exponential law fails.

Let $\mathbf{A} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$ and $\mathbf{B} = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix}$ in $M_2(\mathbb{R})$.

(a) Compute $e^{\mathbf{A}}$, $e^{\mathbf{B}}$, $e^{\mathbf{A}}e^{\mathbf{B}}$ and $e^{\mathbf{B}}e^{\mathbf{A}}$.

(b) Compute $e^{\mathbf{A}+\mathbf{B}}$ in closed form. *Hint:* $(\mathbf{A}+\mathbf{B})^2 = \mathbf{I}$, *so split the series into even and odd terms.*

(c) Verify $\det e^{\mathbf{A}+\mathbf{B}} = e^{\operatorname{tr}(\mathbf{A}+\mathbf{B})}$ and $\det(e^{\mathbf{A}}e^{\mathbf{B}}) = e^{\operatorname{tr}\mathbf{A}}e^{\operatorname{tr}\mathbf{B}}$, and explain why equal determinants do not rescue the identity.

(d) Show that $e^{\mathbf{A}}e^{\mathbf{B}} = e^{\mathbf{C}}$ for **some** $\mathbf{C} \in M_2(\mathbb{R})$, and find $\operatorname{tr}\mathbf{C}$.

Solution.

(a) $\mathbf{A}^2 = \mathbf{B}^2 = 0$, so $e^{\mathbf{A}} = \mathbf{I} + \mathbf{A} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$ and $e^{\mathbf{B}} = \mathbf{I} + \mathbf{B} = \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix}$. Then

$$e^{\mathbf{A}}e^{\mathbf{B}} = \begin{pmatrix} 2 & 1 \\ 1 & 1 \end{pmatrix}, \qquad e^{\mathbf{B}}e^{\mathbf{A}} = \begin{pmatrix} 1 & 1 \\ 1 & 2 \end{pmatrix}.$$

(b) Let $\mathbf{K} = \mathbf{A} + \mathbf{B} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$. Then $\mathbf{K}^2 = \mathbf{I}$, so $\mathbf{K}^{2l} = \mathbf{I}$ and $\mathbf{K}^{2l+1} = \mathbf{K}$. Splitting the partial sums by parity, which is legitimate because each entry sequence is a sum of two convergent sequences (A3),

$$\begin{aligned} e^{\mathbf{K}} &= \Big(\sum_{l\geq 0} \frac{1}{(2l)!}\Big)\mathbf{I} + \Big(\sum_{l\geq 0} \frac{1}{(2l+1)!}\Big)\mathbf{K} \\ &= \frac{e + e^{-1}}{2}\mathbf{I} + \frac{e - e^{-1}}{2}\mathbf{K} = \begin{pmatrix} \frac{e+e^{-1}}{2} & \frac{e-e^{-1}}{2} \\ \frac{e-e^{-1}}{2} & \frac{e+e^{-1}}{2} \end{pmatrix}, \end{aligned}$$

where the two scalar sums were identified by adding and subtracting the series for

e^1 and e^{-1} term by term (A1). Numerically the diagonal entries are about 1.543, not 2, so $e^{\mathbf{A}+\mathbf{B}} \neq e^{\mathbf{A}}e^{\mathbf{B}}$.

(c) $\operatorname{tr}(\mathbf{A}+\mathbf{B}) = 0$ and $\det e^{\mathbf{A}+\mathbf{B}} = \left(\frac{e+e^{-1}}{2}\right)^2 - \left(\frac{e-e^{-1}}{2}\right)^2 = \frac{1}{4}\left[(e+e^{-1})^2 - (e-e^{-1})^2\right] = \frac{1}{4}\cdot 4 = 1 = e^0$. Also $\det(e^{\mathbf{A}}e^{\mathbf{B}}) = 2-1 = 1 = e^0e^0$. The determinants agree because both matrices are products of exponentials of trace-zero matrices; a determinant is one number and cannot distinguish two matrices, so it gives no information about the identity either way. The entries do.

(d) $\mathbf{X} = e^{\mathbf{A}}e^{\mathbf{B}} = \begin{pmatrix} 2 & 1 \\ 1 & 1 \end{pmatrix}$ is symmetric with $\det \mathbf{X} = 1$ and $\operatorname{tr}\mathbf{X} = 3$, so $p_{\mathbf{X}} = x^2 - 3x + 1$, whose roots $\frac{3\pm\sqrt{5}}{2}$ are real, distinct and positive. So $\mathbf{X} = \mathbf{P}\operatorname{diag}(\alpha,\beta)\mathbf{P}^{-1}$ with $\alpha\beta = 1$, $\alpha, \beta > 0$. Put $\mathbf{C} = \mathbf{P}\operatorname{diag}(\log\alpha, \log\beta)\mathbf{P}^{-1}$, a real matrix because $\mathbf{P}$ can be taken real (the eigenvalues are real) and the logarithms are real. By Definition 9.9.1 applied to $f = \exp$, $e^{\mathbf{C}} = \mathbf{P}\operatorname{diag}(\alpha,\beta)\mathbf{P}^{-1} = \mathbf{X}$. Finally $\operatorname{tr}\mathbf{C} = \log\alpha + \log\beta = \log(\alpha\beta) = \log 1 = 0$, as Theorem 9.9.4 (e) requires, since $\det\mathbf{X} = 1$.

Exercise C2: When does every solution die out?.

Let $\mathbf{A} \in M_n(\mathbb{C})$. Prove that the following are equivalent:

(i) every solution of $\mathbf{x}' = \mathbf{A}\mathbf{x}$ satisfies $\mathbf{x}(t) \to \mathbf{0}$ entrywise as $t \to \infty$;

(ii) every eigenvalue λ of $\mathbf{A}$ has $\operatorname{Re}\lambda < 0$.

Hint: compute the entries of $e^{t\mathbf{J}_k(\lambda)}$ and use (A5). For the failing direction, an eigenvector gives a solution you can write down.

Solution.

(ii) $\Rightarrow$ (i). By Theorem 9.9.6 every solution is $\mathbf{x}(t) = e^{t\mathbf{A}}\mathbf{x}_0$, so it suffices to show $e^{t\mathbf{A}} \to 0$ entrywise. Write $\mathbf{A} = \mathbf{P}\mathbf{J}\mathbf{P}^{-1}$ with $\mathbf{J} = \bigoplus_i \mathbf{J}_{k_i}(\lambda_i)$ (Theorem 9.3.1). Each entry of $e^{t\mathbf{A}} = \mathbf{P}e^{t\mathbf{J}}\mathbf{P}^{-1}$ is a fixed linear combination of entries of $e^{t\mathbf{J}}$, so by (A3) it is enough that $e^{t\mathbf{J}} \to 0$. By Corollary 9.9.5, the non-zero entries of $e^{t\mathbf{J}_k(\lambda)}$ are

$$\frac{t^j e^{\lambda t}}{j!} \qquad (0 \le j \le k-1).$$

Writing $\lambda = c + i\omega$ with $c = \operatorname{Re}\lambda < 0$, we get $|t^j e^{\lambda t}| = t^j e^{ct}|e^{i\omega t}| = t^j e^{ct}$ for $t \ge 0$, since $|e^{i\omega t}| = |\cos\omega t + i\sin\omega t| = 1$ by (A1). By (A5) this tends to 0, and a complex sequence tends to 0 exactly when its moduli do. Hence $e^{t\mathbf{J}} \to 0$.

(iii) $\Rightarrow$ (ii). Suppose some eigenvalue λ has $\operatorname{Re}\lambda = c \ge 0$, and let $\mathbf{v} \neq \mathbf{0}$ be an eigenvector. Then $\mathbf{x}(t) = e^{\lambda t}\mathbf{v}$ is a solution: it is differentiable with $\mathbf{x}'(t) = \lambda e^{\lambda t}\mathbf{v} = e^{\lambda t}\mathbf{A}\mathbf{v} = \mathbf{A}\mathbf{x}(t)$, and $\mathbf{x}(0) = \mathbf{v}$. Pick a coordinate with $v_r \neq 0$; then

$$\left|x_r(t)\right| = \left|e^{\lambda t}\right|\,|v_r| = e^{ct}|v_r| \ge |v_r| > 0$$

for every $t \ge 0$, because $e^{ct} \ge 1$ when $c \ge 0$. So $x_r(t)$ does not tend to 0, and (i) fails. This proves the equivalence.

9.10 Convergent and Power-Bounded Matrices

Chapter 8 asked what happens to $\mathbf{A}^m$ as m grows, and could answer only for diagonalizable matrices: the powers of $\mathbf{A}$ behave like the powers of its eigenvalues. For a Markov chain that left a gap, because a transition matrix need not be diagonalizable. The Jordan form closes the gap completely. This section characterizes, in terms of the eigenvalues and the block sizes alone, when $\mathbf{A}^m$ tends to zero, when it stays bounded, when it converges, and when the geometric series $\mathbf{I} + \mathbf{A} + \mathbf{A}^2 + \cdots$ converges.

Convergence here means what it meant in Chapter 8: **entrywise**. No notion of the size of a matrix is used. Chapter 15 introduces norms and re-proves several of these results in a way that also gives numerical bounds; the price of doing without them is that we must look at one entry at a time, and the Jordan form is what makes that possible.

9.10.1 Entrywise limits and bounds

Definition 9.10.1 — Entrywise Convergence and Boundedness

Let $\mathbf{M}_1, \mathbf{M}_2, \ldots$ be matrices in $M_{p\times q}(\mathbb{C})$ and $\mathbf{M} \in M_{p\times q}(\mathbb{C})$.

(a) The sequence $(\mathbf{M}_m)$ **converges** to $\mathbf{M}$, written $\mathbf{M}_m \to \mathbf{M}$, if for **every** position (r, s) the sequence of complex numbers $(\mathbf{M}_m)_{rs}$ converges to $\mathbf{M}_{rs}$. We then write $\mathbf{M} = \lim_m \mathbf{M}_m$.

(b) The sequence $(\mathbf{M}_m)$ is **bounded** if there is a real $c \geq 0$ with $|(\mathbf{M}_m)_{rs}| \leq c$ for **all** m and **all** positions (r, s).

(c) A series $\sum_{k\geq 0} \mathbf{M}_k$ **converges** to $\mathbf{M}$ if its sequence of partial sums $\sum_{k=0}^{K} \mathbf{M}_k$ converges to $\mathbf{M}$.

In words: nothing new is happening. Each of the pq positions is watched separately, and the words mean for matrices exactly what they mean for the finitely many number sequences at those positions. Since a finite set of bounds can be replaced by their maximum, (b) is the same as asking each entry sequence to be bounded.

Remark. **What we assume from analysis.** Beyond the four facts quoted in Chapter 8 §11, this section uses exactly the following.

(B1) **Polynomial against geometric decay.** For every integer $j \geq 0$ and every real r with $0 \leq r < 1$, $m^j r^m \to 0$ as $m \to \infty$.

(B2) **Growth.** For real $r > 1$, the sequence (r^m) is unbounded.

(B3) **Limits.** Limits of convergent sequences of complex numbers respect sums, scalar multiples and products; a convergent sequence is bounded; every subsequence of a convergent sequence converges to the same limit; and $z_m \to z$ implies $|z_m| \to |z|$.

(B4) **Terms of a convergent series.** If $\sum_k z_k$ converges, then $z_k \to 0$.

Two reductions make every proof below short. The first moves the question along a similarity,

so that we may assume $\mathbf{A}$ is a Jordan matrix. The second computes the powers of a single Jordan block.

Lemma 9.10.1 — Convergence and Boundedness Survive a Similarity

Let $\mathbf{A}, \mathbf{B} \in M_n(\mathbb{C})$ with $\mathbf{B} = \mathbf{P}^{-1}\mathbf{A}\mathbf{P}$ for an invertible $\mathbf{P} \in M_n(\mathbb{C})$, and let $Ł \in M_n(\mathbb{C})$. Then:

(a) $\mathbf{A}^m \to Ł$ if and only if $\mathbf{B}^m \to \mathbf{P}^{-1}Ł\mathbf{P}$;

(b) $(\mathbf{A}^m)$ is bounded if and only if $(\mathbf{B}^m)$ is bounded.

Proof. By Proposition 3.7.6 (c), $\mathbf{B}^m = \mathbf{P}^{-1}\mathbf{A}^m\mathbf{P}$ for every $m \geq 0$. Writing out the products (Definition 0.9.9), the (r,s)-entry of $\mathbf{B}^m$ is

$$(\mathbf{B}^m)_{rs} = \sum_{u,v} (\mathbf{P}^{-1})_{ru}\,(\mathbf{A}^m)_{uv}\,\mathbf{P}_{vs},$$

a linear combination of the entries of $\mathbf{A}^m$ with coefficients that do not depend on m. So if $\mathbf{A}^m \to Ł$, then by (B3) each entry of $\mathbf{B}^m$ converges to the matching combination of the entries of $Ł$, that is, $\mathbf{B}^m \to \mathbf{P}^{-1}Ł\mathbf{P}$; and if $|(\mathbf{A}^m)_{uv}| \leq c$ for all m, u, v, then $|(\mathbf{B}^m)_{rs}| \leq c \sum_{u,v} |(\mathbf{P}^{-1})_{ru}|\,|\mathbf{P}_{vs}|$, a bound independent of m, so $(\mathbf{B}^m)$ is bounded. The converses follow by exchanging the roles of $\mathbf{A}$ and $\mathbf{B}$, using $\mathbf{A} = \mathbf{P}\mathbf{B}\mathbf{P}^{-1}$.

■

For the second reduction, recall from Lemma 9.9.1, applied to the polynomial x^m, that

$$\big(\mathbf{J}_k(\lambda)^m\big)_{r,\,r+j} = \binom{m}{j}\lambda^{\,m-j} \qquad (0 \leq j \leq k-1),$$

with zeros below the diagonal. Everything in this section is read off this one formula. Two remarks about it: the binomial coefficient is bounded by m^j, since

$$\binom{m}{j} = \frac{m(m-1)\cdots(m-j+1)}{j!} \leq \frac{m^j}{j!} \leq m^j \qquad (m \geq j \geq 1),$$

and $\binom{m}{1} = m$ grows without bound, while $\binom{m}{0} = 1$ is constant. So the only question is whether the geometric factor λ^m beats the polynomial factor m^j.

Quick check. Compute $|(\mathbf{J}_3(\lambda)^m)_{1,3}|$ for $\lambda = \frac{1}{2}$ and for $\lambda = 1$, and say in each case whether it tends to 0, stays bounded, or grows without bound.

Solution. Here $j = 2$, so the entry is $\binom{m}{2}\lambda^{m-2}$, of modulus $\frac{m(m-1)}{2}|\lambda|^{m-2}$. For $\lambda = \frac{1}{2}$ this is $2 \cdot \frac{m(m-1)}{2} 2^{-m} \leq 2m^2 2^{-m}$, which tends to 0 by (B1) with $j = 2$ and $r = \frac{1}{2}$. For $\lambda = 1$ it is $\frac{m(m-1)}{2}$, which grows without bound. The modulus of λ decides, and when $|\lambda| = 1$ the block size decides.

9.10.2 Powers tending to zero

The powers of $\mathbf{A}$ die out exactly when every eigenvalue has modulus less than one.

Theorem 9.10.2 — Powers Tending to Zero

Let $\mathbf{A} \in M_n(\mathbb{C})$, $n \geq 1$. Then $\mathbf{A}^m \to 0$ if and only if every eigenvalue λ of $\mathbf{A}$ satisfies $|\lambda| < 1$.

Idea. ($\Leftarrow$) Pass to the Jordan form and look at one entry: it is $\binom{m}{j}\lambda^{m-j}$, a polynomial in m times a geometric sequence that decays, and geometric decay wins. ($\Rightarrow$) The other direction needs no Jordan form at all: an eigenvector turns $\mathbf{A}^m$ into λ^m.

Proof. ($\Leftarrow$) Suppose $|\lambda| < 1$ for every $\lambda \in \operatorname{spec}(\mathbf{A})$. By Theorem 9.3.1, $\mathbf{A} = \mathbf{P}\mathbf{J}\mathbf{P}^{-1}$ with $\mathbf{J} = \mathbf{J}_{k_1}(\lambda_1) \oplus \cdots \oplus \mathbf{J}_{k_d}(\lambda_d)$ a Jordan matrix, whose diagonal entries λ_i are the eigenvalues of $\mathbf{A}$ (Corollary 9.3.2 (a)). By Theorem 7.1.4 (b), $\mathbf{J}^m$ is the direct sum of the blocks $\mathbf{J}_{k_i}(\lambda_i)^m$, so each entry of $\mathbf{J}^m$ is either 0 for every m or of the form $\binom{m}{j}\lambda_i^{m-j}$ with $0 \leq j \leq k_i - 1$. For the latter, with $r = |\lambda_i| < 1$, if $r = 0$ the entry is 0 for $m > j$; otherwise, for $m \geq j$,

$$\left|\binom{m}{j}\lambda_i^{m-j}\right| \leq m^j r^{\,m-j} = r^{-j}\, m^j r^m \longrightarrow 0$$

by (B1), the factor r^{-j} being a constant. So $\mathbf{J}^m \to 0$, and $\mathbf{A}^m \to \mathbf{P}\,0\,\mathbf{P}^{-1} = 0$ by Lemma 9.10.1 (a).

($\Rightarrow$) Suppose $\mathbf{A}^m \to 0$ and let $\lambda \in \operatorname{spec}(\mathbf{A})$ with eigenvector $\mathbf{v} \neq \mathbf{0}$. Then $\mathbf{A}^m\mathbf{v} = \lambda^m\mathbf{v}$ for every m (induction on m). Pick a coordinate r with $v_r \neq 0$. The r-th entry of $\mathbf{A}^m\mathbf{v}$ is a linear combination of entries of $\mathbf{A}^m$ with coefficients $v_1, \ldots, v_n$, so it tends to 0 by (B3); that entry is $\lambda^m v_r$, so $\lambda^m \to 0$ and hence $|\lambda|^m = |\lambda^m| \to 0$ by (B3). If $|\lambda| \geq 1$, then $|\lambda|^m \geq 1$ for every m and the limit cannot be 0. Hence $|\lambda| < 1$. This proves the theorem.

■

Note the asymmetry: the hard direction needs the Jordan form, the easy one needs only an eigenvector. That pattern repeats in the next two theorems.

Warning. **The condition is on the eigenvalues, not on the entries.** Every entry of $\mathbf{A} = \begin{pmatrix} 0.9 & 0.9 \\ 0.9 & 0.9 \end{pmatrix}$ has modulus less than 1, yet $\mathbf{A}\mathbf{1} = 1.8\,\mathbf{1}$, so 1.8 is an eigenvalue and $\mathbf{A}^m\mathbf{1} = 1.8^m\mathbf{1}$ grows without bound. Conversely, a matrix with huge entries can have all eigenvalues 0: the matrix $\begin{pmatrix} 0 & 10^6 \\ 0 & 0 \end{pmatrix}$ squares to 0. Nothing can be concluded from the size of the entries alone.

9.10.3 Powers that stay bounded

Dropping "tends to zero" to "stays bounded" allows eigenvalues on the unit circle, but only if they carry no chains: a block of size ≥ 2 contributes an entry $\binom{m}{1}\lambda^{m-1}$ of modulus m.

Theorem 9.10.3 — Power-Bounded Matrices

Let $\mathbf{A} \in M_n(\mathbb{C})$, $n \geq 1$, with Jordan form $\mathbf{J}$. The sequence $(\mathbf{A}^m)_{m \geq 0}$ is bounded if and only if

(i) every eigenvalue λ of $\mathbf{A}$ satisfies $|\lambda| \leq 1$, and

(ii) every eigenvalue λ with $|\lambda| = 1$ has **all** of its blocks in $\mathbf{J}$ of size 1, equivalently $a_{\mathbf{A}}(\lambda) = g_{\mathbf{A}}(\lambda)$, equivalently $x - \lambda$ occurs to the first power in $m_{\mathbf{A}}$.

Proof. Write $\mathbf{A} = \mathbf{P}\mathbf{J}\mathbf{P}^{-1}$ with $\mathbf{J} = \mathbf{J}_{k_1}(\lambda_1) \oplus \cdots \oplus \mathbf{J}_{k_d}(\lambda_d)$ (Theorem 9.3.1). By Lemma 9.10.1 (b), $(\mathbf{A}^m)$ is bounded if and only if $(\mathbf{J}^m)$ is, and by Theorem 7.1.4 (b) the latter holds if and only if every block sequence $\left(\mathbf{J}_{k_i}(\lambda_i)^m\right)$ is bounded. The three reformulations in (ii) are Corollary 9.3.2 (a), (b) and (c): all λ-blocks have size 1 exactly when their number equals their total size, and exactly when the largest of their sizes is 1.

($\Leftarrow$) Assume (i) and (ii), and fix a block $\mathbf{J}_k(\lambda)$ of $\mathbf{J}$. If $|\lambda| < 1$, then $\mathbf{J}_k(\lambda)^m \to 0$ by Theorem 9.10.2 applied to the single block $\mathbf{J}_k(\lambda)$, whose only eigenvalue is λ, hence $\left(\mathbf{J}_k(\lambda)^m\right)$ is bounded by (B3). If $|\lambda| = 1$, then $k = 1$ by (ii), so $\mathbf{J}_k(\lambda)^m = (\lambda^m)$ is a 1×1 matrix of modulus $|\lambda|^m = 1$. Either way the block sequence is bounded, so $(\mathbf{J}^m)$ is bounded and so is $(\mathbf{A}^m)$.

($\Rightarrow$) Assume $(\mathbf{A}^m)$ is bounded, hence so is $(\mathbf{J}^m)$, hence so is every block sequence.

Proof of (i). Let λ be an eigenvalue and $\mathbf{J}_k(\lambda)$ one of its blocks. The $(1,1)$-entry of $\mathbf{J}_k(\lambda)^m$ is λ^m, so $\left(|\lambda|^m\right)$ is bounded; by (B2) this forces $|\lambda| \leq 1$.

Proof of (ii). Suppose some eigenvalue λ with $|\lambda| = 1$ had a block $\mathbf{J}_k(\lambda)$ with $k \geq 2$. Its $(1,2)$-entry at the m-th power is $\binom{m}{1}\lambda^{m-1} = m\lambda^{m-1}$, of modulus $m|\lambda|^{m-1} = m$, which is unbounded — contradicting the boundedness of that block sequence. So every such block has size 1. This proves the theorem.

■

9.10.4 Powers that converge

Boundedness is not convergence: $\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}^m$ alternates between two matrices forever. Among the eigenvalues of modulus 1, only $\lambda = 1$ has convergent powers, because λ^m has to sit still.

Theorem 9.10.4 — Convergent Matrices

Let $\mathbf{A} \in M_n(\mathbb{C})$, $n \geq 1$, with Jordan form $\mathbf{J}$. Then $(\mathbf{A}^m)$ converges if and only if every eigenvalue λ of $\mathbf{A}$ satisfies

(i) $|\lambda| < 1$, or

(ii) $\lambda = 1$ and all of its blocks in $\mathbf{J}$ have size 1.

In that case

$$\lim_{m \to \infty} \mathbf{A}^m = \mathbf{\Pi},$$

where $\mathbf{\Pi} \in M_n(\mathbb{C})$ is the matrix, in the standard basis, of the projection onto $E_1(\mathbf{A})$

along $\bigoplus_{\lambda\neq 1} G_\lambda(\mathbf{A})$ if $1 \in \operatorname{spec}(\mathbf{A})$, and $\mathbf{\Pi} = 0$ otherwise.

Idea. For the shape of the answer, take the Jordan form and let $m \to \infty$ in each block: the blocks with $|\lambda| < 1$ go to 0, the blocks $\mathbf{J}_1(1) = (1)$ stay at 1. So $\mathbf{J}^m$ tends to the 0/1 diagonal matrix that marks the 1-blocks, which is the matrix of a projection; conjugating back identifies the two subspaces. For the converse, the $(1,1)$-entry of a block is λ^m, and if that converges to z then so does $\lambda^{m+1} = \lambda \cdot \lambda^m$, giving $z = \lambda z$ and forcing $\lambda = 1$ or $z = 0$.

Proof. Write $\mathbf{A} = \mathbf{P}\mathbf{J}\mathbf{P}^{-1}$ with $\mathbf{J} = \mathbf{J}_{k_1}(\lambda_1) \oplus \cdots \oplus \mathbf{J}_{k_d}(\lambda_d)$ (Theorem 9.3.1), and let $\mathcal{B} = (\mathbf{b}_1, \ldots, \mathbf{b}_n)$ be the corresponding Jordan basis, the columns of $\mathbf{P}$. For each i let $C_i \subseteq \mathbb{C}^n$ be the span of the k_i basis vectors belonging to block i, so that $\mathbb{C}^n = C_1 \oplus \cdots \oplus C_d$.

($\Leftarrow$) Suppose every eigenvalue satisfies (i) or (ii). Fix a block. If $|\lambda_i| < 1$, then $\mathbf{J}_{k_i}(\lambda_i)^m \to 0$ by Theorem 9.10.2 applied to the block $\mathbf{J}_{k_i}(\lambda_i)$, whose only eigenvalue is λ_i. If $\lambda_i = 1$, then $k_i = 1$ by (ii) and $\mathbf{J}_1(1)^m = (1)$ for every m. By Theorem 7.1.4 (b), $\mathbf{J}^m$ is the direct sum of these, so

$$\mathbf{J}^m \longrightarrow \mathbf{E},$$

where $\mathbf{E}$ is the diagonal matrix carrying 1 in the positions of the blocks with $\lambda_i = 1$ and 0 everywhere else. By Lemma 9.10.1 (a), $\mathbf{A}^m \to \mathbf{P}\mathbf{E}\mathbf{P}^{-1}$.

It remains to identify $\mathbf{P}\mathbf{E}\mathbf{P}^{-1}$. The matrix $\mathbf{E}$ is the matrix in the basis $\mathcal{B}$ of the projection onto

$$U \coloneqq \bigoplus_{\lambda_i = 1} C_i \qquad \text{along} \qquad W \coloneqq \bigoplus_{\lambda_i \neq 1} C_i,$$

because $\mathbf{E}$ fixes each basis vector of the first family and kills each of the second (Theorem 3.10.1). Since the columns of $\mathbf{P}$ are the vectors of $\mathcal{B}$, $\mathbf{P}$ is the change-of-coordinates matrix from $\mathcal{B}$ to the standard basis, so $\mathbf{P}\mathbf{E}\mathbf{P}^{-1}$ is the matrix of that projection in the standard basis (Theorem 3.7.3). Now, for any $\mu \in \operatorname{spec}(\mathbf{A})$,

$$\bigoplus_{\lambda_i = \mu} C_i = G_\mu(\mathbf{A}).$$

Indeed each C_i with $\lambda_i = \mu$ is killed by $(\mathbf{A} - \mu\mathbf{I})^{k_i}$, hence lies in $G_\mu(\mathbf{A})$ (Corollary 9.1.2 (a)); the sum on the left is direct and has dimension $\sum_{\lambda_i=\mu} k_i = a_{\mathbf{A}}(\mu)$ by Corollary 9.3.2 (a); and $\dim G_\mu(\mathbf{A}) = a_{\mathbf{A}}(\mu)$ by Theorem 9.1.3 (c). An inclusion of subspaces with equal dimensions is an equality (Theorem 1.6.8, applied inside $G_\mu(\mathbf{A})$). Hence $W = \bigoplus_{\lambda\neq 1} G_\lambda(\mathbf{A})$, and $U = G_1(\mathbf{A})$ if $1 \in \operatorname{spec}(\mathbf{A})$, with $U = \{\mathbf{0}\}$ otherwise. Finally, when $1 \in \operatorname{spec}(\mathbf{A})$, condition (ii) says all 1-blocks have size 1, so $g_{\mathbf{A}}(1) = a_{\mathbf{A}}(1)$ by Corollary 9.3.2 (a), (b); since $E_1(\mathbf{A}) \subseteq G_1(\mathbf{A})$ with $\dim E_1(\mathbf{A}) = g_{\mathbf{A}}(1) = a_{\mathbf{A}}(1) = \dim G_1(\mathbf{A})$, we get $G_1(\mathbf{A}) = E_1(\mathbf{A})$. So $\lim_m \mathbf{A}^m = \mathbf{\Pi}$ as stated.

($\Rightarrow$) Suppose $(\mathbf{A}^m)$ converges. By Lemma 9.10.1 (a) so does $(\mathbf{J}^m)$, hence so does each block sequence. Fix a block $\mathbf{J}_k(\lambda)$.

Case $|\lambda| > 1$. Impossible: a convergent sequence is bounded (B3), so this is excluded by Theorem 9.10.3.

Case $|\lambda| = 1$ *and* $\lambda \neq 1$. The $(1,1)$-entries give a convergent sequence $\lambda^m \to z$. The sequence $(\lambda^{m+1})_{m\geq 0}$ is a tail of the same sequence, so it also converges to z; on the other hand $\lambda^{m+1} = \lambda \cdot \lambda^m \to \lambda z$ by (B3). Hence $z = \lambda z$, that is, $(1-\lambda)z = 0$, and $\lambda \neq 1$

forces $z = 0$. But $|\lambda^m| = 1$ for every m, so $|z| = 1$ by (B3), a contradiction. So this case does not occur either.

Case $\lambda = 1$. If $k \geq 2$, the $(1,2)$-entry of $\mathbf{J}_k(1)^m$ is $\binom{m}{1}1^{m-1} = m$, which does not converge. So $k = 1$.

The three cases leave exactly (i) and (ii). This proves the theorem.

■

The limit deserves a sentence. It is a projection, so $\mathbf{\Pi}^2 = \mathbf{\Pi}$ — which had to be true, since $\mathbf{\Pi}^2 = \lim_m \mathbf{A}^m \lim_m \mathbf{A}^m = \lim_m \mathbf{A}^{2m} = \mathbf{\Pi}$ by (B3) — and it acts as the identity on the eigenvectors for 1 and annihilates everything belonging to the other eigenvalues. In the long run, $\mathbf{A}$ forgets all of $\mathbb{C}^n$ except the fixed space $E_1(\mathbf{A})$.

Example. (Deciding and Computing Limits of Powers)

For each matrix, decide whether $\mathbf{A}^m$ tends to 0, stays bounded, converges, and compute $\lim \mathbf{A}^m$ when it exists.

(a) $\mathbf{A}_1 = \begin{pmatrix} 2 & 1 \\ -1 & 0 \end{pmatrix}$.

(b) $\mathbf{A}_2 = \begin{pmatrix} 0 & -\frac{1}{2} \\ \frac{1}{2} & 0 \end{pmatrix}$.

(c) $\mathbf{A}_3 = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \frac{1}{3} & 1 \\ 0 & 0 & \frac{1}{3} \end{pmatrix}$.

Solution.

(a) $p_{\mathbf{A}_1} = x(x-2)+1 = (x-1)^2$, so the only eigenvalue is 1. Put $\mathbf{N} = \mathbf{A}_1 - \mathbf{I} = \begin{pmatrix} 1 & 1 \\ -1 & -1 \end{pmatrix}$; then $\mathbf{N} \neq 0$ and $\mathbf{N}^2 = \begin{pmatrix} 1-1 & 1-1 \\ -1+1 & -1+1 \end{pmatrix} = 0$, so $g_{\mathbf{A}_1}(1) = 2 - \operatorname{rank}\mathbf{N} = 1$ and the Jordan form is $\mathbf{J}_2(1)$. Condition (ii) of Theorem 9.10.3 fails, so $(\mathbf{A}_1^m)$ is **unbounded**, and in particular does not converge. Explicitly, $\mathbf{I}$ and $\mathbf{N}$ commute and $\mathbf{N}^2 = 0$, so the binomial theorem gives

$$\mathbf{A}_1^m = (\mathbf{I}+\mathbf{N})^m = \mathbf{I} + m\mathbf{N} = \begin{pmatrix} 1+m & m \\ -m & 1-m \end{pmatrix},$$

which grows linearly.

(b) $p_{\mathbf{A}_2} = x^2 + \frac{1}{4}$, with roots $\pm\frac{i}{2}$, both of modulus $\frac{1}{2} < 1$. By Theorem 9.10.2, $\mathbf{A}_2^m \to 0$ (so also bounded and convergent). Explicitly $\mathbf{A}_2^2 = -\frac{1}{4}\mathbf{I}$, so $\mathbf{A}_2^{2l} = (-\frac{1}{4})^l\mathbf{I}$ and $\mathbf{A}_2^{2l+1} = (-\frac{1}{4})^l\mathbf{A}_2$, and every entry has modulus at most $4^{-l} \to 0$.

(c) $\mathbf{A}_3 = (1) \oplus \mathbf{J}_2(\frac{1}{3})$ is already a Jordan matrix. Its eigenvalues are 1, with a single block of size 1, and $\frac{1}{3}$, with $|\frac{1}{3}| < 1$. So condition (i) or (ii) holds for each eigenvalue and $\mathbf{A}_3^m$ converges by Theorem 9.10.4. With $\mathbf{P} = \mathbf{I}$, the matrix $\mathbf{E}$ of the proof is $\operatorname{diag}(1,0,0)$, so

$$\lim_m \mathbf{A}_3^m = \operatorname{diag}(1,0,0),$$

the projection onto $E_1(\mathbf{A}_3) = \operatorname{span}(\mathbf{e}_1)$ along $G_{1/3}(\mathbf{A}_3) = \operatorname{span}(\mathbf{e}_2, \mathbf{e}_3)$. Explicitly,

by Lemma 9.9.1,

$$\mathbf{A}_3^m = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 3^{-m} & m\,3^{-(m-1)} \\ 0 & 0 & 3^{-m} \end{pmatrix},$$

and $m\,3^{-(m-1)} = 3m\,3^{-m} \to 0$ by (B1).

9.10.5 Markov chains, finished

Chapter 8 proved that a Markov chain settles down under three hypotheses: $\mathbf{A}$ diagonalizable over $\mathbb{C}$, $a_{\mathbf{A}}(1) = 1$, and $|\lambda| < 1$ for every other eigenvalue (Theorem 8.11.4). The first hypothesis can now be dropped, and more: for a stochastic matrix, the block condition of Theorem 9.10.3 holds automatically, because the powers of a stochastic matrix have entries in $[0, 1]$.

Corollary 9.10.5 — Convergence of a Markov Chain

Let $\mathbf{A} \in M_n(\mathbb{R})$ be stochastic (Definition 8.11.1), $n \geq 1$. Then:

(a) $(\mathbf{A}^m)$ is bounded; consequently every eigenvalue $\lambda \in \mathbb{C}$ of $\mathbf{A}$ satisfies $|\lambda| \leq 1$, and every eigenvalue with $|\lambda| = 1$ has only 1×1 blocks. In particular $a_{\mathbf{A}}(1) = g_{\mathbf{A}}(1)$.

(b) $(\mathbf{A}^m)$ converges if and only if 1 is the **only** eigenvalue of $\mathbf{A}$ of modulus 1; and then $\lim_m \mathbf{A}^m$ is the projection onto $E_1(\mathbf{A})$ along $\bigoplus_{\lambda \neq 1} G_\lambda(\mathbf{A})$.

Proof.

(a) By Proposition 8.11.3 (b), every $\mathbf{A}^m$ is stochastic, so its entries are non-negative and each of its columns sums to 1; hence every entry lies in $[0, 1]$ and $(\mathbf{A}^m)$ is bounded with $c = 1$. Now apply the $(\Rightarrow)$ direction of Theorem 9.10.3. Since $1 \in \operatorname{spec}(\mathbf{A})$ by Proposition 8.11.3 (c), the 1-blocks exist and all have size 1, so $a_{\mathbf{A}}(1) = g_{\mathbf{A}}(1)$ by Corollary 9.3.2 (a), (b).

(b) By (a), every eigenvalue has $|\lambda| \leq 1$ and every eigenvalue of modulus 1 has only 1×1 blocks. So the criterion of Theorem 9.10.4 — each eigenvalue has $|\lambda| < 1$, or equals 1 with only 1×1 blocks — holds precisely when no eigenvalue $\lambda \neq 1$ has $|\lambda| = 1$. The limit is the one given by Theorem 9.10.4.

■

So the only obstruction to a Markov chain settling down is an eigenvalue of modulus 1 other than 1 itself — periodicity, in the language of probability. Chapter 8's warning example, the swap $\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$, has the eigenvalue -1 and is exactly this obstruction.

Example. (A Two-State Chain)

Let $\mathbf{A} = \begin{pmatrix} 3/4 & 1/2 \\ 1/4 & 1/2 \end{pmatrix}$. Decide whether $\mathbf{A}^m$ converges and find the limit.

Solution. $\mathbf{A}$ is stochastic: the entries are non-negative, and each column sums to 1. Its characteristic polynomial is

$$p_{\mathbf{A}} = \left(x - \tfrac{3}{4}\right)\left(x - \tfrac{1}{2}\right) - \tfrac{1}{8} = x^2 - \tfrac{5}{4}x + \tfrac{1}{4} = (x-1)\left(x - \tfrac{1}{4}\right),$$

so $\operatorname{spec}(\mathbf{A}) = \{1, \tfrac{1}{4}\}$ and the only eigenvalue of modulus 1 is 1. By Corollary 9.10.5 (b), $\mathbf{A}^m$ converges.

For the limit, $E_1(\mathbf{A}) = \ker(\mathbf{A} - \mathbf{I})$, and $\mathbf{A} - \mathbf{I} = \begin{pmatrix} -1/4 & 1/2 \\ 1/4 & -1/2 \end{pmatrix}$ gives $\operatorname{span}((2,1))$; the steady state is $\mathbf{v} = (\tfrac{2}{3}, \tfrac{1}{3})$, the multiple of $(2,1)$ whose entries sum to 1. Also $E_{1/4}(\mathbf{A}) = \ker(\mathbf{A} - \tfrac{1}{4}\mathbf{I})$, and $\mathbf{A} - \tfrac{1}{4}\mathbf{I} = \begin{pmatrix} 1/2 & 1/2 \\ 1/4 & 1/4 \end{pmatrix}$ gives $\operatorname{span}((1,-1))$. Since the two eigenvalues are distinct, $G_{1/4}(\mathbf{A}) = E_{1/4}(\mathbf{A})$ and the limit $\mathbf{\Pi}$ is the projection onto $\operatorname{span}((2,1))$ along $\operatorname{span}((1,-1))$. Computing it in the basis $\mathcal{C} = \big((2,1),(1,-1)\big)$: with $\mathbf{Q} = \begin{pmatrix} 2 & 1 \\ 1 & -1 \end{pmatrix}$, $\det \mathbf{Q} = -3$ and $\mathbf{Q}^{-1} = \tfrac{1}{3}\begin{pmatrix} 1 & 1 \\ 1 & -2 \end{pmatrix}$, so

$$\mathbf{\Pi} = \mathbf{Q}\operatorname{diag}(1,0)\mathbf{Q}^{-1} = \begin{pmatrix} 2 & 0 \\ 1 & 0 \end{pmatrix} \cdot \tfrac{1}{3}\begin{pmatrix} 1 & 1 \\ 1 & -2 \end{pmatrix} = \tfrac{1}{3}\begin{pmatrix} 2 & 2 \\ 1 & 1 \end{pmatrix} = \begin{pmatrix} 2/3 & 2/3 \\ 1/3 & 1/3 \end{pmatrix}.$$

Check. $\mathbf{\Pi} = \mathbf{v}\mathbf{1}^{\top}$, as Theorem 8.11.4 predicts; $\mathbf{\Pi}^2 = \mathbf{\Pi}$ since $\mathbf{1}^{\top}\mathbf{v} = 1$; the columns of $\mathbf{\Pi}$ are the steady state, so every initial probability vector $\mathbf{x}_0$ gives $\mathbf{x}_m = \mathbf{A}^m\mathbf{x}_0 \to \mathbf{\Pi}\mathbf{x}_0 = \mathbf{v}(\mathbf{1}^{\top}\mathbf{x}_0) = \mathbf{v}$. And $\mathbf{A}^2 = \begin{pmatrix} 11/16 & 5/8 \\ 5/16 & 3/8 \end{pmatrix}$ is already close to $\mathbf{\Pi}$, the error decaying like 4^{-m}.

9.10.6 The geometric series of a matrix

The scalar identity $\sum_k a^k = (1-a)^{-1}$ for $|a| < 1$ has a matrix version, with the same proof and the same hypothesis read off the eigenvalues.

Theorem 9.10.6 — Neumann Series

Let $\mathbf{A} \in M_n(\mathbb{C})$, $n \geq 1$. Then the series $\sum_{k\geq 0} \mathbf{A}^k$ converges if and only if every eigenvalue λ of $\mathbf{A}$ satisfies $|\lambda| < 1$. In that case $\mathbf{I} - \mathbf{A}$ is invertible and

$$\sum_{k=0}^{\infty} \mathbf{A}^k = (\mathbf{I} - \mathbf{A})^{-1}.$$

Idea. Telescoping gives $(\mathbf{I} - \mathbf{A})(\mathbf{I} + \mathbf{A} + \cdots + \mathbf{A}^K) = \mathbf{I} - \mathbf{A}^{K+1}$, an exact identity for every K. If $\mathbf{I} - \mathbf{A}$ is invertible, solve it for the partial sum and let $K \to \infty$, where Theorem 9.10.2 kills $\mathbf{A}^{K+1}$. Conversely, the terms of a convergent series tend to 0, which is the hypothesis of that theorem again.

Proof. ($\Leftarrow$) Suppose $|\lambda| < 1$ for every $\lambda \in \operatorname{spec}(\mathbf{A})$. In particular $1 \notin \operatorname{spec}(\mathbf{A})$, so $0 \notin \operatorname{spec}(\mathbf{I} - \mathbf{A})$ — a vector with $(\mathbf{I} - \mathbf{A})\mathbf{v} = \mathbf{0}$ is a vector with $\mathbf{A}\mathbf{v} = \mathbf{v}$ — and $\mathbf{I} - \mathbf{A}$ is

invertible (Theorem 8.2.6). Put $\mathbf{S}_K = \sum_{k=0}^{K} \mathbf{A}^k$. Multiplying out and canceling,

$$(\mathbf{I}-\mathbf{A})\mathbf{S}_K = \sum_{k=0}^{K} \mathbf{A}^k - \sum_{k=1}^{K+1} \mathbf{A}^k = \mathbf{I} - \mathbf{A}^{K+1},$$

hence $\mathbf{S}_K = (\mathbf{I}-\mathbf{A})^{-1}\big(\mathbf{I}-\mathbf{A}^{K+1}\big)$. By Theorem 9.10.2, $\mathbf{A}^{K+1} \to 0$. Each entry of $\mathbf{S}_K$ is a fixed linear combination of the entries of $\mathbf{I}-\mathbf{A}^{K+1}$, with coefficients from $(\mathbf{I}-\mathbf{A})^{-1}$, so by (B3) it converges to the corresponding combination for $\mathbf{I}$, that is, $\mathbf{S}_K \to (\mathbf{I}-\mathbf{A})^{-1}\mathbf{I} = (\mathbf{I}-\mathbf{A})^{-1}$.

($\Rightarrow$) Suppose $\sum_k \mathbf{A}^k$ converges. Fix a position (r,s); the series of complex numbers $\sum_k (\mathbf{A}^k)_{rs}$ converges, so $(\mathbf{A}^k)_{rs} \to 0$ by (B4). This holds at every position, so $\mathbf{A}^k \to 0$, and Theorem 9.10.2 gives $|\lambda| < 1$ for every eigenvalue. This proves the theorem.

■

Example. (Inverting by Summing a Series)

Let $\mathbf{A} = \begin{pmatrix} 0 & 1/2 \\ 1/2 & 0 \end{pmatrix}$. Verify that $\sum_k \mathbf{A}^k$ converges, sum it, and compare with $(\mathbf{I}-\mathbf{A})^{-1}$.

Solution. $p_{\mathbf{A}} = x^2 - \frac{1}{4}$, so $\operatorname{spec}(\mathbf{A}) = \{\frac{1}{2}, -\frac{1}{2}\}$ and both eigenvalues have modulus $\frac{1}{2} < 1$. By Theorem 9.10.6 the series converges.

Summing it. $\mathbf{A}^2 = \frac{1}{4}\mathbf{I}$, so $\mathbf{A}^{2l} = 4^{-l}\mathbf{I}$ and $\mathbf{A}^{2l+1} = 4^{-l}\mathbf{A}$. Grouping the partial sums by parity, which is legitimate because each entry sequence splits into two convergent pieces (B3),

$$\sum_{k\ge 0} \mathbf{A}^k = \Big(\sum_{l\ge 0} 4^{-l}\Big)(\mathbf{I}+\mathbf{A}) = \frac{1}{1-\frac{1}{4}}(\mathbf{I}+\mathbf{A}) = \tfrac{4}{3}\begin{pmatrix} 1 & 1/2 \\ 1/2 & 1 \end{pmatrix} = \begin{pmatrix} 4/3 & 2/3 \\ 2/3 & 4/3 \end{pmatrix},$$

the scalar sum being the case $n=1$ of Theorem 9.10.6 applied to the 1×1 matrix $(\frac{1}{4})$.

The inverse. $\mathbf{I}-\mathbf{A} = \begin{pmatrix} 1 & -1/2 \\ -1/2 & 1 \end{pmatrix}$ has determinant $1-\frac{1}{4} = \frac{3}{4}$, so by Theorem 0.9.8

$$(\mathbf{I}-\mathbf{A})^{-1} = \tfrac{4}{3}\begin{pmatrix} 1 & 1/2 \\ 1/2 & 1 \end{pmatrix},$$

in agreement.

Remark. The first thing every criterion in this section looks at is the largest modulus of an eigenvalue,

$$\rho(\mathbf{A}) = \max\{|\lambda| : \lambda \in \operatorname{spec}(\mathbf{A})\},$$

called the **spectral radius** of $\mathbf{A}$. Two of the criteria need nothing else: $\mathbf{A}^m \to 0$ if and only if $\rho(\mathbf{A}) < 1$, and $\sum_k \mathbf{A}^k$ converges if and only if $\rho(\mathbf{A}) < 1$. The other two need more when $\rho(\mathbf{A}) = 1$: boundedness also asks for the block sizes at modulus 1, and convergence asks in addition that 1 be the only eigenvalue of modulus 1. Chapter 15 measures matrices by norms, proves that the spectral radius never exceeds the norm of $\mathbf{A}$ induced by any vector norm, and recovers $\rho(\mathbf{A})$ as a limit built from the norms of the

powers $\mathbf{A}^m$; that is what turns these exact criteria into usable estimates.

9.10.7 Exercises

9.10.7.1 A. Check your understanding

Exercise A1.

(a) Define entrywise convergence and entrywise boundedness for a sequence of matrices.

(b) Write down the entries of $\mathbf{J}_k(\lambda)^m$, and say which one shows that a block of size ≥ 2 with $|\lambda| = 1$ has unbounded powers.

(c) State the three criteria: $\mathbf{A}^m \to 0$, $(\mathbf{A}^m)$ bounded, $(\mathbf{A}^m)$ convergent.

(d) True or false: if every entry of $\mathbf{A}$ has modulus less than 1, then $\mathbf{A}^m \to 0$. Justify your answer.

(e) True or false: if $(\mathbf{A}^m)$ is bounded then it converges. Justify your answer.

(f) For which $\mathbf{A}$ does $\sum_k \mathbf{A}^k$ converge, and what is the sum?

Solution.

(a) $\mathbf{M}_m \to \mathbf{M}$ if $(\mathbf{M}_m)_{rs} \to \mathbf{M}_{rs}$ for every position (r, s); $(\mathbf{M}_m)$ is bounded if there is one constant c with $|(\mathbf{M}_m)_{rs}| \leq c$ for all m and all (r, s) (Definition 9.10.1).

(b) $\big(\mathbf{J}_k(\lambda)^m\big)_{r,r+j} = \binom{m}{j}\lambda^{m-j}$ for $0 \leq j \leq k-1$, with zeros below the diagonal (Lemma 9.9.1 with $p = x^m$). The entry with $j = 1$ is $m\lambda^{m-1}$, of modulus m when $|\lambda| = 1$.

(c) $\mathbf{A}^m \to 0$ iff every eigenvalue has $|\lambda| < 1$ (Theorem 9.10.2); $(\mathbf{A}^m)$ is bounded iff every eigenvalue has $|\lambda| \leq 1$ and those with $|\lambda| = 1$ have only 1×1 blocks (Theorem 9.10.3); $(\mathbf{A}^m)$ converges iff every eigenvalue has $|\lambda| < 1$ or equals 1 with only 1×1 blocks (Theorem 9.10.4).

(d) False. $\mathbf{A} = \begin{pmatrix} 0.9 & 0.9 \\ 0.9 & 0.9 \end{pmatrix}$ has the eigenvalue 1.8, and $\mathbf{A}^m\mathbf{1} = 1.8^m\mathbf{1}$ is unbounded; see the warning after Theorem 9.10.2.

(e) False. $\mathbf{A} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$ satisfies $\mathbf{A}^2 = \mathbf{I}$, so $\mathbf{A}^m$ alternates between $\mathbf{I}$ and $\mathbf{A}$ and is bounded but not convergent. Its eigenvalues are ± 1, and the eigenvalue -1 is what Theorem 9.10.4 excludes.

(f) Exactly when every eigenvalue has $|\lambda| < 1$, and then the sum is $(\mathbf{I} - \mathbf{A})^{-1}$ (Theorem 9.10.6).

9.10.7.2 B. Practice

Exercise B1: Decide the behavior.

For each matrix over $\mathbb{C}$, decide whether $\mathbf{A}^m \to 0$, whether $(\mathbf{A}^m)$ is bounded, and whether $(\mathbf{A}^m)$ converges. Justify your answer.

(a) $\mathbf{A}_1 = \begin{pmatrix} 1/2 & 1 \\ 0 & 1/2 \end{pmatrix}$.

(b) $\mathbf{A}_2 = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$.

(c) $\mathbf{A}_3 = \mathbf{J}_2(1) \oplus \mathbf{J}_1\left(\frac{1}{2}\right) \in M_3(\mathbb{C})$.

(d) $\mathbf{A}_4 = \begin{pmatrix} 0 & 0 & 5 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}$.

Solution.

(a) The only eigenvalue is $\frac{1}{2}$, of modulus < 1, so $\mathbf{A}_1^m \to 0$ by Theorem 9.10.2; hence it is bounded and convergent. (The superdiagonal 1 is irrelevant: by Lemma 9.9.1 the $(1,2)$-entry of $\mathbf{A}_1^m$ is $m\,2^{-(m-1)} \to 0$ by (B1).)

(b) $p_{\mathbf{A}_2} = x^2 + 1$, so $\operatorname{spec}(\mathbf{A}_2) = \{i, -i\}$, both of modulus 1, and the eigenvalues are distinct, so every block has size 1. By Theorem 9.10.3, $(\mathbf{A}_2^m)$ is **bounded**; it does not tend to 0 (Theorem 9.10.2) and does not converge, since the eigenvalue i has modulus 1 and is not 1 (Theorem 9.10.4). Concretely $\mathbf{A}_2^4 = \mathbf{I}$, so the powers cycle through four matrices.

(c) The eigenvalue 1 has a block of size 2, so Theorem 9.10.3 (ii) fails: $(\mathbf{A}_3^m)$ is **unbounded**, hence neither convergent nor tending to 0. The $(1,2)$-entry of $\mathbf{A}_3^m$ is m.

(d) $\mathbf{A}_4^2 = 0$, so $\mathbf{A}_4^m = 0$ for $m \geq 2$ and $\mathbf{A}_4^m \to 0$ trivially: all eigenvalues are 0. The large entry 5 does not matter, illustrating the warning after Theorem 9.10.2.

Exercise B2: Computing limits.

(a) Let $\mathbf{A} = \begin{pmatrix} 1/2 & 1/2 \\ 1/2 & 1/2 \end{pmatrix}$. Show that $\mathbf{A}^m$ converges and find the limit, both by Theorem 9.10.4 and by a direct computation of $\mathbf{A}^m$.

(b) Let $\mathbf{B} = \begin{pmatrix} 1 & 1/3 \\ 0 & 1/3 \end{pmatrix}$. Find $\lim_m \mathbf{B}^m$ and identify it as a projection.

Solution.

(a) $p_{\mathbf{A}} = x^2 - x = x(x-1)$, so $\operatorname{spec}(\mathbf{A}) = \{0, 1\}$. The eigenvalue 0 has $|0| < 1$ and the eigenvalue 1 has $a_{\mathbf{A}}(1) = 1$, so its single block has size 1; by Theorem 9.10.4 the powers converge, and the limit is the projection onto $E_1(\mathbf{A})$ along $G_0(\mathbf{A}) = E_0(\mathbf{A})$. Now $\mathbf{A} - \mathbf{I} = \begin{pmatrix} -1/2 & 1/2 \\ 1/2 & -1/2 \end{pmatrix}$ gives $E_1(\mathbf{A}) = \operatorname{span}((1,1))$ and $E_0(\mathbf{A}) = \ker \mathbf{A} = \operatorname{span}((1,-1))$. With $\mathbf{Q} = \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}$ and $\mathbf{Q}^{-1} = \frac{1}{2}\begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}$,

$$\lim_m \mathbf{A}^m = \mathbf{Q}\,\operatorname{diag}(1,0)\mathbf{Q}^{-1} = \tfrac{1}{2}\begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix} = \mathbf{A}.$$

Directly. $\mathbf{A}^2 = \mathbf{A}$, so $\mathbf{A}^m = \mathbf{A}$ for every $m \geq 1$ and the limit is $\mathbf{A}$. ($\mathbf{A}$ is itself a projection, and the theorem returns it unchanged.)

(b) $\mathbf{B}$ is upper triangular, so $\operatorname{spec}(\mathbf{B}) = \{1, \frac{1}{3}\}$ (Theorem 6.4.6). Both criteria hold: $|\frac{1}{3}| < 1$, and $a_{\mathbf{B}}(1) = 1$ so the 1-block has size 1. Solving $(\mathbf{B} - \mathbf{I})\mathbf{x} = \mathbf{0}$ with $\mathbf{B} - \mathbf{I} = \begin{pmatrix} 0 & 1/3 \\ 0 & -2/3 \end{pmatrix}$ gives $E_1(\mathbf{B}) = \operatorname{span}(\mathbf{e}_1)$; solving $(\mathbf{B} - \frac{1}{3}\mathbf{I})\mathbf{x} = \mathbf{0}$ with $\mathbf{B} - \frac{1}{3}\mathbf{I} = \begin{pmatrix} 2/3 & 1/3 \\ 0 & 0 \end{pmatrix}$ gives $E_{1/3}(\mathbf{B}) = \operatorname{span}((1, -2))$. With $\mathbf{Q} = \begin{pmatrix} 1 & 1 \\ 0 & -2 \end{pmatrix}$ we have $\det \mathbf{Q} = -2$ and $\mathbf{Q}^{-1} = \frac{1}{-2}\begin{pmatrix} -2 & -1 \\ 0 & 1 \end{pmatrix} = \begin{pmatrix} 1 & 1/2 \\ 0 & -1/2 \end{pmatrix}$. Multiplying in two steps, $\mathbf{Q}\operatorname{diag}(1, 0) = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}$ and then

$$\lim_m \mathbf{B}^m = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} \mathbf{Q}^{-1} = \begin{pmatrix} 1 & 1/2 \\ 0 & 0 \end{pmatrix}.$$

This is the projection onto $\operatorname{span}(\mathbf{e}_1)$ along $\operatorname{span}((1, -2))$: it fixes $\mathbf{e}_1$ and sends $(1, -2)$ to $(1 - 1, 0) = \mathbf{0}$. *Check.* $\mathbf{B}^m = \begin{pmatrix} 1 & c_m \\ 0 & 3^{-m} \end{pmatrix}$ with $c_1 = \frac{1}{3}$ and $c_{m+1} = \frac{1}{3}(1 + c_m)$, read off $\mathbf{B}^{m+1} = \mathbf{B}^m\mathbf{B}$; the first values are $\frac{1}{3}, \frac{4}{9}, \frac{13}{27}$, climbing towards the fixed point $c = \frac{1}{3}(1 + c)$, that is $c = \frac{1}{2}$.

Exercise B3: A Neumann series.

Let $\mathbf{A} = \begin{pmatrix} 1/3 & 1/3 \\ 0 & 1/3 \end{pmatrix}$.

(a) Explain why $\sum_k \mathbf{A}^k$ converges.
(b) Compute $(\mathbf{I} - \mathbf{A})^{-1}$ directly.
(c) Compute the partial sum $\mathbf{I} + \mathbf{A} + \mathbf{A}^2$ and compare it with (b).

Solution.

(a) $\mathbf{A}$ is upper triangular with both diagonal entries $\frac{1}{3}$, so $\operatorname{spec}(\mathbf{A}) = \{\frac{1}{3}\}$ (Theorem 6.4.6) and $|\frac{1}{3}| < 1$. By Theorem 9.10.6 the series converges, with sum $(\mathbf{I}-\mathbf{A})^{-1}$.

(b) $\mathbf{I} - \mathbf{A} = \begin{pmatrix} 2/3 & -1/3 \\ 0 & 2/3 \end{pmatrix}$, of determinant $\frac{4}{9}$. By Theorem 0.9.8,

$$(\mathbf{I} - \mathbf{A})^{-1} = \tfrac{9}{4}\begin{pmatrix} 2/3 & 1/3 \\ 0 & 2/3 \end{pmatrix} = \begin{pmatrix} 3/2 & 3/4 \\ 0 & 3/2 \end{pmatrix}.$$

(c) Write $\mathbf{A} = \frac{1}{3}(\mathbf{I} + \mathbf{M})$ with $\mathbf{M} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$, $\mathbf{M}^2 = 0$; then $\mathbf{A}^k = 3^{-k}(\mathbf{I} + k\mathbf{M})$ by the binomial theorem, the two summands commuting. So

$$\mathbf{I} + \mathbf{A} + \mathbf{A}^2 = (1 + \tfrac{1}{3} + \tfrac{1}{9})\mathbf{I} + (\tfrac{1}{3} + \tfrac{2}{9})\mathbf{M} = \tfrac{13}{9}\mathbf{I} + \tfrac{5}{9}\mathbf{M} = \begin{pmatrix} 13/9 & 5/9 \\ 0 & 13/9 \end{pmatrix}.$$

Summing the whole series the same way, $(\mathbf{I}-\mathbf{A})^{-1} = \big(\sum_{k\ge 0} 3^{-k}\big)\mathbf{I} + \big(\sum_{k\ge 0} k3^{-k}\big)\mathbf{M}$, so comparing with (b) reads off $\sum_k 3^{-k} = \frac{3}{2}$ and $\sum_k k3^{-k} = \frac{3}{4}$. The two partial sums $\frac{13}{9}$ and $\frac{5}{9}$, about 1.44 and 0.56, are on their way to $\frac{3}{2}$ and $\frac{3}{4}$; the convergence is geometric, as the factor 3^{-k} shows.

9.10.7.3 C. Going deeper

Exercise C1: Bounded but not convergent.

(a) Give an example of $\mathbf{A} \in M_2(\mathbb{R})$ with $(\mathbf{A}^m)$ bounded but not convergent, and one with $(\mathbf{A}^m)$ convergent but $\mathbf{A}^m \not\to 0$.

(b) Prove that if $\mathbf{A}^m \to Ł$, then $Ł^2 = Ł$ and $\mathbf{A}Ł = Ł\mathbf{A} = Ł$.

(c) Deduce that if $\mathbf{A}^m \to Ł$ with $Ł$ **invertible**, then $Ł = \mathbf{I}$ and $\mathbf{A} = \mathbf{I}$.

(d) Give an invertible $\mathbf{A}$ with $\mathbf{A}^m \to Ł$ and $Ł \notin \{0, \mathbf{I}\}$, so that the invertibility of $Ł$, not of $\mathbf{A}$, is what part (c) needs.

Solution.

(a) For the first, $\mathbf{A} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$: $\mathbf{A}^2 = \mathbf{I}$, so $\mathbf{A}^m$ alternates between $\mathbf{I}$ and $\mathbf{A}$ and is bounded but not convergent; its eigenvalues are ± 1. For the second, $\mathbf{A} = \begin{pmatrix} 1 & 0 \\ 0 & 1/2 \end{pmatrix}$: $\mathbf{A}^m = \operatorname{diag}(1, 2^{-m}) \to \operatorname{diag}(1, 0) \neq 0$.

(b) Each entry of $\mathbf{A}^m\mathbf{A}^m = \mathbf{A}^{2m}$ is a sum of products of entries of $\mathbf{A}^m$, so by (B3) it converges to the corresponding expression in the entries of $Ł$; hence $\mathbf{A}^{2m} \to Ł^2$. But $(\mathbf{A}^{2m})_m$ is a subsequence of $(\mathbf{A}^m)_m$ — more precisely, for each position the sequence $(\mathbf{A}^{2m})_{rs}$ is a subsequence of the convergent sequence $(\mathbf{A}^m)_{rs}$, so it has the same limit $Ł_{rs}$. Hence $Ł^2 = Ł$. Similarly $\mathbf{A}^{m+1} = \mathbf{A}\mathbf{A}^m = \mathbf{A}^m\mathbf{A}$, and the left side is a tail of the convergent sequence, so it tends to $Ł$, while the two right sides tend to $\mathbf{A}Ł$ and $Ł\mathbf{A}$ by (B3). Hence $\mathbf{A}Ł = Ł\mathbf{A} = Ł$.

(c) Suppose $\mathbf{A}^m \to Ł$ with $Ł$ invertible. By (b), $Ł^2 = Ł$; multiplying by $Ł^{-1}$ gives $Ł = \mathbf{I}$. Then $\mathbf{A}Ł = Ł$ reads $\mathbf{A} = \mathbf{I}$. (Conversely $\mathbf{A} = \mathbf{I}$ gives $\mathbf{A}^m = \mathbf{I} \to \mathbf{I}$, so this case really occurs.)

(d) $\mathbf{A} = \operatorname{diag}(1, \frac{1}{2})$ is invertible, and $\mathbf{A}^m = \operatorname{diag}(1, 2^{-m}) \to \operatorname{diag}(1, 0) = Ł$, which is neither 0 nor $\mathbf{I}$ — and not invertible. So no hypothesis on $\mathbf{A}$ alone forces $Ł \in \{0, \mathbf{I}\}$: by Theorem 9.10.4 the limit is the projection onto $E_1(\mathbf{A})$ along the other generalized eigenspaces, and that projection is 0 or $\mathbf{I}$ only in the extreme cases $1 \notin \operatorname{spec}(\mathbf{A})$ and $E_1(\mathbf{A}) = \mathbb{C}^n$.

Exercise C2: Chapter 8's Markov theorem without diagonalizability.

Let $\mathbf{A} \in M_n(\mathbb{R})$ be stochastic with $a_{\mathbf{A}}(1) = 1$ and $|\lambda| < 1$ for every eigenvalue $\lambda \neq 1$.

(a) Prove that $\mathbf{1}^\top\mathbf{w} = 0$ for every $\mathbf{w} \in G_\lambda(\mathbf{A})$ with $\lambda \neq 1$. *Hint:* $\mathbf{1}^\top(\mathbf{A} - \lambda\mathbf{I}) = (1 - \lambda)\mathbf{1}^\top$.

(b) Prove that $(\mathbf{A}^m)$ converges to a **stochastic** matrix $\mathbf{\Pi}$, and deduce that $\mathbf{A}$ has a steady state $\mathbf{v}$ with $E_1(\mathbf{A}) = \operatorname{span}(\mathbf{v})$.

(c) Deduce that $\mathbf{\Pi} = \mathbf{v}\mathbf{1}^\top$ and that $\mathbf{A}^m\mathbf{x}_0 \to \mathbf{v}$ for every probability vector $\mathbf{x}_0$, **without** assuming that $\mathbf{A}$ is diagonalizable.

Solution.

(a) Since $\mathbf{A}$ is stochastic, $\mathbf{1}^\top\mathbf{A} = \mathbf{1}^\top$ (Proposition 8.11.3 (c)), so $\mathbf{1}^\top(\mathbf{A} - \lambda\mathbf{I}) = \mathbf{1}^\top - \lambda\mathbf{1}^\top = (1 - \lambda)\mathbf{1}^\top$. Iterating n times, $\mathbf{1}^\top(\mathbf{A} - \lambda\mathbf{I})^n = (1 - \lambda)^n\mathbf{1}^\top$. Let $\mathbf{w} \in G_\lambda(\mathbf{A})$,

so $(\mathbf{A}-\lambda\mathbf{I})^n\mathbf{w}=\mathbf{0}$ (Corollary 9.1.2 (a)). Then

$$0=\mathbf{1}^\top(\mathbf{A}-\lambda\mathbf{I})^n\mathbf{w}=(1-\lambda)^n\,\mathbf{1}^\top\mathbf{w},$$

and $\lambda\neq 1$ gives $(1-\lambda)^n\neq 0$, so $\mathbf{1}^\top\mathbf{w}=0$.

(b) By hypothesis 1 is the only eigenvalue of modulus 1, so $(\mathbf{A}^m)$ converges by Corollary 9.10.5 (b); call the limit $\mathbf{\Pi}$. Every $\mathbf{A}^m$ is stochastic (Proposition 8.11.3 (b)), so all its entries are ≥ 0 and each of its columns sums to 1. Both properties pass to the limit: a limit of real numbers ≥ 0 is ≥ 0, and a column sum is a finite sum of entries, so it converges to the sum of the limits (Chapter 8 §11). Hence $\mathbf{\Pi}$ is stochastic, and in particular $\mathbf{\Pi}\neq 0$.
By Theorem 9.10.4, $\mathbf{\Pi}$ is the projection onto $E_1(\mathbf{A})$ along $\bigoplus_{\lambda\neq 1}G_\lambda(\mathbf{A})$, so $\operatorname{im}T_{\mathbf{\Pi}}=E_1(\mathbf{A})$. Since $a_{\mathbf{A}}(1)=1$ and $1\leq g_{\mathbf{A}}(1)\leq a_{\mathbf{A}}(1)$ (Theorem 8.3.1), $E_1(\mathbf{A})$ is a line. Each column of $\mathbf{\Pi}$ lies in $\operatorname{im}T_{\mathbf{\Pi}}=E_1(\mathbf{A})$ (Definition 0.9.9: column j is $\mathbf{\Pi}\mathbf{e}_j$) and is a probability vector, hence is fixed by $\mathbf{A}$ and is a steady state. Any two probability vectors on the same line are equal: if $\mathbf{w}=c\mathbf{v}$ with both entry sums equal to 1, then $1=c$. So all the columns of $\mathbf{\Pi}$ are one and the same steady state $\mathbf{v}$, and $E_1(\mathbf{A})=\operatorname{span}(\mathbf{v})$.

(c) All columns of $\mathbf{\Pi}$ equal $\mathbf{v}$, which is exactly the statement $\mathbf{\Pi}=\mathbf{v}\mathbf{1}^\top$. (Independently of (b), part (a) confirms it: $\mathbf{v}\mathbf{1}^\top$ fixes $\mathbf{v}$ because $\mathbf{1}^\top\mathbf{v}=1$, and kills every $\mathbf{w}\in G_\lambda(\mathbf{A})$ with $\lambda\neq 1$ because $\mathbf{1}^\top\mathbf{w}=0$; by Theorem 9.1.3 (a) those two conditions determine the projection onto $E_1(\mathbf{A})=G_1(\mathbf{A})$ along the rest, using $\dim G_1(\mathbf{A})=a_{\mathbf{A}}(1)=1=\dim E_1(\mathbf{A})$ and Theorem 1.6.8.) For a probability vector $\mathbf{x}_0$, each entry of $\mathbf{A}^m\mathbf{x}_0$ is a fixed linear combination of entries of $\mathbf{A}^m$, so by (B3)

$$\mathbf{A}^m\mathbf{x}_0\longrightarrow\mathbf{\Pi}\mathbf{x}_0=\mathbf{v}\,(\mathbf{1}^\top\mathbf{x}_0)=\mathbf{v}\,(x_{01}+\cdots+x_{0n})=\mathbf{v}.$$

No diagonalizability was used: the blocks for the eigenvalues $\lambda\neq 1$ may have any sizes, since Theorem 9.10.2 does not care. This removes the diagonalizability hypothesis from Theorem 8.11.4.

Chapter 10

Inner Product Spaces

Nine chapters have described vector spaces without measuring anything in them. We can say that a list spans, that a subspace has dimension four, that two matrices are similar; we cannot say that a vector has length 3, that two vectors are perpendicular, or that one vector is the closest point of a plane to another. Every picture in the book so far has secretly used lengths and angles that the theory did not supply. This chapter supplies them, with a single piece of extra structure: an **inner product**, abstracted from the dot product on $\mathbb{R}^n$ by keeping exactly the properties that make the law of cosines work.

The gain is out of all proportion to the cost. Length gives the Cauchy–Schwarz and triangle inequalities. Perpendicularity gives orthonormal bases, in which coordinates are read off by a single inner product and Gram–Schmidt produces one from any basis at all. Splitting a space into a subspace and its orthogonal complement gives the nearest point of a subspace to a given vector, and with it least squares, the standard answer to an inconsistent system. The Riesz representation theorem pays off a debt from Chapter 4: an inner product is precisely the extra data that makes V and V^* the same space. From Riesz comes the **adjoint** T^*, which turns the four fundamental subspaces into two orthogonal decompositions, and the isometries, which are the maps that preserve the whole geometry. The chapter ends with the computational and classical faces of the same ideas: the QR factorization, Fourier series and orthogonal polynomials. **Throughout, the field is $\mathbb{R}$ or $\mathbb{C}$**, because the construction needs both an ordering, so that a length squared can be positive, and complex conjugation, so that it can be real.

What you need. From Chapter 0, the complex conjugate and modulus with their arithmetic (Definition 0.6.2, Theorem 0.6.2) and the trace (Definition 0.9.12, Theorem 0.9.6). From Chapter 1, independence, bases, dimension, basis extension and direct sums (Definition 1.4.1, Theorem 1.6.4, Theorem 1.6.5, Theorem 1.7.4). From Chapter 2, the Invertible Matrix Theorem (Theorem 2.4.4). From Chapter 3, the matrix of a linear map, the coordinate isomorphism and Rank–Nullity (Definition 3.6.1, Corollary 3.5.5, Theorem 3.3.1). From Chapter 4, the dual space, the annihilator and the dual map, together with the warning that an isomorphism $V \cong V^*$ needs a choice (Definition 4.1.2, Definition 4.2.1, Definition 4.4.1, Theorem 4.4.2). From Chapter 5, the root bound and Lagrange interpolation (Corollary 5.1.4, Theorem 5.6.1). From Chapter 6, multiplicativity of the determinant and the non-negativity of Gram determinants (Theorem 6.5.4, Corollary 6.7.3). Chapter 8 is used only in examples and in one classification (Definition 8.2.1); nothing before Section 7 needs an eigenvalue.

10.0.1 Roadmap

- **Inner products and norms.** The axioms, abstracted from the dot product; length, orthogonality, Pythagoras, Cauchy–Schwarz and the triangle inequality.
- **Orthonormal bases and Gram–Schmidt.** Coordinates that cost one inner product each, the process that builds such a basis from any basis, and Gram matrices.
- **Orthogonal complements and projections.** The splitting $V = U \oplus U^{\perp}$, the projection P_U, and the fact that $P_U\mathbf{v}$ is the point of U nearest to $\mathbf{v}$.
- **Least squares and minimum-norm solutions.** What to do with an inconsistent system: the normal equations, and the smallest solution of an underdetermined one.
- **The Riesz representation theorem.** Every linear functional is an inner product with one fixed vector, which is the chosen isomorphism $V \cong V^*$ that Chapter 4 could not supply.
- **The adjoint.** Moving an operator to the other side of an inner product, the matrix $\mathbf{A}^*$, and the four fundamental subspaces in orthogonal form.
- **Isometries and unitary maps.** The maps that preserve all lengths, their many equivalent descriptions, and the classification of O(2).
- **QR, Householder and Hessenberg.** Gram–Schmidt as a matrix factorization, reflections that do the same job more robustly, and the first step of a serious eigenvalue algorithm.
- **Bessel, Parseval and Fourier series.** What an orthonormal list captures of a vector, and the classical Fourier coefficients as an instance.
- **Orthogonal polynomials.** Gram–Schmidt on $1, x, x^2, \ldots$, the three-term recurrence, real roots, and Gaussian quadrature.

10.0.2 Named moves

- **To show a vector is zero, pair it with itself.** Only $\mathbf{0}$ has $\langle \mathbf{z}, \mathbf{z} \rangle = 0$, so an identity of that form ends the argument.
- **To move T across an inner product, pay with T^*.** The adjoint is the price of the transfer, and most proofs about special operators compute one inner product in two ways.
- **Work with the norm squared, then expand.** Square roots do not expand; $\|\mathbf{u}+\mathbf{v}\|^2 = \langle \mathbf{u}+\mathbf{v}, \mathbf{u}+\mathbf{v} \rangle$ does.
- **Fix an orthonormal basis.** In its coordinates every inner product becomes the dot product, and an abstract statement becomes a matrix statement.
- **Project, then subtract.** The same move orthogonalizes a list (Gram–Schmidt), finds the nearest point of a subspace, and solves a least-squares problem.

10.1 Inner Products and Norms

Nine chapters, and we have not measured anything. We can say that a list is independent, that a subspace has dimension four, that an operator is diagonalizable. We cannot yet say that a vector has length 3, or that two vectors meet at a right angle. Geometry has appeared only in pictures, never in the theory. This section puts it into the theory, by abstracting the one operation in $\mathbb{R}^n$ that already computes lengths and angles: the dot product.

10.1.1 The field for this chapter

Throughout Chapter 10 the field F is $\mathbb{R}$ or $\mathbb{C}$. This is not laziness; two features of these fields are used on every page, and no other field has both.

The first is **positivity**. The point of the whole construction is that $\langle \mathbf{v}, \mathbf{v} \rangle$ should be the square of a length, so it must be a number we can compare with 0. Over $\mathbb{F}_p$ there is no ordering compatible with the arithmetic at all: in $\mathbb{F}_5$, adding 1 to itself five times returns to 0, so no non-zero element can be called "positive" in any useful sense. Over $\mathbb{Q}$ there is an ordering, but lengths would not exist, since $\sqrt{2} \notin \mathbb{Q}$. Over $\mathbb{R}$ every sum of squares is ≥ 0 and every non-negative number has a square root, and that is exactly what we need.

The second is **conjugation**. Over $\mathbb{C}$ the naive sum of squares fails immediately: $1^2 + i^2 = 0$, so "$z_1^2 + z_2^2$" is not a length for $(1, i) \neq \mathbf{0}$. The repair is to use $z\overline{z} = |z|^2$ instead of z^2 (Theorem 0.6.2 (c)), and this needs the complex conjugate. We write $\overline{a}$ for the conjugate of $a \in F$, with the convention that $\overline{a} = a$ when $F = \mathbb{R}$; every formula below then reads correctly over both fields at once.

10.1.2 From the dot product to the axioms

In $\mathbb{R}^n$ the dot product is

$$\mathbf{x} \cdot \mathbf{y} = x_1 y_1 + \cdots + x_n y_n.$$

It computes lengths, because $\mathbf{x} \cdot \mathbf{x} = x_1^2 + \cdots + x_n^2$ is the square of the Euclidean length by Pythagoras. It computes angles too. For non-zero $\mathbf{x}, \mathbf{y} \in \mathbb{R}^2$ at an angle θ, the law of cosines applied to the triangle with sides $\mathbf{x}$, $\mathbf{y}$ and $\mathbf{x} - \mathbf{y}$ says

$$\|\mathbf{x} - \mathbf{y}\|^2 = \|\mathbf{x}\|^2 + \|\mathbf{y}\|^2 - 2\|\mathbf{x}\|\|\mathbf{y}\| \cos\theta,$$

while expanding the left side entry by entry gives $\|\mathbf{x}\|^2 + \|\mathbf{y}\|^2 - 2(\mathbf{x} \cdot \mathbf{y})$. Comparing the two, $\mathbf{x} \cdot \mathbf{y} = \|\mathbf{x}\|\|\mathbf{y}\| \cos\theta$. So one bilinear expression carries both length and angle, and perpendicularity is the single equation $\mathbf{x} \cdot \mathbf{y} = 0$.

Which properties of the dot product did that argument use? Only three: it is linear in each slot separately, it is symmetric, and $\mathbf{x} \cdot \mathbf{x} > 0$ for $\mathbf{x} \neq \mathbf{0}$. Those three we can demand of an abstract space. Over $\mathbb{C}$, as we saw, symmetry has to be weakened to conjugate symmetry, and the price is small: a conjugate bar in the second slot.

An inner product is a way of multiplying two vectors into a scalar so that a vector paired with itself has positive "length squared".

Definition 10.1.1 — Inner Product

Let F be $\mathbb{R}$ or $\mathbb{C}$, and let V be a vector space **over** F. An **inner product** on V is a map

$$\langle \cdot, \cdot \rangle \colon V \times V \to F$$

such that for all $\mathbf{u}, \mathbf{v}, \mathbf{w} \in V$ and all $a, b \in F$:

(IP1) $\langle a\mathbf{u} + b\mathbf{v}, \mathbf{w} \rangle = a\langle \mathbf{u}, \mathbf{w} \rangle + b\langle \mathbf{v}, \mathbf{w} \rangle$ (**linear in the first slot**);

(IP2) $\langle \mathbf{v}, \mathbf{u} \rangle = \overline{\langle \mathbf{u}, \mathbf{v} \rangle}$ (**conjugate symmetry**);

(IP3) $\langle \mathbf{v}, \mathbf{v} \rangle > 0$ for **every non-zero** $\mathbf{v} \in V$ (**positive definiteness**).

A vector space equipped with an inner product is an **inner product space**. When $F = \mathbb{R}$ it is a **real** inner product space, when $F = \mathbb{C}$ a **complex** one.

In words, clause by clause. (IP1) says that if we freeze the second slot, what is left is a linear functional on V: the inner product distributes over sums and lets scalars out of the **first** argument untouched. (IP2) says that swapping the two arguments conjugates the answer; over $\mathbb{R}$ it is plain symmetry, $\langle \mathbf{v}, \mathbf{u} \rangle = \langle \mathbf{u}, \mathbf{v} \rangle$. (IP3) says that a non-zero vector pairs with itself to give a **strictly** positive number. For the inequality in (IP3) to mean anything, $\langle \mathbf{v}, \mathbf{v} \rangle$ must be a **real** number; it is, and the reason is (IP2), as the next result shows. Note also what (IP3) does **not** say: it says nothing about $\langle \mathbf{u}, \mathbf{v} \rangle$ for $\mathbf{u} \neq \mathbf{v}$, which may be negative, or not even real.

The first consequences are small, and we will use all of them constantly.

Theorem 10.1.1 — First Properties of an Inner Product

Let V be an inner product space over F. For all $\mathbf{u}, \mathbf{v}, \mathbf{w} \in V$ and $a, b \in F$:

(a) $\langle \mathbf{v}, \mathbf{v} \rangle$ is a **real** number, and $\langle \mathbf{v}, \mathbf{v} \rangle \geq 0$ with equality if and only if $\mathbf{v} = \mathbf{0}$;
(b) $\langle \mathbf{u}, a\mathbf{v} + b\mathbf{w} \rangle = \overline{a}\langle \mathbf{u}, \mathbf{v} \rangle + \overline{b}\langle \mathbf{u}, \mathbf{w} \rangle$ (**conjugate-linear in the second slot**);
(c) $\langle \mathbf{0}, \mathbf{v} \rangle = \langle \mathbf{v}, \mathbf{0} \rangle = 0$;
(d) if $\langle \mathbf{u}, \mathbf{w} \rangle = \langle \mathbf{v}, \mathbf{w} \rangle$ for **every** $\mathbf{w} \in V$, then $\mathbf{u} = \mathbf{v}$.

Idea. Each part is one application of an axiom. For (a), a number equal to its own conjugate is real. For (b), swap slots with (IP2), use (IP1), and swap back. For (d), the only vector orthogonal to everything is the zero vector, and we find that out by pairing the difference **with itself**: that is the move to remember.

Proof.

(a) By (IP2) with $\mathbf{u} = \mathbf{v}$, $\langle \mathbf{v}, \mathbf{v} \rangle = \overline{\langle \mathbf{v}, \mathbf{v} \rangle}$, and a complex number equal to its own conjugate has zero imaginary part, so $\langle \mathbf{v}, \mathbf{v} \rangle \in \mathbb{R}$. If $\mathbf{v} \neq \mathbf{0}$, then $\langle \mathbf{v}, \mathbf{v} \rangle > 0$ by (IP3). If $\mathbf{v} = \mathbf{0}$, then $\langle \mathbf{0}, \mathbf{0} \rangle = \langle 0 \cdot \mathbf{0}, \mathbf{0} \rangle = 0\langle \mathbf{0}, \mathbf{0} \rangle = 0$ by (IP1). Hence $\langle \mathbf{v}, \mathbf{v} \rangle \geq 0$ always, with equality exactly when $\mathbf{v} = \mathbf{0}$.

(b) Using (IP2), then (IP1), then (IP2) again,

$$\begin{aligned} \langle \mathbf{u}, a\mathbf{v} + b\mathbf{w} \rangle &= \overline{\langle a\mathbf{v} + b\mathbf{w}, \mathbf{u} \rangle} \\ &= \overline{a\langle \mathbf{v}, \mathbf{u} \rangle + b\langle \mathbf{w}, \mathbf{u} \rangle} \\ &= \overline{a}\,\overline{\langle \mathbf{v}, \mathbf{u} \rangle} + \overline{b}\,\overline{\langle \mathbf{w}, \mathbf{u} \rangle} \\ &= \overline{a}\langle \mathbf{u}, \mathbf{v} \rangle + \overline{b}\langle \mathbf{u}, \mathbf{w} \rangle, \end{aligned}$$

where the third equality uses Theorem 0.6.2 (a) and (b).

(c) $\langle \mathbf{0}, \mathbf{v} \rangle = \langle 0 \cdot \mathbf{0}, \mathbf{v} \rangle = 0\langle \mathbf{0}, \mathbf{v} \rangle = 0$ by (IP1), and $\langle \mathbf{v}, \mathbf{0} \rangle = \overline{\langle \mathbf{0}, \mathbf{v} \rangle} = 0$ by (IP2).

(d) Put $\mathbf{z} = \mathbf{u} - \mathbf{v}$. For every $\mathbf{w}$, (IP1) gives $\langle \mathbf{z}, \mathbf{w} \rangle = \langle \mathbf{u}, \mathbf{w} \rangle - \langle \mathbf{v}, \mathbf{w} \rangle = 0$. Take $\mathbf{w} = \mathbf{z}$: then $\langle \mathbf{z}, \mathbf{z} \rangle = 0$, so $\mathbf{z} = \mathbf{0}$ by (a), that is, $\mathbf{u} = \mathbf{v}$.

■

Part (d) is the first appearance of the move that runs through the whole chapter: **to show a**

vector is zero, pair it with itself. There is exactly one vector of length zero, so an identity of the form $\langle \mathbf{z}, \mathbf{z} \rangle = 0$ is a proof that $\mathbf{z} = \mathbf{0}$.

Part (b) is where the conjugate becomes visible in practice. An inner product over $\mathbb{C}$ is **not** bilinear: scalars leave the second slot wearing a bar. A map with properties (IP1) and (b) is called **sesquilinear**, from the Latin for "one and a half times linear".

10.1.3 Examples

The dot product on $\mathbb{R}^n$. Define $\langle \mathbf{x}, \mathbf{y} \rangle = x_1 y_1 + \cdots + x_n y_n$. (IP1) holds because each term is linear in x_i; (IP2) is the commutativity of multiplication in $\mathbb{R}$, and conjugation is the identity; (IP3) holds because $\langle \mathbf{x}, \mathbf{x} \rangle = x_1^2 + \cdots + x_n^2$ is a sum of squares of real numbers, which is 0 only when every $x_i = 0$. This is the **standard** inner product on $\mathbb{R}^n$, and it is the model for everything else.

The standard inner product on $\mathbb{C}^n$. Define

$$\langle \mathbf{x}, \mathbf{y} \rangle = x_1 \overline{y_1} + \cdots + x_n \overline{y_n}.$$

(IP1) is clear. For (IP2), $\overline{\langle \mathbf{x}, \mathbf{y} \rangle} = \sum \overline{x_i} y_i = \langle \mathbf{y}, \mathbf{x} \rangle$ by Theorem 0.6.2 (a), (b). For (IP3), $\langle \mathbf{x}, \mathbf{x} \rangle = \sum x_i \overline{x_i} = \sum |x_i|^2$ by Theorem 0.6.2 (c), a sum of non-negative **real** numbers, zero only when every $x_i = 0$. The conjugates are doing exactly one job: making the diagonal values real and non-negative.

Weighted inner products. Fix real numbers $w_1, \ldots, w_n > 0$ and put $\langle \mathbf{x}, \mathbf{y} \rangle = \sum_i w_i x_i \overline{y_i}$ on F^n. The same three checks go through, with $\langle \mathbf{x}, \mathbf{x} \rangle = \sum w_i |x_i|^2$; the weights must be **strictly** positive, or (IP3) fails for a standard basis vector. In the degenerate case $n = 1$ and $w_1 = 1$, this is $\langle x, y \rangle = x\overline{y}$ on F itself, the smallest non-zero inner product space there is. It matters because it is where the axioms are just the arithmetic of $|\cdot|$.

Continuous functions. Let $V = C[0,1]$ be the space of continuous functions $f\colon [0,1] \to F$, and set

$$\langle f, g \rangle = \int_0^1 f(t)\overline{g(t)}\,\mathrm{d}t.$$

(IP1) is linearity of the integral, and (IP2) follows because conjugation commutes with integration. For (IP3), $\langle f, f \rangle = \int_0^1 |f(t)|^2\,\mathrm{d}t \geq 0$, and we must rule out equality for $f \neq 0$. Here is the one fact from analysis we assume: if f is continuous and $f(c) \neq 0$ for some c, then $|f| \geq |f(c)|/2$ on some interval of positive length δ around c, so $\int_0^1 |f|^2 \geq \delta |f(c)|^2/4 > 0$. Continuity is not decoration; the non-example below shows what happens without it.

Matrices: the Frobenius inner product. First a piece of notation we will need all chapter.

Definition 10.1.2 — Conjugate Transpose

For $\mathbf{A} \in M_{m\times n}(F)$, the **conjugate transpose** $\mathbf{A}^* \in M_{n\times m}(F)$ is the matrix with entries $(\mathbf{A}^*)_{ij} = \overline{a_{ji}}$. A square matrix with $\mathbf{A}^* = \mathbf{A}$ is **Hermitian**.

Over $\mathbb{R}$, $\mathbf{A}^* = \mathbf{A}^\top$ and Hermitian means symmetric (Definition 0.9.11). Now on $V = M_{m\times n}(F)$ define

$$\langle \mathbf{A}, \mathbf{B} \rangle = \operatorname{tr}(\mathbf{B}^* \mathbf{A}).$$

Writing out the trace, $\operatorname{tr}(\mathbf{B}^*\mathbf{A}) = \sum_j \sum_i \overline{b_{ij}} a_{ij}$, so this is the standard inner product of F^{mn} after listing the entries in a column. In particular (IP1)–(IP3) hold, with $\langle \mathbf{A}, \mathbf{A} \rangle = \sum_{i,j} |a_{ij}|^2$. This is the **Frobenius inner product**; for $n = 1$ it is the standard inner product on F^m.

Polynomials sampled at nodes. Fix $n+1$ **distinct** scalars $c_0, \ldots, c_n \in F$ and define, on $V = F[x]_{\leq n}$,

$$\langle p, q \rangle = \sum_{i=0}^{n} p(c_i)\overline{q(c_i)}.$$

(IP1) and (IP2) hold because evaluation at c_i is linear (Theorem 0.8.5) and the standard inner product on F^{n+1} has them; indeed $\langle p, q \rangle$ is the standard inner product of the sample vectors $(p(c_0), \ldots, p(c_n))$ and $(q(c_0), \ldots, q(c_n))$. Positivity is the interesting clause. If $\langle p, p \rangle = \sum |p(c_i)|^2 = 0$, then p vanishes at all $n+1$ distinct nodes. A non-zero polynomial of degree at most n has at most n distinct roots (Corollary 5.1.4), so $p = 0$. The **number** of nodes is what makes this work, and the non-example below removes one.

10.1.4 Non-examples, by minimal change

Change a sign: the hyperbolic form on $\mathbb{R}^2$. Let $\beta(\mathbf{x}, \mathbf{y}) = x_1 y_1 - x_2 y_2$. Bilinearity survives, since each term is still linear in each slot, and so does symmetry. What fails is (IP3), and the witness is $\mathbf{e}_2$: $\beta(\mathbf{e}_2, \mathbf{e}_2) = -1 < 0$. The vector $(1, 1)$ is worse still: it is non-zero, yet $\beta((1,1),(1,1)) = 0$, so it would be a non-zero vector of length 0. Forms like β are useful (they are the subject of the chapter on bilinear forms), but they are not inner products.

Drop the conjugate on $\mathbb{C}^2$. Let $\langle \mathbf{u}, \mathbf{v} \rangle = \mathbf{u}^\top \mathbf{v} = u_1 v_1 + u_2 v_2$ on $\mathbb{C}^2$. This map is linear in **both** slots and symmetric, so it satisfies (IP1) and looks tidier than the standard product. Take $\mathbf{u} = (1, i)$. Then

$$\langle \mathbf{u}, \mathbf{u} \rangle = 1^2 + i^2 = 1 - 1 = 0,$$

with $\mathbf{u} \neq \mathbf{0}$. Clause (IP3) fails. This one example is the whole reason for the conjugate: over $\mathbb{C}$, sums of squares vanish on non-zero vectors, sums of squared **moduli** do not.

Enlarge the space: drop continuity. Keep the formula $\langle f, g \rangle = \int_0^1 fg$, but let V be all Riemann-integrable functions $[0, 1] \to \mathbb{R}$. Linearity and symmetry are untouched. Let f be 1 at $t = \frac{1}{2}$ and 0 elsewhere. It is integrable, non-zero as a function, and $\int_0^1 f^2 = 0$. Positivity fails, so $\langle \cdot, \cdot \rangle$ is only **positive semidefinite** here. There are two standard repairs: restrict to continuous functions, as above, or regard two functions as equal when they differ on a negligible set. We take the first, and every function space in this chapter will be a space of continuous functions.

Remove a node. On $\mathbb{R}[x]_{\leq 2}$, put $\langle p, q \rangle = p(0)q(0) + p(1)q(1)$: the node example with one node too few. Bilinearity and symmetry hold. But $p = x^2 - x$ is a non-zero polynomial of degree 2 with $p(0) = p(1) = 0$, so $\langle p, p \rangle = 0$. The clause that fails is (IP3), and it fails because two nodes cannot pin down a quadratic.

Why this definition. Each clause earns its place. Without (IP3) there can be non-zero vectors $\mathbf{v}$ with $\langle \mathbf{v}, \mathbf{v} \rangle = 0$, and the proof of Theorem 10.1.1 (d) breaks down, because pairing a vector with itself no longer detects zero. (The form $x_1 y_1 - x_2 y_2$ below shows that the conclusion of (d) may survive anyway; what is lost is the argument for it, and with it every later proof that runs through $\langle \mathbf{v}, \mathbf{v} \rangle = 0 \Rightarrow \mathbf{v} = \mathbf{0}$.) Without (IP2) the diagonal values need not be real, and "$\langle \mathbf{v}, \mathbf{v} \rangle > 0$" is meaningless. Linearity in the first slot rather than the second is a convention, but once chosen it must be kept: with (IP2) in place, linearity in one slot forces conjugate-linearity in the other, so a map cannot be linear in both unless $F = \mathbb{R}$.

Warning. **The conjugate goes in the second slot here, and books differ.** With our convention, $\langle a\mathbf{u}, \mathbf{v}\rangle = a\langle \mathbf{u}, \mathbf{v}\rangle$ and $\langle \mathbf{u}, a\mathbf{v}\rangle = \overline{a}\langle \mathbf{u}, \mathbf{v}\rangle$. Many books, especially in physics, put the conjugate in the first slot, so that their $\langle \mathbf{u}, \mathbf{v}\rangle$ is our $\langle \mathbf{v}, \mathbf{u}\rangle$. Every formula involving a lone conjugate then flips. When you read a formula elsewhere, check the convention first; when you write one, say which you use.

Quick check. Is $\langle \mathbf{x}, \mathbf{y}\rangle = x_1y_1 + x_2y_2 + x_1y_2$ an inner product on $\mathbb{R}^2$? If not, name the clause that fails and give a witness.

Solution. No. It is bilinear, and $\langle \mathbf{x}, \mathbf{x}\rangle = x_1^2 + x_2^2 + x_1x_2 = (x_1 + \tfrac{1}{2}x_2)^2 + \tfrac{3}{4}x_2^2 > 0$ for $\mathbf{x} \neq \mathbf{0}$, so (IP1) and (IP3) both hold. The clause that fails is (IP2): with $\mathbf{u} = \mathbf{e}_1$ and $\mathbf{v} = \mathbf{e}_2$ we get $\langle \mathbf{u}, \mathbf{v}\rangle = 1$ but $\langle \mathbf{v}, \mathbf{u}\rangle = 0$. Symmetrizing the cross term, to $x_1y_1 + x_2y_2 + \tfrac{1}{2}(x_1y_2 + x_2y_1)$, repairs it.

10.1.5 Norms

By Theorem 10.1.1 (a), the number $\langle \mathbf{v}, \mathbf{v}\rangle$ is real and ≥ 0, so it has a unique non-negative real square root. That square root is the length we were after.

Definition 10.1.3 — Induced Norm

Let V be an inner product space. The **norm** of $\mathbf{v} \in V$ is

$$\|\mathbf{v}\| \coloneqq \sqrt{\langle \mathbf{v}, \mathbf{v}\rangle},$$

the **non-negative** real square root. A vector with $\|\mathbf{v}\| = 1$ is a **unit vector**, and replacing a non-zero $\mathbf{v}$ by $\mathbf{v}/\|\mathbf{v}\|$ is called **normalizing** it.

On $\mathbb{R}^n$ with the dot product this is the Euclidean length $\sqrt{x_1^2 + \cdots + x_n^2}$, and on $\mathbb{C}^n$ it is $\sqrt{\sum |x_i|^2}$. On $C[0,1]$ it is $\left(\int_0^1 |f|^2\right)^{1/2}$, and on matrices it is the **Frobenius norm** $\left(\sum |a_{ij}|^2\right)^{1/2}$. By definition $\|\mathbf{v}\|^2 = \langle \mathbf{v}, \mathbf{v}\rangle$ always, and this identity, read from right to left, is the most-used step in the chapter: **work with the norm squared, then expand.**

Theorem 10.1.2 — Properties of the Induced Norm

Let V be an inner product space over F, $\mathbf{u}, \mathbf{v} \in V$ and $c \in F$. Then:

(a) $\|\mathbf{v}\| \geq 0$, with $\|\mathbf{v}\| = 0$ if and only if $\mathbf{v} = \mathbf{0}$;
(b) $\|c\mathbf{v}\| = |c|\|\mathbf{v}\|$;
(c) $\|\mathbf{u} + \mathbf{v}\|^2 = \|\mathbf{u}\|^2 + 2\,\mathrm{Re}\langle \mathbf{u}, \mathbf{v}\rangle + \|\mathbf{v}\|^2$.

Proof.

(a) Immediate from Theorem 10.1.1 (a) and the fact that a non-negative real number has square root 0 only when it is 0.

(b) By (IP1) and Theorem 10.1.1 (b), $\langle c\mathbf{v}, c\mathbf{v}\rangle = c\overline{c}\langle \mathbf{v}, \mathbf{v}\rangle = |c|^2\|\mathbf{v}\|^2$ using Theorem 0.6.2 (c). Taking non-negative square roots gives $\|c\mathbf{v}\| = |c|\|\mathbf{v}\|$, since $|c| \geq 0$.

(c) Expand one slot at a time, by (IP1) and then Theorem 10.1.1 (b):

$$\begin{aligned}\|\mathbf{u}+\mathbf{v}\|^2 &= \langle \mathbf{u}+\mathbf{v}, \mathbf{u}+\mathbf{v}\rangle \\ &= \langle \mathbf{u},\mathbf{u}\rangle + \langle \mathbf{u},\mathbf{v}\rangle + \langle \mathbf{v},\mathbf{u}\rangle + \langle \mathbf{v},\mathbf{v}\rangle.\end{aligned}$$

By (IP2), $\langle \mathbf{v},\mathbf{u}\rangle = \overline{\langle \mathbf{u},\mathbf{v}\rangle}$, and $z+\overline{z} = 2\operatorname{Re} z$ by Theorem 0.6.2 (c). This gives the stated identity.

■

Part (c) is the workhorse. Over $\mathbb{R}$ the middle term is just $2\langle \mathbf{u},\mathbf{v}\rangle$, and the identity is the familiar $(a+b)^2 = a^2+2ab+b^2$ for vectors. Replacing $\mathbf{v}$ by $-\mathbf{v}$ gives $\|\mathbf{u}-\mathbf{v}\|^2 = \|\mathbf{u}\|^2 - 2\operatorname{Re}\langle \mathbf{u},\mathbf{v}\rangle + \|\mathbf{v}\|^2$, and adding the two versions gives the **parallelogram law**

$$\|\mathbf{u}+\mathbf{v}\|^2 + \|\mathbf{u}-\mathbf{v}\|^2 = 2\|\mathbf{u}\|^2 + 2\|\mathbf{v}\|^2. \tag{$*$}$$

We return to $(*)$ in the last warning of this section.

Warning. **A squared norm is real and non-negative, never complex.** If a computation in a complex space produces $\|\mathbf{v}\|^2 = 2i$, or a negative number, something has gone wrong — most often a missing conjugate. For $\mathbf{v} = (1, i) \in \mathbb{C}^2$, the correct value is $\|\mathbf{v}\|^2 = |1|^2 + |i|^2 = 2$, while the conjugate-free expression $\mathbf{v}^{\top}\mathbf{v}$ gives 0. Use the answer as a check on the work.

10.1.6 Orthogonality and Pythagoras

With a norm in hand, the special relation $\langle \mathbf{u},\mathbf{v}\rangle = 0$ deserves its name.

Definition 10.1.4 — Orthogonal Vectors

Let V be an inner product space. Vectors $\mathbf{u},\mathbf{v} \in V$ are **orthogonal**, written $\mathbf{u} \perp \mathbf{v}$, if $\langle \mathbf{u},\mathbf{v}\rangle = 0$. A list $(\mathbf{v}_1,\dots,\mathbf{v}_k)$ is **orthogonal** if $\mathbf{v}_i \perp \mathbf{v}_j$ whenever $i \neq j$.

The relation is symmetric: $\langle \mathbf{u},\mathbf{v}\rangle = 0$ if and only if $\langle \mathbf{v},\mathbf{u}\rangle = \overline{\langle \mathbf{u},\mathbf{v}\rangle} = 0$, so "$\mathbf{u} \perp \mathbf{v}$" needs no order. The zero vector is orthogonal to everything (Theorem 10.1.1 (c)), and by part (a) of the same result it is the **only** vector orthogonal to itself. In $\mathbb{R}^n$ this is perpendicularity in the usual sense, by the law of cosines computation above: $\cos\theta = 0$ exactly when $\mathbf{x}\cdot\mathbf{y} = 0$. In $\mathbb{C}^2$, the vectors $(1, i)$ and $(1, -i)$ are orthogonal, since $1\cdot\overline{1} + i\cdot\overline{(-i)} = 1 + i\cdot i = 0$.

Theorem 10.1.3 — Pythagorean Theorem

Let $(\mathbf{v}_1,\dots,\mathbf{v}_k)$ be an orthogonal list in an inner product space. Then

$$\|\mathbf{v}_1 + \cdots + \mathbf{v}_k\|^2 = \|\mathbf{v}_1\|^2 + \cdots + \|\mathbf{v}_k\|^2.$$

Proof. Expand the left side by (IP1) and Theorem 10.1.1 (b):

$$\Big\langle \sum_i \mathbf{v}_i,\ \sum_j \mathbf{v}_j \Big\rangle = \sum_i \sum_j \langle \mathbf{v}_i, \mathbf{v}_j\rangle.$$

Every term with $i \neq j$ is 0, because the list is orthogonal. What survives is $\sum_i \langle \mathbf{v}_i, \mathbf{v}_i \rangle = \sum_i \|\mathbf{v}_i\|^2$, as claimed.

■

So orthogonality is exactly the condition under which squared lengths add. This is why the relation is worth naming, and why the rest of the chapter works so hard to produce orthogonal vectors.

Warning. **Over $\mathbb{C}$, the converse of Pythagoras fails.** By Theorem 10.1.2 (c), $\|\mathbf{u}+\mathbf{v}\|^2 = \|\mathbf{u}\|^2 + \|\mathbf{v}\|^2$ says only that $\mathrm{Re}\langle \mathbf{u}, \mathbf{v} \rangle = 0$, not that $\langle \mathbf{u}, \mathbf{v} \rangle = 0$. In $\mathbb{C}$ with $\langle z, w \rangle = z\overline{w}$, take $\mathbf{u} = 1$ and $\mathbf{v} = i$: then $\langle \mathbf{u}, \mathbf{v} \rangle = \bar{i} = -i \neq 0$, yet $\|1+i\|^2 = 2 = \|1\|^2 + \|i\|^2$. Over $\mathbb{R}$ the converse does hold, since there Re does nothing.

Theorem 10.1.4 — Orthogonal Non-zero Vectors Are Independent

Let $(\mathbf{v}_1, \ldots, \mathbf{v}_k)$ be an orthogonal list of **non-zero** vectors in an inner product space. Then the list is linearly independent.

Idea. Start a dependence relation in the standard way, and then do the one thing an inner product allows: pair the relation with a single $\mathbf{v}_j$. Orthogonality kills every term except the j-th, and what is left is $a_j\|\mathbf{v}_j\|^2 = 0$ with $\|\mathbf{v}_j\| \neq 0$.

Proof. Let $a_1\mathbf{v}_1 + \cdots + a_k\mathbf{v}_k = \mathbf{0}$ with $a_1, \ldots, a_k \in F$. Fix j and take the inner product of both sides with $\mathbf{v}_j$. By (IP1) and Theorem 10.1.1 (c),

$$0 = \Big\langle \sum_i a_i \mathbf{v}_i,\ \mathbf{v}_j \Big\rangle = \sum_i a_i \langle \mathbf{v}_i, \mathbf{v}_j \rangle = a_j \|\mathbf{v}_j\|^2,$$

where the last equality holds because $\langle \mathbf{v}_i, \mathbf{v}_j \rangle = 0$ for $i \neq j$. Since $\mathbf{v}_j \neq \mathbf{0}$, Theorem 10.1.1 (a) gives $\|\mathbf{v}_j\|^2 > 0$, so $a_j = 0$. As j was arbitrary, all the coefficients vanish, and the list is linearly independent by Definition 1.4.1.

■

The hypothesis "non-zero" cannot be dropped: the list $(\mathbf{e}_1, \mathbf{0})$ is orthogonal and dependent. With it, the result is a free supply of independent lists, and this is what makes the next section possible.

10.1.7 The Cauchy–Schwarz inequality

Angles came from the formula $\cos\theta = (\mathbf{x}\cdot\mathbf{y})/(\|\mathbf{x}\|\|\mathbf{y}\|)$. To define an angle by that formula in an abstract space, we must know that the right-hand side lies in $[-1, 1]$. That is exactly the following inequality, the most used inequality in the subject.

Theorem 10.1.5 — Cauchy–Schwarz Inequality

Let V be an inner product space and $\mathbf{u}, \mathbf{v} \in V$. Then

$$|\langle \mathbf{u}, \mathbf{v} \rangle| \leq \|\mathbf{u}\| \, \|\mathbf{v}\|,$$

with equality if and only if the list $(\mathbf{u}, \mathbf{v})$ is linearly dependent.

Idea. Picture $\mathbf{u}$ and $\mathbf{v}$ in $\mathbb{R}^2$. Drop a perpendicular from the tip of $\mathbf{u}$ onto the line through $\mathbf{v}$. The foot of the perpendicular is a multiple $c\mathbf{v}$, and the two legs $c\mathbf{v}$ and $\mathbf{u} - c\mathbf{v}$ of the resulting right triangle have squared lengths adding to $\|\mathbf{u}\|^2$. Since one leg has squared length $|\langle \mathbf{u}, \mathbf{v} \rangle|^2 / \|\mathbf{v}\|^2$, the inequality is just "a leg is no longer than the hypotenuse", and equality means the other leg is $\mathbf{0}$. The picture proves nothing in an abstract space, so we check algebraically that $\mathbf{u} - c\mathbf{v} \perp \mathbf{v}$ for the right c, and then let Pythagoras do the work.

Proof. If $\mathbf{v} = \mathbf{0}$, both sides are 0 by Theorem 10.1.1 (c), and $(\mathbf{u}, \mathbf{0})$ is dependent, so the statement holds. Suppose $\mathbf{v} \neq \mathbf{0}$, so $\|\mathbf{v}\| > 0$, and put

$$c = \frac{\langle \mathbf{u}, \mathbf{v} \rangle}{\|\mathbf{v}\|^2}, \qquad \mathbf{z} = \mathbf{u} - c\mathbf{v}.$$

Then $\mathbf{z} \perp \mathbf{v}$, since by (IP1)

$$\langle \mathbf{z}, \mathbf{v} \rangle = \langle \mathbf{u}, \mathbf{v} \rangle - c\langle \mathbf{v}, \mathbf{v} \rangle = \langle \mathbf{u}, \mathbf{v} \rangle - \langle \mathbf{u}, \mathbf{v} \rangle = 0,$$

and hence also $\mathbf{z} \perp c\mathbf{v}$. Now $\mathbf{u} = \mathbf{z} + c\mathbf{v}$ is a sum of two orthogonal vectors, so Theorem 10.1.3 and Theorem 10.1.2 (b) give

$$\|\mathbf{u}\|^2 = \|\mathbf{z}\|^2 + |c|^2 \|\mathbf{v}\|^2 = \|\mathbf{z}\|^2 + \frac{|\langle \mathbf{u}, \mathbf{v} \rangle|^2}{\|\mathbf{v}\|^2}. \tag{$\dagger$}$$

Since $\|\mathbf{z}\|^2 \geq 0$, dropping it gives $\|\mathbf{u}\|^2 \|\mathbf{v}\|^2 \geq |\langle \mathbf{u}, \mathbf{v} \rangle|^2$, and taking non-negative square roots proves the inequality.

Equality holds in ($\dagger$) exactly when $\|\mathbf{z}\| = 0$, that is (Theorem 10.1.2 (a)) exactly when $\mathbf{u} = c\mathbf{v}$. If $\mathbf{u} = c\mathbf{v}$, the list $(\mathbf{u}, \mathbf{v})$ is dependent. Conversely, suppose $(\mathbf{u}, \mathbf{v})$ is dependent, say $a\mathbf{u} + b\mathbf{v} = \mathbf{0}$ with a, b not both 0. Here $a \neq 0$, since $a = 0$ would give $b\mathbf{v} = \mathbf{0}$ with $b \neq 0$ and hence $\mathbf{v} = \mathbf{0}$, which we have excluded. So $\mathbf{u} = d\mathbf{v}$ with $d = -b/a$, and then $c = d\langle \mathbf{v}, \mathbf{v} \rangle / \|\mathbf{v}\|^2 = d$, so $\mathbf{z} = \mathbf{0}$. This proves the equality case.

■

The proof is worth rereading for its shape: the vector $\mathbf{z}$ was **found** from a picture and then **checked** from the axioms. That is the standard way to work in an abstract inner product space.

Corollary 10.1.6 — Triangle Inequality

Let V be an inner product space and $\mathbf{u}, \mathbf{v} \in V$. Then

$$\|\mathbf{u} + \mathbf{v}\| \leq \|\mathbf{u}\| + \|\mathbf{v}\|.$$

Proof. For any complex number z we have $\operatorname{Re} z \leq |z|$, as in the proof of Theorem 0.6.4.

Hence, by Theorem 10.1.2 (c) and then Theorem 10.1.5,

$$\begin{aligned}\|\mathbf{u}+\mathbf{v}\|^2 &= \|\mathbf{u}\|^2 + 2\,\mathrm{Re}\langle \mathbf{u},\mathbf{v}\rangle + \|\mathbf{v}\|^2 \\ &\le \|\mathbf{u}\|^2 + 2|\langle \mathbf{u},\mathbf{v}\rangle| + \|\mathbf{v}\|^2 \\ &\le \|\mathbf{u}\|^2 + 2\|\mathbf{u}\|\|\mathbf{v}\| + \|\mathbf{v}\|^2 \\ &= \big(\|\mathbf{u}\| + \|\mathbf{v}\|\big)^2.\end{aligned}$$

Both $\|\mathbf{u}+\mathbf{v}\|$ and $\|\mathbf{u}\|+\|\mathbf{v}\|$ are ≥ 0, so taking square roots preserves the inequality.

■

Together, Theorem 10.1.2 (a), (b) and Corollary 10.1.6 say that $\|\cdot\|$ is a **norm** in the general sense studied in Chapter 15. Chapter 15 also shows that not every norm arises from an inner product; the last warning of this section explains how to tell.

Definition 10.1.5 — Angle Between Vectors

Let V be a **real** inner product space and let $\mathbf{u},\mathbf{v}\in V$ be **non-zero**. The **angle** between $\mathbf{u}$ and $\mathbf{v}$ is the unique $\theta\in[0,\pi]$ with

$$\cos\theta = \frac{\langle \mathbf{u},\mathbf{v}\rangle}{\|\mathbf{u}\|\,\|\mathbf{v}\|}.$$

The definition needs Theorem 10.1.5 twice over. Cauchy–Schwarz says the quotient has absolute value at most 1, so it lies in $[-1,1]$; and cos is a strictly decreasing bijection from $[0,\pi]$ onto $[-1,1]$, so exactly one θ qualifies. Without the inequality the formula could ask for the angle whose cosine is 7. Note also that $\theta=\pi/2$ if and only if $\langle \mathbf{u},\mathbf{v}\rangle=0$, so the definition is consistent with Definition 10.1.4.

Over $\mathbb{C}$ there is no angle, because $\langle \mathbf{u},\mathbf{v}\rangle$ is not real. The quantity $|\langle \mathbf{u},\mathbf{v}\rangle|/(\|\mathbf{u}\|\|\mathbf{v}\|)\in[0,1]$ still makes sense, and it still measures how far the two vectors are from being orthogonal.

Example. (Three Angles)

Compute the angle between $\mathbf{u}=(1,1,0)$ and $\mathbf{v}=(1,0,1)$ in $\mathbb{R}^3$ with the dot product; between $p=1$ and $q=x$ in $\mathbb{R}[x]_{\le 1}$ with $\langle p,q\rangle=\int_0^1 pq$; and between $\mathbf{A}=\begin{pmatrix}1&1\\1&1\end{pmatrix}$ and $\mathbf{B}=\begin{pmatrix}1&-1\\1&-1\end{pmatrix}$ in $M_2(\mathbb{R})$ with the Frobenius inner product.

Solution. In $\mathbb{R}^3$: $\langle \mathbf{u},\mathbf{v}\rangle=1$, $\|\mathbf{u}\|=\|\mathbf{v}\|=\sqrt{2}$, so $\cos\theta=1/2$ and $\theta=\pi/3$.

In $\mathbb{R}[x]_{\le 1}$: $\langle 1,x\rangle=\int_0^1 t\,dt=\tfrac12$, $\|1\|^2=\int_0^1 1=1$ and $\|x\|^2=\int_0^1 t^2\,dt=\tfrac13$. Hence

$$\cos\theta=\frac{1/2}{1\cdot 1/\sqrt{3}}=\frac{\sqrt{3}}{2},$$

so $\theta=\pi/6$. The constant 1 and the function x are far from orthogonal on $[0,1]$, which is believable: both are positive there.

In $M_2(\mathbb{R})$: $\langle \mathbf{A}, \mathbf{B} \rangle = 1-1+1-1 = 0$, so $\theta = \pi/2$. The two matrices are orthogonal, with $\|\mathbf{A}\| = \|\mathbf{B}\| = 2$. As a check on Pythagoras, $\mathbf{A}+\mathbf{B} = \begin{pmatrix} 2 & 0 \\ 2 & 0 \end{pmatrix}$ has $\|\mathbf{A}+\mathbf{B}\|^2 = 8 = 4+4$.

Quick check. In $\mathbb{C}^2$ with the standard inner product, compute $\langle (1,i), (1,1) \rangle$ and $\langle (1,1), (1,i) \rangle$. Check the answers against (IP2), and against Cauchy–Schwarz.

Solution. $\langle (1,i), (1,1) \rangle = 1 \cdot \overline{1} + i \cdot \overline{1} = 1+i$, and $\langle (1,1), (1,i) \rangle = 1 \cdot \overline{1} + 1 \cdot \overline{i} = 1-i$. They are conjugates, as (IP2) requires. For Cauchy–Schwarz, $|1+i| = \sqrt{2}$, while $\|(1,i)\| = \sqrt{2}$ and $\|(1,1)\| = \sqrt{2}$, so the inequality reads $\sqrt{2} \leq 2$. It is strict, which is right: $(1,i)$ and $(1,1)$ are independent.

Warning. **Not every norm comes from an inner product.** A function $\|\cdot\|$ can satisfy positivity, homogeneity and the inequality of Corollary 10.1.6 without being $\sqrt{\langle \mathbf{v}, \mathbf{v} \rangle}$ for any inner product. The test is the parallelogram law $(*)$: every induced norm satisfies it, as we derived from Theorem 10.1.2 (c), so a norm that violates it is induced by nothing. Take $\|\mathbf{x}\|_\infty = \max(|x_1|, |x_2|)$ on $\mathbb{R}^2$ with $\mathbf{u} = \mathbf{e}_1$, $\mathbf{v} = \mathbf{e}_2$. Then $\|\mathbf{u}+\mathbf{v}\|_\infty = \|\mathbf{u}-\mathbf{v}\|_\infty = 1$, so the left side of $(*)$ is 2, while the right side is 4. Remarkably, the law is not only necessary but sufficient; Exercise (C1: The parallelogram law characterizes inner-product norms) proves the substance of that in $\mathbb{R}^2$, and Chapter 15 takes up general norms.

10.1.8 Exercises

10.1.8.1 A. Check your understanding

Exercise A1.

(a) State the three axioms of an inner product on a vector space over $F = \mathbb{R}$ or $\mathbb{C}$, and say in which slot the map is linear.

(b) Why must the field be $\mathbb{R}$ or $\mathbb{C}$? Name the two features used.

(c) Explain why $\langle \mathbf{v}, \mathbf{v} \rangle$ is always a real number.

(d) True or false: an inner product on a complex space is linear in the second slot. Justify your answer.

(e) State the Cauchy–Schwarz inequality, its equality case, and one place where the equality case is used.

(f) True or false: if $\|\mathbf{u}+\mathbf{v}\|^2 = \|\mathbf{u}\|^2 + \|\mathbf{v}\|^2$ in a complex inner product space, then $\mathbf{u} \perp \mathbf{v}$. Justify your answer.

Solution.

(a) (IP1) $\langle a\mathbf{u}+b\mathbf{v}, \mathbf{w} \rangle = a\langle \mathbf{u}, \mathbf{w} \rangle + b\langle \mathbf{v}, \mathbf{w} \rangle$; (IP2) $\langle \mathbf{v}, \mathbf{u} \rangle = \overline{\langle \mathbf{u}, \mathbf{v} \rangle}$; (IP3) $\langle \mathbf{v}, \mathbf{v} \rangle > 0$ for $\mathbf{v} \neq \mathbf{0}$ (Definition 10.1.1). It is linear in the **first** slot.

(b) Positivity, so that $\langle \mathbf{v}, \mathbf{v} \rangle > 0$ has meaning and square roots exist, and conjugation, so that $\langle \mathbf{v}, \mathbf{v} \rangle$ is real and non-negative over $\mathbb{C}$.

(c) By (IP2) with $\mathbf{u} = \mathbf{v}$, the number equals its own conjugate, so its imaginary part is 0 (Theorem 10.1.1 (a)).

(d) False. It is **conjugate**-linear in the second slot: $\langle \mathbf{u}, a\mathbf{v}\rangle = \overline{a}\langle \mathbf{u}, \mathbf{v}\rangle$ (Theorem 10.1.1 (b)). For example, in $\mathbb{C}$ with $\langle z, w\rangle = z\overline{w}$, $\langle 1, i\rangle = -i$ while $i\langle 1, 1\rangle = i$.

(e) $|\langle \mathbf{u}, \mathbf{v}\rangle| \leq \|\mathbf{u}\|\|\mathbf{v}\|$, with equality if and only if $(\mathbf{u}, \mathbf{v})$ is dependent (Theorem 10.1.5). The inequality is what makes Definition 10.1.5 well posed: it puts the quotient $\langle \mathbf{u}, \mathbf{v}\rangle/(\|\mathbf{u}\|\|\mathbf{v}\|)$ inside $[-1, 1]$, where arccos is defined. The equality case then says which vectors sit at the ends of that interval: $\cos\theta = \pm 1$ exactly for dependent pairs, that is, $\theta = 0$ or $\theta = \pi$.

(f) False. It says only $\mathrm{Re}\langle \mathbf{u}, \mathbf{v}\rangle = 0$. In $\mathbb{C}$ with $\langle z, w\rangle = z\overline{w}$, take $\mathbf{u} = 1$, $\mathbf{v} = i$: then $\langle \mathbf{u}, \mathbf{v}\rangle = -i \neq 0$ but $\|1 + i\|^2 = 2 = 1 + 1$.

10.1.8.2 B. Practice

Exercise B1: Determine which are inner products.

Determine which of the following are inner products on the stated space. For those that are, verify the axioms; for those that are not, name the clause that fails and give an explicit witness.

(a) On $\mathbb{R}^2$: $\langle \mathbf{x}, \mathbf{y}\rangle = x_1y_1 + 3x_2y_2$.

(b) On $\mathbb{R}^2$: $\langle \mathbf{x}, \mathbf{y}\rangle = x_1y_1 + x_1y_2 + x_2y_1 + 2x_2y_2$.

(c) On $\mathbb{C}^2$: $\langle \mathbf{x}, \mathbf{y}\rangle = x_1\overline{y_1} + x_2y_2$.

(d) On $M_2(\mathbb{R})$: $\langle \mathbf{A}, \mathbf{B}\rangle = \mathrm{tr}(\mathbf{AB})$.

(e) On $\mathbb{R}[x]_{\leq 2}$: $\langle p, q\rangle = p(0)q(0) + p(1)q(1) + p(2)q(2)$.

Solution.

(a) An inner product: it is the weighted product with weights $1, 3 > 0$. Bilinearity and symmetry are clear, and $\langle \mathbf{x}, \mathbf{x}\rangle = x_1^2 + 3x_2^2 = 0$ forces $x_1 = x_2 = 0$.

(b) An inner product. It is bilinear term by term, and symmetric because the two cross terms are interchanged by swapping $\mathbf{x}$ and $\mathbf{y}$. For positivity, complete the square:

$$\langle \mathbf{x}, \mathbf{x}\rangle = x_1^2 + 2x_1x_2 + 2x_2^2 = (x_1 + x_2)^2 + x_2^2,$$

which is 0 only if $x_2 = 0$ and $x_1 + x_2 = 0$, that is $\mathbf{x} = \mathbf{0}$.

(c) Not an inner product. (IP2) fails: with $\mathbf{x} = (0, 1)$ and $\mathbf{y} = (0, i)$ we get $\langle \mathbf{x}, \mathbf{y}\rangle = i$ and $\langle \mathbf{y}, \mathbf{x}\rangle = i$, while (IP2) would require $\langle \mathbf{y}, \mathbf{x}\rangle = \overline{i} = -i$. Positivity fails too, at $\mathbf{x} = (0, i)$: $\langle \mathbf{x}, \mathbf{x}\rangle = i^2 = -1$.

(d) Not an inner product. It is bilinear, and symmetric by Theorem 0.9.6 (3). But (IP3) fails for $\mathbf{N} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} \neq 0$, since $\mathbf{N}^2 = 0$ and so $\langle \mathbf{N}, \mathbf{N}\rangle = \mathrm{tr}(\mathbf{N}^2) = 0$. Replacing $\mathrm{tr}(\mathbf{AB})$ by $\mathrm{tr}(\mathbf{B}^\top\mathbf{A})$ repairs it: that is the Frobenius inner product.

(e) An inner product: the node example with the three distinct nodes $0, 1, 2$ on $\mathbb{R}[x]_{\leq 2}$. Bilinearity and symmetry come from linearity of evaluation. If $\langle p, p\rangle = p(0)^2 + p(1)^2 + p(2)^2 = 0$, then p has three distinct roots and degree at most 2, so $p = 0$ by Corollary 5.1.4.

Exercise B2: Norms and angles.

(a) In $\mathbb{R}^3$ with the dot product, find $\|\mathbf{u}\|$, $\|\mathbf{v}\|$ and the cosine of the angle between $\mathbf{u} = (1, 2, 2)$ and $\mathbf{v} = (2, -1, 2)$.

(b) In $\mathbb{R}[x]_{\le 2}$ with $\langle p, q\rangle = \int_{-1}^{1} pq$, compute $\|1\|$, $\|x\|$ and $\langle 1, x\rangle$. What is the angle between 1 and x?

(c) In $M_2(\mathbb{C})$ with the Frobenius inner product, compute $\|\mathbf{A}\|$ for $\mathbf{A} = \begin{pmatrix} 1 & i \\ 0 & 1+i \end{pmatrix}$.

Solution.

(a) $\|\mathbf{u}\| = \sqrt{1+4+4} = 3$ and $\|\mathbf{v}\| = \sqrt{4+1+4} = 3$. Also $\langle \mathbf{u}, \mathbf{v}\rangle = 2 - 2 + 4 = 4$, so $\cos\theta = 4/9$. Cauchy–Schwarz reads $4 \le 9$, and it is strict, as it must be for an independent pair.

(b) $\|1\|^2 = \int_{-1}^{1} 1\,dt = 2$, so $\|1\| = \sqrt{2}$; $\|x\|^2 = \int_{-1}^{1} t^2\,dt = \frac{2}{3}$, so $\|x\| = \sqrt{2/3}$; and $\langle 1, x\rangle = \int_{-1}^{1} t\,dt = 0$. The angle is $\pi/2$: on a symmetric interval, the constants are orthogonal to the odd functions. Compare this with Example (Three Angles), where the interval $[0, 1]$ gave the angle $\pi/6$ instead. **The geometry depends on the inner product, not only on the vectors.**

(c) $\|\mathbf{A}\|^2 = |1|^2 + |i|^2 + 0 + |1+i|^2 = 1 + 1 + 2 = 4$, so $\|\mathbf{A}\| = 2$.

Exercise B3: Cauchy–Schwarz, concretely.

(a) Verify Theorem 10.1.5 for $\mathbf{a} = (1, 2, 3)$ and $\mathbf{b} = (3, 2, 1)$ in $\mathbb{R}^3$ with the dot product, and say whether the inequality is strict.

(b) Deduce from Theorem 10.1.5 the classical inequality

$$\Big(\sum_{i=1}^{n} a_i b_i\Big)^2 \le \Big(\sum_{i=1}^{n} a_i^2\Big)\Big(\sum_{i=1}^{n} b_i^2\Big)$$

for all real a_i, b_i.

(c) Hence show that $(a_1 + \cdots + a_n)^2 \le n(a_1^2 + \cdots + a_n^2)$ for all real a_i.

Solution.

(a) $\langle \mathbf{a}, \mathbf{b}\rangle = 3 + 4 + 3 = 10$, so $|\langle \mathbf{a}, \mathbf{b}\rangle|^2 = 100$, while $\|\mathbf{a}\|^2\|\mathbf{b}\|^2 = 14 \cdot 14 = 196$. So $10 \le 14$, strictly. It must be strict, since $\mathbf{a}$ and $\mathbf{b}$ are not multiples of each other.

(b) Apply Theorem 10.1.5 on $\mathbb{R}^n$ with the dot product to $\mathbf{a} = (a_1, \dots, a_n)$ and $\mathbf{b} = (b_1, \dots, b_n)$. Then $\langle \mathbf{a}, \mathbf{b}\rangle = \sum a_i b_i$, $\|\mathbf{a}\|^2 = \sum a_i^2$ and $\|\mathbf{b}\|^2 = \sum b_i^2$, and squaring the inequality $|\langle \mathbf{a}, \mathbf{b}\rangle| \le \|\mathbf{a}\|\|\mathbf{b}\|$ gives the claim.

(c) Take $b_i = 1$ for all i in (b). Then $\sum a_i b_i = \sum a_i$ and $\sum b_i^2 = n$, so $(\sum a_i)^2 \le n \sum a_i^2$. Equality holds exactly when $\mathbf{a}$ is a multiple of $(1, \dots, 1)$, that is, when all the a_i are equal.

Exercise B4: A lower bound for a difference of norms.

Let V be an inner product space and $\mathbf{u}, \mathbf{v} \in V$. Prove that

$$\big|\|\mathbf{u}\| - \|\mathbf{v}\|\big| \le \|\mathbf{u} - \mathbf{v}\|.$$

Solution. Write $\mathbf{u} = (\mathbf{u} - \mathbf{v}) + \mathbf{v}$. By Corollary 10.1.6,

$$\|\mathbf{u}\| \le \|\mathbf{u} - \mathbf{v}\| + \|\mathbf{v}\|,$$

so $\|\mathbf{u}\| - \|\mathbf{v}\| \le \|\mathbf{u} - \mathbf{v}\|$. Swapping the roles of $\mathbf{u}$ and $\mathbf{v}$ gives $\|\mathbf{v}\| - \|\mathbf{u}\| \le \|\mathbf{v} - \mathbf{u}\|$, and $\|\mathbf{v} - \mathbf{u}\| = |-1|\|\mathbf{u} - \mathbf{v}\| = \|\mathbf{u} - \mathbf{v}\|$ by Theorem 10.1.2 (b). The quantity $|\|\mathbf{u}\| - \|\mathbf{v}\||$ is one of the two numbers just bounded, so it is at most $\|\mathbf{u} - \mathbf{v}\|$. This proves the inequality.

10.1.8.3 C. Going deeper

Exercise C1: The parallelogram law characterizes inner-product norms.

Let $\|\cdot\|$ be a norm on $\mathbb{R}^2$, that is, a function $\mathbb{R}^2 \to \mathbb{R}$ satisfying the three properties of Theorem 10.1.2 (a), (b) and Corollary 10.1.6. Suppose it satisfies the parallelogram law

$$\|\mathbf{u} + \mathbf{v}\|^2 + \|\mathbf{u} - \mathbf{v}\|^2 = 2\|\mathbf{u}\|^2 + 2\|\mathbf{v}\|^2$$

for all $\mathbf{u}, \mathbf{v}$, and define $\beta(\mathbf{u}, \mathbf{v}) = \frac{1}{4}\big(\|\mathbf{u} + \mathbf{v}\|^2 - \|\mathbf{u} - \mathbf{v}\|^2\big)$.

(a) Show that $\beta(\mathbf{u}, \mathbf{u}) = \|\mathbf{u}\|^2$, that $\beta(\mathbf{u}, \mathbf{v}) = \beta(\mathbf{v}, \mathbf{u})$, and that $\beta(\mathbf{u}, \mathbf{0}) = 0$.

(b) Prove that $\beta(\mathbf{u}, \mathbf{v}) + \beta(\mathbf{u}, \mathbf{w}) = 2\beta\big(\mathbf{u}, \frac{1}{2}(\mathbf{v} + \mathbf{w})\big)$ for all $\mathbf{u}, \mathbf{v}, \mathbf{w}$.

(c) Deduce that $\beta(\mathbf{u}, \mathbf{v}) + \beta(\mathbf{u}, \mathbf{w}) = \beta(\mathbf{u}, \mathbf{v} + \mathbf{w})$.

(d) Granting that $\beta(\mathbf{u}, t\mathbf{v}) = t\beta(\mathbf{u}, \mathbf{v})$ for all $t \in \mathbb{R}$, conclude that β is an inner product on $\mathbb{R}^2$ whose induced norm is $\|\cdot\|$.

Hint: for (b), apply the parallelogram law to the pair $\mathbf{u} + \frac{1}{2}(\mathbf{v} + \mathbf{w})$, $\frac{1}{2}(\mathbf{v} - \mathbf{w})$, and then to the pair $\mathbf{u} - \frac{1}{2}(\mathbf{v} + \mathbf{w})$, $\frac{1}{2}(\mathbf{w} - \mathbf{v})$.

Solution.

(a) $\beta(\mathbf{u}, \mathbf{u}) = \frac{1}{4}(\|2\mathbf{u}\|^2 - \|\mathbf{0}\|^2) = \frac{1}{4} \cdot 4\|\mathbf{u}\|^2 = \|\mathbf{u}\|^2$, using homogeneity. Symmetry holds because $\|\mathbf{v} - \mathbf{u}\| = \|\mathbf{u} - \mathbf{v}\|$, again by homogeneity with $c = -1$. Finally $\beta(\mathbf{u}, \mathbf{0}) = \frac{1}{4}(\|\mathbf{u}\|^2 - \|\mathbf{u}\|^2) = 0$.

(b) Put $\mathbf{m} = \frac{1}{2}(\mathbf{v} + \mathbf{w})$ and $\mathbf{d} = \frac{1}{2}(\mathbf{v} - \mathbf{w})$, so that $\mathbf{v} = \mathbf{m} + \mathbf{d}$ and $\mathbf{w} = \mathbf{m} - \mathbf{d}$. Apply the parallelogram law to $\mathbf{u} + \mathbf{m}$ and $\mathbf{d}$: since $(\mathbf{u} + \mathbf{m}) + \mathbf{d} = \mathbf{u} + \mathbf{v}$ and $(\mathbf{u} + \mathbf{m}) - \mathbf{d} = \mathbf{u} + \mathbf{w}$,

$$\|\mathbf{u} + \mathbf{v}\|^2 + \|\mathbf{u} + \mathbf{w}\|^2 = 2\|\mathbf{u} + \mathbf{m}\|^2 + 2\|\mathbf{d}\|^2.$$

Apply it to $\mathbf{u} - \mathbf{m}$ and $\mathbf{d}$: since $(\mathbf{u} - \mathbf{m}) - \mathbf{d} = \mathbf{u} - \mathbf{v}$ and $(\mathbf{u} - \mathbf{m}) + \mathbf{d} = \mathbf{u} - \mathbf{w}$,

$$\|\mathbf{u} - \mathbf{v}\|^2 + \|\mathbf{u} - \mathbf{w}\|^2 = 2\|\mathbf{u} - \mathbf{m}\|^2 + 2\|\mathbf{d}\|^2.$$

Subtracting the second from the first, the terms $2\|\mathbf{d}\|^2$ cancel, and dividing by 4 gives $\beta(\mathbf{u}, \mathbf{v}) + \beta(\mathbf{u}, \mathbf{w}) = 2\beta(\mathbf{u}, \mathbf{m})$, which is the claim.

(c) Take $\mathbf{w} = \mathbf{0}$ in (b). By (a), $\beta(\mathbf{u}, \mathbf{0}) = 0$, so $\beta(\mathbf{u}, \mathbf{v}) = 2\beta(\mathbf{u}, \frac{1}{2}\mathbf{v})$ for all $\mathbf{v}$. Applying

this with $\mathbf{v}+\mathbf{w}$ in place of $\mathbf{v}$, we get $2\beta(\mathbf{u},\frac{1}{2}(\mathbf{v}+\mathbf{w}))=\beta(\mathbf{u},\mathbf{v}+\mathbf{w})$, and the left side is $\beta(\mathbf{u},\mathbf{v})+\beta(\mathbf{u},\mathbf{w})$ by (b).

(d) By (c) and the granted homogeneity, β is linear in its second slot, and by the symmetry in (a) it is then linear in the first as well, so (IP1) and (IP2) hold (conjugation is trivial over $\mathbb{R}$). For (IP3), $\beta(\mathbf{u},\mathbf{u})=\|\mathbf{u}\|^2>0$ for $\mathbf{u}\neq\mathbf{0}$, since a norm vanishes only at $\mathbf{0}$. So β is an inner product, and its induced norm is $\sqrt{\beta(\mathbf{u},\mathbf{u})}=\|\mathbf{u}\|$.

Remark. The granted step in (d) is where analysis enters: additivity from (c) gives $\beta(\mathbf{u},t\mathbf{v})=t\beta(\mathbf{u},\mathbf{v})$ for every **rational** t by induction, and the extension to real t uses that $t\mapsto\beta(\mathbf{u},t\mathbf{v})$ is continuous, which follows from continuity of the norm. Nothing else in the argument needs anything beyond the three norm properties.

Exercise C2: Recovering the inner product from the norm.

Let V be an inner product space over F.

(a) For $F=\mathbb{R}$, prove the polarization identity $\langle\mathbf{u},\mathbf{v}\rangle=\frac{1}{4}\big(\|\mathbf{u}+\mathbf{v}\|^2-\|\mathbf{u}-\mathbf{v}\|^2\big)$.

(b) For $F=\mathbb{C}$, prove that

$$\langle\mathbf{u},\mathbf{v}\rangle=\frac{1}{4}\sum_{k=0}^{3}i^k\,\|\mathbf{u}+i^k\mathbf{v}\|^2.$$

(c) Deduce that two inner products on V with the same induced norm are equal.

Solution.

(a) By Theorem 10.1.2 (c) and its version with $-\mathbf{v}$, and since Re is the identity on $\mathbb{R}$,

$$\|\mathbf{u}+\mathbf{v}\|^2-\|\mathbf{u}-\mathbf{v}\|^2=4\langle\mathbf{u},\mathbf{v}\rangle.$$

Dividing by 4 gives the identity.

(b) Write $z=\langle\mathbf{u},\mathbf{v}\rangle$. By Theorem 10.1.2 (c) and Theorem 10.1.1 (b),

$$\|\mathbf{u}+i^k\mathbf{v}\|^2=\|\mathbf{u}\|^2+\|\mathbf{v}\|^2+2\,\mathrm{Re}\,\big(\overline{i^k}z\big),$$

where we used $\|i^k\mathbf{v}\|=|i^k|\|\mathbf{v}\|=\|\mathbf{v}\|$. Now $\sum_{k=0}^{3}i^k=1+i-1-i=0$, so the terms $\|\mathbf{u}\|^2+\|\mathbf{v}\|^2$ contribute nothing. Writing $z=a+bi$ with $a,b\in\mathbb{R}$, the four remaining terms $2i^k\,\mathrm{Re}(\overline{i^k}z)$ are, for $k=0,1,2,3$,

$$2a,\quad 2ib,\quad 2a,\quad 2ib,$$

since $\mathrm{Re}(z)=a$, $\mathrm{Re}(-iz)=b$, $\mathrm{Re}(-z)=-a$ and $\mathrm{Re}(iz)=-b$. Their sum is $4a+4bi=4z$, and dividing by 4 gives the identity.

(c) Both (a) and (b) express $\langle\mathbf{u},\mathbf{v}\rangle$ using only the norm. So if two inner products induce the same norm, the right-hand sides agree for all $\mathbf{u},\mathbf{v}$, hence so do the left-hand sides.

Exercise C3: The equality cases.

Let V be an inner product space.

(a) Prove that $\|\mathbf{u}+\mathbf{v}\| = \|\mathbf{u}\| + \|\mathbf{v}\|$ if and only if one of $\mathbf{u}, \mathbf{v}$ is a **non-negative real** multiple of the other.

(b) Deduce the equality condition in the classical inequality of Exercise (B3: Cauchy–Schwarz, concretely) (b): for real a_i, b_i, equality holds if and only if one of the vectors $(a_1, \dots, a_n)$, $(b_1, \dots, b_n)$ is a multiple of the other.

(c) Give real numbers a_i, b_i, not all zero, with $\sum a_i b_i < 0$ and equality in the classical inequality, and explain why this does **not** contradict (a).

Solution.

(a) ($\Leftarrow$) If $\mathbf{v} = \mathbf{0}$ both sides are $\|\mathbf{u}\|$. If $\mathbf{u} = t\mathbf{v}$ with $t \geq 0$, then $\|\mathbf{u}+\mathbf{v}\| = (t+1)\|\mathbf{v}\| = t\|\mathbf{v}\| + \|\mathbf{v}\| = \|\mathbf{u}\| + \|\mathbf{v}\|$ by Theorem 10.1.2 (b).
($\Rightarrow$) Suppose $\|\mathbf{u}+\mathbf{v}\| = \|\mathbf{u}\| + \|\mathbf{v}\|$. Squaring and using Theorem 10.1.2 (c),

$$2\,\mathrm{Re}\langle \mathbf{u}, \mathbf{v}\rangle = 2\|\mathbf{u}\|\|\mathbf{v}\|.$$

The chain in the proof of Corollary 10.1.6 is therefore an equality throughout, so $\mathrm{Re}\langle \mathbf{u}, \mathbf{v}\rangle = |\langle \mathbf{u}, \mathbf{v}\rangle| = \|\mathbf{u}\|\|\mathbf{v}\|$. The second equality and Theorem 10.1.5 make $(\mathbf{u}, \mathbf{v})$ dependent. Assume $\mathbf{v} \neq \mathbf{0}$ (otherwise $\mathbf{v} = 0\mathbf{u}$ and we are done) and write $\mathbf{u} = c\mathbf{v}$. Then $\langle \mathbf{u}, \mathbf{v}\rangle = c\|\mathbf{v}\|^2$, and the first equality says $\mathrm{Re}(c)\|\mathbf{v}\|^2 = |c|\|\mathbf{v}\|^2$, so $\mathrm{Re}\, c = |c|$, which forces c to be real and ≥ 0.

(b) Apply Theorem 10.1.5 on $\mathbb{R}^n$ as in Exercise (B3: Cauchy–Schwarz, concretely) (b). Squaring removes the sign, so equality in the squared inequality is equality in $|\langle \mathbf{a}, \mathbf{b}\rangle| = \|\mathbf{a}\|\|\mathbf{b}\|$, which by Theorem 10.1.5 holds exactly when $(\mathbf{a}, \mathbf{b})$ is dependent, that is, when one of the two vectors is a multiple of the other.

(c) Take $n = 1$, $a_1 = 1$, $b_1 = -1$: then $\sum a_i b_i = -1$ and both sides of the classical inequality equal 1. There is no contradiction with (a), because (a) is about equality in Corollary 10.1.6, which needs a non-negative multiple, while the classical inequality is the **squared** Cauchy–Schwarz inequality, which is blind to the sign. Here $\|\mathbf{a} + \mathbf{b}\| = 0 \neq 2 = \|\mathbf{a}\| + \|\mathbf{b}\|$.

10.2 Orthonormal Bases and Gram–Schmidt

A basis lets us write every vector in coordinates, but finding those coordinates costs work: in Definition 1.5.2 the scalars $a_1, \dots, a_n$ come from solving a linear system. In an inner product space one kind of basis makes that cost disappear. If the basis vectors are mutually orthogonal unit vectors, then the i-th coordinate of $\mathbf{v}$ is just $\langle \mathbf{v}, \mathbf{e}_i\rangle$, one inner product, computed without reference to the others. This section defines such bases, shows that every finite-dimensional inner product space has one, and gives the algorithm that produces them.

10.2.1 Orthonormal lists

The standard basis of $\mathbb{R}^n$ has two features beyond being a basis: distinct vectors are orthogonal, and each has length 1. The two conditions can be packed into a single formula using the Kronecker delta δ_{ij}, which is 1 when $i = j$ and 0 otherwise.

An orthonormal list is a list of unit vectors that are pairwise perpendicular.

Definition 10.2.1 — Orthonormal List

Let V be an inner product space. A list $(\mathbf{e}_1, \dots, \mathbf{e}_k)$ of vectors of V is **orthonormal** if

$$\langle \mathbf{e}_i, \mathbf{e}_j \rangle = \delta_{ij} \qquad \text{for all } i, j \in \{1, \dots, k\},$$

that is, if $\langle \mathbf{e}_i, \mathbf{e}_j \rangle = 0$ whenever $i \neq j$ (**orthogonal**) and $\|\mathbf{e}_i\| = 1$ for every i (**normalized**).

In words: the single equation $\langle \mathbf{e}_i, \mathbf{e}_j \rangle = \delta_{ij}$ carries two conditions at once, because the case $i \neq j$ says the vectors are orthogonal and the case $i = j$ says $\|\mathbf{e}_i\|^2 = 1$. The list must be **ordered**, as every list in this book is, but nothing in the definition depends on the order. Note that no vector of an orthonormal list is $\mathbf{0}$, since $\|\mathbf{0}\| = 0 \neq 1$; so by Theorem 10.1.4, **every orthonormal list is linearly independent**. That single sentence is why orthonormality is so useful: independence, which normally takes an argument, comes for free.

Definition 10.2.2 — Orthonormal Basis

An **orthonormal basis** of an inner product space V is an orthonormal list that is a basis of V.

Examples.

- **The standard basis.** In F^n with the standard inner product, $\langle \mathbf{e}_i, \mathbf{e}_j \rangle = \delta_{ij}$ by inspection. This is the model, and the notation $\mathbf{e}_i$ is deliberately reused for orthonormal vectors in a general space.
- **A rotated basis of $\mathbb{R}^2$.** The list $\left(\frac{1}{\sqrt{2}}(1,1),\ \frac{1}{\sqrt{2}}(1,-1)\right)$ is orthonormal: the inner product of the two vectors is $\frac{1}{2}(1-1) = 0$, and each has norm $\frac{1}{\sqrt{2}}\sqrt{2} = 1$. Geometrically it is the standard basis turned through $\pi/4$.
- **A basis of $\mathbb{R}^3$.** The columns of $\frac{1}{3}\begin{pmatrix} 1 & 2 & 2 \\ 2 & 1 & -2 \\ 2 & -2 & 1 \end{pmatrix}$ form an orthonormal list: each has norm $\frac{1}{3}\sqrt{1+4+4} = 1$, and the three pairwise inner products are $\frac{1}{9}(2+2-4)$, $\frac{1}{9}(2-4+2)$ and $\frac{1}{9}(4-2-2)$, all 0. Being independent and of length $3 = \dim \mathbb{R}^3$, it is a basis (Theorem 1.6.4 (a)).
- **Matrix units.** In $M_{m\times n}(F)$ with the Frobenius inner product, the matrix units $\mathbf{E}_{ij}$ satisfy $\langle \mathbf{E}_{ij}, \mathbf{E}_{pq} \rangle = 1$ if $(i,j) = (p,q)$ and 0 otherwise, since only one entry of each is non-zero. So the standard basis of $M_{m\times n}(F)$ is orthonormal.
- **The Lagrange basis.** On $F[x]_{\le n}$ with the node inner product $\langle p, q \rangle = \sum_{i=0}^{n} p(c_i)\overline{q(c_i)}$ of the previous section, the Lagrange polynomials $\ell_0, \dots, \ell_n$ of Definition 5.6.1 vanish at every node but their own, where they take the value 1; that is, $\ell_i(c_j) = \delta_{ij}$. Hence $\langle \ell_i, \ell_j \rangle = \sum_k \ell_i(c_k)\overline{\ell_j(c_k)} = \delta_{ij}$: the Lagrange basis is an orthonormal basis for this inner

product. An interpolation formula and an orthonormal expansion turn out to be the same statement.

- **The degenerate case.** The empty list is orthonormal, vacuously, and it is an orthonormal basis of $V = \{\mathbf{0}\}$. This is not a joke: it is the base case of every induction below.

Non-example by minimal change. In $\mathbb{R}^2$, the list $((1,1),(1,-1))$ is orthogonal, and it is a basis. It is **not** orthonormal, because $\|(1,1)\| = \sqrt{2} \neq 1$. The failure is only in the normalization, and it is repaired by dividing each vector by its norm, which changes neither the spans nor the orthogonality (Theorem 10.1.2 (b)). Scaling is always available; orthogonality is the real content.

10.2.2 Coordinates in an orthonormal basis

Here is the payoff promised in the opening.

Theorem 10.2.1 — Coordinates, Inner Products and Norms in an Orthonormal Basis

Let $(\mathbf{e}_1, \dots, \mathbf{e}_n)$ be an orthonormal basis of an inner product space V, and let $\mathbf{u}, \mathbf{v} \in V$. Then:

(a) $\mathbf{v} = \sum_{i=1}^{n} \langle \mathbf{v}, \mathbf{e}_i \rangle \, \mathbf{e}_i$;

(b) $\langle \mathbf{u}, \mathbf{v} \rangle = \sum_{i=1}^{n} \langle \mathbf{u}, \mathbf{e}_i \rangle \, \overline{\langle \mathbf{v}, \mathbf{e}_i \rangle}$;

(c) $\|\mathbf{v}\|^2 = \sum_{i=1}^{n} |\langle \mathbf{v}, \mathbf{e}_i \rangle|^2$ (**Parseval's identity** for a finite orthonormal basis).

Idea. For (a) we already know that $\mathbf{v} = \sum a_i \mathbf{e}_i$ for unique scalars a_i; the only question is what they are. Pair both sides with $\mathbf{e}_j$: orthonormality kills every term except the j-th, and that one survives with coefficient 1. Parts (b) and (c) then follow by expanding, since the coordinates are now known.

Proof.

(a) Since $(\mathbf{e}_1, \dots, \mathbf{e}_n)$ is a basis, Theorem 1.5.1 gives scalars $a_1, \dots, a_n \in F$ with $\mathbf{v} = \sum_i a_i \mathbf{e}_i$. Fix j. Pairing with $\mathbf{e}_j$ and using (IP1),

$$\langle \mathbf{v}, \mathbf{e}_j \rangle = \sum_{i=1}^{n} a_i \langle \mathbf{e}_i, \mathbf{e}_j \rangle = \sum_{i=1}^{n} a_i \delta_{ij} = a_j,$$

by Definition 10.2.1. So $a_j = \langle \mathbf{v}, \mathbf{e}_j \rangle$ for every j, which is (a).

(b) Write $\mathbf{u} = \sum_i \langle \mathbf{u}, \mathbf{e}_i \rangle \mathbf{e}_i$ and $\mathbf{v} = \sum_j \langle \mathbf{v}, \mathbf{e}_j \rangle \mathbf{e}_j$ by (a). Expanding the first slot with (IP1) and the second with Theorem 10.1.1 (b),

$$\langle \mathbf{u}, \mathbf{v} \rangle = \sum_i \sum_j \langle \mathbf{u}, \mathbf{e}_i \rangle \, \overline{\langle \mathbf{v}, \mathbf{e}_j \rangle} \, \langle \mathbf{e}_i, \mathbf{e}_j \rangle.$$

Only the terms with $i = j$ survive, and there $\langle \mathbf{e}_i, \mathbf{e}_i \rangle = 1$. This is (b).

(c) Take $\mathbf{u} = \mathbf{v}$ in (b): the i-th term becomes $\langle \mathbf{v}, \mathbf{e}_i \rangle \overline{\langle \mathbf{v}, \mathbf{e}_i \rangle} = |\langle \mathbf{v}, \mathbf{e}_i \rangle|^2$ by Theorem 0.6.2 (c), and the left side is $\|\mathbf{v}\|^2$.

■

Read (b) again: in the coordinates supplied by an orthonormal basis, **every** inner product becomes the standard inner product of F^n. So an orthonormal basis does not merely simplify coordinates; it turns an abstract inner product space into F^n with the dot product. We record that as a corollary below, and use it repeatedly: **to make an abstract statement concrete, fix an orthonormal basis.**

Example. (Reading Off Coordinates)

Let $\mathbf{e}_1 = \frac{1}{3}(1, 2, 2)$, $\mathbf{e}_2 = \frac{1}{3}(2, 1, -2)$, $\mathbf{e}_3 = \frac{1}{3}(2, -2, 1)$, the orthonormal basis of $\mathbb{R}^3$ found above. Write $\mathbf{v} = (3, 0, 3)$ in this basis, and check Parseval's identity.

Solution. By Theorem 10.2.1 (a), the coordinates are

$$\begin{aligned} \langle \mathbf{v}, \mathbf{e}_1 \rangle &= \tfrac{1}{3}(3 + 0 + 6) = 3, \\ \langle \mathbf{v}, \mathbf{e}_2 \rangle &= \tfrac{1}{3}(6 + 0 - 6) = 0, \\ \langle \mathbf{v}, \mathbf{e}_3 \rangle &= \tfrac{1}{3}(6 + 0 + 3) = 3, \end{aligned}$$

so $\mathbf{v} = 3\mathbf{e}_1 + 0\mathbf{e}_2 + 3\mathbf{e}_3$. No system was solved. Checking directly, $3\mathbf{e}_1 + 3\mathbf{e}_3 = (1, 2, 2) + (2, -2, 1) = (3, 0, 3)$. For Parseval, $\|\mathbf{v}\|^2 = 9 + 0 + 9 = 18$, and indeed $3^2 + 0^2 + 3^2 = 18$.

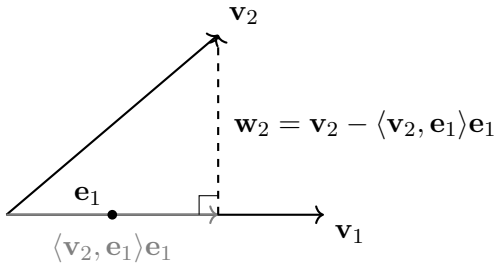
Quick check. With the same $\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3$, find the coordinates of $\mathbf{v} = (1, 1, 1)$ and verify Parseval's identity.

Solution. $\langle \mathbf{v}, \mathbf{e}_1 \rangle = \frac{1}{3}(1+2+2) = \frac{5}{3}$, $\langle \mathbf{v}, \mathbf{e}_2 \rangle = \frac{1}{3}(2+1-2) = \frac{1}{3}$, $\langle \mathbf{v}, \mathbf{e}_3 \rangle = \frac{1}{3}(2-2+1) = \frac{1}{3}$. Then $\frac{25}{9} + \frac{1}{9} + \frac{1}{9} = \frac{27}{9} = 3 = \|\mathbf{v}\|^2$, as Parseval requires.

10.2.3 The Gram–Schmidt process

Everything so far assumed that an orthonormal basis was handed to us. Does one always exist? The answer is yes in finite dimension, and the proof is an algorithm that we will use constantly.

The idea comes from a picture in $\mathbb{R}^3$. Given independent $\mathbf{v}_1, \mathbf{v}_2$, normalize $\mathbf{v}_1$ to get $\mathbf{e}_1$. The vector $\mathbf{v}_2$ is generally not perpendicular to $\mathbf{e}_1$; but its "shadow" on the line through $\mathbf{e}_1$ is the multiple $\langle \mathbf{v}_2, \mathbf{e}_1 \rangle \mathbf{e}_1$, and subtracting the shadow leaves a vector $\mathbf{w}_2$ perpendicular to $\mathbf{e}_1$. Normalize it. Then repeat with $\mathbf{v}_3$, subtracting its shadows on both $\mathbf{e}_1$ and $\mathbf{e}_2$.



Project, subtract, normalize. The right angle at the foot is the only thing that has to be checked, and one line of algebra checks it.

Theorem 10.2.2 — Gram–Schmidt Process

Let V be an inner product space and let $(\mathbf{v}_1, \dots, \mathbf{v}_m)$ be a **linearly independent** list in V. Define recursively

$$\mathbf{w}_k = \mathbf{v}_k - \sum_{i=1}^{k-1} \langle \mathbf{v}_k, \mathbf{e}_i \rangle \, \mathbf{e}_i, \qquad \mathbf{e}_k = \frac{\mathbf{w}_k}{\|\mathbf{w}_k\|} \qquad (k = 1, \dots, m).$$

Then every $\mathbf{w}_k$ is non-zero, so the recursion is defined, and:

(a) $(\mathbf{e}_1, \dots, \mathbf{e}_m)$ is an orthonormal list;
(b) $\operatorname{span}(\mathbf{e}_1, \dots, \mathbf{e}_k) = \operatorname{span}(\mathbf{v}_1, \dots, \mathbf{v}_k)$ for every $k = 1, \dots, m$;
(c) if $(\mathbf{v}_1, \dots, \mathbf{v}_r)$ is already orthonormal for some $r \le m$, then $\mathbf{e}_i = \mathbf{v}_i$ for $i \le r$.

In particular, every finite-dimensional inner product space has an orthonormal basis.

Idea. Induction on k, with the statement "$(\mathbf{e}_1, \dots, \mathbf{e}_k)$ is orthonormal and spans $\operatorname{span}(\mathbf{v}_1, \dots, \mathbf{v}_k)$" as the hypothesis. Two things need care. First, $\mathbf{w}_k \neq \mathbf{0}$: if it were $\mathbf{0}$, then $\mathbf{v}_k$ would lie in $\operatorname{span}(\mathbf{e}_1, \dots, \mathbf{e}_{k-1}) = \operatorname{span}(\mathbf{v}_1, \dots, \mathbf{v}_{k-1})$, contradicting independence. That is the only place independence is used, and it is used exactly there. Second, $\mathbf{w}_k \perp \mathbf{e}_j$ for $j < k$: pair and watch the sum collapse.

Proof. We prove by induction on k that $\mathbf{w}_k \neq \mathbf{0}$, that $(\mathbf{e}_1, \dots, \mathbf{e}_k)$ is orthonormal, and that $\operatorname{span}(\mathbf{e}_1, \dots, \mathbf{e}_k) = \operatorname{span}(\mathbf{v}_1, \dots, \mathbf{v}_k)$.

Base case $k = 1$. The empty sum is $\mathbf{0}$, so $\mathbf{w}_1 = \mathbf{v}_1$, which is non-zero because a list containing $\mathbf{0}$ is dependent. Then $\mathbf{e}_1 = \mathbf{v}_1 / \|\mathbf{v}_1\|$ has norm 1 by Theorem 10.1.2 (b), and $\operatorname{span}(\mathbf{e}_1) = \operatorname{span}(\mathbf{v}_1)$ since each vector is a non-zero multiple of the other.

Induction step. Let $2 \le k \le m$ and suppose the claim holds for $k - 1$. Put $U = \operatorname{span}(\mathbf{e}_1, \dots, \mathbf{e}_{k-1}) = \operatorname{span}(\mathbf{v}_1, \dots, \mathbf{v}_{k-1})$.

First, $\mathbf{w}_k \neq \mathbf{0}$. If $\mathbf{w}_k = \mathbf{0}$, then $\mathbf{v}_k = \sum_{i<k} \langle \mathbf{v}_k, \mathbf{e}_i \rangle \mathbf{e}_i \in U = \operatorname{span}(\mathbf{v}_1, \dots, \mathbf{v}_{k-1})$, so $\mathbf{v}_k$ would be a linear combination of the earlier $\mathbf{v}_i$, making $(\mathbf{v}_1, \dots, \mathbf{v}_m)$ dependent, contrary to hypothesis. Hence $\|\mathbf{w}_k\| > 0$ and $\mathbf{e}_k$ is defined, with $\|\mathbf{e}_k\| = 1$.

Next, $\mathbf{e}_k \perp \mathbf{e}_j$ for every $j < k$. By (IP1) and the induction hypothesis $\langle \mathbf{e}_i, \mathbf{e}_j \rangle = \delta_{ij}$,

$$\langle \mathbf{w}_k, \mathbf{e}_j \rangle = \langle \mathbf{v}_k, \mathbf{e}_j \rangle - \sum_{i=1}^{k-1} \langle \mathbf{v}_k, \mathbf{e}_i \rangle \, \delta_{ij} = \langle \mathbf{v}_k, \mathbf{e}_j \rangle - \langle \mathbf{v}_k, \mathbf{e}_j \rangle = 0,$$

and $\mathbf{e}_k$ is a scalar multiple of $\mathbf{w}_k$, so $\langle \mathbf{e}_k, \mathbf{e}_j \rangle = 0$ as well. Together with the induction hypothesis, $(\mathbf{e}_1, \dots, \mathbf{e}_k)$ is orthonormal, which is (a).

For (b), $\mathbf{e}_k$ is a linear combination of $\mathbf{v}_k$ and $\mathbf{e}_1, \dots, \mathbf{e}_{k-1}$, hence lies in $\operatorname{span}(\mathbf{v}_1, \dots, \mathbf{v}_k)$ by the induction hypothesis; so $\operatorname{span}(\mathbf{e}_1, \dots, \mathbf{e}_k) \subseteq \operatorname{span}(\mathbf{v}_1, \dots, \mathbf{v}_k)$. Conversely $\mathbf{v}_k = \|\mathbf{w}_k\| \mathbf{e}_k + \sum_{i<k} \langle \mathbf{v}_k, \mathbf{e}_i \rangle \mathbf{e}_i \in \operatorname{span}(\mathbf{e}_1, \dots, \mathbf{e}_k)$, and the earlier $\mathbf{v}_i$ lie there by the induction hypothesis. The two spans are equal, completing the induction.

For (c), suppose $(\mathbf{v}_1, \dots, \mathbf{v}_r)$ is orthonormal and that $\mathbf{e}_i = \mathbf{v}_i$ for all $i < k$, where $k \le r$. Then $\langle \mathbf{v}_k, \mathbf{e}_i \rangle = \langle \mathbf{v}_k, \mathbf{v}_i \rangle = 0$ for $i < k$, so $\mathbf{w}_k = \mathbf{v}_k$ and $\|\mathbf{w}_k\| = 1$, giving $\mathbf{e}_k = \mathbf{v}_k$. Induction on k proves (c).

Finally, let V be finite-dimensional. If $V = \{\mathbf{0}\}$, the empty list is an orthonormal basis. Otherwise take any basis $(\mathbf{v}_1, \dots, \mathbf{v}_n)$ of V and apply the process: by (a) the output is orthonormal, and by (b) it spans $\operatorname{span}(\mathbf{v}_1, \dots, \mathbf{v}_n) = V$, so it is an orthonormal basis.

■

Two remarks on the formulas. The vector subtracted from $\mathbf{v}_k$ is exactly the expansion of $\mathbf{v}_k$ in the orthonormal basis $(\mathbf{e}_1, \dots, \mathbf{e}_{k-1})$ of U, which by Theorem 10.2.1 (a) is the best available "copy of $\mathbf{v}_k$ inside U"; the next section will call it the orthogonal projection of $\mathbf{v}_k$ onto U. And the subtraction is the same move that produced the vector $\mathbf{z}$ in the proof of Theorem 10.1.5. **Project, then subtract** is one move used twice.

Corollary 10.2.3 — Extending an Orthonormal List

Let V be a finite-dimensional inner product space and let $(\mathbf{e}_1, \dots, \mathbf{e}_r)$ be an orthonormal list in V. Then there are vectors $\mathbf{e}_{r+1}, \dots, \mathbf{e}_n \in V$ such that $(\mathbf{e}_1, \dots, \mathbf{e}_n)$ is an orthonormal basis of V.

Proof. The list $(\mathbf{e}_1, \dots, \mathbf{e}_r)$ is linearly independent by Theorem 10.1.4, since its vectors are orthogonal and non-zero. By Theorem 1.6.5 there are $\mathbf{v}_{r+1}, \dots, \mathbf{v}_n \in V$ making $(\mathbf{e}_1, \dots, \mathbf{e}_r, \mathbf{v}_{r+1}, \dots, \mathbf{v}_n)$ a basis of V. Apply Theorem 10.2.2 to that basis. By part (c) the first r output vectors are $\mathbf{e}_1, \dots, \mathbf{e}_r$ unchanged, and by (a) and (b) the whole output is an orthonormal basis of V.

■

10.2.4 Two worked examples

Example. (Gram–Schmidt in $\mathbb{R}^3$)

Apply the Gram–Schmidt process of Theorem 10.2.2 to $\mathbf{v}_1 = (1,1,1)$, $\mathbf{v}_2 = (0,1,1)$, $\mathbf{v}_3 = (0,0,1)$ in $\mathbb{R}^3$ with the dot product.

Solution. Step 1. $\|\mathbf{v}_1\|^2 = 3$, so $\mathbf{e}_1 = \frac{1}{\sqrt{3}}(1,1,1)$.

Step 2. $\langle \mathbf{v}_2, \mathbf{e}_1 \rangle = \frac{1}{\sqrt{3}}(0+1+1) = \frac{2}{\sqrt{3}}$, so

$$\mathbf{w}_2 = (0,1,1) - \tfrac{2}{3}(1,1,1) = \tfrac{1}{3}(-2,1,1).$$

Then $\|\mathbf{w}_2\|^2 = \frac{1}{9}(4+1+1) = \frac{2}{3}$, and $\mathbf{e}_2 = \frac{1}{\sqrt{6}}(-2,1,1)$.

Step 3. $\langle \mathbf{v}_3, \mathbf{e}_1 \rangle = \frac{1}{\sqrt{3}}$ and $\langle \mathbf{v}_3, \mathbf{e}_2 \rangle = \frac{1}{\sqrt{6}}$, so

$$\mathbf{w}_3 = (0,0,1) - \tfrac{1}{3}(1,1,1) - \tfrac{1}{6}(-2,1,1) = \left(0, -\tfrac{1}{2}, \tfrac{1}{2}\right).$$

Then $\|\mathbf{w}_3\|^2 = \frac{1}{2}$ and $\mathbf{e}_3 = \frac{1}{\sqrt{2}}(0,-1,1)$.

Check. The three vectors have norm 1, and $\langle \mathbf{e}_1, \mathbf{e}_2\rangle = \frac{1}{\sqrt{18}}(-2+1+1) = 0$, $\langle \mathbf{e}_1, \mathbf{e}_3\rangle = \frac{1}{\sqrt{6}}(0-1+1) = 0$, $\langle \mathbf{e}_2, \mathbf{e}_3\rangle = \frac{1}{\sqrt{12}}(0-1+1) = 0$. The span condition is visible too: $\mathbf{e}_1$ is a multiple of $\mathbf{v}_1$, and $\mathbf{e}_2$ is a combination of $\mathbf{v}_1$ and $\mathbf{v}_2$.

The next example runs the same three steps in a function space, where no picture is available and only the algebra is left.

Example. (Gram–Schmidt on $1, x, x^2$)

Apply the Gram–Schmidt process of Theorem 10.2.2 to $(1, x, x^2)$ in $\mathbb{R}[x]_{\le 2}$ with

$$\langle p, q\rangle = \int_{-1}^{1} p(t)q(t)\,\mathrm{d}t.$$

Solution. Step 1. $\|1\|^2 = \int_{-1}^{1} 1\,\mathrm{d}t = 2$, so $\mathbf{e}_1 = 1/\sqrt{2}$.

Step 2. $\langle x, \mathbf{e}_1\rangle = \frac{1}{\sqrt{2}}\int_{-1}^{1} t\,\mathrm{d}t = 0$, since the integrand is odd. So $\mathbf{w}_2 = x$, and $\|x\|^2 = \int_{-1}^{1} t^2\,\mathrm{d}t = \frac{2}{3}$, giving $\mathbf{e}_2 = \sqrt{3/2}\,x$.

Step 3. $\langle x^2, \mathbf{e}_1\rangle = \frac{1}{\sqrt{2}}\cdot\frac{2}{3}$ and $\langle x^2, \mathbf{e}_2\rangle = \sqrt{3/2}\int_{-1}^{1} t^3\,\mathrm{d}t = 0$, again by oddness. Hence

$$\mathbf{w}_3 = x^2 - \tfrac{1}{\sqrt{2}}\cdot\tfrac{2}{3}\cdot\tfrac{1}{\sqrt{2}} = x^2 - \tfrac{1}{3}.$$

Its squared norm is

$$\int_{-1}^{1}\left(t^2 - \tfrac{1}{3}\right)^2\mathrm{d}t = \tfrac{2}{5} - \tfrac{4}{9} + \tfrac{2}{9} = \tfrac{8}{45},$$

so $\mathbf{e}_3 = \frac{\sqrt{10}}{4}(3x^2-1)$.

The monic polynomials produced along the way are 1, x and $x^2 - \frac{1}{3}$. These are, up to scaling, the first three **Legendre polynomials**; the usual normalization takes $P_2 = \frac{1}{2}(3x^2-1) = \frac{3}{2}(x^2 - \frac{1}{3})$, fixed by the convention $P_k(1) = 1$ rather than by the norm. Section 10 of this chapter takes up such families in general.

Notice how much work the oddness of the integrand did: two of the three inner products were 0 before any computation. Symmetry of the weight is worth looking for.

Warning. **Gram–Schmidt depends on the order of the list.** Run the process on $((0,1),(1,1))$ in $\mathbb{R}^2$: it returns $((0,1),(1,0))$. Run it on $((1,1),(0,1))$, the same two vectors in the other order: it returns $\big(\frac{1}{\sqrt{2}}(1,1), \frac{1}{\sqrt{2}}(-1,1)\big)$. Both outputs are orthonormal bases of $\mathbb{R}^2$, and they are different. An orthonormal basis is never unique (for $\dim V \ge 1$ one can always replace $\mathbf{e}_1$ by $-\mathbf{e}_1$); the process returns **an** orthonormal basis adapted to the given order, not **the** orthonormal basis.

Quick check. Run Gram–Schmidt on $((1,0),(1,1))$ in $\mathbb{R}^2$, and then on $((1,1),(1,0))$. Do you get the same list?

Solution. First order: $\mathbf{e}_1 = (1,0)$; $\langle (1,1), \mathbf{e}_1\rangle = 1$, so $\mathbf{w}_2 = (1,1) - (1,0) = (0,1)$ and $\mathbf{e}_2 = (0,1)$. Output $((1,0),(0,1))$.

Second order: $\mathbf{e}_1 = \frac{1}{\sqrt{2}}(1,1)$; $\langle (1,0), \mathbf{e}_1 \rangle = \frac{1}{\sqrt{2}}$, so $\mathbf{w}_2 = (1,0) - \frac{1}{2}(1,1) = \frac{1}{2}(1,-1)$ and $\mathbf{e}_2 = \frac{1}{\sqrt{2}}(1,-1)$. Output $\big(\frac{1}{\sqrt{2}}(1,1), \frac{1}{\sqrt{2}}(1,-1)\big)$. Not the same list, and not even the same set of lines.

Warning. **The classical process is numerically fragile.** Computed with rounding, the vectors $\mathbf{e}_1, \mathbf{e}_2, \dots$ drift out of orthogonality, and the drift grows with k and with how nearly dependent the input list is. Nothing above is wrong — the fault is in the arithmetic, not the mathematics — but in practice one uses a rearranged version or reflections instead. Section 8 of this chapter gives the reflection-based method, and Chapter 23 explains why it is the stable one.

10.2.5 All inner product spaces of the same dimension look alike

Corollary 10.2.4 — Classification of Finite-Dimensional Inner Product Spaces

Let V be an inner product space over F with $\dim V = n$. Then there is an isomorphism $T\colon V \to F^n$ with

$$\langle T\mathbf{u}, T\mathbf{v} \rangle = \langle \mathbf{u}, \mathbf{v} \rangle \qquad \text{for all } \mathbf{u}, \mathbf{v} \in V,$$

where the right-hand inner product is that of V and the left-hand one is the standard inner product of F^n. An isomorphism with this property is an **isometric isomorphism**, so every n-dimensional inner product space over F is isometrically isomorphic to F^n.

Proof. By Theorem 10.2.2, V has an orthonormal basis $\mathcal{E} = (\mathbf{e}_1, \dots, \mathbf{e}_n)$. Let $T\colon V \to F^n$ be the coordinate map $T\mathbf{v} = [\mathbf{v}]_{\mathcal{E}}$, an isomorphism by Corollary 3.5.5. By Theorem 10.2.1 (a), the i-th entry of $T\mathbf{v}$ is $\langle \mathbf{v}, \mathbf{e}_i \rangle$. Hence the standard inner product of $T\mathbf{u}$ and $T\mathbf{v}$ in F^n is $\sum_i \langle \mathbf{u}, \mathbf{e}_i \rangle \overline{\langle \mathbf{v}, \mathbf{e}_i \rangle}$, which equals $\langle \mathbf{u}, \mathbf{v} \rangle$ by Theorem 10.2.1 (b). ∎

So dimension is a complete invariant of finite-dimensional inner product spaces over a fixed field: there is nothing to classify. This should be compared with Theorem 3.5.4, which said the same for vector spaces; adding an inner product adds no new invariant. What becomes interesting is the interaction of the inner product with a given operator, and that is the subject of Chapter 11. Isometries in general are the subject of Section 7 of this chapter.

10.2.6 Gram matrices

Given a list of vectors, all of its inner products can be collected into one matrix, and that matrix turns out to answer questions about the list.

Definition 10.2.3 — Gram Matrix

Let $(\mathbf{v}_1, \dots, \mathbf{v}_k)$ be a list in an inner product space V over F. Its **Gram matrix** is

$\mathbf{G} \in M_k(F)$ with entries

$$(\mathbf{G})_{ij} = \langle \mathbf{v}_j, \mathbf{v}_i \rangle \qquad (1 \le i, j \le k).$$

The order of the subscripts looks backwards and is chosen on purpose: it makes $\mathbf{G}$ act on coefficient vectors the right way round, as part (b) below shows. For a real list the distinction disappears, since then $\langle \mathbf{v}_j, \mathbf{v}_i \rangle = \langle \mathbf{v}_i, \mathbf{v}_j \rangle$.

For example, the Gram matrix of $((1,1,0),(1,0,1),(0,1,1))$ in $\mathbb{R}^3$ is $\begin{pmatrix} 2 & 1 & 1 \\ 1 & 2 & 1 \\ 1 & 1 & 2 \end{pmatrix}$, with the squared norms on the diagonal.

Over $\mathbb{C}$ the order of the subscripts becomes visible. For $\mathbf{v}_1 = (1,0)$ and $\mathbf{v}_2 = (i,1)$ in $\mathbb{C}^2$, the off-diagonal entries are

$$(\mathbf{G})_{12} = \langle \mathbf{v}_2, \mathbf{v}_1 \rangle = i, \qquad (\mathbf{G})_{21} = \langle \mathbf{v}_1, \mathbf{v}_2 \rangle = \overline{i} = -i,$$

so $\mathbf{G} = \begin{pmatrix} 1 & i \\ -i & 2 \end{pmatrix}$, which is Hermitian but not symmetric. Part (b) below says $\mathbf{x}^*\mathbf{G}\mathbf{x} = \|x_1\mathbf{v}_1 + x_2\mathbf{v}_2\|^2$; with $\mathbf{x} = (1,1)$ both sides are 3, since $\mathbf{v}_1 + \mathbf{v}_2 = (1+i, 1)$. Writing $(\mathbf{G})_{ij} = \langle \mathbf{v}_i, \mathbf{v}_j \rangle$ instead would transpose $\mathbf{G}$ and leave that identity reading $\mathbf{x}^*\mathbf{G}^{\top}\mathbf{x}$.

Theorem 10.2.5 — Properties of the Gram Matrix

Let $(\mathbf{v}_1, \dots, \mathbf{v}_k)$ be a list in an inner product space V over F, with Gram matrix $\mathbf{G}$. Then:

(a) $\mathbf{G}$ is **Hermitian**, $\mathbf{G}^* = \mathbf{G}$, and its diagonal entries are the real numbers $\|\mathbf{v}_i\|^2 \ge 0$;

(b) $\mathbf{x}^*\mathbf{G}\mathbf{x} = \left\| \sum_j x_j \mathbf{v}_j \right\|^2$ for every $\mathbf{x} \in F^k$;

(c) $\mathbf{G}$ is invertible if and only if $(\mathbf{v}_1, \dots, \mathbf{v}_k)$ is linearly independent;

(d) $\det \mathbf{G}$ is a real number with $\det \mathbf{G} \ge 0$, and $\det \mathbf{G} > 0$ exactly when the list is linearly independent.

Idea. Part (b) is the whole theorem: the quadratic expression $\mathbf{x}^*\mathbf{G}\mathbf{x}$ is a squared length, so it vanishes only for the coefficient vectors of genuine dependence relations. That identifies $\operatorname{nul}(\mathbf{G})$ with the set of dependence relations and gives (c) at once. For (d), fix an orthonormal basis of the span and write $\mathbf{G} = \mathbf{A}^*\mathbf{A}$ for a coordinate matrix $\mathbf{A}$; a determinant of that shape is a squared modulus.

Proof.

(a) By (IP2), $(\mathbf{G}^*)_{ij} = \overline{(\mathbf{G})_{ji}} = \overline{\langle \mathbf{v}_i, \mathbf{v}_j \rangle} = \langle \mathbf{v}_j, \mathbf{v}_i \rangle = (\mathbf{G})_{ij}$. The diagonal entries are $\langle \mathbf{v}_i, \mathbf{v}_i \rangle = \|\mathbf{v}_i\|^2$, real and ≥ 0 by Theorem 10.1.1 (a).

(b) Write $\mathbf{u} = \sum_j x_j \mathbf{v}_j$. Expanding by (IP1) and Theorem 10.1.1 (b),

$$\|\mathbf{u}\|^2 = \sum_i \sum_j x_j \overline{x_i} \langle \mathbf{v}_j, \mathbf{v}_i \rangle = \sum_i \overline{x_i} \sum_j (\mathbf{G})_{ij} x_j,$$

and the right-hand side is exactly the entry of the 1×1 matrix $\mathbf{x}^*\mathbf{G}\mathbf{x}$.

(c) We show $\operatorname{nul}(\mathbf{G}) = \{\mathbf{x} \in F^k : \sum_j x_j \mathbf{v}_j = \mathbf{0}\}$. If $\sum_j x_j \mathbf{v}_j = \mathbf{0}$, then for each i,

$(\mathbf{Gx})_i = \sum_j \langle \mathbf{v}_j, \mathbf{v}_i \rangle x_j = \langle \sum_j x_j \mathbf{v}_j, \mathbf{v}_i \rangle = 0$ by (IP1), so $\mathbf{Gx} = \mathbf{0}$. Conversely, if $\mathbf{Gx} = \mathbf{0}$, then $\mathbf{x}^* \mathbf{Gx} = 0$, so $\| \sum_j x_j \mathbf{v}_j \| = 0$ by (b) and hence $\sum_j x_j \mathbf{v}_j = \mathbf{0}$ by Theorem 10.1.2 (a). Now $\mathbf{G}$ is invertible if and only if $\mathbf{Gx} = \mathbf{0}$ forces $\mathbf{x} = \mathbf{0}$ (Theorem 2.4.4, (a) $\Leftrightarrow$ (b)), which by the displayed equality of sets says exactly that the only dependence relation among the $\mathbf{v}_j$ is the trivial one.

(d) Let $U = \operatorname{span}(\mathbf{v}_1, \dots, \mathbf{v}_k)$, let $r = \dim U$, and let $(\mathbf{e}_1, \dots, \mathbf{e}_r)$ be an orthonormal basis of U, which exists by Theorem 10.2.2. Let $\mathbf{A} \in M_{r \times k}(F)$ have as its j-th column the coordinate vector of $\mathbf{v}_j$, so that $\mathbf{v}_j = \sum_p a_{pj} \mathbf{e}_p$. By Theorem 10.2.1 (b),

$$(\mathbf{G})_{ij} = \langle \mathbf{v}_j, \mathbf{v}_i \rangle = \sum_{p=1}^{r} a_{pj} \overline{a_{pi}} = (\mathbf{A}^* \mathbf{A})_{ij},$$

so $\mathbf{G} = \mathbf{A}^* \mathbf{A}$.

If the list is dependent, then $\mathbf{G}$ is singular by (c) and $\det \mathbf{G} = 0$. If it is independent, then $r = k$ and $\mathbf{A}$ is square. By Theorem 6.4.5, $\det(\mathbf{A}^*) = \det(\overline{\mathbf{A}})$, and $\det(\overline{\mathbf{A}}) = \overline{\det \mathbf{A}}$, because by the Leibniz formula (Theorem 6.4.3) the determinant is a sum of products of entries and conjugation preserves sums and products (Theorem 0.6.2). Hence, by Theorem 6.5.4,

$$\det \mathbf{G} = \det(\mathbf{A}^*) \det(\mathbf{A}) = \overline{\det \mathbf{A}} \det \mathbf{A} = |\det \mathbf{A}|^2.$$

This is real and ≥ 0, and it is > 0 because $\mathbf{A}$ is the matrix of an isomorphism onto its coordinates, hence invertible with $\det \mathbf{A} \neq 0$ (Theorem 6.5.2).

■

Over $\mathbb{R}$, with $V = \mathbb{R}^n$ and the dot product, part (d) is the statement Chapter 6 reached from Cauchy–Binet: Corollary 6.7.3 says that $\det(\mathbf{A}\mathbf{A}^{\top}) \geq 0$ for a real $\mathbf{A}$, with equality exactly when the rows of $\mathbf{A}$ are dependent. Taking the rows of $\mathbf{A}$ to be $\mathbf{v}_1, \dots, \mathbf{v}_k$ makes $\mathbf{A}\mathbf{A}^{\top}$ the Gram matrix, so that corollary is the special case of (d) in which the ambient space is $\mathbb{R}^n$. The pointer left there is now paid: a Gram matrix is exactly a matrix of pairwise inner products, and its determinant is non-negative for that reason.

Example. (Deciding Independence with a Gram Matrix)

Decide whether $((1,1,0),(1,0,1),(0,1,-1))$ is independent in $\mathbb{R}^3$, using its Gram matrix.

Solution. The pairwise dot products give

$$\mathbf{G} = \begin{pmatrix} 2 & 1 & 1 \\ 1 & 2 & -1 \\ 1 & -1 & 2 \end{pmatrix},$$

and expanding along the first row, $\det \mathbf{G} = 2(4-1) - 1(2+1) + 1(-1-2) = 6 - 3 - 3 = 0$. By Theorem 10.2.5 (d) the list is dependent. Indeed $\mathbf{Gx} = \mathbf{0}$ for $\mathbf{x} = (1,-1,-1)$, and Theorem 10.2.5 (c) says this is a dependence relation: $(1,1,0) - (1,0,1) - (0,1,-1) = \mathbf{0}$.

Two features of this method are worth noting. It never needs coordinates in the ambient space, so it works verbatim for polynomials and functions, where writing the vectors as columns is not an option. And the answer comes with a witness: a null vector of $\mathbf{G}$ is a dependence relation,

ready to read off.

10.2.7 Exercises

10.2.7.1 A. Check your understanding

Exercise A1.

(a) Define an orthonormal list, using the Kronecker delta, and say what an orthonormal basis is.

(b) Why is every orthonormal list linearly independent? Name the result used.

(c) Write down the coordinates of $\mathbf{v}$ in an orthonormal basis $(\mathbf{e}_1, \dots, \mathbf{e}_n)$, and state Parseval's identity.

(d) True or false: the Gram–Schmidt process (Theorem 10.2.2) applied to a list and to the same list in reverse order produces the same orthonormal list. Justify your answer.

(e) State the criterion for linear independence in terms of the Gram matrix.

(f) True or false: every 3-dimensional real inner product space is isometrically isomorphic to $\mathbb{R}^3$ with the dot product. Justify your answer.

Solution.

(a) A list $(\mathbf{e}_1, \dots, \mathbf{e}_k)$ with $\langle \mathbf{e}_i, \mathbf{e}_j \rangle = \delta_{ij}$ for all i, j (Definition 10.2.1); an orthonormal basis is such a list that is also a basis (Definition 10.2.2).

(b) Its vectors are pairwise orthogonal and non-zero (each has norm 1), so Theorem 10.1.4 applies.

(c) $\mathbf{v} = \sum_i \langle \mathbf{v}, \mathbf{e}_i \rangle \mathbf{e}_i$, and $\|\mathbf{v}\|^2 = \sum_i |\langle \mathbf{v}, \mathbf{e}_i \rangle|^2$ (Theorem 10.2.1).

(d) False. On $((0,1),(1,1))$ the process returns $((0,1),(1,0))$, while on $((1,1),(0,1))$ it returns $\big(\frac{1}{\sqrt{2}}(1,1), \frac{1}{\sqrt{2}}(-1,1)\big)$.

(e) The list is independent if and only if its Gram matrix is invertible, if and only if $\det \mathbf{G} > 0$ (Theorem 10.2.5 (c), (d)).

(f) True. By Corollary 10.2.4, the coordinate map with respect to any orthonormal basis is an isometric isomorphism onto $\mathbb{R}^3$.

10.2.7.2 B. Practice

Exercise B1: Gram–Schmidt with numbers.

Apply the Gram–Schmidt process of Theorem 10.2.2 to each list, with the dot product.

(a) $((1,0,1),(1,1,0),(0,1,1))$ in $\mathbb{R}^3$.

(b) $((1,1,0,0),(1,0,1,0),(0,0,1,1))$ in $\mathbb{R}^4$.

Solution.

(a) $\|(1,0,1)\|^2 = 2$, so $\mathbf{e}_1 = \frac{1}{\sqrt{2}}(1,0,1)$. Next $\langle (1,1,0), \mathbf{e}_1\rangle = \frac{1}{\sqrt{2}}$, so

$$\mathbf{w}_2 = (1,1,0) - \tfrac{1}{2}(1,0,1) = \tfrac{1}{2}(1,2,-1),$$

with $\|\mathbf{w}_2\|^2 = \frac{1}{4}\cdot 6 = \frac{3}{2}$, giving $\mathbf{e}_2 = \frac{1}{\sqrt{6}}(1,2,-1)$. Finally $\langle (0,1,1), \mathbf{e}_1\rangle = \frac{1}{\sqrt{2}}$ and $\langle (0,1,1), \mathbf{e}_2\rangle = \frac{1}{\sqrt{6}}$, so

$$\mathbf{w}_3 = (0,1,1) - \tfrac{1}{2}(1,0,1) - \tfrac{1}{6}(1,2,-1) = \tfrac{2}{3}(-1,1,1),$$

with $\|\mathbf{w}_3\|^2 = \frac{4}{9}\cdot 3 = \frac{4}{3}$, giving $\mathbf{e}_3 = \frac{1}{\sqrt{3}}(-1,1,1)$.

(b) $\mathbf{e}_1 = \frac{1}{\sqrt{2}}(1,1,0,0)$. Then $\langle (1,0,1,0), \mathbf{e}_1\rangle = \frac{1}{\sqrt{2}}$, so

$$\mathbf{w}_2 = (1,0,1,0) - \tfrac{1}{2}(1,1,0,0) = \tfrac{1}{2}(1,-1,2,0),$$

with $\|\mathbf{w}_2\|^2 = \frac{1}{4}\cdot 6 = \frac{3}{2}$ and $\mathbf{e}_2 = \frac{1}{\sqrt{6}}(1,-1,2,0)$. Finally $\langle (0,0,1,1), \mathbf{e}_1\rangle = 0$ and $\langle (0,0,1,1), \mathbf{e}_2\rangle = \frac{2}{\sqrt{6}}$, so

$$\mathbf{w}_3 = (0,0,1,1) - \tfrac{1}{3}(1,-1,2,0) = \tfrac{1}{3}(-1,1,1,3),$$

with $\|\mathbf{w}_3\|^2 = \frac{1}{9}\cdot 12 = \frac{4}{3}$ and $\mathbf{e}_3 = \frac{1}{2\sqrt{3}}(-1,1,1,3)$.

Exercise B2: Gram–Schmidt on polynomials.

In $\mathbb{R}[x]_{\le 2}$ with $\langle p, q\rangle = \int_0^1 p(t)q(t)\,\mathrm{d}t$, apply the Gram–Schmidt process of Theorem 10.2.2 to $(1, x, x^2)$. Compare the monic outputs with those of Example (Gram–Schmidt on $1, x, x^2$) and explain the difference.

Solution. $\|1\|^2 = 1$, so $\mathbf{e}_1 = 1$. Then $\langle x, 1\rangle = \int_0^1 t\,\mathrm{d}t = \frac{1}{2}$, so $\mathbf{w}_2 = x - \frac{1}{2}$ and

$$\|\mathbf{w}_2\|^2 = \int_0^1 \left(t - \tfrac{1}{2}\right)^2 \mathrm{d}t = \tfrac{1}{3} - \tfrac{1}{2} + \tfrac{1}{4} = \tfrac{1}{12},$$

giving $\mathbf{e}_2 = \sqrt{3}\,(2x-1)$. Next $\langle x^2, \mathbf{e}_1\rangle = \frac{1}{3}$ and

$$\langle x^2, \mathbf{e}_2\rangle = \sqrt{3}\int_0^1 (2t^3 - t^2)\,\mathrm{d}t = \sqrt{3}\left(\tfrac{1}{2} - \tfrac{1}{3}\right) = \tfrac{\sqrt{3}}{6},$$

so $\mathbf{w}_3 = x^2 - \frac{1}{3} - \frac{\sqrt{3}}{6}\cdot\sqrt{3}(2x-1) = x^2 - x + \frac{1}{6}$. Its squared norm is

$$\int_0^1 \left(t^2 - t + \tfrac{1}{6}\right)^2 \mathrm{d}t = \tfrac{1}{180},$$

so $\mathbf{e}_3 = \sqrt{5}\,(6x^2 - 6x + 1)$.

The monic outputs are 1, $x - \frac{1}{2}$, $x^2 - x + \frac{1}{6}$, whereas on $[-1,1]$ they were 1, x, $x^2 - \frac{1}{3}$. Orthogonality is a property of the inner product, not of the polynomials: changing the interval changes which polynomials are orthogonal. These are the shifted Legendre polynomials, and the substitution $t \mapsto 2t - 1$ carries one family to the other.

Exercise B3: Coordinates without solving a system.

Let $\mathbf{e}_1 = \frac{1}{3}(1,2,2)$, $\mathbf{e}_2 = \frac{1}{3}(2,1,-2)$, $\mathbf{e}_3 = \frac{1}{3}(2,-2,1)$ in $\mathbb{R}^3$.

(a) Write $\mathbf{v} = (1,-1,4)$ in this basis.

(b) Compute $\|\mathbf{v}\|^2$ in two ways, and state which theorem says the answers agree.

(c) Compute $\langle \mathbf{v}, \mathbf{u} \rangle$ for $\mathbf{u} = (3,0,3)$ from the coordinates of $\mathbf{v}$ and $\mathbf{u}$, using Example (Reading Off Coordinates) for $\mathbf{u}$.

Solution.

(a) $\langle \mathbf{v}, \mathbf{e}_1 \rangle = \frac{1}{3}(1-2+8) = \frac{7}{3}$, $\langle \mathbf{v}, \mathbf{e}_2 \rangle = \frac{1}{3}(2-1-8) = -\frac{7}{3}$, $\langle \mathbf{v}, \mathbf{e}_3 \rangle = \frac{1}{3}(2+2+4) = \frac{8}{3}$. So $\mathbf{v} = \frac{7}{3}\mathbf{e}_1 - \frac{7}{3}\mathbf{e}_2 + \frac{8}{3}\mathbf{e}_3$.

(b) Directly, $\|\mathbf{v}\|^2 = 1 + 1 + 16 = 18$. From the coordinates, $\frac{49}{9} + \frac{49}{9} + \frac{64}{9} = \frac{162}{9} = 18$. They agree by Theorem 10.2.1 (c).

(c) The coordinates of $\mathbf{u}$ are $(3,0,3)$ by Example (Reading Off Coordinates), so by Theorem 10.2.1 (b),

$$\langle \mathbf{v}, \mathbf{u} \rangle = \tfrac{7}{3} \cdot 3 + \big(-\tfrac{7}{3}\big) \cdot 0 + \tfrac{8}{3} \cdot 3 = 7 + 8 = 15.$$

Directly, $\langle \mathbf{v}, \mathbf{u} \rangle = 3 + 0 + 12 = 15$.

Exercise B4: Gram matrices.

For each list, write down the Gram matrix and use it to decide whether the list is independent.

(a) $((1,1,0),(1,0,1),(0,1,1))$ in $\mathbb{R}^3$ with the dot product.

(b) $((1,i),(i,1))$ in $\mathbb{C}^2$ with the standard inner product.

(c) $(1, x, x^2 - \frac{1}{3})$ in $\mathbb{R}[x]_{\le 2}$ with $\langle p, q \rangle = \int_{-1}^{1} pq$.

Solution.

(a) $\mathbf{G} = \begin{pmatrix} 2 & 1 & 1 \\ 1 & 2 & 1 \\ 1 & 1 & 2 \end{pmatrix}$, and expanding along the first row, $\det \mathbf{G} = 2(4-1) - 1(2-1) + 1(1-2) = 6 - 1 - 1 = 4 > 0$. By Theorem 10.2.5 (d) the list is independent.

(b) $\langle (1,i),(1,i) \rangle = 1 + 1 = 2$ and $\langle (i,1),(1,i) \rangle = i\overline{1} + 1\overline{i} = i - i = 0$, so $\mathbf{G} = 2\mathbf{I}_2$ by Theorem 10.2.5 (a). Then $\det \mathbf{G} = 4 > 0$ and the list is independent; in fact it is orthogonal, so Theorem 10.1.4 already gives the answer.

(c) These are the monic outputs of Example (Gram–Schmidt on $1, x, x^2$), so they are pairwise orthogonal, and $\mathbf{G} = \operatorname{diag}(2, \frac{2}{3}, \frac{8}{45})$. Its determinant is $2 \cdot \frac{2}{3} \cdot \frac{8}{45} = \frac{32}{135} > 0$, so the list is independent. A Gram matrix is diagonal exactly when the list is orthogonal.

10.2.7.3 C. Going deeper

Exercise C1: The Gram matrix determines the list.

Let $(\mathbf{v}_1,\dots,\mathbf{v}_k)$ be a list in an inner product space V and $(\mathbf{w}_1,\dots,\mathbf{w}_k)$ a list in an inner product space W, both over F, with the **same** Gram matrix: $\langle \mathbf{v}_j,\mathbf{v}_i\rangle = \langle \mathbf{w}_j,\mathbf{w}_i\rangle$ for all i,j.

(a) Prove that $\sum_j x_j\mathbf{v}_j=\mathbf{0}$ if and only if $\sum_j x_j\mathbf{w}_j=\mathbf{0}$, for every $\mathbf{x}\in F^k$.

(b) Deduce that there is a well-defined isomorphism $T\colon \operatorname{span}(\mathbf{v}_1,\dots,\mathbf{v}_k)\to\operatorname{span}(\mathbf{w}_1,\dots,\mathbf{w}_k)$ with $T\mathbf{v}_j=\mathbf{w}_j$ for every j.

(c) Prove that T is an isometric isomorphism, that is, $\langle T\mathbf{u},T\mathbf{u}'\rangle=\langle\mathbf{u},\mathbf{u}'\rangle$ for all $\mathbf{u},\mathbf{u}'$ in the domain.

Solution.

(a) Let $\mathbf{G}$ be the common Gram matrix. By Theorem 10.2.5 (b), $\big\|\sum_j x_j\mathbf{v}_j\big\|^2 = \mathbf{x}^{*}\mathbf{G}\mathbf{x} = \big\|\sum_j x_j\mathbf{w}_j\big\|^2$. By Theorem 10.1.2 (a), one side is 0 if and only if the other is, and a norm is 0 only at the zero vector.

(b) Every element of $U=\operatorname{span}(\mathbf{v}_1,\dots,\mathbf{v}_k)$ is $\sum_j x_j\mathbf{v}_j$ for some $\mathbf{x}$. Define $T\big(\sum_j x_j\mathbf{v}_j\big)=\sum_j x_j\mathbf{w}_j$. This is well defined: if $\sum_j x_j\mathbf{v}_j=\sum_j y_j\mathbf{v}_j$, then $\sum_j(x_j-y_j)\mathbf{v}_j=\mathbf{0}$, so $\sum_j(x_j-y_j)\mathbf{w}_j=\mathbf{0}$ by (a), that is $\sum_j x_j\mathbf{w}_j=\sum_j y_j\mathbf{w}_j$. It is linear because the formula is linear in $\mathbf{x}$, it is surjective onto $\operatorname{span}(\mathbf{w}_1,\dots,\mathbf{w}_k)$ by construction, and it is injective: if $T(\sum x_j\mathbf{v}_j)=\mathbf{0}$, then $\sum x_j\mathbf{w}_j=\mathbf{0}$, so $\sum x_j\mathbf{v}_j=\mathbf{0}$ by (a).

(c) Let $\mathbf{u}=\sum_j x_j\mathbf{v}_j$ and $\mathbf{u}'=\sum_i y_i\mathbf{v}_i$. Expanding by (IP1) and Theorem 10.1.1 (b),

$$\langle\mathbf{u},\mathbf{u}'\rangle=\sum_{i}\sum_{j} x_j\overline{y_i}\,\langle\mathbf{v}_j,\mathbf{v}_i\rangle,$$

and the same computation in W gives $\langle T\mathbf{u},T\mathbf{u}'\rangle=\sum_i\sum_j x_j\overline{y_i}\langle\mathbf{w}_j,\mathbf{w}_i\rangle$. The two sums are equal term by term, since the Gram matrices agree.

Exercise C2: Gram–Schmidt on a dependent list.

Let $(\mathbf{v}_1,\dots,\mathbf{v}_m)$ be a list in an inner product space, **not** assumed independent, and run the recursion of Theorem 10.2.2.

(a) Let k be the smallest index with $\mathbf{v}_k\in\operatorname{span}(\mathbf{v}_1,\dots,\mathbf{v}_{k-1})$. Prove that the recursion is defined up to $\mathbf{e}_{k-1}$ and that $\mathbf{w}_k=\mathbf{0}$, so the step $\mathbf{e}_k=\mathbf{w}_k/\|\mathbf{w}_k\|$ fails.

(b) Repair the process: show that if, whenever $\mathbf{w}_k=\mathbf{0}$, we discard $\mathbf{v}_k$ and continue with $\mathbf{v}_{k+1}$, the output is an orthonormal basis of $\operatorname{span}(\mathbf{v}_1,\dots,\mathbf{v}_m)$.

(c) Run the repaired process on $((1,1,0),(2,2,0),(1,0,1))$ in $\mathbb{R}^3$.

Solution.

(a) The list $(\mathbf{v}_1,\dots,\mathbf{v}_{k-1})$ is independent, since a dependence among its members would, by Theorem 1.4.1, put some $\mathbf{v}_j$ with $j<k$ in the span of its predecessors, contradicting the minimality of k. So Theorem 10.2.2 applies to it and produces $\mathbf{e}_1,\dots,\mathbf{e}_{k-1}$ with $\operatorname{span}(\mathbf{e}_1,\dots,\mathbf{e}_{k-1})=\operatorname{span}(\mathbf{v}_1,\dots,\mathbf{v}_{k-1})=:U$. Since $\mathbf{v}_k\in U$, Theorem 10.2.1 (a) applied inside U gives $\mathbf{v}_k=\sum_{i<k}\langle\mathbf{v}_k,\mathbf{e}_i\rangle\mathbf{e}_i$, which is precisely the vector subtracted, so $\mathbf{w}_k=\mathbf{0}$. Dividing by $\|\mathbf{w}_k\|=0$ is impossible.

(b) Let $\mathbf{e}_1, \dots, \mathbf{e}_s$ be the vectors that the repaired process outputs. The proof of Theorem 10.2.2 shows, unchanged, that after processing $\mathbf{v}_1, \dots, \mathbf{v}_k$ the accumulated list is orthonormal and spans $\operatorname{span}(\mathbf{v}_1, \dots, \mathbf{v}_k)$: the only step that used independence was the claim $\mathbf{w}_k \neq \mathbf{0}$, and in the repaired process a step with $\mathbf{w}_k = \mathbf{0}$ discards a $\mathbf{v}_k$ that lies in the span already built, so the span does not change. Taking $k = m$, the output is an orthonormal list spanning $\operatorname{span}(\mathbf{v}_1, \dots, \mathbf{v}_m)$, hence an orthonormal basis of it.

(c) $\mathbf{e}_1 = \frac{1}{\sqrt{2}}(1,1,0)$. For $\mathbf{v}_2 = (2,2,0)$: $\langle \mathbf{v}_2, \mathbf{e}_1 \rangle = \frac{4}{\sqrt{2}} = 2\sqrt{2}$, so $\mathbf{w}_2 = (2,2,0) - 2\sqrt{2} \cdot \frac{1}{\sqrt{2}}(1,1,0) = \mathbf{0}$, and $\mathbf{v}_2$ is discarded. For $\mathbf{v}_3 = (1,0,1)$: $\langle \mathbf{v}_3, \mathbf{e}_1 \rangle = \frac{1}{\sqrt{2}}$, so $\mathbf{w}_3 = (1,0,1) - \frac{1}{2}(1,1,0) = \frac{1}{2}(1,-1,2)$, with $\|\mathbf{w}_3\|^2 = \frac{6}{4} = \frac{3}{2}$ and $\mathbf{e}_2 = \frac{1}{\sqrt{6}}(1,-1,2)$. The output $\left(\frac{1}{\sqrt{2}}(1,1,0), \frac{1}{\sqrt{6}}(1,-1,2)\right)$ is an orthonormal basis of the plane spanned by the three given vectors.

10.3 Orthogonal Complements and Projections

Chapter 1 proved that every subspace of a finite-dimensional space has a complement, and then warned that it has many: the x-axis in $\mathbb{R}^2$ is complemented by every other line through the origin. An inner product breaks the tie. Among all the complements of U there is now one built from U alone, the set of vectors perpendicular to everything in U, and the projection onto U along it turns out to solve an approximation problem: it finds the vector of U closest to a given $\mathbf{v}$. This section constructs that complement, that projection, and that answer.

Throughout, V is an inner product space over $F = \mathbb{R}$ or $F = \mathbb{C}$, with inner product $\langle \cdot, \cdot \rangle$ (Definition 10.1.1) and induced norm $\|\cdot\|$ (Definition 10.1.3). We do **not** assume V is finite-dimensional; what we assume, each time, is that the subspace we project onto is.

10.3.1 Orthogonal complements

In $\mathbb{R}^3$, a plane U through the origin has a distinguished line attached to it: the normal line, the set of vectors perpendicular to the whole plane. Nothing about the plane had to be chosen to produce it. That construction is available in any inner product space, and it is available for any subset, not only for subspaces.

The orthogonal complement of U collects every vector that is perpendicular to all of U at once.

Definition 10.3.1 — Orthogonal complement

Let V be an inner product space over F and let $S \subseteq V$ be **any** subset. The **orthogonal complement** of S is

$$S^{\perp} = \{\, \mathbf{v} \in V : \langle \mathbf{v}, \mathbf{s} \rangle = 0 \text{ for every } \mathbf{s} \in S \,\},$$

read "S perp".

In words: $\mathbf{v}$ belongs to $S^\perp$ when $\mathbf{v}$ is orthogonal (Definition 10.1.4) to **every** single element of S, not merely to some of them. The quantifier is what makes the definition useful, and it is also what makes $S^\perp$ a subspace even when S is not. Note that the condition could equally be written $\langle \mathbf{s}, \mathbf{v} \rangle = 0$ for every $\mathbf{s} \in S$, since $\langle \mathbf{s}, \mathbf{v} \rangle = \overline{\langle \mathbf{v}, \mathbf{s} \rangle}$ and a complex number vanishes exactly when its conjugate does. We will use whichever slot is convenient.

Proposition 10.3.1 — Perp is always a subspace

For every subset S of an inner product space V, the set $S^\perp$ is a subspace of V. Moreover $S^\perp = \operatorname{span}(S)^\perp$.

Proof. We apply the Subspace Test (Theorem 1.2.1). First, $\langle \mathbf{0}, \mathbf{s} \rangle = 0$ for every $\mathbf{s}$, because $\langle \cdot, \mathbf{s} \rangle$ is linear in the first slot and a linear map sends $\mathbf{0}$ to 0 (Theorem 3.1.1); so $\mathbf{0} \in S^\perp$. Next, let $\mathbf{v}, \mathbf{w} \in S^\perp$ and $a \in F$. For every $\mathbf{s} \in S$,

$$\langle \mathbf{v} + \mathbf{w}, \mathbf{s} \rangle = \langle \mathbf{v}, \mathbf{s} \rangle + \langle \mathbf{w}, \mathbf{s} \rangle = 0, \qquad \langle a\mathbf{v}, \mathbf{s} \rangle = a \langle \mathbf{v}, \mathbf{s} \rangle = 0,$$

both by linearity in the first slot. Hence $\mathbf{v} + \mathbf{w} \in S^\perp$ and $a\mathbf{v} \in S^\perp$.

For the second claim, $S \subseteq \operatorname{span}(S)$ gives $\operatorname{span}(S)^\perp \subseteq S^\perp$. Conversely let $\mathbf{v} \in S^\perp$ and let $\mathbf{u} = a_1 \mathbf{s}_1 + \cdots + a_k \mathbf{s}_k$ with $\mathbf{s}_i \in S$. Then

$$\langle \mathbf{u}, \mathbf{v} \rangle = a_1 \langle \mathbf{s}_1, \mathbf{v} \rangle + \cdots + a_k \langle \mathbf{s}_k, \mathbf{v} \rangle = 0,$$

since each $\langle \mathbf{s}_i, \mathbf{v} \rangle = \overline{\langle \mathbf{v}, \mathbf{s}_i \rangle} = 0$. So $\langle \mathbf{v}, \mathbf{u} \rangle = \overline{\langle \mathbf{u}, \mathbf{v} \rangle} = 0$, and $\mathbf{v} \in \operatorname{span}(S)^\perp$.

■

The second half is what makes computation possible: to test membership in $U^\perp$ it is enough to test against a spanning list of U, not against all of U.

Examples.

- **The extremes.** $\{\mathbf{0}\}^\perp = V$, since $\langle \mathbf{v}, \mathbf{0} \rangle = 0$ always. And $V^\perp = \{\mathbf{0}\}$: if $\mathbf{v} \in V^\perp$, then in particular $\langle \mathbf{v}, \mathbf{v} \rangle = 0$, and positive definiteness forces $\mathbf{v} = \mathbf{0}$. This is the "pair it with itself" move, and it is the shape in which positivity almost always enters; it is the only place where positivity is used; we will use it again and again.
- **A plane in $\mathbb{R}^3$.** Let $U = \{(x, y, z) : x + y + z = 0\}$ with the dot product. The condition $x + y + z = 0$ says exactly $\langle (x, y, z), (1, 1, 1) \rangle = 0$, so $U = \{(1, 1, 1)\}^\perp$. The Orthogonal Decomposition Theorem below will give the converse, $U^\perp = \operatorname{span}((1, 1, 1))$.
- **A subset that is not a subspace.** In $\mathbb{R}^3$, take $S = \{(1, 0, 0), (1, 1, 0)\}$, two vectors and nothing else. Then $S^\perp = \{(x, y, z) : x = 0,\ x + y = 0\} = \operatorname{span}((0, 0, 1))$, a subspace, as Proposition 10.3.1 promises. It equals $\operatorname{span}(S)^\perp$, the perp of the xy-plane.
- **Polynomials.** On $\mathbb{R}[x]_{\le 2}$ with $\langle p, q \rangle = \int_{-1}^{1} p(t) q(t)\, \mathrm{d}t$, let $U = \operatorname{span}(1)$ be the constants. Then $p \in U^\perp$ means $\int_{-1}^{1} p(t)\, \mathrm{d}t = 0$: the polynomials of average value zero. For instance x and $x^2 - \frac{1}{3}$ lie in $U^\perp$, and they span it, since the Orthogonal Decomposition Theorem below gives $\dim U^\perp = 3 - 1 = 2$.

Non-example by minimal change. Weaken "for every $\mathbf{s} \in S$" to "for some $\mathbf{s} \in S$". With $S = \{\mathbf{e}_1, \mathbf{e}_2\}$ in $\mathbb{R}^2$, the weakened set is $\{\mathbf{v} : \langle \mathbf{v}, \mathbf{e}_1 \rangle = 0 \text{ or } \langle \mathbf{v}, \mathbf{e}_2 \rangle = 0\}$, the union of the two axes. Closure under scalars still holds, and $\mathbf{0}$ still belongs; what fails is closure under addition, since $(1, 0) + (0, 1) = (1, 1)$ lies on neither axis. This is the union of Example (The Union of the

Two Axes) again, in new clothing. The universal quantifier is doing real work.

Why this definition. One could try to define "the" complement of U by choosing a basis of U, extending it, and spanning the new vectors, which is what Theorem 1.7.6 does. That answer depends on every choice made along the way. The definition above depends only on U and on the inner product, and the next theorem shows that it really is a complement.

10.3.2 The orthogonal decomposition

Here is the theorem that makes $U^{\perp}$ more than a definition. Note the hypothesis: U must be finite-dimensional, but V need not be. The reason is that the proof needs an orthonormal basis of U, and Gram–Schmidt supplies one only for a finite list.

Theorem 10.3.2 — Orthogonal Decomposition Theorem

Let V be an inner product space over F and let U be a **finite-dimensional** subspace of V. Then:

(a) $V = U \oplus U^{\perp}$;
(b) $(U^{\perp})^{\perp} = U$;
(c) if in addition V is finite-dimensional, then $\dim U^{\perp} = \dim V - \dim U$.

Idea. For (a) we must produce, from an arbitrary $\mathbf{v}$, a piece inside U and a piece perpendicular to U. Fix an orthonormal basis of U. Theorem 10.2.1 says that a vector **of** U is the sum of its coordinates against that basis; so for a $\mathbf{v}$ that is not in U, the same sum is the natural guess for the U-piece. Then we subtract and check. That is the move of Gram–Schmidt — project, then subtract — used once instead of repeatedly. Uniqueness of the splitting is the "pair with itself" move. For (b), one inclusion is free and the other is (a) applied twice.

Proof.

(a) Since U is finite-dimensional, it has an orthonormal basis $(\mathbf{e}_1, \dots, \mathbf{e}_k)$ by Theorem 10.2.2. Let $\mathbf{v} \in V$ and put

$$\mathbf{u} = \sum_{i=1}^{k} \langle \mathbf{v}, \mathbf{e}_i \rangle \mathbf{e}_i \in U, \qquad \mathbf{w} = \mathbf{v} - \mathbf{u}.$$

For each j,

$$\langle \mathbf{w}, \mathbf{e}_j \rangle = \langle \mathbf{v}, \mathbf{e}_j \rangle - \sum_{i=1}^{k} \langle \mathbf{v}, \mathbf{e}_i \rangle \langle \mathbf{e}_i, \mathbf{e}_j \rangle = \langle \mathbf{v}, \mathbf{e}_j \rangle - \langle \mathbf{v}, \mathbf{e}_j \rangle = 0,$$

where the middle step uses $\langle \mathbf{e}_i, \mathbf{e}_j \rangle = \delta_{ij}$. So $\mathbf{w}$ is orthogonal to each $\mathbf{e}_j$, hence to $\operatorname{span}(\mathbf{e}_1, \dots, \mathbf{e}_k) = U$ by Proposition 10.3.1. Therefore $\mathbf{v} = \mathbf{u} + \mathbf{w} \in U + U^{\perp}$. The sum is direct: if $\mathbf{x} \in U \cap U^{\perp}$, then $\langle \mathbf{x}, \mathbf{x} \rangle = 0$ because $\mathbf{x} \in U^{\perp}$ and $\mathbf{x} \in U$, so $\mathbf{x} = \mathbf{0}$ by positive definiteness. By Theorem 1.7.4, $V = U \oplus U^{\perp}$.

(b) ($\subseteq$) Let $\mathbf{u} \in U$. For every $\mathbf{w} \in U^{\perp}$ we have $\langle \mathbf{w}, \mathbf{u} \rangle = 0$, hence $\langle \mathbf{u}, \mathbf{w} \rangle = \overline{\langle \mathbf{w}, \mathbf{u} \rangle} = 0$. So $\mathbf{u} \in (U^{\perp})^{\perp}$.

($\supseteq$) Let $\mathbf{v} \in (U^\perp)^\perp$. By (a), write $\mathbf{v} = \mathbf{u} + \mathbf{w}$ with $\mathbf{u} \in U$ and $\mathbf{w} \in U^\perp$. By the inclusion just proved, $\mathbf{u} \in (U^\perp)^\perp$, so $\mathbf{w} = \mathbf{v} - \mathbf{u} \in (U^\perp)^\perp$ as well. Thus $\mathbf{w}$ lies in both $U^\perp$ and $(U^\perp)^\perp$, giving $\langle \mathbf{w}, \mathbf{w} \rangle = 0$ and $\mathbf{w} = \mathbf{0}$. Hence $\mathbf{v} = \mathbf{u} \in U$.

(c) By (a), $U^\perp$ is a complement of U in V, so $\dim U^\perp = \dim V - \dim U$ by Theorem 1.7.6.

■

Part (b) is worth pausing on. For a general subspace of a general vector space there is no operation "$\perp$" to apply twice, and even for the annihilator of Chapter 4 the analogous statement needed the double dual. Here it is a two-line consequence of (a). Part (c) says that $\perp$ exchanges dimension k with dimension $n - k$, just as the annihilator does (Theorem 4.2.2); Section 5 explains why the two facts are the same fact.

Quick check. Positive definiteness was used twice in the proof of Theorem 10.3.2, in the same way each time. Where? To see that it cannot be dropped, take $\mathbb{R}^2$ with the indefinite form $\beta(\mathbf{x}, \mathbf{y}) = x_1 y_1 - x_2 y_2$, let $U = \operatorname{span}((1, 1))$, and write $U^\perp$ for the set of $\mathbf{v}$ with $\beta(\mathbf{v}, \mathbf{u}) = 0$ for all $\mathbf{u} \in U$. Compute $U \cap U^\perp$.

Solution. It was used to show $U \cap U^\perp = \{\mathbf{0}\}$ in (a), and again for $\mathbf{w} = \mathbf{0}$ in (b); both times through "$\langle \mathbf{x}, \mathbf{x} \rangle = 0$ forces $\mathbf{x} = \mathbf{0}$".

With β, the vector $\mathbf{u} = (1, 1)$ satisfies $\beta(\mathbf{u}, \mathbf{u}) = 1 - 1 = 0$, so $\mathbf{u}$ is "orthogonal to itself" and $\mathbf{u} \in U^\perp$. Hence $U \cap U^\perp = U \neq \{\mathbf{0}\}$, and the sum $U + U^\perp$ is not direct. Indeed $U^\perp = \{(x_1, x_2) : x_1 - x_2 = 0\} = U$ here, so $U + U^\perp = U$ is not all of $\mathbb{R}^2$. Both conclusions of the theorem fail.

10.3.3 Orthogonal projection

Once $V = U \oplus U^\perp$, Chapter 3 hands us an operator: the projection onto U along $U^\perp$ (Theorem 3.10.1). It deserves its own name and symbol, because the complement is no longer a choice.

Definition 10.3.2 — Orthogonal projection

Let U be a finite-dimensional subspace of an inner product space V. By Theorem 10.3.2 (a), every $\mathbf{v} \in V$ has a unique splitting $\mathbf{v} = \mathbf{u} + \mathbf{w}$ with $\mathbf{u} \in U$ and $\mathbf{w} \in U^\perp$. The **orthogonal projection onto** U is the operator $P_U \in \mathcal{L}(V)$ defined by

$$P_U \mathbf{v} = \mathbf{u}.$$

The definition makes sense because the splitting exists and is unique, and P_U is linear by Theorem 3.10.1 (b), which also gives $P_U^2 = P_U$, $\operatorname{im} P_U = U$ and $\ker P_U = U^\perp$. Nothing so far tells us how to compute $P_U \mathbf{v}$. The proof of Theorem 10.3.2 does, and that is the next theorem.

Theorem 10.3.3 — Projection formula

Let U be a finite-dimensional subspace of an inner product space V, with orthonormal

basis $(\mathbf{e}_1, \dots, \mathbf{e}_k)$. Then for every $\mathbf{v} \in V$:

(a) $P_U\mathbf{v} = \sum_{i=1}^{k} \langle \mathbf{v}, \mathbf{e}_i \rangle \mathbf{e}_i$;

(b) $\langle P_U\mathbf{u}, \mathbf{v} \rangle = \langle \mathbf{u}, P_U\mathbf{v} \rangle$ for all $\mathbf{u}, \mathbf{v} \in V$;

(c) $\|P_U\mathbf{v}\| \le \|\mathbf{v}\|$, with equality if and only if $\mathbf{v} \in U$.

Idea. Part (a) is not a new computation: the vector $\mathbf{u}$ built in the proof of Theorem 10.3.2 (a) was exactly this sum, and by uniqueness of the splitting it must be $P_U\mathbf{v}$. For (b), split **both** $\mathbf{u}$ and $\mathbf{v}$, and watch the cross terms die. For (c), split $\mathbf{v}$ and use Pythagoras.

Proof.

(a) Put $\mathbf{u} = \sum_i \langle \mathbf{v}, \mathbf{e}_i \rangle \mathbf{e}_i$ and $\mathbf{w} = \mathbf{v} - \mathbf{u}$. The proof of Theorem 10.3.2 (a) showed $\mathbf{u} \in U$ and $\mathbf{w} \in U^{\perp}$. Since the splitting of $\mathbf{v}$ in $U \oplus U^{\perp}$ is unique (Definition 1.7.2), $P_U\mathbf{v} = \mathbf{u}$.

(b) Write $\mathbf{u} = \mathbf{u}_1 + \mathbf{u}_2$ and $\mathbf{v} = \mathbf{v}_1 + \mathbf{v}_2$ with $\mathbf{u}_1, \mathbf{v}_1 \in U$ and $\mathbf{u}_2, \mathbf{v}_2 \in U^{\perp}$. Then $\langle \mathbf{u}_1, \mathbf{v}_2 \rangle = 0$ because $\mathbf{v}_2 \in U^{\perp}$ and $\mathbf{u}_1 \in U$, and $\langle \mathbf{u}_2, \mathbf{v}_1 \rangle = 0$ for the same reason with the roles swapped. Hence

$$\langle P_U\mathbf{u}, \mathbf{v} \rangle = \langle \mathbf{u}_1, \mathbf{v}_1 + \mathbf{v}_2 \rangle = \langle \mathbf{u}_1, \mathbf{v}_1 \rangle = \langle \mathbf{u}_1 + \mathbf{u}_2, \mathbf{v}_1 \rangle = \langle \mathbf{u}, P_U\mathbf{v} \rangle.$$

(c) With $\mathbf{v} = \mathbf{v}_1 + \mathbf{v}_2$ as above, $\mathbf{v}_1$ and $\mathbf{v}_2$ are orthogonal, so $\|\mathbf{v}\|^2 = \|\mathbf{v}_1\|^2 + \|\mathbf{v}_2\|^2$ by Theorem 10.1.3. Since $\|\mathbf{v}_2\|^2 \ge 0$, this gives $\|P_U\mathbf{v}\|^2 = \|\mathbf{v}_1\|^2 \le \|\mathbf{v}\|^2$. Equality holds if and only if $\|\mathbf{v}_2\| = 0$, that is $\mathbf{v}_2 = \mathbf{0}$, that is $\mathbf{v} = \mathbf{v}_1 \in U$.

■

Two comments. First, the right-hand side of (a) visibly depends on the orthonormal basis chosen, while the left-hand side does not; so the sum $\sum_i \langle \mathbf{v}, \mathbf{e}_i \rangle \mathbf{e}_i$ is the same for every orthonormal basis of U. That is a genuine piece of information, obtained for free. Second, property (b) says that P_U can be moved from one slot of the inner product to the other at no cost. Section 6 will call such an operator **self-adjoint** and write the property as $P_U^* = P_U$; we proved the property here so that nothing later depends on the order of the sections.

Orthonormal bases are convenient but not obligatory, and by hand it is usually faster to skip the square roots.

Corollary 10.3.4 — Projecting with an orthogonal basis

Let U be a finite-dimensional subspace of an inner product space V, and let $(\mathbf{u}_1, \dots, \mathbf{u}_k)$ be an **orthogonal** basis of U, so that $\langle \mathbf{u}_i, \mathbf{u}_j \rangle = 0$ for $i \ne j$ and every $\mathbf{u}_i \ne \mathbf{0}$. Then

$$P_U\mathbf{v} = \sum_{i=1}^{k} \frac{\langle \mathbf{v}, \mathbf{u}_i \rangle}{\langle \mathbf{u}_i, \mathbf{u}_i \rangle} \mathbf{u}_i \qquad \text{for every } \mathbf{v} \in V.$$

Proof. Each $\mathbf{u}_i$ is non-zero, so $\|\mathbf{u}_i\| > 0$ and $\mathbf{e}_i = \mathbf{u}_i / \|\mathbf{u}_i\|$ is defined. Each $\mathbf{e}_i$ is a non-zero multiple of $\mathbf{u}_i$, so $(\mathbf{e}_1, \dots, \mathbf{e}_k)$ is again a basis of U, and it is orthonormal:

$\langle \mathbf{e}_i, \mathbf{e}_j \rangle = \langle \mathbf{u}_i, \mathbf{u}_j \rangle / (\|\mathbf{u}_i\| \|\mathbf{u}_j\|) = \delta_{ij}$. By Theorem 10.3.3 (a),

$$P_U \mathbf{v} = \sum_{i=1}^{k} \langle \mathbf{v}, \mathbf{e}_i \rangle \, \mathbf{e}_i = \sum_{i=1}^{k} \frac{\langle \mathbf{v}, \mathbf{u}_i \rangle}{\|\mathbf{u}_i\|^2} \, \mathbf{u}_i,$$

where the two factors $1/\|\mathbf{u}_i\|$ come out unchanged, the one in the second slot because $\|\mathbf{u}_i\|$ is real. Finally $\|\mathbf{u}_i\|^2 = \langle \mathbf{u}_i, \mathbf{u}_i \rangle$ by Definition 10.1.3.

■

Each summand $\langle \mathbf{v}, \mathbf{u}_i \rangle \mathbf{u}_i / \langle \mathbf{u}_i, \mathbf{u}_i \rangle$ is the projection of $\mathbf{v}$ onto the line $\operatorname{span}(\mathbf{u}_i)$: the case $k = 1$ of the corollary.

10.3.4 Best approximation and distance

Now the payoff. Of all the vectors of U, which is nearest to a given $\mathbf{v}$? In $\mathbb{R}^3$, dropping a perpendicular from a point to a plane is the familiar recipe, and the recipe is correct in every inner product space.

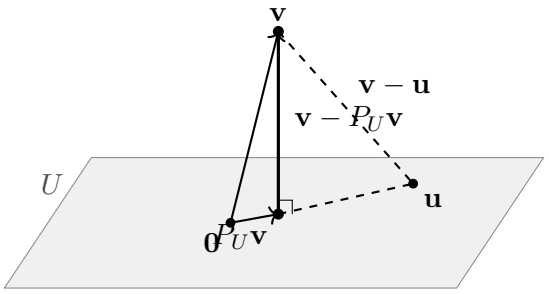
Theorem 10.3.5 — Best Approximation Theorem

Let U be a finite-dimensional subspace of an inner product space V, and let $\mathbf{v} \in V$. Then

$$\|\mathbf{v} - P_U \mathbf{v}\| \le \|\mathbf{v} - \mathbf{u}\| \qquad \text{for every } \mathbf{u} \in U,$$

and equality holds **only** for $\mathbf{u} = P_U \mathbf{v}$.

Idea. Insert $P_U \mathbf{v}$ into the difference: $\mathbf{v} - \mathbf{u} = (\mathbf{v} - P_U \mathbf{v}) + (P_U \mathbf{v} - \mathbf{u})$. The first bracket is perpendicular to U and the second lies in U, so the two are orthogonal, and Pythagoras turns the comparison into "a sum of two squares is at least one of them". The picture is a right triangle with hypotenuse $\mathbf{v} - \mathbf{u}$.



Proof. Let $\mathbf{u} \in U$ and write

$$\mathbf{v} - \mathbf{u} = (\mathbf{v} - P_U \mathbf{v}) + (P_U \mathbf{v} - \mathbf{u}).$$

The first bracket lies in $U^\perp$, since $\mathbf{v} - P_U \mathbf{v}$ is the $U^\perp$-part of $\mathbf{v}$ in Theorem 10.3.2 (a). The second lies in U, since $P_U \mathbf{v} \in U$ and $\mathbf{u} \in U$. Hence the two brackets are orthogonal,

and Theorem 10.1.3 gives

$$\|\mathbf{v}-\mathbf{u}\|^2 = \|\mathbf{v}-P_U\mathbf{v}\|^2 + \|P_U\mathbf{v}-\mathbf{u}\|^2 \geq \|\mathbf{v}-P_U\mathbf{v}\|^2.$$

Taking square roots proves the inequality, since the norm is non-negative. Equality forces $\|P_U\mathbf{v}-\mathbf{u}\|^2 = 0$, hence $P_U\mathbf{v}-\mathbf{u} = \mathbf{0}$ by positive definiteness, that is $\mathbf{u} = P_U\mathbf{v}$. This proves the theorem.

■

So the minimum is attained, and attained at exactly one point. That lets us define a distance.

Definition 10.3.3 — Distance to a subspace

Let U be a finite-dimensional subspace of an inner product space V and let $\mathbf{v} \in V$. The **distance from $\mathbf{v}$ to U** is

$$d(\mathbf{v}, U) = \min_{\mathbf{u}\in U}\|\mathbf{v}-\mathbf{u}\| = \|\mathbf{v}-P_U\mathbf{v}\|.$$

The word **minimum** is justified, not sloppy: Theorem 10.3.5 says the values $\|\mathbf{v}-\mathbf{u}\|$ really do have a smallest one. Note also that $d(\mathbf{v}, U) = 0$ if and only if $\mathbf{v} \in U$, and that, when V is finite-dimensional, $d(\mathbf{v}, U) = \|P_{U^\perp}\mathbf{v}\|$, since $\mathbf{v} - P_U\mathbf{v}$ is the $U^\perp$-component of $\mathbf{v}$. (The hypothesis is needed for $P_{U^\perp}$ to be defined at all: Definition 10.3.2 asks the subspace projected onto to be finite-dimensional, and $U^\perp$ is not, in the infinite-dimensional setting this section is careful to allow.) When $U^\perp$ is the smaller of the two, computing that component is the faster route.

Example. (Distance from a point to a plane)

In $\mathbb{R}^3$ with the dot product, let $U = \{(x, y, z) : x + y + z = 0\}$ and $\mathbf{v} = (1, 2, 3)$. Find $P_U\mathbf{v}$ and $d(\mathbf{v}, U)$, twice: once through $U^\perp$, and once through an orthonormal basis of U.

Solution. Through $U^\perp$. Put $\mathbf{n} = (1, 1, 1)$. Every $(x, y, z) \in U$ satisfies $\langle(x, y, z), \mathbf{n}\rangle = x + y + z = 0$, so $\mathbf{n} \in U^\perp$. Since U is the solution set of one non-trivial equation, $\dim U = 2$, so $\dim U^\perp = 3 - 2 = 1$ by Theorem 10.3.2 (c), and therefore $U^\perp = \operatorname{span}(\mathbf{n})$. By Corollary 10.3.4 with the one-element basis $(\mathbf{n})$,

$$P_{U^\perp}\mathbf{v} = \frac{\langle\mathbf{v}, \mathbf{n}\rangle}{\langle\mathbf{n}, \mathbf{n}\rangle}\mathbf{n} = \frac{1+2+3}{3}(1, 1, 1) = (2, 2, 2),$$

so $P_U\mathbf{v} = \mathbf{v} - (2, 2, 2) = (-1, 0, 1)$ and $d(\mathbf{v}, U) = \|(2, 2, 2)\| = 2\sqrt{3}$.

Through an orthonormal basis of U. The vectors $(1, -1, 0)$ and $(1, 1, -2)$ lie in U and are orthogonal to each other, so

$$\mathbf{e}_1 = \tfrac{1}{\sqrt{2}}(1, -1, 0), \qquad \mathbf{e}_2 = \tfrac{1}{\sqrt{6}}(1, 1, -2)$$

is an orthonormal basis of U. Then $\langle\mathbf{v}, \mathbf{e}_1\rangle = (1 - 2)/\sqrt{2} = -1/\sqrt{2}$ and $\langle\mathbf{v}, \mathbf{e}_2\rangle = (1 + 2 - 6)/\sqrt{6} = -3/\sqrt{6}$, so Theorem 10.3.3 (a) gives

$$P_U\mathbf{v} = -\tfrac{1}{\sqrt{2}}\mathbf{e}_1 - \tfrac{3}{\sqrt{6}}\mathbf{e}_2 = -\tfrac{1}{2}(1, -1, 0) - \tfrac{1}{2}(1, 1, -2) = (-1, 0, 1),$$

the same answer. *Check:* $(-1)+0+1=0$, so $P_U\mathbf{v}\in U$; and $\mathbf{v}-P_U\mathbf{v}=(2,2,2)$ is a multiple of $\mathbf{n}$, so it lies in $U^\perp$. The two conditions together identify the splitting, by uniqueness.

The next example is the same theorem in a space of functions, where "closest" is no longer something one can see.

Example. (The best quadratic approximation to a cubic)

On $V=\mathbb{R}[x]_{\le 3}$ with $\langle p,q\rangle=\int_{-1}^{1}p(t)q(t)\,dt$, let $U=\mathbb{R}[x]_{\le 2}$. Find the polynomial of U closest to x^3, and the distance.

Solution. The list $(1,x,x^2-\frac{1}{3})$ is a basis of U, being three independent polynomials of degrees $0,1,2$ (Theorem 1.4.4) in a space of dimension 3. It is **orthogonal**: $\langle 1,x\rangle=0$ and $\langle x,x^2-\frac{1}{3}\rangle=0$ because the integrands are odd, and

$$\langle 1,x^2-\tfrac{1}{3}\rangle=\int_{-1}^{1}\Big(t^2-\tfrac{1}{3}\Big)dt=\tfrac{2}{3}-\tfrac{2}{3}=0.$$

Now apply Corollary 10.3.4 to $\mathbf{v}=x^3$. Two of the three coefficients vanish because t^3 is odd: $\langle x^3,1\rangle=0$ and $\langle x^3,x^2-\frac{1}{3}\rangle=0$. The remaining one is

$$\frac{\langle x^3,x\rangle}{\langle x,x\rangle}=\frac{\int_{-1}^{1}t^4\,dt}{\int_{-1}^{1}t^2\,dt}=\frac{2/5}{2/3}=\frac{3}{5}.$$

Hence $P_U(x^3)=\frac{3}{5}x$. The error is $x^3-\frac{3}{5}x$, with

$$\begin{aligned}\|x^3-\tfrac{3}{5}x\|^2&=\int_{-1}^{1}\Big(t^6-\tfrac{6}{5}t^4+\tfrac{9}{25}t^2\Big)dt\\&=\tfrac{2}{7}-\tfrac{6}{5}\cdot\tfrac{2}{5}+\tfrac{9}{25}\cdot\tfrac{2}{3}=\tfrac{2}{7}-\tfrac{6}{25}=\tfrac{8}{175},\end{aligned}$$

so $d(x^3,U)=\sqrt{8/175}=\frac{2}{35}\sqrt{14}\approx 0.214$.

Check. The error should be orthogonal to U. Against 1 and $x^2-\frac{1}{3}$ this holds because $t^3-\frac{3}{5}t$ is odd; against x it reads $\int_{-1}^{1}(t^4-\frac{3}{5}t^2)\,dt=\frac{2}{5}-\frac{3}{5}\cdot\frac{2}{3}=0$. Notice that the answer is **not** the Taylor polynomial of x^3 at 0, which is 0: Taylor approximates near one point, while P_U spreads the error over the whole interval.

10.3.5 Three traps

Warning. $U^\perp$ **is not the annihilator** U^0**.** Both objects consist of things that "kill" U, but they live in different places: $U^\perp\subseteq V$ is made of **vectors** (Definition 10.3.1), while $U^0\subseteq V^*$ is made of **functionals** (Definition 4.2.1). The annihilator exists over every field and needs no extra structure; the orthogonal complement needs an inner product, so it needs $F=\mathbb{R}$ or $F=\mathbb{C}$. They do have the same dimension, $\dim V-\dim U$ (Theorem 4.2.2, Theorem 10.3.2 (c)), and that is not a coincidence: Section 5 produces an explicit bijection $U^\perp\to U^0$. Until then, keep them apart.

Warning. **"Orthogonal projection" is a special case of Chapter 3's projections, not a synonym.** An operator with $P^2 = P$ is a projection onto $\operatorname{im} P$ **along** $\ker P$ (Definition 3.10.1, Theorem 3.10.1), and Chapter 3, §10 stressed that the direction matters: on $\mathbb{R}^2$, both $\begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}$ and $\begin{pmatrix} 1 & -1 \\ 0 & 0 \end{pmatrix}$ are projections onto the x-axis. Only the first is *orthogonal*, because only for the first is the kernel the perpendicular line; the second projects along $\operatorname{span}((1,1))$ and is called **oblique**. So P_U carries more information than "$P^2 = P$ and $\operatorname{im} P = U$": it also says which complement is used. Theorem 10.3.3 (b) is the extra property, and Exercise C3 below shows that it singles out the orthogonal projections among all projections.

Warning. $U^\perp$ **depends on the inner product, not only on** U**.** In $\mathbb{R}^2$ let $U = \operatorname{span}((1,1))$. With the dot product, $U^\perp = \operatorname{span}((1,-1))$. With the weighted inner product $\langle \mathbf{x}, \mathbf{y} \rangle = 2x_1y_1 + x_2y_2$, a vector (a,b) is orthogonal to $(1,1)$ when $2a + b = 0$, so $U^\perp = \operatorname{span}((1,-2))$. Same subspace, different perpendicular. The symbol $\perp$ always hides a choice of $\langle \cdot, \cdot \rangle$, and when two inner products are in play the notation must say which.

10.3.6 Exercises

10.3.6.1 A. Check your understanding

Exercise A1.

(a) Define the orthogonal complement $S^\perp$ of a subset S of an inner product space.

(b) True or false: $S^\perp$ is a subspace only when S is a subspace. Justify your answer.

(c) State the Orthogonal Decomposition Theorem, including every hypothesis.

(d) Let U be a 3-dimensional subspace of $\mathbb{R}^7$. What is $\dim U^\perp$, and what is $\dim (U^\perp)^\perp$?

(e) What quantity does $P_U \mathbf{v}$ minimize, and over what set?

(f) Name two differences between $U^\perp$ and the annihilator U^0.

Solution.

(a) $S^\perp = \{\mathbf{v} \in V : \langle \mathbf{v}, \mathbf{s} \rangle = 0 \text{ for every } \mathbf{s} \in S\}$ (Definition 10.3.1).

(b) False. $S^\perp$ is a subspace for **every** subset S, by Proposition 10.3.1, and it equals $\operatorname{span}(S)^\perp$. For instance $\{(1,0,0),(1,1,0)\}^\perp = \operatorname{span}((0,0,1))$ in $\mathbb{R}^3$.

(c) If V is an inner product space over $\mathbb{R}$ or $\mathbb{C}$ and U is a **finite-dimensional** subspace, then $V = U \oplus U^\perp$ and $(U^\perp)^\perp = U$; if V is also finite-dimensional, then $\dim U^\perp = \dim V - \dim U$ (Theorem 10.3.2). V itself need not be finite-dimensional.

(d) $\dim U^\perp = 7 - 3 = 4$ and $\dim (U^\perp)^\perp = \dim U = 3$, by Theorem 10.3.2 (c) and (b).

(e) It minimizes $\|\mathbf{v} - \mathbf{u}\|$ over $\mathbf{u} \in U$, and it is the **only** minimizer (Theorem 10.3.5).

(f) $U^\perp$ consists of vectors of V, U^0 of functionals in V^*; and $U^\perp$ needs an inner product (so $F = \mathbb{R}$ or $\mathbb{C}$), while U^0 is defined over any field. A third difference: $U^\perp$ is a complement of U inside V, whereas U^0 is not a subspace of V at all.

10.3.6.2 B. Practice

Exercise B1: A complement and a projection in $\mathbb{R}^4$.

In $\mathbb{R}^4$ with the dot product, let $U = \operatorname{span}\big((1,1,0,0),\ (0,0,1,1)\big)$.

(a) Find a basis of $U^\perp$ and verify the dimension count.
(b) Compute $P_U\mathbf{v}$ and $d(\mathbf{v}, U)$ for $\mathbf{v} = (1,2,3,4)$.
(c) Verify directly that $\mathbf{v} - P_U\mathbf{v} \in U^\perp$.

Solution.

(a) By Proposition 10.3.1 it is enough to be orthogonal to the two spanning vectors, so $(a,b,c,d) \in U^\perp$ means $a+b=0$ and $c+d=0$. Hence

$$U^\perp = \operatorname{span}\big((1,-1,0,0),\ (0,0,1,-1)\big),$$

these two being independent (look at the first and third entries). So $\dim U^\perp = 2 = 4-2$, as Theorem 10.3.2 (c) requires.

(b) The spanning list of U is orthogonal, so Corollary 10.3.4 applies with $\mathbf{u}_1 = (1,1,0,0)$, $\mathbf{u}_2 = (0,0,1,1)$, both of squared norm 2:

$$P_U\mathbf{v} = \frac{1+2}{2}\mathbf{u}_1 + \frac{3+4}{2}\mathbf{u}_2 = \left(\tfrac{3}{2}, \tfrac{3}{2}, \tfrac{7}{2}, \tfrac{7}{2}\right).$$

Then $\mathbf{v} - P_U\mathbf{v} = \left(-\tfrac{1}{2}, \tfrac{1}{2}, -\tfrac{1}{2}, \tfrac{1}{2}\right)$ and $d(\mathbf{v}, U) = \sqrt{4 \cdot \tfrac{1}{4}} = 1$.

(c) The vector $\left(-\tfrac{1}{2}, \tfrac{1}{2}, -\tfrac{1}{2}, \tfrac{1}{2}\right)$ satisfies $a+b=0$ and $c+d=0$, so it lies in $U^\perp$ by (a).

Exercise B2: Distance from a point to a plane.

In $\mathbb{R}^3$ with the dot product, let $U = \{(x,y,z) : 2x - y + 2z = 0\}$ and $\mathbf{v} = (1,2,3)$. Compute $d(\mathbf{v}, U)$ and $P_U\mathbf{v}$, and check that $P_U\mathbf{v}$ lies in U. Hence write down the general formula for the distance from $\mathbf{v}$ to the plane $\{\mathbf{x} : \langle \mathbf{x}, \mathbf{n}\rangle = 0\}$, $\mathbf{n} \neq \mathbf{0}$.

Solution. The plane is $\{\mathbf{n}\}^\perp$ for $\mathbf{n} = (2,-1,2)$, and $\mathbf{n} \in U^\perp$ with $\dim U^\perp = 3 - 2 = 1$ (Theorem 10.3.2 (c)), so $U^\perp = \operatorname{span}(\mathbf{n})$. Here $\langle \mathbf{v}, \mathbf{n}\rangle = 2 - 2 + 6 = 6$ and $\langle \mathbf{n}, \mathbf{n}\rangle = 4 + 1 + 4 = 9$, so

$$P_{U^\perp}\mathbf{v} = \tfrac{6}{9}\mathbf{n} = \left(\tfrac{4}{3}, -\tfrac{2}{3}, \tfrac{4}{3}\right), \qquad P_U\mathbf{v} = \mathbf{v} - P_{U^\perp}\mathbf{v} = \left(-\tfrac{1}{3}, \tfrac{8}{3}, \tfrac{5}{3}\right).$$

Check: $2(-\tfrac{1}{3}) - \tfrac{8}{3} + 2 \cdot \tfrac{5}{3} = \tfrac{-2-8+10}{3} = 0$, so $P_U\mathbf{v} \in U$. The distance is $d(\mathbf{v}, U) = \|\tfrac{6}{9}\mathbf{n}\| = \tfrac{6}{9} \cdot 3 = 2$.

In general $d(\mathbf{v}, U) = \|P_{U^\perp}\mathbf{v}\| = \big|\langle \mathbf{v}, \mathbf{n}\rangle\big|\, \|\mathbf{n}\| / \|\mathbf{n}\|^2 = \big|\langle \mathbf{v}, \mathbf{n}\rangle\big| / \|\mathbf{n}\|$, which for $\mathbf{n} = (2,-1,2)$ and $\mathbf{v} = (1,2,3)$ gives $6/3 = 2$.

Exercise B3: The best quadratic approximation to a quartic.

On $\mathbb{R}[x]_{\le 4}$ with $\langle p, q\rangle = \int_{-1}^{1} p(t)q(t)\,dt$, let $U = \mathbb{R}[x]_{\le 2}$. Find $P_U(x^4)$ and $d(x^4, U)$. *Hint: the orthogonal basis of Example (The best quadratic approximation to a cubic)*

still works.

Solution. Use the orthogonal basis $(1, x, x^2 - \frac{1}{3})$ of U from Example (The best quadratic approximation to a cubic), with $\langle 1, 1\rangle = 2$ and

$$\langle x^2 - \tfrac{1}{3}, x^2 - \tfrac{1}{3}\rangle = \int_{-1}^{1} \Big(t^4 - \tfrac{2}{3}t^2 + \tfrac{1}{9}\Big)\mathrm{d}t = \tfrac{2}{5} - \tfrac{4}{9} + \tfrac{2}{9} = \tfrac{8}{45}.$$

The coefficients against x^4 are $\langle x^4, 1\rangle = \frac{2}{5}$, $\langle x^4, x\rangle = 0$ (odd integrand) and

$$\langle x^4, x^2 - \tfrac{1}{3}\rangle = \int_{-1}^{1} \Big(t^6 - \tfrac{1}{3}t^4\Big)\mathrm{d}t = \tfrac{2}{7} - \tfrac{1}{3}\cdot\tfrac{2}{5} = \tfrac{16}{105}.$$

By Corollary 10.3.4,

$$P_U(x^4) = \frac{2/5}{2}\cdot 1 + \frac{16/105}{8/45}\Big(x^2 - \tfrac{1}{3}\Big) = \tfrac{1}{5} + \tfrac{6}{7}\Big(x^2 - \tfrac{1}{3}\Big) = \tfrac{6}{7}x^2 - \tfrac{3}{35}.$$

For the distance, Theorem 10.1.3 applied to $x^4 = P_U(x^4) + (x^4 - P_U(x^4))$ gives $d^2 = \|x^4\|^2 - \|P_U(x^4)\|^2$. Here $\|x^4\|^2 = \int_{-1}^{1} t^8\,\mathrm{d}t = \frac{2}{9}$ and, the basis being orthogonal,

$$\|P_U(x^4)\|^2 = \Big(\tfrac{1}{5}\Big)^2\cdot 2 + \Big(\tfrac{6}{7}\Big)^2\cdot\tfrac{8}{45} = \tfrac{2}{25} + \tfrac{32}{245} = \tfrac{258}{1225}.$$

Hence $d^2 = \frac{2}{9} - \frac{258}{1225} = \frac{2450-2322}{11025} = \frac{128}{11025}$ and $d(x^4, U) = \frac{8\sqrt{2}}{105} \approx 0.108$.

10.3.6.3 C. Going deeper

Exercise C1: Perp turns sums into intersections.

Let U and W be subspaces of an inner product space V.

(a) Prove that $(U + W)^\perp = U^\perp \cap W^\perp$. (No finiteness is needed.)

(b) Assume now that V is finite-dimensional. Deduce that $(U \cap W)^\perp = U^\perp + W^\perp$.

Solution.

(a) ($\subseteq$) Let $\mathbf{v} \in (U + W)^\perp$. Since $U \subseteq U + W$ (Theorem 1.7.1), $\mathbf{v}$ is orthogonal to every element of U, so $\mathbf{v} \in U^\perp$; likewise $\mathbf{v} \in W^\perp$.
($\supseteq$) Let $\mathbf{v} \in U^\perp \cap W^\perp$ and let $\mathbf{u} + \mathbf{w} \in U + W$ with $\mathbf{u} \in U$, $\mathbf{w} \in W$. Then $\langle \mathbf{v}, \mathbf{u} + \mathbf{w}\rangle = \langle \mathbf{v}, \mathbf{u}\rangle + \langle \mathbf{v}, \mathbf{w}\rangle = 0$, using additivity in the second slot. Hence $\mathbf{v} \in (U + W)^\perp$.

(b) Apply (a) to the subspaces $U^\perp$ and $W^\perp$:

$$\big(U^\perp + W^\perp\big)^\perp = (U^\perp)^\perp \cap (W^\perp)^\perp = U \cap W,$$

where the second equality is Theorem 10.3.2 (b), available because V is finite-dimensional, so all subspaces are (Theorem 1.6.7). Now take $\perp$ of both ends and use Theorem 10.3.2 (b) once more, this time on the subspace $U^\perp + W^\perp$:

$$U^\perp + W^\perp = \Big(\big(U^\perp + W^\perp\big)^\perp\Big)^\perp = (U \cap W)^\perp.$$

This proves the second identity.

Exercise C2: A subspace with no orthogonal complement.

Let $V = \mathbb{R}[x]$, with the **coefficient inner product**

$$\langle p, q\rangle = \sum_{k\geq 0} a_k b_k \quad \text{for } p = \sum_k a_k x^k,\ q = \sum_k b_k x^k,$$

a finite sum, since a polynomial has only finitely many non-zero coefficients. Let $U = \{\, p \in V : p(1) = 0 \,\}$.

(a) Verify that $\langle \cdot, \cdot \rangle$ is an inner product on V and that U is a subspace with $U \neq V$.

(b) Prove that $U^\perp = \{0\}$. Conclude that $U \oplus U^\perp \neq V$, so Theorem 10.3.2 fails without the hypothesis that U is finite-dimensional.

(c) Explain what goes wrong geometrically by exhibiting, for each $m \geq 1$, an element $p_m \in U$ with $\|p_m - 1\| = 1/\sqrt{m}$.

Solution.

(a) The form is symmetric and bilinear over $\mathbb{R}$ because each term $a_k b_k$ is, and $\langle p, p\rangle = \sum_k a_k^2 > 0$ whenever some $a_k \neq 0$, that is whenever $p \neq 0$. So it is an inner product. The map $\varepsilon \colon p \mapsto p(1)$ is linear (Theorem 0.8.5), so $U = \ker \varepsilon$ is a subspace (Theorem 3.2.1). It is proper, since the constant polynomial 1 has $\varepsilon(1) = 1 \neq 0$.

(b) Note first that $x^i - x^j \in U$ for all $i, j \geq 0$, since $1 - 1 = 0$. Let $q = \sum_k b_k x^k \in U^\perp$. Pairing with $x^i - x^j$ gives $b_i - b_j = 0$, so all the coefficients of q are equal, say to c. But only finitely many of them are non-zero, and there are infinitely many indices, so $c = 0$ and $q = 0$. Hence $U^\perp = \{0\}$ and $U + U^\perp = U \neq V$.

(c) Take $p_m = 1 - \frac{1}{m}(x + x^2 + \cdots + x^m)$. Then $p_m(1) = 1 - m \cdot \frac{1}{m} = 0$, so $p_m \in U$, while

$$\|p_m - 1\|^2 = \left\| \tfrac{1}{m}(x + \cdots + x^m) \right\|^2 = m \cdot \frac{1}{m^2} = \frac{1}{m}.$$

So the polynomial $1 \notin U$ has elements of U arbitrarily close to it: U leaves no room outside itself for a perpendicular direction, and the best approximation to 1 from U does not exist (the distances $\|1 - p\|$ get arbitrarily close to 0 without reaching it). The obstruction is not the dimension of V as such but the fact that U is not *closed*: filling in the missing limits is exactly what the theory of Hilbert spaces does, and there Theorem 10.3.2 is recovered for closed subspaces. That is analysis, not linear algebra, and we do not pursue it.

Exercise C3: Which projections are orthogonal.

Let V be a finite-dimensional inner product space and let $P \in \mathcal{L}(V)$ satisfy $P^2 = P$. Prove that the following are equivalent:

(a) $P = P_U$ for some subspace U;

(b) $\langle P\mathbf{u}, \mathbf{v}\rangle = \langle \mathbf{u}, P\mathbf{v}\rangle$ for all $\mathbf{u}, \mathbf{v} \in V$;

(c) $\ker P = (\operatorname{im} P)^\perp$.

Hint: for (b) ⇒ (c), pair a vector of $\ker P$ *with* $P\mathbf{v}$.

Solution.

(a) ⇒ (b) is Theorem 10.3.3 (b).

(b) ⇒ (c). ($\subseteq$) Let $\mathbf{x} \in \ker P$ and let $P\mathbf{v} \in \operatorname{im} P$ be arbitrary. Then

$$\langle \mathbf{x}, P\mathbf{v} \rangle = \overline{\langle P\mathbf{v}, \mathbf{x} \rangle} = \overline{\langle \mathbf{v}, P\mathbf{x} \rangle} = \overline{\langle \mathbf{v}, \mathbf{0} \rangle} = 0,$$

using (b) in the second equality. So $\mathbf{x} \in (\operatorname{im} P)^{\perp}$. ($\supseteq$) Let $\mathbf{x} \in (\operatorname{im} P)^{\perp}$. Then

$$\langle P\mathbf{x}, P\mathbf{x} \rangle = \langle \mathbf{x}, P(P\mathbf{x}) \rangle = \langle \mathbf{x}, P\mathbf{x} \rangle = 0,$$

the first equality by (b), the second by $P^2 = P$, and the third because $P\mathbf{x} \in \operatorname{im} P$ while $\mathbf{x} \in (\operatorname{im} P)^{\perp}$. Positive definiteness gives $P\mathbf{x} = \mathbf{0}$, so $\mathbf{x} \in \ker P$.

(c) ⇒ (a). Put $U = \operatorname{im} P$. By Theorem 3.10.1 (a), $V = \operatorname{im} P \oplus \ker P = U \oplus U^{\perp}$, and P is the identity on U and zero on $\ker P = U^{\perp}$. By the uniqueness clause of Theorem 3.10.1 (b), P is the projection onto U along $U^{\perp}$, which is P_U by Definition 10.3.2.

10.4 Least Squares and Minimum-Norm Solutions

Chapter 2 taught us to decide whether $\mathbf{Ax} = \mathbf{b}$ has a solution, and to find them all when it does. Real data rarely cooperates. Measure a quantity that depends linearly on two unknowns, take ten measurements, and you have ten equations in two unknowns; each measurement carries a little error, and the ten equations are almost certainly inconsistent. Refusing to answer is not useful. This section replaces the question "which $\mathbf{x}$ solves $\mathbf{Ax} = \mathbf{b}$?" with "which $\mathbf{x}$ comes closest?", and shows that the new question always has an answer, computed by solving a square system.

The other half of the section handles the opposite complaint. When a system is consistent but underdetermined, there are too many solutions, and we want a canonical one. Orthogonality picks it: exactly one solution is perpendicular to the kernel, and it is the shortest.

Throughout, $F = \mathbb{R}$ or $F = \mathbb{C}$, and F^n and F^m carry the standard inner product $\langle \mathbf{x}, \mathbf{y} \rangle = \sum_i x_i \overline{y_i}$, with $\|\mathbf{x}\|^2 = \sum_i |x_i|^2$.

10.4.1 The residual, and a piece of notation

Given $\mathbf{A} \in M_{m \times n}(F)$ and $\mathbf{b} \in F^m$, write $\mathbf{r} = \mathbf{b} - \mathbf{Ax}$ for the **residual** of a candidate $\mathbf{x}$. The system is consistent exactly when some $\mathbf{x}$ makes $\mathbf{r} = \mathbf{0}$. When none does, we ask for the $\mathbf{x}$ making $\mathbf{r}$ as short as possible, that is, minimizing

$$\|\mathbf{Ax} - \mathbf{b}\|^2 = \sum_{i=1}^{m} \big|(\mathbf{Ax})_i - b_i\big|^2,$$

a **sum of squares**; hence the name **least squares**.

Two observations turn this into geometry. First, as $\mathbf{x}$ ranges over F^n, the vector $\mathbf{Ax}$ ranges over exactly the column space $\mathrm{col}(\mathbf{A}) \subseteq F^m$ (Theorem 0.9.3), a finite-dimensional subspace. Second, minimizing $\|\mathbf{Ax}-\mathbf{b}\|$ over all $\mathbf{x}$ is therefore the same as finding the point of $\mathrm{col}(\mathbf{A})$ nearest to $\mathbf{b}$. We already know that point: it is $P_{\mathrm{col}(\mathbf{A})}\mathbf{b}$, by Theorem 10.3.5. All that remains is to turn "the residual is perpendicular to $\mathrm{col}(\mathbf{A})$" into equations, and for that we need one piece of notation.

Recall the conjugate transpose $\mathbf{A}^* \in M_{n\times m}(F)$ of Definition 10.1.2: the matrix with entries $(\mathbf{A}^*)_{ij} = \overline{a_{ji}}$, obtained by transposing and then conjugating every entry, so that $\mathbf{A}^* = \mathbf{A}^{\top}$ over $\mathbb{R}$. Comparing entries and using Theorem 0.9.5 together with the rules for conjugation (Theorem 0.6.2) gives

$$(\mathbf{A}+\mathbf{B})^* = \mathbf{A}^*+\mathbf{B}^*, \quad (c\mathbf{A})^* = \overline{c}\,\mathbf{A}^*, \quad (\mathbf{AB})^* = \mathbf{B}^*\mathbf{A}^*, \quad \mathbf{A}^{**} = \mathbf{A},$$

whenever the sizes match. The third is the one worth seeing done: $((\mathbf{AB})^*)_{ij} = \overline{(\mathbf{AB})_{ji}} = \overline{\sum_k a_{jk}b_{ki}} = \sum_k \overline{b_{ki}}\,\overline{a_{jk}} = \sum_k (\mathbf{B}^*)_{ik}(\mathbf{A}^*)_{kj} = (\mathbf{B}^*\mathbf{A}^*)_{ij}$, which is where the order reverses. The one consequence we really use is the following.

Lemma 10.4.1 — Moving a matrix across the inner product

Let $\mathbf{A} \in M_{m\times n}(F)$. Then for all $\mathbf{x} \in F^n$ and $\mathbf{y} \in F^m$,

$$\langle \mathbf{Ax}, \mathbf{y}\rangle = \langle \mathbf{x}, \mathbf{A}^*\mathbf{y}\rangle, \qquad \langle \mathbf{y}, \mathbf{Ax}\rangle = \langle \mathbf{A}^*\mathbf{y}, \mathbf{x}\rangle.$$

Proof. Regarding vectors as columns, $\langle \mathbf{u}, \mathbf{w}\rangle = \mathbf{w}^*\mathbf{u}$, a 1×1 matrix identified with its entry. Hence

$$\langle \mathbf{Ax}, \mathbf{y}\rangle = \mathbf{y}^*(\mathbf{Ax}) = (\mathbf{y}^*\mathbf{A})\mathbf{x} = \big((\mathbf{A}^*\mathbf{y})^*\big)\mathbf{x} = \langle \mathbf{x}, \mathbf{A}^*\mathbf{y}\rangle,$$

where the third equality uses $(\mathbf{A}^*\mathbf{y})^* = \mathbf{y}^*\mathbf{A}^{**} = \mathbf{y}^*\mathbf{A}$. The second identity follows by conjugating the first, since $\langle \mathbf{y}, \mathbf{Ax}\rangle = \overline{\langle \mathbf{Ax}, \mathbf{y}\rangle}$ and $\overline{\langle \mathbf{x}, \mathbf{A}^*\mathbf{y}\rangle} = \langle \mathbf{A}^*\mathbf{y}, \mathbf{x}\rangle$. ∎

The lemma is the matrix case of a general principle: *to move a map across an inner product, pay with its adjoint.* Section 6 develops that principle for linear maps between abstract inner product spaces; here the two lines above are all we need.

10.4.2 The normal equations

Theorem 10.4.2 — Least Squares Theorem

Let $\mathbf{A} \in M_{m\times n}(F)$ and $\mathbf{b} \in F^m$, and write $U = \mathrm{col}(\mathbf{A})$. For $\mathbf{x} \in F^n$, the following are equivalent:

(a) $\|\mathbf{Ax}-\mathbf{b}\| \le \|\mathbf{Az}-\mathbf{b}\|$ for every $\mathbf{z} \in F^n$;
(b) $\mathbf{Ax} = P_U\mathbf{b}$;
(c) $\mathbf{A}^*\mathbf{Ax} = \mathbf{A}^*\mathbf{b}$.

Moreover such an $\mathbf{x}$ always exists. A vector satisfying these conditions is called a **least-squares solution** of $\mathbf{Ax} = \mathbf{b}$, and the equations in (c) are the **normal equations**.

Idea. Condition (a) is a minimization over $\mathbf{x}$; condition (b) is the same minimization rewritten in F^m, where Theorem 10.3.5 has already solved it. So (a) $\Leftrightarrow$ (b) is a translation, not an argument. The content is (b) $\Leftrightarrow$ (c): saying $\mathbf{Ax} = P_U\mathbf{b}$ is the same as saying the residual is perpendicular to U, and "perpendicular to every column of $\mathbf{A}$" is what $\mathbf{A}^*(\mathbf{b} - \mathbf{Ax}) = \mathbf{0}$ says. Existence is free, because $P_U\mathbf{b}$ lies in $U = \mathrm{col}(\mathbf{A})$ and so is $\mathbf{Ax}$ for some $\mathbf{x}$.

Proof. Since $\{\mathbf{Az} : \mathbf{z} \in F^n\} = \mathrm{col}(\mathbf{A}) = U$ (Theorem 0.9.3), condition (a) says that $\mathbf{Ax}$ is a vector of U at least as close to $\mathbf{b}$ as every other vector of U. By Theorem 10.3.5 the unique such vector is $P_U\mathbf{b}$. Hence (a) $\Leftrightarrow$ (b).

(b) $\Leftrightarrow$ (c). Write $\mathbf{b} = P_U\mathbf{b} + (\mathbf{b} - P_U\mathbf{b})$, the splitting of Theorem 10.3.2 (a) with $\mathbf{b} - P_U\mathbf{b} \in U^\perp$. For $\mathbf{x} \in F^n$ we have $\mathbf{Ax} \in U$, so $\mathbf{b} - \mathbf{Ax} \in U^\perp$ holds if and only if $\mathbf{Ax}$ is the U-part of $\mathbf{b}$, that is, if and only if $\mathbf{Ax} = P_U\mathbf{b}$. It remains to see that

$$\mathbf{b} - \mathbf{Ax} \in U^\perp \iff \mathbf{A}^*\mathbf{Ax} = \mathbf{A}^*\mathbf{b}.$$

Put $\mathbf{r} = \mathbf{b} - \mathbf{Ax}$. By Proposition 10.3.1, $\mathbf{r} \in U^\perp$ if and only if $\mathbf{r}$ is orthogonal to every $\mathbf{Az}$, and by Lemma 10.4.1,

$$\langle \mathbf{r}, \mathbf{Az} \rangle = \langle \mathbf{A}^*\mathbf{r}, \mathbf{z} \rangle \qquad \text{for every } \mathbf{z} \in F^n.$$

If $\mathbf{A}^*\mathbf{r} = \mathbf{0}$, all these vanish. Conversely, if all vanish, take $\mathbf{z} = \mathbf{A}^*\mathbf{r}$ to get $\langle \mathbf{A}^*\mathbf{r}, \mathbf{A}^*\mathbf{r} \rangle = 0$, hence $\mathbf{A}^*\mathbf{r} = \mathbf{0}$ by positive definiteness. So $\mathbf{r} \in U^\perp$ if and only if $\mathbf{A}^*\mathbf{r} = \mathbf{0}$, which rearranges to $\mathbf{A}^*\mathbf{Ax} = \mathbf{A}^*\mathbf{b}$.

Existence. $P_U\mathbf{b} \in U = \mathrm{col}(\mathbf{A})$, so $P_U\mathbf{b} = \mathbf{Ax}$ for some $\mathbf{x} \in F^n$, and that $\mathbf{x}$ satisfies (b).

■

Three things are worth extracting. The normal equations are a **square** $n \times n$ system, whatever the shape of $\mathbf{A}$. They are **always consistent**, by the existence clause, even when $\mathbf{Ax} = \mathbf{b}$ is not. And the minimizing *value* $\mathbf{Ax}$ is unique — it is $P_U\mathbf{b}$ — even if the minimizing $\mathbf{x}$ is not.

Warning. **"Closest" is measured by the inner product, so the answer moves when the inner product does.** Least squares is not a coordinate-free notion: it minimizes $\|\mathbf{Ax} - \mathbf{b}\|$ for a particular norm on F^m, and rescaling one coordinate — reporting one measurement in centimeters instead of meters, say — is a change of inner product. Concretely, for the data $(0, 2), (1, 1), (2, 8)$ the least-squares line is $y = \frac{2}{3} + 3t$; if the middle point is trusted twice as much, so that the second coordinate of F^3 is weighted by 2, the best line becomes $y = 3t$. Both are correct answers to their own question, and Exercise C1 works the general case out. Before fitting, decide which errors count equally.

Quick check. The system $\mathbf{Ax} = \mathbf{b}$ may have no solution at all, yet the normal equations $\mathbf{A}^*\mathbf{Ax} = \mathbf{A}^*\mathbf{b}$ always have one. Where does the proof arrange that, and what stops the same argument from solving $\mathbf{Ax} = \mathbf{b}$ itself?

Solution. The existence clause uses that $P_U\mathbf{b}$ lies in $U = \mathrm{col}(\mathbf{A})$, and every vector of $\mathrm{col}(\mathbf{A})$ is $\mathbf{Ax}$ for some $\mathbf{x}$. So the normal equations ask $\mathbf{Ax}$ to hit $P_U\mathbf{b}$, a target that is inside the column space by construction. The original system asks $\mathbf{Ax}$ to hit $\mathbf{b}$, which need not be in $\mathrm{col}(\mathbf{A})$ at all. Projecting first is exactly the step that moves the target into reach; what is given up is the requirement $\mathbf{r} = \mathbf{0}$, which becomes $\mathbf{r} \perp \mathrm{col}(\mathbf{A})$.

10.4.3 When is the least-squares solution unique?

The minimizers of $\|\mathbf{Ax}-\mathbf{b}\|$ are the solutions of the normal equations, so they form the solution set of a linear system: a coset $\mathbf{x}_0 + \mathrm{nul}(\mathbf{A}^*\mathbf{A})$ (Theorem 2.1.3). To read off uniqueness we therefore need $\mathrm{nul}(\mathbf{A}^*\mathbf{A})$, and the following small lemma computes it.

Lemma 10.4.3 — The null space of $\mathbf{A}^*\mathbf{A}$

Let $\mathbf{A} \in M_{m\times n}(F)$. Then $\mathrm{nul}(\mathbf{A}^*\mathbf{A}) = \mathrm{nul}(\mathbf{A})$.

Proof. ($\supseteq$) If $\mathbf{Ax} = \mathbf{0}$, then $\mathbf{A}^*\mathbf{Ax} = \mathbf{A}^*\mathbf{0} = \mathbf{0}$.

($\subseteq$) Suppose $\mathbf{A}^*\mathbf{Ax} = \mathbf{0}$. Pair with $\mathbf{x}$ and move $\mathbf{A}^*$ across using Lemma 10.4.1:

$$0 = \langle \mathbf{A}^*(\mathbf{Ax}), \mathbf{x}\rangle = \langle \mathbf{Ax}, \mathbf{Ax}\rangle = \|\mathbf{Ax}\|^2.$$

Hence $\mathbf{Ax} = \mathbf{0}$ by positive definiteness. This proves the lemma. ∎

This is the "pair it with itself" move once more, and it is the whole reason the normal equations behave well. It will return in Section 6 in the form $\ker(T^*T) = \ker T$ for a linear map T between inner product spaces, with the same two-line proof; the matrix statement above is the case we need now.

Corollary 10.4.4 — Uniqueness of the least-squares solution

Let $\mathbf{A} \in M_{m\times n}(F)$ and $\mathbf{b} \in F^m$. The following are equivalent:

(a) $\mathbf{Ax} = \mathbf{b}$ has exactly one least-squares solution (for one, equivalently for every, $\mathbf{b}$);
(b) the columns of $\mathbf{A}$ are linearly independent, that is $\mathrm{rank}\,\mathbf{A} = n$;
(c) $\mathbf{A}^*\mathbf{A}$ is invertible.

In that case the least-squares solution is $\mathbf{x} = (\mathbf{A}^*\mathbf{A})^{-1}\mathbf{A}^*\mathbf{b}$.

Proof. By Theorem 10.4.2 the least-squares solutions are the solutions of $\mathbf{A}^*\mathbf{Ax} = \mathbf{A}^*\mathbf{b}$, a consistent system; by Theorem 2.1.3 its solution set is a coset of $\mathrm{nul}(\mathbf{A}^*\mathbf{A})$, which is $\mathrm{nul}(\mathbf{A})$ by Lemma 10.4.3. So the solution is unique, for one $\mathbf{b}$ or for all, exactly when $\mathrm{nul}(\mathbf{A}) = \{\mathbf{0}\}$. Now $\mathrm{nul}(\mathbf{A}) = \{\mathbf{0}\}$ says precisely that the only vanishing linear combination of the columns of $\mathbf{A}$ is the trivial one, that is, that the columns are independent; and by Theorem 2.5.7 this is the same as $\mathrm{rank}\,\mathbf{A} = n$. This proves (a) $\Leftrightarrow$ (b).

(b) $\Leftrightarrow$ (c). The matrix $\mathbf{A}^*\mathbf{A}$ is $n \times n$, so it is invertible if and only if $\operatorname{nul}(\mathbf{A}^*\mathbf{A}) = \{\mathbf{0}\}$ (Theorem 2.4.4). By Lemma 10.4.3 this happens exactly when $\operatorname{nul}(\mathbf{A}) = \{\mathbf{0}\}$.

Finally, if $\mathbf{A}^*\mathbf{A}$ is invertible, multiplying the normal equations on the left by $(\mathbf{A}^*\mathbf{A})^{-1}$ gives the stated formula.

■

Warning. $(\mathbf{A}^*\mathbf{A})^{-1}$ **is not** $\mathbf{A}^{-1}(\mathbf{A}^*)^{-1}$**.** The rule $(\mathbf{BC})^{-1} = \mathbf{C}^{-1}\mathbf{B}^{-1}$ needs $\mathbf{B}$ and $\mathbf{C}$ to be invertible, and in least squares $\mathbf{A}$ is usually not even square. Take

$$\mathbf{A} = \begin{pmatrix} 1 & 0 \\ 1 & 1 \\ 0 & 1 \end{pmatrix}, \qquad \mathbf{A}^\top\mathbf{A} = \begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix}, \qquad (\mathbf{A}^\top\mathbf{A})^{-1} = \frac{1}{3}\begin{pmatrix} 2 & -1 \\ -1 & 2 \end{pmatrix}.$$

The left side exists; the symbols $\mathbf{A}^{-1}$ and $(\mathbf{A}^\top)^{-1}$ do not exist at all, since $\mathbf{A}$ is 3×2. The formula $\mathbf{x} = (\mathbf{A}^*\mathbf{A})^{-1}\mathbf{A}^*\mathbf{b}$ must be read as one object $(\mathbf{A}^*\mathbf{A})^{-1}$ applied to $\mathbf{A}^*\mathbf{b}$, never simplified.

10.4.4 Fitting a line and a parabola

Example. (The least-squares line through four points)

Find the line $y = c + dt$ that minimizes the sum of the squared vertical errors at the four data points

$$(1, 3), \quad (2, 1), \quad (3, 5), \quad (4, 5).$$

Compute the residual and the minimum value of the sum of squares.

Solution. Asking for $c + dt_i = y_i$ at the four points is the system $\mathbf{Ax} = \mathbf{b}$ with

$$\mathbf{A} = \begin{pmatrix} 1 & 1 \\ 1 & 2 \\ 1 & 3 \\ 1 & 4 \end{pmatrix}, \qquad \mathbf{x} = \begin{pmatrix} c \\ d \end{pmatrix}, \qquad \mathbf{b} = \begin{pmatrix} 3 \\ 1 \\ 5 \\ 5 \end{pmatrix},$$

and $\|\mathbf{Ax} - \mathbf{b}\|^2$ is exactly the sum of the squared vertical errors. The columns of $\mathbf{A}$ are independent (they are not multiples of each other), so Corollary 10.4.4 gives a unique answer. Over $\mathbb{R}$, $\mathbf{A}^* = \mathbf{A}^\top$, and

$$\mathbf{A}^\top\mathbf{A} = \begin{pmatrix} 4 & 10 \\ 10 & 30 \end{pmatrix}, \qquad \mathbf{A}^\top\mathbf{b} = \begin{pmatrix} 3+1+5+5 \\ 3+2+15+20 \end{pmatrix} = \begin{pmatrix} 14 \\ 40 \end{pmatrix}.$$

The normal equations $4c + 10d = 14$, $10c + 30d = 40$ simplify to $2c + 5d = 7$ and $c + 3d = 4$; subtracting twice the second from the first gives $-d = -1$, so $d = 1$ and $c = 1$. The least-squares line is

$$y = 1 + t.$$

Its values at $t = 1, 2, 3, 4$ are $2, 3, 4, 5$, so the residual is

$$\mathbf{r} = \mathbf{b} - \mathbf{Ax} = (3, 1, 5, 5) - (2, 3, 4, 5) = (1, -2, 1, 0),$$

and the minimum sum of squares is $\|\mathbf{r}\|^2 = 1+4+1+0 = 6$.

Check. The residual must be orthogonal to both columns of $\mathbf{A}$: $1-2+1+0=0$ and $1-4+3+0=0$. Both hold, which confirms the normal equations.

The same machinery fits any linear combination of prescribed functions; only the columns of $\mathbf{A}$ change. "Linear" refers to the unknown coefficients, not to the shape of the curve.

Example. (The least-squares parabola)

Find the quadratic $y = a + bt + ct^2$ minimizing the sum of squared errors at

$$(-2,7), \quad (-1,6), \quad (0,2), \quad (1,0), \quad (2,5).$$

Solution. Now $\mathbf{A}$ has columns $(1,1,1,1,1)$, (t_i) and (t_i^2):

$$\mathbf{A} = \begin{pmatrix} 1 & -2 & 4 \\ 1 & -1 & 1 \\ 1 & 0 & 0 \\ 1 & 1 & 1 \\ 1 & 2 & 4 \end{pmatrix}, \qquad \mathbf{b} = \begin{pmatrix} 7 \\ 6 \\ 2 \\ 0 \\ 5 \end{pmatrix}.$$

Because the nodes are symmetric about 0, every odd power sums to zero: $\sum t_i = 0$ and $\sum t_i^3 = 0$. With $\sum t_i^2 = 10$ and $\sum t_i^4 = 34$,

$$\mathbf{A}^\top\mathbf{A} = \begin{pmatrix} 5 & 0 & 10 \\ 0 & 10 & 0 \\ 10 & 0 & 34 \end{pmatrix}, \qquad \mathbf{A}^\top\mathbf{b} = \begin{pmatrix} 20 \\ -10 \\ 54 \end{pmatrix}.$$

The middle equation decouples: $10b = -10$, so $b = -1$. The outer two are $5a + 10c = 20$ and $10a + 34c = 54$; the first gives $a = 4 - 2c$, and substituting gives $40 + 14c = 54$, so $c = 1$ and $a = 2$. The least-squares parabola is

$$y = 2 - t + t^2.$$

Its values at the nodes are $8, 4, 2, 2, 4$, so $\mathbf{r} = (-1, 2, 0, -2, 1)$ and the minimum sum of squares is $\|\mathbf{r}\|^2 = 1+4+0+4+1 = 10$.

Check. $\sum r_i = 0$, $\sum t_i r_i = 2-2+0-2+2 = 0$ and $\sum t_i^2 r_i = -4+2+0-2+4 = 0$: the residual is orthogonal to all three columns.

Two practical remarks. Choosing the nodes symmetrically, as above, made $\mathbf{A}^\top\mathbf{A}$ nearly diagonal and the arithmetic painless; the same trick appears again in Section 9 when the columns are trigonometric functions. And although the normal equations are the right way to *understand* least squares, they are not always the right way to *compute* it: Section 8 solves the same problem through a QR factorization, which avoids forming $\mathbf{A}^*\mathbf{A}$ at all.

10.4.5 The minimum-norm solution

Now the opposite situation: $\mathbf{Ax} = \mathbf{b}$ is consistent, but $\mathbf{A}$ has a non-trivial null space, so the solutions form an infinite family $\mathbf{x}_0 + \mathrm{nul}(\mathbf{A})$ (Theorem 2.1.3). Which one should we report?

Orthogonality answers.

Theorem 10.4.5 — Minimum-Norm Solution

Let $\mathbf{A} \in M_{m\times n}(F)$ and let $\mathbf{b} \in F^m$ be such that $\mathbf{Ax} = \mathbf{b}$ is consistent. Write $K = \operatorname{nul}(\mathbf{A})$. Then:

(a) exactly one solution $\mathbf{x}_{\min}$ of $\mathbf{Ax} = \mathbf{b}$ lies in $K^\perp$;
(b) $\|\mathbf{x}_{\min}\| < \|\mathbf{x}\|$ for every other solution $\mathbf{x}$.

We call $\mathbf{x}_{\min}$ the **minimum-norm solution**.

Idea. The solution set is a coset $\mathbf{x}_0 + K$, and $F^n = K \oplus K^\perp$. Throwing away the K-part of $\mathbf{x}_0$ keeps it a solution, because that part is in the kernel, and lands it in $K^\perp$. Once there, Pythagoras compares it with every other solution: the others differ from it by a kernel vector, which is perpendicular to it and only adds length.

Proof.

(a) *Existence.* Let $\mathbf{x}_0$ be any solution. Since K is a subspace of the finite-dimensional space F^n, Theorem 10.3.2 (a) gives $F^n = K \oplus K^\perp$; write $\mathbf{x}_0 = \mathbf{k} + \mathbf{x}_{\min}$ with $\mathbf{k} \in K$ and $\mathbf{x}_{\min} \in K^\perp$. Then $\mathbf{Ax}_{\min} = \mathbf{Ax}_0 - \mathbf{Ak} = \mathbf{b} - \mathbf{0} = \mathbf{b}$, so $\mathbf{x}_{\min}$ is a solution lying in $K^\perp$.
Uniqueness. If $\mathbf{x}_{\min}$ and $\mathbf{y}$ are solutions in $K^\perp$, then $\mathbf{A}(\mathbf{x}_{\min} - \mathbf{y}) = \mathbf{0}$, so $\mathbf{x}_{\min} - \mathbf{y} \in K \cap K^\perp = \{\mathbf{0}\}$ by Theorem 10.3.2 (a).

(b) Every solution has the form $\mathbf{x} = \mathbf{x}_{\min} + \mathbf{k}$ with $\mathbf{k} \in K$, by Theorem 2.1.3. Since $\mathbf{x}_{\min} \in K^\perp$ and $\mathbf{k} \in K$, the two are orthogonal, and Theorem 10.1.3 gives

$$\|\mathbf{x}\|^2 = \|\mathbf{x}_{\min}\|^2 + \|\mathbf{k}\|^2.$$

If $\mathbf{x} \neq \mathbf{x}_{\min}$, then $\mathbf{k} \neq \mathbf{0}$, so $\|\mathbf{k}\|^2 > 0$ and $\|\mathbf{x}\| > \|\mathbf{x}_{\min}\|$. This proves the theorem. ∎

The subspace $K^\perp$ has a matrix description that makes $\mathbf{x}_{\min}$ computable. For $\mathbf{x} \in F^n$,

$$\begin{aligned} \mathbf{x} \in \operatorname{col}(\mathbf{A}^*)^\perp &\iff \langle \mathbf{x}, \mathbf{A}^*\mathbf{y}\rangle = 0 \ \text{ for all } \mathbf{y} \in F^m \\ &\iff \langle \mathbf{Ax}, \mathbf{y}\rangle = 0 \ \text{ for all } \mathbf{y} \in F^m \\ &\iff \mathbf{Ax} = \mathbf{0}, \end{aligned}$$

where the first step is Definition 10.3.1 together with $\operatorname{col}(\mathbf{A}^*) = \{\mathbf{A}^*\mathbf{y} : \mathbf{y} \in F^m\}$ (Theorem 0.9.3), the second is Lemma 10.4.1, and the last uses the choice $\mathbf{y} = \mathbf{Ax}$ with positive definiteness. So $\operatorname{nul}(\mathbf{A}) = \operatorname{col}(\mathbf{A}^*)^\perp$, and applying $\perp$ once more (Theorem 10.3.2 (b)) gives

$$\big(\operatorname{nul}(\mathbf{A})\big)^\perp = \operatorname{col}(\mathbf{A}^*).$$

In words: the minimum-norm solution is the unique solution that is a combination of the columns of $\mathbf{A}^*$, that is, of the conjugated rows of $\mathbf{A}$. Section 6 proves the same statement for linear maps, together with the three companion identities that make up the four fundamental subspaces.

Example. (A minimum-norm solution)

Find the solution of smallest norm of

$$\begin{cases} x_1 + x_2 + x_3 = 3, \\ x_1 + 2x_2 + 3x_3 = 7. \end{cases}$$

Solution. Here $\mathbf{A} = \begin{pmatrix} 1 & 1 & 1 \\ 1 & 2 & 3 \end{pmatrix}$. Subtracting the first equation from the second gives $x_2 + 2x_3 = 4$, so $x_2 = 4 - 2x_3$ and then $x_1 = 3 - x_2 - x_3 = x_3 - 1$. With $t = x_3$ the solutions are

$$\mathbf{x}(t) = (-1, 4, 0) + t(1, -2, 1), \qquad t \in \mathbb{R},$$

so $K = \operatorname{nul}(\mathbf{A}) = \operatorname{span}((1, -2, 1))$. By Theorem 10.4.5 the answer is the unique t with $\mathbf{x}(t) \perp (1, -2, 1)$:

$$\langle \mathbf{x}(t), (1, -2, 1) \rangle = (-1 + t) - 2(4 - 2t) + t = 6t - 9 = 0, \qquad t = \tfrac{3}{2}.$$

Hence $\mathbf{x}_{\min} = \left(\tfrac{1}{2}, 1, \tfrac{3}{2}\right)$, with $\|\mathbf{x}_{\min}\|^2 = \tfrac{1}{4} + 1 + \tfrac{9}{4} = \tfrac{7}{2}$.

Check. It is a solution, since $\tfrac{1}{2} + 1 + \tfrac{3}{2} = 3$ and $\tfrac{1}{2} + 2 + \tfrac{9}{2} = 7$, and it is orthogonal to the kernel, since $\tfrac{1}{2} - 2 + \tfrac{3}{2} = 0$. By the identity $(\operatorname{nul} \mathbf{A})^{\perp} = \operatorname{col}(\mathbf{A}^{\top})$ above it must also be a combination of the rows of $\mathbf{A}$, and it is: $\mathbf{x}_{\min} = \tfrac{1}{2}(1, 2, 3)$, half the second row. Finally, the solution $\mathbf{x}(0) = (-1, 4, 0)$ has $\|\mathbf{x}(0)\|^2 = 17 > \tfrac{7}{2}$, as Theorem 10.4.5 (b) requires.

The two answers of this section — the least-squares solution and the minimum-norm solution — are usually wanted together: given any $\mathbf{A}$ and $\mathbf{b}$, first minimize $\|\mathbf{A}\mathbf{x} - \mathbf{b}\|$, then among the minimizers take the shortest. Chapter 12 packages the combined answer as a single matrix, the **pseudoinverse** $\mathbf{A}^{+}$, with $\mathbf{x} = \mathbf{A}^{+}\mathbf{b}$ in all cases at once.

10.4.6 Exercises

10.4.6.1 A. Check your understanding

Exercise A1.

(a) Define a least-squares solution of $\mathbf{A}\mathbf{x} = \mathbf{b}$, and write down the normal equations.

(b) True or false: if $\mathbf{A}\mathbf{x} = \mathbf{b}$ is consistent, then its solutions are exactly its least-squares solutions. Justify your answer.

(c) Explain in one sentence why the normal equations are always consistent.

(d) Give a condition on the columns of $\mathbf{A}$ equivalent to uniqueness of the least-squares solution.

(e) Where does the minimum-norm solution of a consistent system live, and why is it unique there?

(f) True or false: $(\mathbf{A}^{*}\mathbf{A})^{-1} = \mathbf{A}^{-1}(\mathbf{A}^{*})^{-1}$. Justify your answer.

Solution.

(a) A vector $\mathbf{x} \in F^n$ with $\|\mathbf{A}\mathbf{x} - \mathbf{b}\| \le \|\mathbf{A}\mathbf{z} - \mathbf{b}\|$ for every $\mathbf{z} \in F^n$. The normal

equations are $\mathbf{A}^*\mathbf{A}\mathbf{x} = \mathbf{A}^*\mathbf{b}$ (Theorem 10.4.2).

(b) True. If $\mathbf{A}\mathbf{x}_0 = \mathbf{b}$ then $\|\mathbf{A}\mathbf{x}_0 - \mathbf{b}\| = 0$, which is the smallest possible value, so $\mathbf{x}_0$ is a least-squares solution; conversely a least-squares solution $\mathbf{x}$ has $\|\mathbf{A}\mathbf{x} - \mathbf{b}\| \le 0$, hence $\mathbf{A}\mathbf{x} = \mathbf{b}$. Least squares extends the notion of a solution without changing it when solutions exist.

(c) Because the target $P_{\mathrm{col}(\mathbf{A})}\mathbf{b}$ lies in $\mathrm{col}(\mathbf{A})$ by construction, so $\mathbf{A}\mathbf{x} = P_{\mathrm{col}(\mathbf{A})}\mathbf{b}$ is solvable (Theorem 10.4.2, existence).

(d) The columns are linearly independent, equivalently $\mathrm{rank}\,\mathbf{A} = n$, equivalently $\mathbf{A}^*\mathbf{A}$ is invertible (Corollary 10.4.4).

(e) In $(\mathrm{nul}\,\mathbf{A})^\perp = \mathrm{col}(\mathbf{A}^*)$. Two solutions there would differ by an element of $\mathrm{nul}(\mathbf{A}) \cap (\mathrm{nul}\,\mathbf{A})^\perp = \{\mathbf{0}\}$ (Theorem 10.4.5).

(f) False, and usually meaningless: $\mathbf{A}$ need not be square, so $\mathbf{A}^{-1}$ need not exist, while $(\mathbf{A}^*\mathbf{A})^{-1}$ can exist perfectly well — see the 3×2 example in the warning after Corollary 10.4.4.

10.4.6.2 B. Practice

Exercise B1: A least-squares line.

Find the least-squares line $y = c + dt$ for the data $(0,3), (1,2), (2,3), (3,6)$. Compute the residual, verify that it is orthogonal to both columns of $\mathbf{A}$, and give the minimum sum of squares.

Solution. With $\mathbf{A}$ having columns $(1,1,1,1)$ and $(0,1,2,3)$ and $\mathbf{b} = (3,2,3,6)$,

$$\mathbf{A}^\top\mathbf{A} = \begin{pmatrix} 4 & 6 \\ 6 & 14 \end{pmatrix}, \qquad \mathbf{A}^\top\mathbf{b} = \begin{pmatrix} 14 \\ 0+2+6+18 \end{pmatrix} = \begin{pmatrix} 14 \\ 26 \end{pmatrix}.$$

The normal equations are $2c + 3d = 7$ and $3c + 7d = 13$. Multiplying the first by 3 and the second by 2 and subtracting gives $9d - 14d = 21 - 26$, so $d = 1$, and then $c = 2$. The line is $y = 2 + t$.

Its values at $t = 0,1,2,3$ are $2,3,4,5$, so $\mathbf{r} = (1,-1,-1,1)$. Orthogonality: $1-1-1+1 = 0$ against the first column and $0 - 1 - 2 + 3 = 0$ against the second. The minimum sum of squares is $\|\mathbf{r}\|^2 = 4$.

Exercise B2: A least-squares parabola.

Find the least-squares quadratic $y = a + bt + ct^2$ for the data $(-1,2), (0,8), (1,6), (2,16)$, and the minimum sum of squares. *Hint: write down* $\mathbf{A}^\top\mathbf{A}$ *from the power sums* $\sum t_i^k$, $k = 0, \dots, 4$.

Solution. The power sums are $\sum 1 = 4$, $\sum t_i = 2$, $\sum t_i^2 = 6$, $\sum t_i^3 = 8$, $\sum t_i^4 = 18$, so

$$\mathbf{A}^\top\mathbf{A} = \begin{pmatrix} 4 & 2 & 6 \\ 2 & 6 & 8 \\ 6 & 8 & 18 \end{pmatrix}, \qquad \mathbf{A}^\top\mathbf{b} = \begin{pmatrix} 2+8+6+16 \\ -2+0+6+32 \\ 2+0+6+64 \end{pmatrix} = \begin{pmatrix} 32 \\ 36 \\ 72 \end{pmatrix}.$$

Solving: from the first two equations, $2a + b + 3c = 16$ and $a + 3b + 4c = 18$; eliminating a gives $5b + 5c = 20$, so $b + c = 4$. The third equation is $3a + 4b + 9c = 36$. Substituting $b =$

$4-c$ into $2a+b+3c=16$ gives $2a+2c=12$, so $a=6-c$; then $3(6-c)+4(4-c)+9c=36$ becomes $34+2c=36$, so $c=1$, $b=3$, $a=5$. The parabola is

$$y = 5 + 3t + t^2.$$

Its values at $t=-1,0,1,2$ are $3,5,9,15$, so $\mathbf{r}=(-1,3,-3,1)$ and the minimum sum of squares is $1+9+9+1=20$. *Check:* $\sum r_i = 0$, $\sum t_i r_i = 1+0-3+2=0$, $\sum t_i^2 r_i = -1+0-3+4=0$.

Exercise B3: A minimum-norm solution.

Find the minimum-norm solution of

$$\begin{cases} x_1 + x_3 = 2, \\ x_2 + x_3 = 3, \end{cases}$$

and verify that it is orthogonal to $\mathrm{nul}(\mathbf{A})$.

Solution. With $x_3 = t$ the solutions are $\mathbf{x}(t) = (2-t,\ 3-t,\ t) = (2,3,0) + t(-1,-1,1)$, so $\mathrm{nul}(\mathbf{A}) = \mathrm{span}((-1,-1,1))$. By Theorem 10.4.5 we need $\langle \mathbf{x}(t), (-1,-1,1)\rangle = 0$:

$$-(2-t) - (3-t) + t = 3t - 5 = 0, \qquad t = \tfrac{5}{3}.$$

So $\mathbf{x}_{\min} = \left(\tfrac{1}{3}, \tfrac{4}{3}, \tfrac{5}{3}\right)$, with $\|\mathbf{x}_{\min}\|^2 = \frac{1+16+25}{9} = \frac{14}{3}$. It solves the system, since $\frac{1}{3}+\frac{5}{3}=2$ and $\frac{4}{3}+\frac{5}{3}=3$, and $-\frac{1}{3}-\frac{4}{3}+\frac{5}{3}=0$ confirms the orthogonality. For comparison, $\|(2,3,0)\|^2 = 13 > \frac{14}{3}$.

10.4.6.3 C. Going deeper

Exercise C1: Weighted least squares.

Let $\mathbf{A} \in M_{m\times n}(\mathbb{R})$, $\mathbf{b} \in \mathbb{R}^m$, and let $w_1, \dots, w_m > 0$ be weights, with $\mathbf{W} = \mathrm{diag}(w_1, \dots, w_m)$.

(a) Show that $\langle \mathbf{x}, \mathbf{y}\rangle_{\mathbf{W}} = \mathbf{y}^{\top}\mathbf{W}\mathbf{x}$ is an inner product on $\mathbb{R}^m$.

(b) Prove that the minimizers of $\sum_{i=1}^{m} w_i\big((\mathbf{A}\mathbf{x})_i - b_i\big)^2$ are exactly the solutions of $\mathbf{A}^{\top}\mathbf{W}\mathbf{A}\mathbf{x} = \mathbf{A}^{\top}\mathbf{W}\mathbf{b}$.

(c) For the data $(0,2),(1,1),(2,8)$ with weights $(1,2,1)$, find the weighted least-squares line, and compare it with the unweighted one.

Solution.

(a) It is bilinear and symmetric because $\mathbf{y}^{\top}\mathbf{W}\mathbf{x} = \sum_i w_i x_i y_i$, and $\langle \mathbf{x}, \mathbf{x}\rangle_{\mathbf{W}} = \sum_i w_i x_i^2 > 0$ whenever some $x_i \neq 0$, because every $w_i > 0$. (This is where positivity of the weights is used; a zero weight would destroy definiteness.)

(b) Write $\|\cdot\|_{\mathbf{W}}$ for the norm induced by $\langle\cdot,\cdot\rangle_{\mathbf{W}}$. The quantity to minimize is exactly $\|\mathbf{A}\mathbf{x}-\mathbf{b}\|_{\mathbf{W}}^2$. The proof of Theorem 10.4.2 used nothing about the inner product except its axioms, so it applies verbatim with $\langle\cdot,\cdot\rangle_{\mathbf{W}}$ in place of the standard one: the minimizers are the $\mathbf{x}$ for which $\mathbf{A}\mathbf{x}-\mathbf{b}$ is $\langle\cdot,\cdot\rangle_{\mathbf{W}}$-orthogonal to $\mathrm{col}(\mathbf{A})$, that is,

for which $\langle \mathbf{Ax}-\mathbf{b}, \mathbf{Az}\rangle_{\mathbf{W}} = 0$ for all $\mathbf{z} \in \mathbb{R}^n$. Now

$$\langle \mathbf{Ax}-\mathbf{b}, \mathbf{Az}\rangle_{\mathbf{W}} = (\mathbf{Az})^{\top}\mathbf{W}(\mathbf{Ax}-\mathbf{b}) = \mathbf{z}^{\top}\big(\mathbf{A}^{\top}\mathbf{WAx}-\mathbf{A}^{\top}\mathbf{Wb}\big),$$

and this vanishes for all $\mathbf{z} \in \mathbb{R}^n$ exactly when $\mathbf{A}^{\top}\mathbf{WAx}-\mathbf{A}^{\top}\mathbf{Wb}=\mathbf{0}$, by taking $\mathbf{z}$ equal to that vector.

(c) With $\mathbf{A}$ having columns $(1,1,1)$ and $(0,1,2)$, $\mathbf{b}=(2,1,8)$ and $\mathbf{W}=\operatorname{diag}(1,2,1)$,

$$\mathbf{A}^{\top}\mathbf{WA} = \begin{pmatrix} 4 & 4 \\ 4 & 6 \end{pmatrix}, \qquad \mathbf{A}^{\top}\mathbf{Wb} = \begin{pmatrix} 2+2+8 \\ 0+2+16 \end{pmatrix} = \begin{pmatrix} 12 \\ 18 \end{pmatrix},$$

so $4c+4d=12$ and $4c+6d=18$, giving $d=3$ and $c=0$: the weighted line is $y=3t$. Unweighted, $\mathbf{A}^{\top}\mathbf{A} = \begin{pmatrix} 3 & 3 \\ 3 & 5 \end{pmatrix}$ and $\mathbf{A}^{\top}\mathbf{b}=(11,17)$, giving $3c+3d=11$, $3c+5d=17$, so $d=3$ and $c=\frac{2}{3}$: the unweighted line is $y=\frac{2}{3}+3t$. The middle point is trusted twice as much in the weighted fit, and the line moves down to pass closer to it. The weighted fit has weighted error $4+2\cdot 4+4=16$, smaller than the weighted error $\frac{160}{9}$ of the unweighted line, while the unweighted fit has plain error $\frac{32}{3}$, smaller than the plain error 12 of the weighted line: each line wins the contest it was designed for.

Exercise C2: The residual, two ways.

Let $\mathbf{x}$ be a least-squares solution of $\mathbf{Ax}=\mathbf{b}$ and let $\mathbf{r}=\mathbf{b}-\mathbf{Ax}$.

(a) Prove that $\|\mathbf{r}\|^2 = \|\mathbf{b}\|^2 - \|\mathbf{Ax}\|^2$, and also that $\|\mathbf{r}\|^2 = \langle \mathbf{b}, \mathbf{r}\rangle = \|\mathbf{b}\|^2 - \langle \mathbf{A}^{*}\mathbf{b}, \mathbf{x}\rangle$.

(b) Use the second formula to recompute the minimum sum of squares in Example (The least-squares line through four points) without finding the residual vector.

Solution.

(a) By Theorem 10.4.2, $\mathbf{Ax}=P_U\mathbf{b}$ with $U=\operatorname{col}(\mathbf{A})$, so $\mathbf{r}=\mathbf{b}-P_U\mathbf{b}\in U^{\perp}$ while $\mathbf{Ax}\in U$. The two are orthogonal, and $\mathbf{b}=\mathbf{Ax}+\mathbf{r}$, so Theorem 10.1.3 gives $\|\mathbf{b}\|^2=\|\mathbf{Ax}\|^2+\|\mathbf{r}\|^2$, which is the first identity.
For the second, $\langle \mathbf{b},\mathbf{r}\rangle = \langle \mathbf{Ax}+\mathbf{r},\mathbf{r}\rangle = \langle \mathbf{Ax},\mathbf{r}\rangle + \|\mathbf{r}\|^2 = \|\mathbf{r}\|^2$, since $\langle \mathbf{Ax},\mathbf{r}\rangle = \overline{\langle \mathbf{r},\mathbf{Ax}\rangle} = 0$ by orthogonality. Expanding the other way, and using Lemma 10.4.1,

$$\langle \mathbf{b},\mathbf{r}\rangle = \langle \mathbf{b},\mathbf{b}-\mathbf{Ax}\rangle = \|\mathbf{b}\|^2 - \langle \mathbf{b},\mathbf{Ax}\rangle = \|\mathbf{b}\|^2 - \langle \mathbf{A}^{*}\mathbf{b},\mathbf{x}\rangle.$$

(b) In Example (The least-squares line through four points), $\|\mathbf{b}\|^2 = 9+1+25+25=60$, $\mathbf{A}^{\top}\mathbf{b}=(14,40)$ and $\mathbf{x}=(1,1)$, so

$$\|\mathbf{r}\|^2 = 60 - \langle (14,40),(1,1)\rangle = 60-54 = 6,$$

matching the value found there. Only the data already assembled for the normal equations is needed.

Exercise C3: A rank-deficient least-squares problem.

Let
$$\mathbf{A} = \begin{pmatrix} 1 & 0 & 1 \\ 0 & 1 & 1 \\ 1 & 1 & 2 \end{pmatrix}, \qquad \mathbf{b} = \begin{pmatrix} 1 \\ 2 \\ 0 \end{pmatrix}.$$

(a) Show that $\mathbf{Ax} = \mathbf{b}$ is inconsistent and that $\operatorname{rank} \mathbf{A} = 2$.

(b) Describe **all** least-squares solutions.

(c) Find the one of smallest norm, and the minimum sum of squares.

Solution.

(a) The third column is the sum of the first two, so the columns are dependent and $\operatorname{rank} \mathbf{A} \le 2$; the first two columns are independent, so $\operatorname{rank} \mathbf{A} = 2$ and $\operatorname{col}(\mathbf{A}) = \operatorname{span}\big((1,0,1),(0,1,1)\big)$. A vector (b_1, b_2, b_3) lies in $\operatorname{col}(\mathbf{A})$ exactly when $b_3 = b_1 + b_2$; here $0 \neq 1 + 2$, so $\mathbf{b} \notin \operatorname{col}(\mathbf{A})$ and the system is inconsistent.

(b) By Theorem 10.4.2 the least-squares solutions solve $\mathbf{A}^{\top}\mathbf{Ax} = \mathbf{A}^{\top}\mathbf{b}$. Here
$$\mathbf{A}^{\top}\mathbf{A} = \begin{pmatrix} 2 & 1 & 3 \\ 1 & 2 & 3 \\ 3 & 3 & 6 \end{pmatrix}, \qquad \mathbf{A}^{\top}\mathbf{b} = \begin{pmatrix} 1 \\ 2 \\ 3 \end{pmatrix}.$$
Row reducing, the third row is the sum of the first two, and subtracting suitable multiples gives $x_1 + x_3 = 0$ and $x_2 + x_3 = 1$. Hence
$$\mathbf{x}(t) = (0,1,0) + t(-1,-1,1), \qquad t \in \mathbb{R},$$
a coset of $\operatorname{nul}(\mathbf{A}) = \operatorname{span}((-1,-1,1)) = \operatorname{nul}(\mathbf{A}^{\top}\mathbf{A})$, as Lemma 10.4.3 predicts.

(c) The minimizers form a coset of $\operatorname{nul}(\mathbf{A})$, so the argument of Theorem 10.4.5 applies to it verbatim: the shortest is the one orthogonal to $(-1,-1,1)$. From $-(-t) - (1-t) + t = 3t - 1 = 0$ we get $t = \frac{1}{3}$ and
$$\mathbf{x}_{\min} = \left(-\tfrac{1}{3}, \tfrac{2}{3}, \tfrac{1}{3}\right), \qquad \|\mathbf{x}_{\min}\|^2 = \tfrac{1+4+1}{9} = \tfrac{2}{3}.$$
Every minimizer gives the same $\mathbf{Ax} = (0,1,1) = P_{\operatorname{col}(\mathbf{A})}\mathbf{b}$, with residual $\mathbf{r} = (1,1,-1)$ and minimum sum of squares $\|\mathbf{r}\|^2 = 3$. *Check:* $\mathbf{r}$ is orthogonal to $(1,0,1)$ and to $(0,1,1)$, since $1 - 1 = 0$ and $1 - 1 = 0$.

10.5 The Riesz Representation Theorem

Chapter 4 built the dual space V^* of all linear functionals on V, proved that $\dim V^* = \dim V$ in finite dimension, and then delivered a warning: the resulting isomorphism $V \cong V^*$ is not canonical. Every basis of V gives one, different bases give different ones, and no argument singles out a preferred choice (Corollary 4.1.4, and the contrast with the natural map $\mathrm{ev}_V \colon V \to V^{**}$ of Theorem 4.4.6). The chapter closed by promising that an inner product would supply the missing ingredient. This section keeps the promise.

The mechanism is simple to state. Fix $\mathbf{w} \in V$ and let $\varphi_{\mathbf{w}}(\mathbf{v}) = \langle \mathbf{v}, \mathbf{w} \rangle$. Because the inner product is linear in the **first** slot, $\varphi_{\mathbf{w}}$ is a linear functional. The Riesz Representation Theorem says that in finite dimension there are no others.

Throughout, V is a finite-dimensional inner product space over $F = \mathbb{R}$ or $F = \mathbb{C}$, unless the text says otherwise.

10.5.1 Every functional is an inner product

In F^n, Theorem 4.1.1 already told us that every functional has the form $\mathbf{x} \mapsto a_1x_1 + \cdots + a_nx_n$ for a unique row of coefficients. With the standard inner product $\langle \mathbf{x}, \mathbf{y} \rangle = \sum_i x_i\overline{y_i}$, that reads $\varphi(\mathbf{x}) = \langle \mathbf{x}, \mathbf{w} \rangle$ with $\mathbf{w} = (\overline{a_1}, \ldots, \overline{a_n})$. So in coordinates the theorem is a restatement of a fact we already have; the content is that it survives the removal of coordinates.

Theorem 10.5.1 — Riesz Representation Theorem

Let V be a finite-dimensional inner product space over F and let $\varphi \in V^*$. Then there is a **unique** $\mathbf{w} \in V$ such that

$$\varphi(\mathbf{v}) = \langle \mathbf{v}, \mathbf{w} \rangle \qquad \text{for every } \mathbf{v} \in V.$$

If $(\mathbf{e}_1, \ldots, \mathbf{e}_n)$ is any orthonormal basis of V, then $\mathbf{w} = \sum_{i=1}^{n} \overline{\varphi(\mathbf{e}_i)}\, \mathbf{e}_i$.

Idea. Fix an orthonormal basis. Then a linear functional is determined by the n numbers $\varphi(\mathbf{e}_i)$, and a vector is determined by its n coordinates, which Theorem 10.2.1 reads off as inner products. Matching the two lists tells us what $\mathbf{w}$ must be, and the only care needed is the conjugate: $\mathbf{w}$ sits in the second slot, so its coordinates come out conjugated. Uniqueness is the standard move — if two vectors pair identically with everything, subtract and pair the difference with itself.

Proof. Existence. Let $(\mathbf{e}_1, \ldots, \mathbf{e}_n)$ be an orthonormal basis of V, which exists by Theorem 10.2.2, and put

$$\mathbf{w} = \sum_{i=1}^{n} \overline{\varphi(\mathbf{e}_i)}\, \mathbf{e}_i.$$

For each j, conjugate-linearity in the second slot and $\langle \mathbf{e}_j, \mathbf{e}_i \rangle = \delta_{ij}$ give

$$\langle \mathbf{e}_j, \mathbf{w} \rangle = \sum_{i=1}^{n} \overline{\overline{\varphi(\mathbf{e}_i)}}\, \langle \mathbf{e}_j, \mathbf{e}_i \rangle = \varphi(\mathbf{e}_j).$$

So the two linear functionals $\mathbf{v} \mapsto \langle \mathbf{v}, \mathbf{w} \rangle$ and φ agree on a basis, hence are equal by Theorem 3.1.5. (The first is linear because the inner product is linear in the first slot.)

Uniqueness. Suppose $\langle \mathbf{v}, \mathbf{w} \rangle = \langle \mathbf{v}, \mathbf{w}' \rangle$ for every $\mathbf{v}$. Then $\langle \mathbf{v}, \mathbf{w} - \mathbf{w}' \rangle = 0$ for every $\mathbf{v}$, by additivity in the second slot. Taking $\mathbf{v} = \mathbf{w} - \mathbf{w}'$ gives $\|\mathbf{w} - \mathbf{w}'\|^2 = 0$, so $\mathbf{w} = \mathbf{w}'$ by positive definiteness.

■

Call $\mathbf{w}$ the **Riesz vector** of φ. The formula is worth reading twice: the coordinates of $\mathbf{w}$ in an orthonormal basis are the conjugates of the values of φ on that basis. Over $\mathbb{R}$ the conjugation is invisible, which is why real textbooks can omit it and complex ones cannot.

Example. (Two Riesz vectors)

(a) On $V = \mathbb{R}[x]_{\le 1}$ with $\langle p, q\rangle = \int_0^1 p(t)q(t)\,dt$, find the Riesz vector of $\varphi(p) = p(0)$.

(b) On $V = M_n(\mathbb{C})$ with the Frobenius inner product $\langle \mathbf{A}, \mathbf{B}\rangle = \operatorname{tr}(\mathbf{B}^*\mathbf{A})$, find the Riesz vector of $\varphi(\mathbf{A}) = \operatorname{tr}\mathbf{A}$.

Solution.

(a) We look for $w = a + bx$ with $\langle p, w\rangle = p(0)$ for all p. By linearity it is enough to impose this on the basis $(1, x)$:

$$\int_0^1 (a + bt)\,dt = a + \tfrac{b}{2} = 1, \qquad \int_0^1 t(a + bt)\,dt = \tfrac{a}{2} + \tfrac{b}{3} = 0.$$

The second equation gives $a = -\frac{2}{3}b$; substituting into the first gives $-\frac{2}{3}b + \frac{1}{2}b = -\frac{1}{6}b = 1$, so $b = -6$ and $a = 4$. Hence $w = 4 - 6x$.
Check. $\int_0^1 (4 - 6t)\,dt = 4 - 3 = 1$ and $\int_0^1 t(4 - 6t)\,dt = 2 - 2 = 0$, as required; and for a general $p = c + dx$ the pairing gives $c \cdot 1 + d \cdot 0 = c = p(0)$. Note how little w resembles "evaluation at 0": the Riesz vector is manufactured by the inner product, not by the point 0.

(b) We look for $\mathbf{W}$ with $\operatorname{tr}(\mathbf{W}^*\mathbf{A}) = \operatorname{tr}\mathbf{A}$ for every $\mathbf{A}$. Taking $\mathbf{W} = \mathbf{I}_n$ works, since $\mathbf{I}_n^* = \mathbf{I}_n$ and $\operatorname{tr}(\mathbf{I}_n\mathbf{A}) = \operatorname{tr}\mathbf{A}$. By uniqueness, $\mathbf{W} = \mathbf{I}_n$ is the answer. (This example was not solved by the basis formula, but by guessing and then invoking uniqueness — a legitimate and often faster route.)

10.5.2 The Riesz map, and the data Chapter 4 was missing

Uniqueness in Theorem 10.5.1 lets us read the theorem as a statement about a map.

Corollary 10.5.2 — The Riesz map

Let V be a finite-dimensional inner product space over F. Define

$$\Phi\colon V \to V^*, \qquad \Phi(\mathbf{w}) = \langle \cdot, \mathbf{w}\rangle.$$

Then Φ is a bijection, and for all $\mathbf{w}, \mathbf{w}' \in V$ and $c \in F$,

$$\Phi(\mathbf{w} + \mathbf{w}') = \Phi(\mathbf{w}) + \Phi(\mathbf{w}'), \qquad \Phi(c\mathbf{w}) = \overline{c}\,\Phi(\mathbf{w}).$$

In particular Φ is an isomorphism of vector spaces when $F = \mathbb{R}$, and is **conjugate-linear** when $F = \mathbb{C}$.

Proof. Each $\Phi(\mathbf{w})$ lies in V^* because the inner product is linear in the first slot. Surjectivity is the existence half of Theorem 10.5.1 and injectivity is the uniqueness half (if $\Phi(\mathbf{w}) = \Phi(\mathbf{w}')$, then $\mathbf{w} = \mathbf{w}'$). For the two rules, evaluate at an arbitrary $\mathbf{v}$: additivity in the second slot gives $\langle \mathbf{v}, \mathbf{w} + \mathbf{w}'\rangle = \langle \mathbf{v}, \mathbf{w}\rangle + \langle \mathbf{v}, \mathbf{w}'\rangle$, and conjugate-homogeneity in the second slot gives $\langle \mathbf{v}, c\mathbf{w}\rangle = \overline{c}\langle \mathbf{v}, \mathbf{w}\rangle$. Over $\mathbb{R}$ we have $\overline{c} = c$, so Φ is linear, and a

linear bijection is an isomorphism (Theorem 0.4.7).

■

This is the payoff Chapter 4 promised. There, $V \cong V^*$ was proved by choosing a basis $\mathcal{B}$ and sending $\mathbf{v}_i \mapsto \varphi_i$, and the warning was that the isomorphism changes when $\mathcal{B}$ does: a vector does not come with "its" functional. Here Φ is written down with no basis at all. It is not free of choices — it depends on $\langle \cdot, \cdot \rangle$ — but the choice has been made once, in advance, and it is a choice of *geometry* rather than of coordinates. **The inner product is exactly the extra data that turns $V \cong V^*$ from a counting fact into a formula.**

The two descriptions fit together neatly. Let $\mathcal{B} = (\mathbf{v}_1, \dots, \mathbf{v}_n)$ be an **orthonormal** basis of V, with dual basis $(\varphi_1, \dots, \varphi_n)$ (Theorem 4.1.3). Then $\Phi(\mathbf{v}_i)$ is the functional $\mathbf{v} \mapsto \langle \mathbf{v}, \mathbf{v}_i \rangle$, which sends $\mathbf{v}_j$ to δ_{ij}; that is,

$$\Phi(\mathbf{v}_i) = \varphi_i \qquad (i = 1, \dots, n),$$

over either field. Over $\mathbb{R}$, where Φ is linear, this says that Φ **is** Chapter 4's basis-dependent isomorphism $\mathbf{v}_i \mapsto \varphi_i$, for the inner product that declares $\mathcal{B}$ orthonormal. Choosing a basis and choosing an inner product are two ways of supplying the same missing data.

Quick check. Let $\mathcal{B} = (\mathbf{v}_1, \dots, \mathbf{v}_n)$ be an orthonormal basis of a **complex** inner product space and let $(\varphi_1, \dots, \varphi_n)$ be its dual basis. What is the Riesz vector of $i\varphi_1$?

Solution. By the identity $\Phi(\mathbf{v}_i) = \varphi_i$ above, which holds over $\mathbb{C}$ as well, φ_1 has Riesz vector $\mathbf{v}_1$. For $i\varphi_1$, use conjugate-homogeneity in reverse: $\Phi(-i\mathbf{v}_1) = \overline{(-i)}\Phi(\mathbf{v}_1) = i\varphi_1$. So the Riesz vector of $i\varphi_1$ is $-i\mathbf{v}_1$, not $i\mathbf{v}_1$. Alternatively, apply the formula of Theorem 10.5.1: the coordinates of the Riesz vector are $\overline{(i\varphi_1)(\mathbf{v}_j)} = \overline{i\delta_{1j}} = -i\delta_{1j}$.

Warning. **Over $\mathbb{C}$, the Riesz map is not linear, so it is not an isomorphism of complex vector spaces.** It is a bijection, and it is linear over $\mathbb{R}$, but $\Phi(i\mathbf{w}) = -i\Phi(\mathbf{w})$. Complex spaces V and V^* are still isomorphic — they have the same dimension — but the isomorphism produced by an inner product is the conjugate-linear Φ. Most of what we do with Φ (Section 6 builds the adjoint from it) is unaffected, because the conjugation cancels when Φ is used twice.

Warning. **The Riesz vector depends on the inner product, not on φ alone.** On $\mathbb{R}^2$ let $\varphi(\mathbf{x}) = x_1 + x_2$. With the dot product, $\varphi(\mathbf{x}) = \langle \mathbf{x}, (1,1) \rangle$, so $\mathbf{w} = (1,1)$. With the weighted inner product $\langle \mathbf{x}, \mathbf{y} \rangle = 2x_1y_1 + x_2y_2$, we need $2w_1 = 1$ and $w_2 = 1$, so $\mathbf{w} = \left(\frac{1}{2}, 1\right)$. Same functional, different representing vector. Whenever two inner products are in play, the notation must say which Φ is meant.

10.5.3 Annihilators become orthogonal complements

Section 3 warned that the annihilator $U^0 \subseteq V^*$ and the orthogonal complement $U^\perp \subseteq V$ are different objects that happen to have the same dimension. The Riesz map explains the coincidence: it carries one onto the other.

Theorem 10.5.3 — Perp corresponds to the annihilator

Let V be a finite-dimensional inner product space over F, let U be a subspace and let

Φ be the Riesz map. Then

$$\Phi(U^{\perp}) = U^{0}.$$

Equivalently, a functional $\varphi \in V^*$ annihilates U if and only if its Riesz vector lies in $U^{\perp}$.

Proof. Let $\mathbf{w} \in V$. Then

$$\Phi(\mathbf{w}) \in U^{0} \iff \langle \mathbf{u}, \mathbf{w} \rangle = 0 \text{ for every } \mathbf{u} \in U \iff \mathbf{w} \in U^{\perp},$$

the first equivalence being the definition of the annihilator (Definition 4.2.1) applied to the functional $\Phi(\mathbf{w}) = \langle \cdot, \mathbf{w} \rangle$, and the second the definition of the orthogonal complement (Definition 10.3.1). Since Φ is a bijection (Corollary 10.5.2), the set $\Phi(U^{\perp})$ is therefore exactly U^{0}.

■

The dimension count now has a reason rather than a coincidence: $\dim U^{0} = \dim V - \dim U$ (Theorem 4.2.2) and $\dim U^{\perp} = \dim V - \dim U$ (Theorem 10.3.2 (c)) agree because the two spaces correspond under a bijection. (Over $\mathbb{C}$ the bijection is only conjugate-linear, but a conjugate-linear bijection still carries subspaces to subspaces of the same dimension, since $c\Phi(\mathbf{w}) = \Phi(\overline{c}\mathbf{w})$.)

Here is the correspondence in $\mathbb{R}^3$. Let $U = \operatorname{span}((1,2,0))$ with the dot product. Then $U^{\perp} = \{(a,b,c) : a + 2b = 0\} = \operatorname{span}\big((2,-1,0),(0,0,1)\big)$, and U^{0} consists of the functionals $\mathbf{x} \mapsto \alpha x_1 + \beta x_2 + \gamma x_3$ with $\alpha + 2\beta = 0$, spanned by $2x_1 - x_2$ and x_3. These are precisely $\Phi((2,-1,0))$ and $\Phi((0,0,1))$.

Section 6 uses Theorem 10.5.3 in the same way for maps: the dual map $T' \colon W^* \to V^*$ of Chapter 4 and the adjoint $T^* \colon W \to V$ are the same map, read through the two Riesz maps.

10.5.4 What happens in infinite dimension

The proof used an orthonormal basis of the whole of V, so finite dimension was essential, and the theorem genuinely fails without it.

Example. (A functional with no Riesz vector)

Let $V = \mathbb{R}[x]$ with the coefficient inner product $\langle p, q \rangle = \sum_{k \geq 0} a_k b_k$ for $p = \sum_k a_k x^k$ and $q = \sum_k b_k x^k$ (a finite sum, and an inner product by Exercise (C2: A subspace with no orthogonal complement) (a)). Show that $\varphi(p) = p(1)$ has no Riesz vector.

Solution. Suppose $w = \sum_k b_k x^k$ satisfied $\langle p, w \rangle = p(1)$ for every $p \in V$. Taking $p = x^i$ gives

$$b_i = \langle x^i, w \rangle = \varphi(x^i) = 1^i = 1 \qquad \text{for every } i \geq 0.$$

So every coefficient of w equals 1. But a polynomial has only finitely many non-zero coefficients, so no such w exists.

What fails is not "infinite dimension" as a slogan. Two things are missing at once, and the same example shows both. First, V has gaps: Exercise (C2: A subspace with no orthogonal complement) exhibits polynomials $p_m \in \ker \varphi$ with $\|p_m - 1\| = 1/\sqrt{m}$, so the vectors p_m crowd around the polynomial 1 without any limit being forced to lie in $\ker \varphi$. Second, φ is wildly

discontinuous with respect to $\|\cdot\|$: along the same sequence, $\varphi(p_m) = 0$ for every m, while $\varphi(1) = 1$.

Repairing both defects — completing the space, and restricting attention to functionals φ with $|\varphi(\mathbf{v})| \leq C\|\mathbf{v}\|$ — restores the theorem. That statement is the Riesz representation theorem for Hilbert spaces, and it belongs to analysis, not to linear algebra; we record its existence and go no further. What survives here with no hypotheses at all is the easy direction: for every $\mathbf{w} \in V$, the map $\langle \cdot, \mathbf{w} \rangle$ *is* a linear functional. Only the converse needs finite dimension.

10.5.5 Exercises

10.5.5.1 A. Check your understanding

Exercise A1.

(a) State the Riesz Representation Theorem, including every hypothesis.

(b) Write down the formula for the Riesz vector of φ in terms of an orthonormal basis, and say where the conjugate comes from.

(c) True or false: over $\mathbb{C}$, the Riesz map $\Phi\colon V \to V^*$ is a linear isomorphism. Justify your answer.

(d) In what sense does an inner product answer the question Chapter 4 left open about $V \cong V^*$?

(e) Under Φ, which subspace of V^* corresponds to $U^\perp$?

(f) Give an example showing that the theorem fails in infinite dimension.

Solution.

(a) If V is a **finite-dimensional** inner product space over $\mathbb{R}$ or $\mathbb{C}$ and $\varphi \in V^*$, then there is a unique $\mathbf{w} \in V$ with $\varphi(\mathbf{v}) = \langle \mathbf{v}, \mathbf{w} \rangle$ for all $\mathbf{v} \in V$ (Theorem 10.5.1).

(b) $\mathbf{w} = \sum_i \overline{\varphi(\mathbf{e}_i)}\mathbf{e}_i$ for any orthonormal basis $(\mathbf{e}_1, \ldots, \mathbf{e}_n)$. The conjugate appears because $\mathbf{w}$ occupies the second slot, where scalars come out conjugated: to make $\langle \mathbf{e}_j, \mathbf{w} \rangle$ equal $\varphi(\mathbf{e}_j)$, the coefficient of $\mathbf{e}_j$ in $\mathbf{w}$ must be $\overline{\varphi(\mathbf{e}_j)}$.

(c) False. Φ is a bijection, but $\Phi(c\mathbf{w}) = \bar{c}\Phi(\mathbf{w})$, so it is conjugate-linear and not $\mathbb{C}$-linear (Corollary 10.5.2). It is linear over $\mathbb{R}$, and over $\mathbb{R}$ it is an isomorphism.

(d) Chapter 4 showed $V \cong V^*$ by counting dimensions, with an isomorphism depending on a chosen basis and no preferred choice available (Corollary 4.1.4). An inner product supplies a specific map $\Phi(\mathbf{w}) = \langle \cdot, \mathbf{w} \rangle$, written without reference to any basis. The inner product is the extra data; picking an orthonormal basis and picking an inner product that makes a given basis orthonormal are the same act.

(e) U^0, the annihilator of U (Theorem 10.5.3).

(f) On $\mathbb{R}[x]$ with the coefficient inner product, $\varphi(p) = p(1)$ has no Riesz vector: such a vector would need every coefficient equal to 1 (Example (A functional with no Riesz vector)).

10.5.5.2 B. Practice

Exercise B1: Riesz vectors for evaluation.

On $V = \mathbb{R}[x]_{\le 2}$ use the node inner product $\langle p, q\rangle = p(-1)q(-1) + p(0)q(0) + p(1)q(1)$. Find the Riesz vectors of $\varphi(p) = p(0)$ and of $\psi(p) = p(1)$.

Solution. Since $-1, 0, 1$ are three distinct nodes and $\dim V = 3$, a polynomial of V is determined by its values there (Theorem 2.7.3). Writing w for a candidate Riesz vector of φ, the requirement $\langle p, w\rangle = p(0)$ reads

$$p(-1)w(-1) + p(0)w(0) + p(1)w(1) = p(0) \qquad \text{for all } p \in V.$$

Taking for p the three Lagrange polynomials at the nodes, which have value 1 at one node and 0 at the others (Definition 5.6.1), the three equations become $w(-1) = 0$, $w(0) = 1$, $w(1) = 0$. The unique quadratic with those values is $w = 1 - x^2$.

For ψ the same argument gives $w(-1) = 0$, $w(0) = 0$, $w(1) = 1$, whose interpolant is $w = \frac{1}{2}x(x+1)$.

Check. For $p = 3 + 2x - x^2$ we get $p(-1) = 0$, $p(0) = 3$, $p(1) = 4$. Pairing with $1 - x^2$, whose values are $0, 1, 0$, gives $3 = p(0)$; pairing with $\frac{1}{2}x(x+1)$, whose values are $0, 0, 1$, gives $4 = p(1)$.

Exercise B2: Riesz vectors on matrices.

On $M_n(\mathbb{C})$ with the Frobenius inner product $\langle \mathbf{A}, \mathbf{B}\rangle = \operatorname{tr}(\mathbf{B}^*\mathbf{A})$, find the Riesz vector of:

(a) $\varphi(\mathbf{A}) = a_{12}$ (assume $n \ge 2$);
(b) $\varphi_{\mathbf{C}}(\mathbf{A}) = \operatorname{tr}(\mathbf{C}\mathbf{A})$, for a fixed $\mathbf{C} \in M_n(\mathbb{C})$.

Solution.

(a) Let $\mathbf{E}_{12}$ be the matrix unit with a 1 in position $(1,2)$ and zeros elsewhere. Then $\mathbf{E}_{12}^* = \mathbf{E}_{21}$, and $(\mathbf{E}_{21}\mathbf{A})_{kk} = \sum_j (\mathbf{E}_{21})_{kj} a_{jk}$, which is 0 unless $k = 2$, where it equals a_{12}. Hence $\operatorname{tr}(\mathbf{E}_{12}^*\mathbf{A}) = a_{12} = \varphi(\mathbf{A})$, and by uniqueness in Theorem 10.5.1 the Riesz vector is $\mathbf{E}_{12}$.

(b) We need $\mathbf{W}$ with $\operatorname{tr}(\mathbf{W}^*\mathbf{A}) = \operatorname{tr}(\mathbf{C}\mathbf{A})$ for all $\mathbf{A}$. Taking $\mathbf{W}^* = \mathbf{C}$, that is $\mathbf{W} = \mathbf{C}^*$, works. By uniqueness it is the only answer. Part (a) is the case $\mathbf{C} = \mathbf{E}_{21}$, and the example in the text is the case $\mathbf{C} = \mathbf{I}_n$.

Exercise B3: The correspondence in $\mathbb{R}^4$.

In $\mathbb{R}^4$ with the dot product, let $U = \operatorname{span}\big((1,0,1,0),(0,1,0,1)\big)$. Find a basis of $U^{\perp}$ and a basis of U^0, and verify that Φ carries the first to the second.

Solution. A vector (a,b,c,d) lies in $U^{\perp}$ exactly when $a + c = 0$ and $b + d = 0$ (Proposition 10.3.1, testing against the two spanning vectors). So

$$U^{\perp} = \operatorname{span}\big((1,0,-1,0),\ (0,1,0,-1)\big),$$

of dimension $2 = 4 - 2$.

A functional $\varphi(\mathbf{x}) = \alpha x_1 + \beta x_2 + \gamma x_3 + \delta x_4$ lies in U^0 exactly when it kills both spanning vectors, that is, when $\alpha + \gamma = 0$ and $\beta + \delta = 0$. So $U^0 = \operatorname{span}(\varphi_1, \varphi_2)$ with

$$\varphi_1(\mathbf{x}) = x_1 - x_3, \qquad \varphi_2(\mathbf{x}) = x_2 - x_4.$$

Over $\mathbb{R}$, $\Phi(\mathbf{w})(\mathbf{x}) = \langle \mathbf{x}, \mathbf{w} \rangle = \sum_i x_i w_i$, so $\Phi((1,0,-1,0)) = \varphi_1$ and $\Phi((0,1,0,-1)) = \varphi_2$. Since Φ is linear over $\mathbb{R}$ and bijective, it carries the span of the two vectors onto the span of the two functionals, confirming Theorem 10.5.3.

10.5.5.3 C. Going deeper

Exercise C1: Riesz without an orthonormal basis.

Let V be a finite-dimensional inner product space and let $\varphi \in V^*$ be non-zero. Write $K = \ker \varphi$.

(a) Prove that $\dim K^\perp = 1$.

(b) Let $\mathbf{u}$ span $K^\perp$ with $\|\mathbf{u}\| = 1$. Prove that $\mathbf{w} = \overline{\varphi(\mathbf{u})}\,\mathbf{u}$ satisfies $\varphi(\mathbf{v}) = \langle \mathbf{v}, \mathbf{w} \rangle$ for all $\mathbf{v} \in V$.

(c) Deduce Theorem 10.5.1, including the case $\varphi = 0$.

Hint for (b): split $\mathbf{v}$ *using* $V = K \oplus K^\perp$.

Solution.

(a) Since $\varphi \neq 0$, its image is a non-zero subspace of the 1-dimensional space F, so $\operatorname{im} \varphi = F$ and $\operatorname{rank} \varphi = 1$. By Theorem 3.3.1, $\dim K = \dim V - 1$, and by Theorem 10.3.2 (c), $\dim K^\perp = \dim V - \dim K = 1$.

(b) By Theorem 10.3.2 (a), $V = K \oplus K^\perp$, so each $\mathbf{v} \in V$ is $\mathbf{v} = \mathbf{k} + c\mathbf{u}$ with $\mathbf{k} \in K$ and $c \in F$. Then $\varphi(\mathbf{v}) = \varphi(\mathbf{k}) + c\varphi(\mathbf{u}) = c\varphi(\mathbf{u})$. On the other side,

$$\langle \mathbf{v}, \mathbf{w} \rangle = \langle \mathbf{k} + c\mathbf{u}, \overline{\varphi(\mathbf{u})}\mathbf{u} \rangle = \varphi(\mathbf{u})\big(\langle \mathbf{k}, \mathbf{u} \rangle + c\langle \mathbf{u}, \mathbf{u} \rangle\big) = \varphi(\mathbf{u})\, c,$$

using conjugate-homogeneity in the second slot (which conjugates $\overline{\varphi(\mathbf{u})}$ back to $\varphi(\mathbf{u})$), then $\langle \mathbf{k}, \mathbf{u} \rangle = 0$ because $\mathbf{u} \in K^\perp$ and $\mathbf{k} \in K$, and $\langle \mathbf{u}, \mathbf{u} \rangle = \|\mathbf{u}\|^2 = 1$. The two sides agree.

(c) If $\varphi = 0$, then $\mathbf{w} = \mathbf{0}$ represents it. If $\varphi \neq 0$, part (a) supplies a unit vector $\mathbf{u}$ spanning the line $K^\perp$ — any non-zero vector of that line divided by its norm — and part (b) supplies $\mathbf{w}$. Uniqueness is unchanged: if $\langle \mathbf{v}, \mathbf{w} \rangle = \langle \mathbf{v}, \mathbf{w}' \rangle$ for all $\mathbf{v}$, take $\mathbf{v} = \mathbf{w} - \mathbf{w}'$ to get $\|\mathbf{w} - \mathbf{w}'\|^2 = 0$. Note that this proof never mentions a basis of V; it uses only the orthogonal decomposition along the hyperplane $\ker \varphi$.

Exercise C2: Evaluation at 0 is not represented.

Let $V = \mathbb{R}[x]$ with $\langle p, q \rangle = \int_0^1 p(t)q(t)\,\mathrm{d}t$, and let $\varphi(p) = p(0)$. Suppose, for a contradiction, that $w = \sum_{j=0}^{d} c_j x^j$ satisfied $\langle p, w \rangle = p(0)$ for every $p \in V$.

(a) Show that $\displaystyle\sum_{j=0}^{d} \frac{c_j}{k+j+1} = 0$ for every integer $k \geq 1$, and that the same sum equals 1 for $k = 0$.

(b) Let $N(s) = \sum_{j=0}^{d} c_j \prod_{i \neq j} (s+i+1)$, the product running over $i \in \{0, \dots, d\} \setminus \{j\}$. Show that $N(k) = 0$ for every integer $k \geq 1$, and deduce that N is the zero polynomial.

(c) Deduce that every $c_j = 0$, and hence a contradiction.

Solution.

(a) Take $p = x^k$. Then $p(0) = 0$ for $k \geq 1$ and $p(0) = 1$ for $k = 0$, while

$$\langle x^k, w \rangle = \int_0^1 t^k \sum_{j=0}^{d} c_j t^j \, \mathrm{d}t = \sum_{j=0}^{d} c_j \int_0^1 t^{k+j} \, \mathrm{d}t = \sum_{j=0}^{d} \frac{c_j}{k+j+1}.$$

(b) For an integer $k \geq 1$, multiply the identity of (a) by $\prod_{i=0}^{d}(k+i+1)$, a non-zero number. Each term $c_j/(k+j+1)$ becomes $c_j \prod_{i \neq j}(k+i+1)$, so the result is exactly $N(k) = 0$. Thus the polynomial N, of degree at most d, has the infinitely many distinct roots $1, 2, 3, \dots$. A non-zero polynomial of degree d has at most d distinct roots (Corollary 5.1.4), so $N = 0$.

(c) Evaluate N at $s = -(j_0 + 1)$ for a fixed $j_0 \in \{0, \dots, d\}$. Every product $\prod_{i \neq j}(s+i+1)$ with $j \neq j_0$ contains the factor $s + j_0 + 1 = 0$ and so vanishes; the term $j = j_0$ contributes $c_{j_0} \prod_{i \neq j_0}(i - j_0)$, and that product is non-zero because the factors $i - j_0$ are non-zero integers. Since $N = 0$, we get $c_{j_0} = 0$. This holds for every j_0, so $w = 0$. But then the case $k = 0$ of (a) reads $0 = 1$, a contradiction. Hence no Riesz vector exists.

The moral matches Example (A functional with no Riesz vector): point evaluation is a perfectly good linear functional, but on an infinite-dimensional space it is not represented by any vector, whichever of these two inner products we use.

10.6 The Adjoint

Chapter 4 attached to every linear map $T \colon V \to W$ a dual map $T' \colon W^* \to V^*$ running backwards between the dual spaces (Definition 4.4.1). An inner product puts a copy of the dual space back inside the space itself, by the Riesz correspondence of Theorem 10.5.1. Composing the two turns the backward map on functionals into a backward map on vectors, $W \to V$. That map is the **adjoint** T^*, and it is the single most useful construction in this chapter. This section builds it, computes its matrix, uses it to split both V and W into orthogonal pieces, and names the two classes of operators it singles out.

Throughout, F is $\mathbb{R}$ or $\mathbb{C}$, every inner product is linear in the first slot and conjugate-linear in the second, and every inner product space is finite-dimensional over F unless we say otherwise.

10.6.1 Paying to cross the inner product

Here is the situation the adjoint answers. We have a linear map T and an inner product, and an expression like $\langle T\mathbf{v}, \mathbf{w}\rangle$ in which T sits in the first slot. Very often the argument needs T out of the way: we know something about $\mathbf{w}$, or about the second slot, and the T is in the wrong place. Can we move it across?

For matrices the answer is already on the table. Lemma 10.4.1, proved in Section 4, says that for $\mathbf{A} \in M_{m\times n}(F)$, $\mathbf{x} \in F^n$ and $\mathbf{y} \in F^m$,

$$\langle \mathbf{A}\mathbf{x}, \mathbf{y}\rangle = \langle \mathbf{x}, \mathbf{A}^*\mathbf{y}\rangle,$$

with $\mathbf{A}^*$ the conjugate transpose of Definition 10.1.2. The one-line reason is worth repeating, because it is the model for the whole section: writing $\mathbf{y}^*$ for the row vector $\overline{\mathbf{y}}^{\top}$, the standard inner product is the matrix product $\langle \mathbf{x}, \mathbf{y}\rangle = \mathbf{y}^*\mathbf{x}$, so $\langle \mathbf{A}\mathbf{x}, \mathbf{y}\rangle = (\mathbf{y}^*\mathbf{A})\mathbf{x} = (\mathbf{A}^*\mathbf{y})^*\mathbf{x} = \langle \mathbf{x}, \mathbf{A}^*\mathbf{y}\rangle$. So a matrix does cross the inner product, and the price is a conjugate transpose. Over $\mathbb{R}$ the price is a transpose; over $\mathbb{C}$ a transpose and a conjugation.

To move a map from the first slot to the second slot, you pay with a new map going the other way.

That statement is about matrices and the standard inner product. The next theorem says the same map exists for every linear map between finite-dimensional inner product spaces, with no coordinates at all. Riesz does the work: the expression $\langle T\mathbf{v}, \mathbf{w}\rangle$, read as a function of $\mathbf{v}$ with $\mathbf{w}$ frozen, is a linear functional on V, and Theorem 10.5.1 says that every such functional is pairing against one fixed vector.

Theorem 10.6.1 — Existence and Uniqueness of the Adjoint

Let V and W be finite-dimensional inner product spaces over F, and let $T \in \mathcal{L}(V, W)$. Then there is exactly one map $T^*\colon W \to V$ such that

$$\langle T\mathbf{v}, \mathbf{w}\rangle_W = \langle \mathbf{v}, T^*\mathbf{w}\rangle_V \qquad \text{for all } \mathbf{v} \in V,\ \mathbf{w} \in W,$$

and this T^* is linear.

Idea. Freeze $\mathbf{w}$. Then $\mathbf{v} \mapsto \langle T\mathbf{v}, \mathbf{w}\rangle$ is a functional on V, so Riesz hands us one vector that represents it; call it $T^*\mathbf{w}$. That is the whole of existence, and it also gives uniqueness, since the Riesz vector is unique. Linearity is not part of the construction and has to be checked, and the way to check an identity between vectors is the signature move of this chapter: show the difference pairs to zero with everything, then pair it with itself.

Proof. **Existence.** Fix $\mathbf{w} \in W$ and define $\varphi_{\mathbf{w}}\colon V \to F$ by $\varphi_{\mathbf{w}}(\mathbf{v}) := \langle T\mathbf{v}, \mathbf{w}\rangle$. It is linear: for $\mathbf{v}_1, \mathbf{v}_2 \in V$ and $c \in F$,

$$\varphi_{\mathbf{w}}(\mathbf{v}_1 + c\mathbf{v}_2) = \langle T\mathbf{v}_1 + cT\mathbf{v}_2, \mathbf{w}\rangle = \langle T\mathbf{v}_1, \mathbf{w}\rangle + c\langle T\mathbf{v}_2, \mathbf{w}\rangle,$$

using the linearity of T and linearity in the **first** slot (Definition 10.1.1). Since V is finite-dimensional, Theorem 10.5.1 gives a unique $\mathbf{u} \in V$ with $\varphi_{\mathbf{w}}(\mathbf{v}) = \langle \mathbf{v}, \mathbf{u}\rangle$ for all $\mathbf{v} \in V$. Define $T^*\mathbf{w} := \mathbf{u}$. By construction $\langle T\mathbf{v}, \mathbf{w}\rangle = \langle \mathbf{v}, T^*\mathbf{w}\rangle$ for all $\mathbf{v}$, which is the required identity.

Uniqueness. Suppose $S\colon W \to V$ also satisfies $\langle T\mathbf{v}, \mathbf{w}\rangle = \langle \mathbf{v}, S\mathbf{w}\rangle$ for all $\mathbf{v}, \mathbf{w}$. Fix $\mathbf{w}$.

Then $\langle \mathbf{v}, T^*\mathbf{w} - S\mathbf{w}\rangle = 0$ for every $\mathbf{v} \in V$, by conjugate-additivity in the second slot. Taking $\mathbf{v} = T^*\mathbf{w} - S\mathbf{w}$ gives $\|T^*\mathbf{w} - S\mathbf{w}\|^2 = 0$, so $T^*\mathbf{w} = S\mathbf{w}$ by positive definiteness (Definition 10.1.1). As $\mathbf{w}$ was arbitrary, $S = T^*$.

Linearity. Let $\mathbf{w}_1, \mathbf{w}_2 \in W$ and $c \in F$. For every $\mathbf{v} \in V$,

$$\begin{aligned}\langle \mathbf{v}, T^*(\mathbf{w}_1 + c\mathbf{w}_2)\rangle &= \langle T\mathbf{v}, \mathbf{w}_1 + c\mathbf{w}_2\rangle = \langle T\mathbf{v}, \mathbf{w}_1\rangle + \overline{c}\langle T\mathbf{v}, \mathbf{w}_2\rangle \\ &= \langle \mathbf{v}, T^*\mathbf{w}_1\rangle + \overline{c}\langle \mathbf{v}, T^*\mathbf{w}_2\rangle = \langle \mathbf{v}, T^*\mathbf{w}_1 + cT^*\mathbf{w}_2\rangle,\end{aligned}$$

where the second and the last equalities use conjugate-linearity in the second slot. Hence $\langle \mathbf{v}, T^*(\mathbf{w}_1 + c\mathbf{w}_2) - T^*\mathbf{w}_1 - cT^*\mathbf{w}_2\rangle = 0$ for every $\mathbf{v}$, and pairing the right-hand vector with itself makes it $\mathbf{0}$. So T^* is linear. This proves the theorem.

■

Notice where the two conjugations went. The scalar c came out of the second slot as $\overline{c}$ and went back in as c; the two conjugations cancel, which is exactly why T^* is linear and not conjugate-linear. Notice also that only V had to be finite-dimensional: the proof never uses a basis of W. We keep both spaces finite-dimensional because the rest of the section does need it.

10.6.2 The adjoint

The theorem produced an object attached to T and to the two inner products, and it is unique, so it deserves a name and a notation.

The adjoint of T is the map you must apply on the other side of the inner product to leave the value unchanged.

Definition 10.6.1 — Adjoint

Let V and W be finite-dimensional inner product spaces over F and let $T \in \mathcal{L}(V, W)$. The **adjoint** of T is the unique linear map $T^* \in \mathcal{L}(W, V)$ satisfying

$$\langle T\mathbf{v}, \mathbf{w}\rangle = \langle \mathbf{v}, T^*\mathbf{w}\rangle \qquad \text{for all } \mathbf{v} \in V \text{ and all } \mathbf{w} \in W.$$

In words, clause by clause:

- T^* goes **backwards**: its domain is the codomain of T. If $T\colon V \to W$ then $T^*\colon W \to V$, like the dual map and unlike anything else we have attached to T.
- The defining equation is an identity in **two** variables, and it must hold for **all** $\mathbf{v}$ and **all** $\mathbf{w}$. By linearity in the first slot and conjugate-linearity in the second, it is enough to check it when $\mathbf{v}$ and $\mathbf{w}$ range over bases of V and of W, and that is usually how T^* gets computed.
- The left inner product lives in W, the right one in V. They are different inner products; only the notation hides it.
- The definition mentions no basis, but it does mention the two inner products. Change an inner product and T^* changes.

Example. (Four Adjoints)

Compute the adjoint in each case. In (a) and (b) the spaces carry the standard inner

product; in (c) and (d), V and W are arbitrary finite-dimensional inner product spaces.

(a) $T_{\mathbf{A}}\colon \mathbb{C}^3 \to \mathbb{C}^2$ for $\mathbf{A} = \begin{pmatrix} 1+i & 0 & 2 \\ i & 1 & -i \end{pmatrix}$.

(b) The forward shift $S\colon F^3 \to F^3$, $S(x_1, x_2, x_3) = (0, x_1, x_2)$.

(c) id_V and the zero map $V \to W$.

(d) The orthogonal projection $P_U\colon V \to V$ onto a subspace $U \subseteq V$.

Solution.

(a) By Lemma 10.4.1, $\langle \mathbf{Ax}, \mathbf{y}\rangle = \langle \mathbf{x}, \mathbf{A}^*\mathbf{y}\rangle$ for all $\mathbf{x}, \mathbf{y}$, which is the defining identity of the adjoint; so $(T_{\mathbf{A}})^* = T_{\mathbf{A}^*}$ for every matrix, by uniqueness in Theorem 10.6.1. Here

$$\mathbf{A}^* = \begin{pmatrix} 1-i & -i \\ 0 & 1 \\ 2 & i \end{pmatrix},$$

so $T^*_{\mathbf{A}}(y_1, y_2) = \big((1-i)y_1 - iy_2,\ y_2,\ 2y_1 + iy_2\big)$.

(b) Directly from the definition, for $\mathbf{x}, \mathbf{y} \in F^3$,

$$\langle S\mathbf{x}, \mathbf{y}\rangle = 0 \cdot \overline{y_1} + x_1\overline{y_2} + x_2\overline{y_3}, \qquad \langle \mathbf{x}, (y_2, y_3, 0)\rangle = x_1\overline{y_2} + x_2\overline{y_3} + x_3 \cdot 0.$$

The two agree for all $\mathbf{x}$ and $\mathbf{y}$. So S^* is the **backward** shift $S^*(y_1, y_2, y_3) = (y_2, y_3, 0)$. The forward shift pushes coordinates up; its adjoint pushes them down and drops the one that falls off the end.

(c) $\langle \mathrm{id}_V \mathbf{v}, \mathbf{w}\rangle = \langle \mathbf{v}, \mathbf{w}\rangle = \langle \mathbf{v}, \mathrm{id}_V \mathbf{w}\rangle$, so $(\mathrm{id}_V)^* = \mathrm{id}_V$. For the zero map, $\langle 0\mathbf{v}, \mathbf{w}\rangle = 0 = \langle \mathbf{v}, \mathbf{0}\rangle$ for every $\mathbf{w}$, so $0^* = 0$, the zero map $W \to V$. These are the degenerate cases, and they say the adjoint fixes what should be fixed.

(d) By Theorem 10.3.3 (b), $\langle P_U\mathbf{u}, \mathbf{v}\rangle = \langle \mathbf{u}, P_U\mathbf{v}\rangle$ for all $\mathbf{u}, \mathbf{v} \in V$. Since P_U is an operator on V, this is exactly the defining identity for its own adjoint, so $P_U^* = P_U$ by uniqueness in Theorem 10.6.1.

Part (d) is the first place where uniqueness earns its keep: we did not construct P_U^*, we recognized an identity we already had and read the answer off it. That move recurs throughout the section.

Example. (Differentiation on a Polynomial Space)

On $V = \mathbb{R}[x]_{\le 2}$ define $\langle p, q\rangle := a_0b_0 + a_1b_1 + a_2b_2$ for $p = a_0 + a_1x + a_2x^2$ and $q = b_0 + b_1x + b_2x^2$. (This is the standard inner product of $\mathbb{R}^3$ transported by the coordinate map, so it is an inner product, and $\mathcal{E} = (1, x, x^2)$ is an orthonormal basis.) Find the adjoint of $D\colon V \to V$, $D(p) = p'$.

Solution. For p, q as above, $D(p) = a_1 + 2a_2x$, so

$$\langle Dp, q\rangle = a_1b_0 + 2a_2b_1 + 0 \cdot b_2.$$

We need $D^*q = c_0 + c_1x + c_2x^2$ with $\langle p, D^*q\rangle = a_0c_0 + a_1c_1 + a_2c_2$ equal to the line above for **all** a_0, a_1, a_2. Comparing coefficients of a_0, a_1, a_2 gives $c_0 = 0$, $c_1 = b_0$, $c_2 = 2b_1$. Hence

$$D^*(b_0 + b_1x + b_2x^2) = b_0x + 2b_1x^2.$$

So D^* raises degrees where D lowers them. It is not an antiderivative: the coefficient 2 and the discarded b_2 both say so.

Here is a non-example by minimal change, and it explains the conjugate. On $\mathbb{C}^2$, keep the standard inner product but try the plain transpose: is $\langle \mathbf{Ax}, \mathbf{y} \rangle = \langle \mathbf{x}, \mathbf{A}^\top \mathbf{y} \rangle$? Take $\mathbf{A} = \begin{pmatrix} i & 0 \\ 0 & 0 \end{pmatrix}$, which is symmetric, so $\mathbf{A}^\top = \mathbf{A}$, and take $\mathbf{x} = \mathbf{y} = \mathbf{e}_1$. Then $\langle \mathbf{Ae}_1, \mathbf{e}_1 \rangle = \langle (i,0), (1,0) \rangle = i$, while $\langle \mathbf{e}_1, \mathbf{A}^\top \mathbf{e}_1 \rangle = \langle (1,0), (i,0) \rangle = 1 \cdot \overline{i} = -i$. The two sides differ. Everything about the transpose still works — it is linear and it reverses products — but it fails the one clause that matters, the defining identity, and it fails it by a conjugation. Over $\mathbb{R}$ the conjugation is invisible and the transpose is correct.

Why this definition. We could have asked instead for a map R with $\langle R\mathbf{w}, \mathbf{v} \rangle = \langle \mathbf{w}, T\mathbf{v} \rangle$. Conjugating Definition 10.6.1 shows that $R = T^*$ as well, so nothing new appears; the convention above is the one that reads left to right. The notation T^* matches the matrix notation $\mathbf{A}^*$ of Example (Four Adjoints) (a), which is the point of the star. The word *adjoint* is unrelated to the *adjugate* of Definition 6.6.2; the collision of names is historical and the two objects have nothing to do with each other.

Warning. **The adjoint depends on the inner product, not on T alone.** On $\mathbb{R}^2$ take $T(x_1, x_2) = (x_2, 0)$. With the standard inner product, $T^*(y_1, y_2) = (0, y_1)$. With the weighted inner product $\langle \mathbf{x}, \mathbf{y} \rangle_w := x_1 y_1 + 2x_2 y_2$, which is also an inner product, we need $\langle T\mathbf{x}, \mathbf{y} \rangle_w = x_2 y_1$ to equal $\langle \mathbf{x}, S\mathbf{y} \rangle_w = x_1 (S\mathbf{y})_1 + 2x_2 (S\mathbf{y})_2$ for all $\mathbf{x}$, which forces $(S\mathbf{y})_1 = 0$ and $(S\mathbf{y})_2 = \frac{1}{2} y_1$. So the adjoint is now $\mathbf{y} \mapsto (0, \frac{1}{2} y_1)$, a different map. Writing T^* without saying which inner product is meant is as incomplete as writing a matrix of T without saying which basis.

Quick check. Let $T \in \mathcal{L}(V, W)$ with $T \neq 0$. Can $T^* = 0$?

Solution. No. If $T^* = 0$ then $\langle T\mathbf{v}, \mathbf{w} \rangle = \langle \mathbf{v}, \mathbf{0} \rangle = 0$ for all $\mathbf{v}, \mathbf{w}$. Taking $\mathbf{w} = T\mathbf{v}$ gives $\|T\mathbf{v}\|^2 = 0$, so $T\mathbf{v} = \mathbf{0}$ for every $\mathbf{v}$, that is $T = 0$. This is the "pair it with itself" move again.

Finally, the finite-dimensional hypothesis is not decoration.

Example. (A Map With No Adjoint)

On $V = \mathbb{R}[x]$, all polynomials, define $\langle p, q \rangle := \sum_{k \geq 0} a_k b_k$, a finite sum since the coefficients vanish eventually. Show that $T \colon V \to V$, $T(p) := p(1) \cdot 1$, has no adjoint.

Solution. T is linear, being evaluation at 1 followed by multiplication by the constant polynomial 1. Suppose T^* existed. Apply the defining identity with $p = x^k$ and with $q = 1$, the constant polynomial: since $T(x^k) = 1$,

$$\langle x^k, T^*(1) \rangle = \langle T(x^k), 1 \rangle = \langle 1, 1 \rangle = 1 \qquad \text{for every } k \geq 0.$$

But $\langle x^k, T^*(1) \rangle$ is the coefficient of x^k in $T^*(1)$, so every coefficient of the polynomial $T^*(1)$ equals 1. No polynomial has infinitely many non-zero coefficients, a contradiction. So T^* does not exist.

What failed is Riesz: the functional $p \mapsto p(1)$ on $\mathbb{R}[x]$ is not pairing against any vector, precisely as in the infinite-dimensional discussion of Section 5.

10.6.3 Arithmetic of the adjoint

Starring behaves like transposing: it is additive, conjugate-homogeneous, order-reversing on products, and an involution.

Theorem 10.6.2 — Properties of the Adjoint

Let U, V, W be finite-dimensional inner product spaces over F.

(a) For $S, T \in \mathcal{L}(V, W)$, $(S+T)^* = S^* + T^*$.
(b) For $T \in \mathcal{L}(V, W)$ and $c \in F$, $(cT)^* = \overline{c}\, T^*$.
(c) For $T \in \mathcal{L}(U, V)$ and $S \in \mathcal{L}(V, W)$, $(ST)^* = T^* S^*$.
(d) $T^{**} = T$ for every $T \in \mathcal{L}(V, W)$, and $(\mathrm{id}_V)^* = \mathrm{id}_V$.
(e) If $T \in \mathcal{L}(V, W)$ is invertible, then T^* is invertible and $(T^*)^{-1} = (T^{-1})^*$.

Idea. Each claim says that two maps $W \to V$ agree. By the uniqueness in Theorem 10.6.1, it is enough to check that the proposed right-hand side satisfies the defining identity of the left-hand side. So every proof is one chain of inner products, and nothing is ever solved for. Part (e) needs no chain at all: star the two equations $T^{-1}T = \mathrm{id}_V$ and $TT^{-1} = \mathrm{id}_W$ and use (c) and (d).

Proof. Throughout, $\mathbf{v}$ and $\mathbf{w}$ denote arbitrary vectors of the relevant spaces, and each verification ends by invoking uniqueness in Theorem 10.6.1.

(a) $\langle (S+T)\mathbf{v}, \mathbf{w}\rangle = \langle S\mathbf{v}, \mathbf{w}\rangle + \langle T\mathbf{v}, \mathbf{w}\rangle = \langle \mathbf{v}, S^*\mathbf{w}\rangle + \langle \mathbf{v}, T^*\mathbf{w}\rangle = \langle \mathbf{v}, (S^*+T^*)\mathbf{w}\rangle$, the last step by additivity in the second slot.

(b) $\langle (cT)\mathbf{v}, \mathbf{w}\rangle = c\langle T\mathbf{v}, \mathbf{w}\rangle = c\langle \mathbf{v}, T^*\mathbf{w}\rangle = \langle \mathbf{v}, \overline{c}\, T^*\mathbf{w}\rangle$, where the last equality puts $\overline{c}$ into the second slot, which conjugates it back to c.

(c) For $\mathbf{u} \in U$ and $\mathbf{w} \in W$, using the defining identity for S and then for T,

$$\langle (ST)\mathbf{u}, \mathbf{w}\rangle = \langle S(T\mathbf{u}), \mathbf{w}\rangle = \langle T\mathbf{u}, S^*\mathbf{w}\rangle = \langle \mathbf{u}, T^*(S^*\mathbf{w})\rangle = \langle \mathbf{u}, (T^*S^*)\mathbf{w}\rangle.$$

(d) The map $T^* \in \mathcal{L}(W, V)$ has its own adjoint $T^{**} \in \mathcal{L}(V, W)$, determined by $\langle T^*\mathbf{w}, \mathbf{v}\rangle = \langle \mathbf{w}, T^{**}\mathbf{v}\rangle$. Conjugating the defining identity of T^* and using the conjugate symmetry of the inner product (Definition 10.1.1),

$$\langle T^*\mathbf{w}, \mathbf{v}\rangle = \overline{\langle \mathbf{v}, T^*\mathbf{w}\rangle} = \overline{\langle T\mathbf{v}, \mathbf{w}\rangle} = \langle \mathbf{w}, T\mathbf{v}\rangle.$$

So T satisfies the identity that defines T^{**}, and $T^{**} = T$. That $(\mathrm{id}_V)^* = \mathrm{id}_V$ is Example (Four Adjoints) (c).

(e) Suppose T is invertible, with $T^{-1} \in \mathcal{L}(W, V)$. Applying (c) and (d) to $T^{-1}T = \mathrm{id}_V$ and to $TT^{-1} = \mathrm{id}_W$,

$$T^*(T^{-1})^* = (T^{-1}T)^* = (\mathrm{id}_V)^* = \mathrm{id}_V, \qquad (T^{-1})^*T^* = (TT^{-1})^* = \mathrm{id}_W\,.$$

Both composites are identities, so T^* is invertible with inverse $(T^{-1})^*$ (Definition 3.5.1). This proves the theorem.

■

Parts (a) and (b) say that $T \mapsto T^*$ is **conjugate**-linear, not linear: over $\mathbb{C}$ it is the same half-twist that the Riesz map carries in Corollary 10.5.2, and for the same reason. Part (c) is the order reversal familiar from transposes and from dual maps (Theorem 4.4.1 (b)). Part (d) says that starring is an involution, so no new maps appear by starring twice.

10.6.4 The matrix of the adjoint

Now fix bases and compute. The conclusion is the one the opening computation suggests, **provided the bases are orthonormal**; the hypothesis is where all the content sits.

Theorem 10.6.3 — The Matrix of the Adjoint Is the Conjugate Transpose

Let V and W be finite-dimensional inner product spaces over F, let $\mathcal{B} = (\mathbf{v}_1, \dots, \mathbf{v}_n)$ be an **orthonormal** basis of V and $\mathcal{C} = (\mathbf{w}_1, \dots, \mathbf{w}_m)$ an **orthonormal** basis of W, and let $T \in \mathcal{L}(V, W)$. Then

$$[T^*]_{\mathcal{C}}^{\mathcal{B}} = \left([T]_{\mathcal{B}}^{\mathcal{C}}\right)^*.$$

Idea. In an orthonormal basis a coordinate is an inner product (Theorem 10.2.1), so every matrix entry is an inner product, and the defining identity of T^* says precisely how those inner products are related. Write both entries out and compare.

Proof. Write $\mathbf{A} = [T]_{\mathcal{B}}^{\mathcal{C}}$ and $\mathbf{B} = [T^*]_{\mathcal{C}}^{\mathcal{B}}$, of sizes $m \times n$ and $n \times m$. By Definition 3.6.1, the j-th column of $\mathbf{A}$ holds the coordinates of $T\mathbf{v}_j$ in $\mathcal{C}$, and by Theorem 10.2.1 those coordinates are inner products:

$$a_{ij} = \langle T\mathbf{v}_j, \mathbf{w}_i \rangle, \qquad b_{ji} = \langle T^*\mathbf{w}_i, \mathbf{v}_j \rangle.$$

By conjugate symmetry and Definition 10.6.1,

$$b_{ji} = \langle T^*\mathbf{w}_i, \mathbf{v}_j \rangle = \overline{\langle \mathbf{v}_j, T^*\mathbf{w}_i \rangle} = \overline{\langle T\mathbf{v}_j, \mathbf{w}_i \rangle} = \overline{a_{ij}}.$$

So $\mathbf{B}$ is the matrix whose (j, i) entry is $\overline{a_{ij}}$, which is $\mathbf{A}^*$. This proves the theorem.

■

Both hypotheses were used: orthonormality of $\mathcal{C}$ to read off a_{ij}, orthonormality of $\mathcal{B}$ to read off b_{ji}. Drop either one and the conclusion fails.

Warning. **The rule $[T^*]_{\mathcal{B}}^{\mathcal{B}} = \left([T]_{\mathcal{B}}^{\mathcal{B}}\right)^*$ is false in a basis that is not orthonormal.** The next example exhibits a two-dimensional counterexample with integer entries. The correct general statement involves the Gram matrix and is recorded in the remark after it.

Example. (The Transpose Rule Breaks)

Work in $\mathbb{R}^2$ with the standard inner product and let $T(x_1, x_2) = (x_2, 0)$. Let $\mathcal{B} = (\mathbf{b}_1, \mathbf{b}_2)$ with $\mathbf{b}_1 = (1, 0)$ and $\mathbf{b}_2 = (1, 1)$. Compute $[T]_{\mathcal{B}}^{\mathcal{B}}$ and $[T^*]_{\mathcal{B}}^{\mathcal{B}}$, and compare the second with the transpose of the first.

Solution. First, $\mathcal{B}$ is a basis (two independent vectors in $\mathbb{R}^2$) but it is not orthonormal: $\langle \mathbf{b}_1, \mathbf{b}_2 \rangle = 1 \neq 0$ and $\|\mathbf{b}_2\| = \sqrt{2}$.

By Example (Four Adjoints) (a) with $\mathbf{A} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$, the adjoint is $T^*(y_1, y_2) = (0, y_1)$.

The matrix of T. $T\mathbf{b}_1 = (0, 0) = 0\mathbf{b}_1 + 0\mathbf{b}_2$ and $T\mathbf{b}_2 = (1, 0) = 1\mathbf{b}_1 + 0\mathbf{b}_2$, so

$$[T]_{\mathcal{B}}^{\mathcal{B}} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}, \qquad \left([T]_{\mathcal{B}}^{\mathcal{B}}\right)^{\top} = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix}.$$

The matrix of T^*. $T^*\mathbf{b}_1 = (0, 1)$ and $T^*\mathbf{b}_2 = (0, 1)$. Solving $(0, 1) = c_1(1, 0) + c_2(1, 1)$ gives $c_2 = 1$ and $c_1 = -1$, so both columns are $(-1, 1)$:

$$[T^*]_{\mathcal{B}}^{\mathcal{B}} = \begin{pmatrix} -1 & -1 \\ 1 & 1 \end{pmatrix}.$$

The two displayed matrices are different: the transpose rule fails. A quick sanity check that nothing else went wrong: the traces are 0 and 0, and both matrices have rank 1, as they must, since $\operatorname{rank} T = \operatorname{rank} T^* = 1$.

Remark. The correct rule. Let $\mathbf{G}$ be the Gram matrix of $\mathcal{B}$, so $g_{ij} = \langle \mathbf{b}_j, \mathbf{b}_i \rangle$ (Definition 10.2.3), which is invertible because $\mathcal{B}$ is independent (Theorem 10.2.5 (c)). Then $[T^*]_{\mathcal{B}}^{\mathcal{B}} = \mathbf{G}^{-1} \left([T]_{\mathcal{B}}^{\mathcal{B}}\right)^* \mathbf{G}$. In the example, $\mathbf{G} = \begin{pmatrix} 1 & 1 \\ 1 & 2 \end{pmatrix}$ and $\mathbf{G}^{-1} = \begin{pmatrix} 2 & -1 \\ -1 & 1 \end{pmatrix}$, and indeed

$$\begin{pmatrix} 2 & -1 \\ -1 & 1 \end{pmatrix} \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix} \begin{pmatrix} 1 & 1 \\ 1 & 2 \end{pmatrix} = \begin{pmatrix} -1 & -1 \\ 1 & 1 \end{pmatrix}.$$

When $\mathcal{B}$ is orthonormal, $\mathbf{G} = \mathbf{I}$ and the rule collapses to Theorem 10.6.3. Exercise (C3: The adjoint in an arbitrary basis) asks for the general rule.

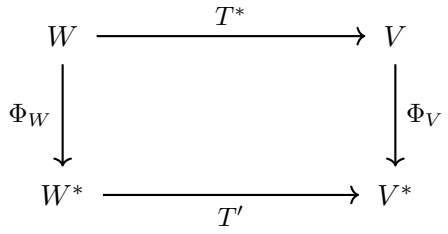
10.6.5 The adjoint and the dual map

Two backward maps are now attached to T: the dual map $T' : W^* \to V^*$ of Chapter 4, which needs no inner product, and the adjoint $T^* : W \to V$, which does. The Riesz map converts one into the other.

Recall from Corollary 10.5.2 the Riesz map, the conjugate-linear bijection

$$\Phi_V : V \to V^*, \qquad \Phi_V(\mathbf{u}) := \langle \cdot, \mathbf{u} \rangle,$$

and likewise Φ_W for W. The following square commutes: the two backward maps run horizontally, the two Riesz maps vertically, and the two routes from W to V^* agree.



the vertical maps are the Riesz maps, one for each space

Theorem 10.6.4 — The Adjoint Is the Dual Map Read Through Riesz

Let V, W be finite-dimensional inner product spaces over F and $T \in \mathcal{L}(V, W)$. Then

$$\Phi_V \circ T^* = T' \circ \Phi_W.$$

Proof. Both sides send $\mathbf{w} \in W$ to a functional on V, so evaluate them at an arbitrary $\mathbf{v} \in V$. By Definition 4.4.1 and the definition of Φ_W,

$$\big(T'(\Phi_W \mathbf{w})\big)(\mathbf{v}) = (\Phi_W \mathbf{w})(T\mathbf{v}) = \langle T\mathbf{v}, \mathbf{w}\rangle,$$

while by Definition 10.6.1 and the definition of Φ_V,

$$\big(\Phi_V(T^*\mathbf{w})\big)(\mathbf{v}) = \langle \mathbf{v}, T^*\mathbf{w}\rangle = \langle T\mathbf{v}, \mathbf{w}\rangle.$$

The two agree for all $\mathbf{v}$ and all $\mathbf{w}$, so the two maps are equal. ∎

Read backwards, the identity says $T^* = \Phi_V^{-1} T' \Phi_W$: transport a vector of W into W^*, pull it back with the dual map, transport it back into V. So the adjoint carries no information that T' does not already carry; what it carries is the inner product used to transport. The matrix statements match too. In dual bases the matrix of T' is the transpose of the matrix of T (Theorem 4.4.2); in orthonormal bases the matrix of T^* is the conjugate transpose (Theorem 10.6.3). The extra conjugation is the price of Φ_V being conjugate-linear, and over $\mathbb{R}$ it disappears, which is why the two constructions are so easily confused there.

10.6.6 The four fundamental subspaces

Chapter 2 attached four subspaces to a matrix: $\mathrm{col}(\mathbf{A})$ and $\mathrm{nul}(\mathbf{A})$ (Definition 2.5.1, Definition 2.5.3) together with $\mathrm{row}(\mathbf{A})$ (Definition 2.5.2) and the null space of the transpose. Chapter 4 related two of them, with Theorem 4.6.5: the row space of $\mathbf{A}$ **is** the annihilator of $\mathrm{nul}(\mathbf{A})$, so every linear equation satisfied by the solution set is a combination of the given ones. That statement lived in the dual space, and Definition 4.2.1 carried a warning with it: over a general field the annihilator has no right to be pictured as a perpendicular. With an inner product, it does. The four subspaces become two orthogonal splittings, one in each of the two spaces.

Theorem 10.6.5 — The Four Fundamental Subspaces

Let V, W be finite-dimensional inner product spaces over F and let $T \in \mathcal{L}(V, W)$. Then

(a) $\ker T^* = (\operatorname{im} T)^\perp$;
(b) $\operatorname{im} T^* = (\ker T)^\perp$;
(c) $V = \ker T \oplus \operatorname{im} T^*$;
(d) $W = \operatorname{im} T \oplus \ker T^*$.

Idea. Only (a) needs an argument, and it is one chain of equivalences: $T^*\mathbf{w} = \mathbf{0}$ says a vector is zero, so pair it with everything, and the defining identity turns "everything" into "everything in the image of T". Then (b) is (a) applied to T^*, using $T^{**} = T$, and complemented with $(U^\perp)^\perp = U$. Parts (c) and (d) are then just the orthogonal decomposition theorem.

Proof.

(a) Let $\mathbf{w} \in W$. Then

$$\mathbf{w} \in \ker T^* \iff T^*\mathbf{w} = \mathbf{0} \iff \langle \mathbf{v}, T^*\mathbf{w}\rangle = 0 \text{ for all } \mathbf{v} \in V$$
$$\iff \langle T\mathbf{v}, \mathbf{w}\rangle = 0 \text{ for all } \mathbf{v} \in V \iff \mathbf{w} \in (\operatorname{im} T)^\perp.$$

The second equivalence is non-degeneracy: forwards it is immediate, and backwards we take $\mathbf{v} = T^*\mathbf{w}$ and get $\|T^*\mathbf{w}\|^2 = 0$. The third is Definition 10.6.1. The fourth is Definition 10.3.1 together with conjugate symmetry, since $\langle T\mathbf{v}, \mathbf{w}\rangle = 0$ if and only if $\langle \mathbf{w}, T\mathbf{v}\rangle = 0$, and the vectors $T\mathbf{v}$ are exactly the elements of $\operatorname{im} T$. Every step is reversible, so both inclusions come at once.

(b) Apply (a) to $T^* \in \mathcal{L}(W, V)$ in place of T. Since $T^{**} = T$ by Theorem 10.6.2 (d), this reads $\ker T = (\operatorname{im} T^*)^\perp$. Taking orthogonal complements and using $(U^\perp)^\perp = U$ for a subspace U of a finite-dimensional space (Theorem 10.3.2 (b)),

$$(\ker T)^\perp = \big((\operatorname{im} T^*)^\perp\big)^\perp = \operatorname{im} T^*.$$

(c) $\ker T$ is a subspace of V (Theorem 3.2.1), so $V = \ker T \oplus (\ker T)^\perp$ by Theorem 10.3.2 (a), and $(\ker T)^\perp = \operatorname{im} T^*$ by (b).

(d) Likewise $W = \operatorname{im} T \oplus (\operatorname{im} T)^\perp$ by Theorem 10.3.2 (a), and $(\operatorname{im} T)^\perp = \ker T^*$ by (a). This proves the theorem.

■

For a matrix $\mathbf{A} \in M_{m\times n}(F)$ with the standard inner products, $T_{\mathbf{A}}^* = T_{\mathbf{A}^*}$, so the theorem reads

$$\operatorname{nul}(\mathbf{A}^*) = \operatorname{col}(\mathbf{A})^\perp, \qquad \operatorname{col}(\mathbf{A}^*) = \operatorname{nul}(\mathbf{A})^\perp,$$

with $F^m = \operatorname{col}(\mathbf{A}) \oplus \operatorname{nul}(\mathbf{A}^*)$ and $F^n = \operatorname{nul}(\mathbf{A}) \oplus \operatorname{col}(\mathbf{A}^*)$. Over $\mathbb{R}$ the columns of $\mathbf{A}^\top$ are the rows of $\mathbf{A}$ turned into vectors, so the second identity is the promised statement that **the row space and the null space are orthogonal complements of each other** in $\mathbb{R}^n$. This is Theorem 4.6.5 with the annihilator replaced by the orthogonal complement, exactly as Corollary 10.5.2 licenses; and taking dimensions returns Rank–Nullity for matrices (Theorem 2.5.7) one more time. Section 4 proved the identity $\operatorname{nul}(\mathbf{A})^\perp = \operatorname{col}(\mathbf{A}^*)$ directly, because the minimum-

norm solution needed it; the theorem above is that computation done once for all four subspaces and for maps rather than matrices.

Example. (All Four Subspaces of a 3×3 Matrix)

For $\mathbf{A} = \begin{pmatrix} 1 & 1 & 0 \\ 0 & 1 & 1 \\ 1 & 2 & 1 \end{pmatrix}$ over $\mathbb{R}$, find bases of the four subspaces and verify the two orthogonality statements.

Solution. Row three is the sum of rows one and two, and rows one and two are independent, so $\operatorname{rank}\mathbf{A} = 2$ and $\operatorname{row}(\mathbf{A})$ has the basis $(1,1,0), (0,1,1)$ (written as vectors).

Null space. $\mathbf{Ax} = \mathbf{0}$ reduces to $x_1 + x_2 = 0$ and $x_2 + x_3 = 0$, so $\operatorname{nul}(\mathbf{A}) = \operatorname{span}\big((1,-1,1)\big)$, of dimension $1 = 3 - 2$, as Theorem 2.5.7 requires.

Orthogonality in the domain. $(1,1,0)\cdot(1,-1,1) = 0$ and $(0,1,1)\cdot(1,-1,1) = 0$. So $\operatorname{row}(\mathbf{A}) \perp \operatorname{nul}(\mathbf{A})$, and since $2 + 1 = 3$ the two are complementary: $\operatorname{nul}(\mathbf{A})^{\perp} = \operatorname{row}(\mathbf{A})$.

Column space. Columns one and two are independent and column three is column two minus column one, so $\operatorname{col}(\mathbf{A}) = \operatorname{span}\big((1,0,1),(1,1,2)\big)$.

Null space of the transpose. $\mathbf{A}^{\top}\mathbf{y} = \mathbf{0}$ reads $y_1 + y_3 = 0$, $y_1 + y_2 + 2y_3 = 0$, $y_2 + y_3 = 0$, giving $\operatorname{nul}(\mathbf{A}^{\top}) = \operatorname{span}\big((-1,-1,1)\big)$.

Orthogonality in the codomain. $(1,0,1)\cdot(-1,-1,1) = 0$ and $(1,1,2)\cdot(-1,-1,1) = 0$, and $2 + 1 = 3$, so $\operatorname{col}(\mathbf{A})^{\perp} = \operatorname{nul}(\mathbf{A}^{\top})$.

Corollary 10.6.6 — Rank of the Adjoint

Let V, W be finite-dimensional inner product spaces over F and $T \in \mathcal{L}(V,W)$. Then

(a) $\operatorname{rank} T^{*} = \operatorname{rank} T$;
(b) $\ker(T^{*}T) = \ker T$, and consequently $\operatorname{rank}(T^{*}T) = \operatorname{rank} T$.

Proof.

(a) By Theorem 10.6.5 (b) and a dimension count,

$$\operatorname{rank} T^{*} = \dim \operatorname{im} T^{*} = \dim(\ker T)^{\perp} = \dim V - \operatorname{nullity} T = \operatorname{rank} T,$$

the middle equality by Theorem 10.3.2 (c) and the last by the Rank–Nullity Theorem (Theorem 3.3.1).

(b) ($\supseteq$) If $T\mathbf{v} = \mathbf{0}$ then $T^{*}T\mathbf{v} = T^{*}\mathbf{0} = \mathbf{0}$. ($\subseteq$) Suppose $T^{*}T\mathbf{v} = \mathbf{0}$. Then

$$\|T\mathbf{v}\|^{2} = \langle T\mathbf{v}, T\mathbf{v}\rangle = \langle \mathbf{v}, T^{*}T\mathbf{v}\rangle = \langle \mathbf{v}, \mathbf{0}\rangle = 0,$$

so $T\mathbf{v} = \mathbf{0}$. Hence the kernels agree. Both $T^{*}T$ and T are defined on V, so Rank–Nullity gives $\operatorname{rank}(T^{*}T) = \dim V - \operatorname{nullity}(T^{*}T) = \dim V - \operatorname{nullity} T = \operatorname{rank} T$.

■

Part (a) is a fourth proof that row rank equals column rank, after the three of Chapters 2, 3 and 4: for a real matrix it says $\operatorname{rank}\mathbf{A}^\top = \operatorname{rank}\mathbf{A}$. Part (b) is the engine of the normal equations: it is why $\mathbf{A}^*\mathbf{A}$ is invertible exactly when $\mathbf{A}$ has independent columns, which is the hypothesis in Corollary 10.4.4.

> *Quick check.* Let $T \in \mathcal{L}(V,W)$ with $\dim V = 4$, $\dim W = 7$ and $\operatorname{rank} T = 3$. What are $\dim\ker T^*$ and $\dim\operatorname{im} T^*$?

> *Solution.* $\operatorname{rank} T^* = 3$ by Corollary 10.6.6 (a), so $\dim\operatorname{im} T^* = 3$; and $T^*: W \to V$ with $\dim W = 7$, so $\dim\ker T^* = 7 - 3 = 4$. The same number comes from Theorem 10.6.5 (a): $\dim(\operatorname{im} T)^\perp = 7 - 3 = 4$.

10.6.7 Self-adjoint and normal operators

For an operator $T \in \mathcal{L}(V)$, the adjoint lives in the same space $\mathcal{L}(V)$, so we may compare T with T^*. Two comparisons matter, and everything in the next chapter rests on them.

A self-adjoint operator is one that costs nothing to move across the inner product.

Definition 10.6.2 — Self-adjoint Operator

An operator $T \in \mathcal{L}(V)$ on a finite-dimensional inner product space is **self-adjoint** if $T^* = T$, that is, if

$$\langle T\mathbf{u}, \mathbf{v}\rangle = \langle \mathbf{u}, T\mathbf{v}\rangle \qquad \text{for all } \mathbf{u}, \mathbf{v} \in V.$$

The matrix counterpart is the **Hermitian** matrix of Definition 10.1.2, $\mathbf{A}^* = \mathbf{A}$; over $\mathbb{R}$ this says $\mathbf{A}^\top = \mathbf{A}$, and the matrix is **symmetric**.

In words: T^* is not a new map but T over again, so T must be an **operator**, with the same space and the same inner product on both sides; and the displayed identity is the defining identity of Definition 10.6.1 with T^* rewritten as T, still required for **all u** and **all v**.

By Theorem 10.6.3, an operator on a finite-dimensional inner product space is self-adjoint exactly when its matrix in one (equivalently every) orthonormal basis is Hermitian. Three examples to keep in mind: the orthogonal projection P_U onto any subspace, self-adjoint by Example (Four Adjoints) (d), which is the geometric case; on $\mathbb{R}^2$, the map of the symmetric $\mathbf{A} = \begin{pmatrix} 2 & 1 \\ 1 & 3 \end{pmatrix}$, where conjugation does nothing and $\mathbf{A}^* = \mathbf{A}^\top = \mathbf{A}$; and on $\mathbb{C}^2$, the map of the Hermitian $\mathbf{A} = \begin{pmatrix} 2 & 1+i \\ 1-i & 3 \end{pmatrix}$, where transposing swaps the two off-diagonal entries and conjugating swaps them back, while the diagonal is real and survives both.

Here is a non-example by minimal change: keep the shape and move the conjugate. The matrix $\mathbf{B} = \begin{pmatrix} 2 & 1+i \\ 1+i & 3 \end{pmatrix}$ is **symmetric**, $\mathbf{B}^\top = \mathbf{B}$, but $\mathbf{B}^* = \begin{pmatrix} 2 & 1-i \\ 1-i & 3 \end{pmatrix} \neq \mathbf{B}$, so the clause $T^* = T$ fails. It fails visibly at $\mathbf{u} = \mathbf{e}_1$ and $\mathbf{v} = \mathbf{e}_2$: $\langle \mathbf{B}\mathbf{e}_1, \mathbf{e}_2\rangle = 1 + i$, while $\langle \mathbf{e}_1, \mathbf{B}\mathbf{e}_2\rangle = \overline{1+i} = 1 - i$. Over $\mathbb{C}$, self-adjointness means Hermitian, never merely symmetric.

Two more self-adjoint operators come for free: the combination $D + D^*$ of Example (Differentiation on a Polynomial Space), and T^*T for any T, since $(T^*T)^* = T^*T^{**} = T^*T$ by Theorem 10.6.2 (c) and (d).

An operator is normal when it and its adjoint may be applied in either order.

Definition 10.6.3 — Normal Operator

An operator $T \in \mathcal{L}(V)$ on a finite-dimensional inner product space is **normal** if it commutes with its adjoint:

$$T^*T = TT^*.$$

In words: normality is one equation between two operators on V, with no vectors and no quantifiers in it. It does not ask that T and T^* be equal, only that their order may be swapped, so it is strictly weaker than self-adjointness.

Four examples, widening as they go. Every self-adjoint operator is normal, since then both sides are T^2. So is every invertible T with $T^{-1} = T^*$ — Section 7 calls these unitary — since then both sides are id_V; the quarter-turn of $\mathbb{R}^2$, with matrix $\begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$ in the standard basis, is one, and it is not self-adjoint. On $\mathbb{C}^2$ the operator with matrix $i\mathbf{I}$ satisfies $(i\mathbf{I})^* = -i\mathbf{I}$ by Theorem 10.6.2 (b), which commutes with $i\mathbf{I}$ but is not equal to it: normal and not self-adjoint. Widest of all, every diagonal matrix $\mathbf{D} = \mathrm{diag}(d_1, \dots, d_n)$ is normal, since $\mathbf{D}^*\mathbf{D} = \mathbf{D}\mathbf{D}^* = \mathrm{diag}(|d_1|^2, \dots, |d_n|^2)$.

A non-example by minimal change: take the diagonal matrix $\mathrm{diag}(1, 0)$ and slide its non-zero entry off the diagonal. The Jordan block $\mathbf{J}_2(0) = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$ on $\mathbb{C}^2$ has

$$\mathbf{J}_2(0)^*\mathbf{J}_2(0) = \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix}, \qquad \mathbf{J}_2(0)\mathbf{J}_2(0)^* = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix},$$

and the two differ. The $(1,1)$ entries say what went wrong. Writing T for the map of $\mathbf{J}_2(0)$, the $(1,1)$ entry of the first matrix is $\langle T^*T\mathbf{e}_1, \mathbf{e}_1\rangle = \|T\mathbf{e}_1\|^2 = 0$ and that of the second is $\langle TT^*\mathbf{e}_1, \mathbf{e}_1\rangle = \|T^*\mathbf{e}_1\|^2 = 1$, so $\|T\mathbf{e}_1\| \neq \|T^*\mathbf{e}_1\|$: the operator kills $\mathbf{e}_1$ and its adjoint stretches it to a unit vector.

Over $\mathbb{C}$, normality is the weakest hypothesis under which the spectral theorem holds, and that is its reason for existing. Chapter 11 will show that the diagonal example is already the general one.

The facts available now, before any eigenvalue theory, are the ones that follow straight from the definition.

Proposition 10.6.7 — First Properties of Self-adjoint Operators

Let $T \in \mathcal{L}(V)$ be self-adjoint on a finite-dimensional inner product space V over F.

(a) $\langle T\mathbf{v}, \mathbf{v}\rangle \in \mathbb{R}$ for every $\mathbf{v} \in V$, even when $F = \mathbb{C}$.
(b) If $\mathcal{B}$ is an orthonormal basis of V, the diagonal entries of $[T]_{\mathcal{B}}^{\mathcal{B}}$ are real.
(c) T is normal.

Proof.

(a) By conjugate symmetry (Definition 10.1.1) and self-adjointness,

$$\overline{\langle T\mathbf{v}, \mathbf{v}\rangle} = \langle \mathbf{v}, T\mathbf{v}\rangle = \langle T\mathbf{v}, \mathbf{v}\rangle.$$

A complex number equal to its own conjugate is real.

(b) Let $\mathcal{B} = (\mathbf{v}_1, \dots, \mathbf{v}_n)$ be orthonormal. By Theorem 10.2.1 the i-th coordinate of $T\mathbf{v}_i$ is $\langle T\mathbf{v}_i, \mathbf{v}_i\rangle$, so the (i,i) entry of $[T]_{\mathcal{B}}^{\mathcal{B}}$ is $a_{ii} = \langle T\mathbf{v}_i, \mathbf{v}_i\rangle$, which is real by (a).

(c) $T^*T = TT = TT^*$.

■

Part (a) is the first hint of the spectral theorem. If $T\mathbf{v} = \lambda\mathbf{v}$ with $\mathbf{v} \neq \mathbf{0}$, then $\langle T\mathbf{v}, \mathbf{v}\rangle = \lambda\|\mathbf{v}\|^2$, and since the left side is real and $\|\mathbf{v}\|^2$ is a positive real, λ must be real: a self-adjoint operator has no non-real eigenvalues. Chapter 11 turns this observation into the spectral theorems: a self-adjoint operator has an orthonormal basis of eigenvectors, with real eigenvalues; on a complex space the operators with an orthonormal basis of eigenvectors are exactly the normal ones, and on a real space exactly the self-adjoint ones. None of that is proved here, and none of it is used before then; but all of it is built from the adjoint and the orthogonal geometry of this chapter.

Warning. **"Self-adjoint" cannot be read off an arbitrary basis.** Being self-adjoint is a property of T together with the inner product, and the Hermitian test applies only in an **orthonormal** basis. The operator $T(x_1, x_2) = (x_2, 0)$ of Example (The Transpose Rule Breaks) is not self-adjoint, and its matrix in the standard orthonormal basis, $\begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$, is correctly non-symmetric. But the self-adjoint operator $P(x_1, x_2) = (x_1, 0)$, the orthogonal projection onto the first axis, has the **non**-symmetric matrix $\begin{pmatrix} 1 & 1 \\ 0 & 0 \end{pmatrix}$ in the basis $\mathcal{B}$ of that example, since $P\mathbf{b}_1 = \mathbf{b}_1$ and $P\mathbf{b}_2 = (1,0) = \mathbf{b}_1$. A non-symmetric matrix is evidence of nothing until the basis is known to be orthonormal.

10.6.8 Exercises

10.6.8.1 A. Check your understanding

Exercise A1.

(a) State the defining property of the adjoint T^* of $T \in \mathcal{L}(V, W)$, including the domain and codomain of T^* and all quantifiers.

(b) Which hypothesis of Theorem 10.6.1 is used to produce T^*, and which theorem supplies it?

(c) True or false: $(cT)^* = cT^*$ for every scalar c. Justify your answer.

(d) State the hypothesis needed for $[T^*]_{\mathcal{C}}^{\mathcal{B}} = \left([T]_{\mathcal{B}}^{\mathcal{C}}\right)^*$, and say what goes wrong without it.

(e) True or false: $\ker T^* = (\ker T)^{\perp}$. Justify your answer.

(f) Give an example of a normal operator that is not self-adjoint.

Solution.

(a) For $T\colon V \to W$, the adjoint is the unique $T^*\colon W \to V$ with $\langle T\mathbf{v}, \mathbf{w}\rangle = \langle \mathbf{v}, T^*\mathbf{w}\rangle$ for **all** $\mathbf{v} \in V$ and **all** $\mathbf{w} \in W$ (Definition 10.6.1).

(b) Finite-dimensionality of V, which is what Theorem 10.5.1 needs in order to repre-

sent the functional $\mathbf{v} \mapsto \langle T\mathbf{v}, \mathbf{w}\rangle$.

(c) False: $(cT)^* = \bar{c}\,T^*$ (Theorem 10.6.2 (b)). Over $\mathbb{R}$ the two agree; over $\mathbb{C}$ take $T = \mathrm{id}$ and $c = i$, so that $(i\ \mathrm{id})^* = -i\ \mathrm{id} \neq i\ \mathrm{id}$.

(d) Both bases must be orthonormal (Theorem 10.6.3). Without it the rule fails: Example (The Transpose Rule Breaks) has $\left([T]_{\mathcal{B}}^{\mathcal{B}}\right)^{\top} = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix}$ but $[T^*]_{\mathcal{B}}^{\mathcal{B}} = \begin{pmatrix} -1 & -1 \\ 1 & 1 \end{pmatrix}$.

(e) False. The correct statements are $\ker T^* = (\operatorname{im} T)^{\perp}$ and $\operatorname{im} T^* = (\ker T)^{\perp}$ (Theorem 10.6.5). The two sides need not even live in the same space when $V \neq W$.

(f) $T = i\ \mathrm{id}$ on $\mathbb{C}^2$: $T^* = -i\ \mathrm{id}$ commutes with T, but $T^* \neq T$.

10.6.8.2 B. Practice

Exercise B1: Adjoints of matrix maps.

Let $\mathbf{A} = \begin{pmatrix} 1+i & 0 & 2 \\ i & 1 & -i \end{pmatrix}$ and $\mathbf{B} = \begin{pmatrix} 0 & 1 \\ i & 0 \end{pmatrix}$, acting between the complex spaces $\mathbb{C}^3 \xrightarrow{T_{\mathbf{A}}} \mathbb{C}^2 \xrightarrow{T_{\mathbf{B}}} \mathbb{C}^2$ with the standard inner products.

(a) Write down $T_{\mathbf{A}}^*$ and $T_{\mathbf{B}}^*$ as matrix maps.

(b) Compute the matrices of $T_{\mathbf{B}}T_{\mathbf{A}}$ and of $(T_{\mathbf{B}}T_{\mathbf{A}})^*$, and verify $(T_{\mathbf{B}}T_{\mathbf{A}})^* = T_{\mathbf{A}}^* T_{\mathbf{B}}^*$ by direct computation.

(c) Verify that $T_{\mathbf{B}}$ is not self-adjoint, and determine whether it is normal.

Solution.

(a) $T_{\mathbf{A}}^* = T_{\mathbf{A}^*}$ and $T_{\mathbf{B}}^* = T_{\mathbf{B}^*}$ (Example (Four Adjoints) (a)), with

$$\mathbf{A}^* = \begin{pmatrix} 1-i & -i \\ 0 & 1 \\ 2 & i \end{pmatrix}, \qquad \mathbf{B}^* = \begin{pmatrix} 0 & -i \\ 1 & 0 \end{pmatrix}.$$

(b) $\mathbf{BA} = \begin{pmatrix} i & 1 & -i \\ i-1 & 0 & 2i \end{pmatrix}$, so

$$(\mathbf{BA})^* = \begin{pmatrix} -i & -i-1 \\ 1 & 0 \\ i & -2i \end{pmatrix}.$$

On the other side,

$$\mathbf{A}^*\mathbf{B}^* = \begin{pmatrix} 1-i & -i \\ 0 & 1 \\ 2 & i \end{pmatrix} \begin{pmatrix} 0 & -i \\ 1 & 0 \end{pmatrix} = \begin{pmatrix} -i & -i(1-i) \\ 1 & 0 \\ i & -2i \end{pmatrix},$$

and $-i(1-i) = -i + i^2 = -1 - i$. The two matrices agree, as Theorem 10.6.2 (c) predicts.

(c) $\mathbf{B}^* \neq \mathbf{B}$, since the $(1,2)$ entries are $-i$ and 1. But

$$\mathbf{B}^*\mathbf{B} = \begin{pmatrix} 0 & -i \\ 1 & 0 \end{pmatrix} \begin{pmatrix} 0 & 1 \\ i & 0 \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} = \begin{pmatrix} 0 & 1 \\ i & 0 \end{pmatrix} \begin{pmatrix} 0 & -i \\ 1 & 0 \end{pmatrix} = \mathbf{B}\mathbf{B}^*,$$

so $T_{\mathbf{B}}$ is normal (Definition 10.6.3) and not self-adjoint.

Exercise B2: Adjoints on a polynomial space.

Let $V = \mathbb{R}[x]_{\le 2}$ and $W = \mathbb{R}[x]_{\le 3}$, each with the coefficient inner product of Example (Differentiation on a Polynomial Space), so that $\mathcal{E} = (1, x, x^2)$ and $\mathcal{F} = (1, x, x^2, x^3)$ are orthonormal bases.

(a) Find the adjoint of $M\colon V \to W$, $M(p) = xp$.

(b) Find the adjoint of $E\colon V \to \mathbb{R}$, $E(p) = p(1)$, where $\mathbb{R}$ carries $\langle s, t\rangle = st$. (Compare Theorem 10.5.1.)

(c) Verify $\operatorname{rank} M^* = \operatorname{rank} M$ directly.

Solution.

(a) $M(1) = x$, $M(x) = x^2$, $M(x^2) = x^3$, so in the two orthonormal bases

$$[M]_{\mathcal{E}}^{\mathcal{F}} = \begin{pmatrix} 0 & 0 & 0 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}, \qquad [M^*]_{\mathcal{F}}^{\mathcal{E}} = \big([M]_{\mathcal{E}}^{\mathcal{F}}\big)^{\top} = \begin{pmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}$$

by Theorem 10.6.3. Hence $M^*(c_0 + c_1x + c_2x^2 + c_3x^3) = c_1 + c_2x + c_3x^2$: delete the constant term and divide by x.

(b) E is linear and $E(a_0 + a_1x + a_2x^2) = a_0 + a_1 + a_2$. For $t \in \mathbb{R}$ we need $\langle p, E^*t\rangle = \langle Ep, t\rangle = (a_0 + a_1 + a_2)t$ for all p, so comparing coefficients of a_0, a_1, a_2 gives $E^*(t) = t(1 + x + x^2)$. In particular $E^*(1) = 1 + x + x^2$ is the Riesz vector of the evaluation functional at 1.

(c) M is injective, since $xp = 0$ forces $p = 0$, so $\operatorname{rank} M = \dim V = 3$ by Theorem 3.3.1. And M^* is surjective: $M^*(xq) = q$ for every $q \in V$. So $\operatorname{rank} M^* = 3$ too, agreeing with Corollary 10.6.6 (a).

Exercise B3: Locating the kernel of the adjoint.

Let $\mathbf{A} = \begin{pmatrix} 1 & 0 \\ 1 & 1 \\ 0 & 1 \end{pmatrix} \in M_{3\times 2}(\mathbb{R})$, and let $T = T_{\mathbf{A}}\colon \mathbb{R}^2 \to \mathbb{R}^3$ with the standard inner products.

(a) Find a basis of $\operatorname{im} T$ and a basis of $\ker T^*$.

(b) Verify directly that every vector of $\ker T^*$ is orthogonal to every vector of $\operatorname{im} T$, and that the dimensions add to 3.

(c) Find $\ker T$ and $\operatorname{im} T^*$, and check Theorem 10.6.5 (b) in this case.

Solution.

(a) The two columns $(1, 1, 0)$ and $(0, 1, 1)$ are independent, so they are a basis of $\operatorname{im} T = \operatorname{col}(\mathbf{A})$ and $\operatorname{rank} T = 2$. Since $T^* = T_{\mathbf{A}^\top}$, the kernel of T^* is $\operatorname{nul}(\mathbf{A}^\top)$: the equations $y_1 + y_2 = 0$ and $y_2 + y_3 = 0$ give $\ker T^* = \operatorname{span}\big((1, -1, 1)\big)$.

(b) $(1,1,0)\cdot(1,-1,1) = 1-1+0 = 0$ and $(0,1,1)\cdot(1,-1,1) = 0-1+1 = 0$. Since these two vectors span $\operatorname{im} T$, orthogonality extends to all of $\operatorname{im} T$ by linearity. The dimensions are $2+1 = 3 = \dim \mathbb{R}^3$, as Theorem 10.6.5 (d) requires.

(c) $\mathbf{Ax} = \mathbf{0}$ gives $x_1 = 0$ and $x_2 = 0$, so $\ker T = \{\mathbf{0}\}$ and $(\ker T)^\perp = \mathbb{R}^2$. On the other side, $\operatorname{rank} T^* = \operatorname{rank} T = 2$ by Corollary 10.6.6 (a), and $\operatorname{im} T^* \subseteq \mathbb{R}^2$, so $\operatorname{im} T^* = \mathbb{R}^2$. The two agree.

10.6.8.3 C. Going deeper

Exercise C1: The adjoint of integration.

Let $V = \mathbb{R}[x]_{\le 1}$ and $W = \mathbb{R}[x]_{\le 2}$ with the coefficient inner products of Exercise (B2: Adjoints on a polynomial space), and let

$$J : V \to W, \qquad J(p)(x) := \int_0^x p(t)\,\mathrm{d}t.$$

(a) Find J^*.

(b) Let $D : W \to V$ be differentiation. Show that $J^* \neq D$, although $DJ = \mathrm{id}_V$.

(c) Explain in one sentence why (b) does not contradict Theorem 10.6.2 (e).

Solution.

(a) $J(1) = x$ and $J(x) = \frac{1}{2}x^2$, so in the orthonormal bases $\mathcal{D} = (1, x)$ of V and $\mathcal{E} = (1, x, x^2)$ of W,

$$[J]_{\mathcal{D}}^{\mathcal{E}} = \begin{pmatrix} 0 & 0 \\ 1 & 0 \\ 0 & \frac{1}{2} \end{pmatrix}, \qquad [J^*]_{\mathcal{E}}^{\mathcal{D}} = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & \frac{1}{2} \end{pmatrix}$$

by Theorem 10.6.3. Hence $J^*(c_0 + c_1 x + c_2 x^2) = c_1 + \frac{1}{2}c_2 x$.

(b) $D(c_0 + c_1 x + c_2 x^2) = c_1 + 2c_2 x$, so J^* and D differ on x^2: $J^*(x^2) = \frac{1}{2}x$ while $D(x^2) = 2x$. Yet $D(J(p)) = p$ for every $p \in V$, by differentiating the integral, or by multiplying the two matrices: $[D]_{\mathcal{E}}^{\mathcal{D}}\,[J]_{\mathcal{D}}^{\mathcal{E}} = \mathbf{I}_2$.

(c) Part (e) of Theorem 10.6.2 applies to an **invertible** map, and J is not invertible: it is injective but not surjective, since $\dim V = 2 < 3 = \dim W$. A one-sided inverse carries no information about the adjoint.

Exercise C2: Skew-adjoint operators.

Let V be a finite-dimensional inner product space over F and let $T \in \mathcal{L}(V)$ satisfy $T^* = -T$ (such a T is called **skew-adjoint**).

(a) Prove that $\langle T\mathbf{v}, \mathbf{v}\rangle$ is purely imaginary for every $\mathbf{v} \in V$ when $F = \mathbb{C}$, and that $\langle T\mathbf{v}, \mathbf{v}\rangle = 0$ for every $\mathbf{v} \in V$ when $F = \mathbb{R}$.

(b) Prove that every skew-adjoint T is normal.

(c) Suppose $F = \mathbb{C}$. Prove that T is skew-adjoint if and only if iT is self-adjoint, and deduce that every $S \in \mathcal{L}(V)$ can be written $S = A + iB$ with A, B self-adjoint.

Solution.

(a) By conjugate symmetry and $T^* = -T$,

$$\overline{\langle T\mathbf{v}, \mathbf{v}\rangle} = \langle \mathbf{v}, T\mathbf{v}\rangle = \langle T^*\mathbf{v}, \mathbf{v}\rangle = -\langle T\mathbf{v}, \mathbf{v}\rangle.$$

A complex number equal to minus its own conjugate has zero real part, so $\langle T\mathbf{v}, \mathbf{v}\rangle$ is purely imaginary. When $F = \mathbb{R}$ the inner product is real, so the same equation reads $\langle T\mathbf{v}, \mathbf{v}\rangle = -\langle T\mathbf{v}, \mathbf{v}\rangle$, forcing $\langle T\mathbf{v}, \mathbf{v}\rangle = 0$.

(b) $T^*T = (-T)T = -T^2$ and $TT^* = T(-T) = -T^2$, so the two agree.

(c) By Theorem 10.6.2 (b), $(iT)^* = \bar{i}T^* = -iT^*$. If $T^* = -T$ then $(iT)^* = iT$, so iT is self-adjoint; conversely, if $(iT)^* = iT$ then $-iT^* = iT$, so $T^* = -T$. For the decomposition put

$$A := \tfrac{1}{2}(S + S^*), \qquad B := \tfrac{1}{2i}(S - S^*).$$

Then $A + iB = \frac{1}{2}(S+S^*) + \frac{1}{2}(S-S^*) = S$. Both are self-adjoint: $A^* = \frac{1}{2}(S^*+S) = A$ by Theorem 10.6.2 (a), (b) and (d), and $\frac{1}{2i}(S - S^*)$ is $-i$ times the skew-adjoint operator $\frac{1}{2}(S - S^*)$, hence self-adjoint by the first part of (c). This is the operator version of writing a complex number as $a + bi$.

Exercise C3: The adjoint in an arbitrary basis.

Let V be a finite-dimensional inner product space, let $\mathcal{B} = (\mathbf{b}_1, \dots, \mathbf{b}_n)$ be **any** ordered basis of V, let $\mathbf{G}$ be its Gram matrix, $g_{ij} = \langle \mathbf{b}_j, \mathbf{b}_i\rangle$, and let $T \in \mathcal{L}(V)$.

(a) Prove that $\langle \mathbf{u}, \mathbf{v}\rangle = [\mathbf{v}]_{\mathcal{B}}^* \, \mathbf{G} \, [\mathbf{u}]_{\mathcal{B}}$ for all $\mathbf{u}, \mathbf{v} \in V$.

(b) Deduce that $[T^*]_{\mathcal{B}}^{\mathcal{B}} = \mathbf{G}^{-1} \left([T]_{\mathcal{B}}^{\mathcal{B}}\right)^* \mathbf{G}$.

(c) Check that (b) returns Theorem 10.6.3 when $\mathcal{B}$ is orthonormal, and verify it on Example (The Transpose Rule Breaks).

Hint: for (b), write the defining identity of T^* in the coordinates of (a) and use that $\mathbf{x}^*\mathbf{M}\mathbf{y} = \mathbf{x}^*\mathbf{N}\mathbf{y}$ for all $\mathbf{x}, \mathbf{y}$ forces $\mathbf{M} = \mathbf{N}$.

Solution.

(a) Write $\mathbf{u} = \sum_j x_j \mathbf{b}_j$ and $\mathbf{v} = \sum_i y_i \mathbf{b}_i$, so $\mathbf{x} = [\mathbf{u}]_{\mathcal{B}}$ and $\mathbf{y} = [\mathbf{v}]_{\mathcal{B}}$. Expanding in the first slot and then in the second,

$$\langle \mathbf{u}, \mathbf{v}\rangle = \sum_{i,j} x_j \overline{y_i} \langle \mathbf{b}_j, \mathbf{b}_i\rangle = \sum_{i,j} \overline{y_i}\, g_{ij}\, x_j = \mathbf{y}^*\mathbf{G}\mathbf{x}.$$

(b) Put $\mathbf{A} = [T]_{\mathcal{B}}^{\mathcal{B}}$ and $\mathbf{B} = [T^*]_{\mathcal{B}}^{\mathcal{B}}$. By Theorem 3.6.1, $[T\mathbf{u}]_{\mathcal{B}} = \mathbf{A}\mathbf{x}$ and $[T^*\mathbf{v}]_{\mathcal{B}} = \mathbf{B}\mathbf{y}$. So (a) turns $\langle T\mathbf{u}, \mathbf{v}\rangle = \langle \mathbf{u}, T^*\mathbf{v}\rangle$ into

$$\mathbf{y}^*\mathbf{G}\mathbf{A}\mathbf{x} = (\mathbf{B}\mathbf{y})^*\mathbf{G}\mathbf{x} = \mathbf{y}^*\mathbf{B}^*\mathbf{G}\mathbf{x} \qquad \text{for all } \mathbf{x}, \mathbf{y} \in F^n.$$

Taking $\mathbf{x} = \mathbf{e}_j$ and $\mathbf{y} = \mathbf{e}_i$ reads off the (i, j) entries, so $\mathbf{G}\mathbf{A} = \mathbf{B}^*\mathbf{G}$. The Gram matrix is invertible (Theorem 10.2.5 (c)), so $\mathbf{B}^* = \mathbf{G}\mathbf{A}\mathbf{G}^{-1}$, and starring both sides gives $\mathbf{B} = (\mathbf{G}^{-1})^*\mathbf{A}^*\mathbf{G}^* = \mathbf{G}^{-1}\mathbf{A}^*\mathbf{G}$, using $\mathbf{G}^* = \mathbf{G}$ (Theorem 10.2.5 (a)) and hence $(\mathbf{G}^{-1})^* = \mathbf{G}^{-1}$.

(c) If $\mathcal{B}$ is orthonormal then $g_{ij} = \delta_{ij}$, so $\mathbf{G} = \mathbf{I}$ and the formula reads $\mathbf{B} = \mathbf{A}^*$, which is Theorem 10.6.3. In Example (The Transpose Rule Breaks) the computation in the remark after it is exactly this formula, with $\mathbf{G} = \begin{pmatrix} 1 & 1 \\ 1 & 2 \end{pmatrix}$.

10.7 Isometries and Unitary Maps

Chapter 3 asked which linear maps are invertible. Now that we can measure, we can ask a sharper question: which linear maps leave the measurements alone? A map that never changes a length never changes an angle either, and the two facts turn out to be the same fact. This section identifies these maps in five equivalent ways, collects them into the orthogonal and unitary groups, and classifies them completely in dimensions two and three, where they are exactly the rotations and reflections that the words suggest. At the end we drop linearity from the hypothesis and get it back as a conclusion.

As throughout the chapter, F is $\mathbb{R}$ or $\mathbb{C}$, inner products are linear in the first slot, and spaces are finite-dimensional unless stated otherwise.

10.7.1 Maps that do not change length

Take the plane with its usual inner product and ask which linear maps move the picture rigidly. Turning the plane about the origin clearly does not change any length. Flipping it across a line through the origin does not either. Scaling by 2 obviously does. Shearing, $(x_1, x_2) \mapsto (x_1 + x_2, x_2)$, also does: it fixes $\mathbf{e}_1$ but sends $\mathbf{e}_2$ to $(1, 1)$, of length $\sqrt{2}$. So "does not change length" is a genuine restriction, and it is worth a name.

An isometry is a linear map that every ruler agrees with: the image of a vector is exactly as long as the vector.

Definition 10.7.1 — Isometry

Let V and W be inner product spaces over F. A linear map $T \in \mathcal{L}(V, W)$ is an **isometry** if

$$\|T\mathbf{v}\| = \|\mathbf{v}\| \qquad \text{for every } \mathbf{v} \in V.$$

In words: the condition is required for **every** vector, not merely for the vectors of a basis, and it compares a norm in W with a norm in V. The word comes from *iso* (equal) and *metron* (measure). Some authors reserve "isometry" for a bijective such map; we do not, and Definition 10.7.2 below names the bijective case separately.

Two consequences are immediate. An isometry is injective, since $T\mathbf{v} = \mathbf{0}$ forces $\|\mathbf{v}\| = \|T\mathbf{v}\| = 0$ and hence $\mathbf{v} = \mathbf{0}$ (Theorem 3.2.3). And if $T\mathbf{v} = \lambda\mathbf{v}$ with $\mathbf{v} \neq \mathbf{0}$, then $\|\mathbf{v}\| = \|\lambda\mathbf{v}\| = |\lambda|\,\|\mathbf{v}\|$ by Theorem 10.1.2 (b), so $|\lambda| = 1$. We record the second observation, which the classification below will use twice.

Proposition 10.7.1 — Eigenvalues of an Isometry Have Modulus 1

Let $T \in \mathcal{L}(V)$ be an isometry of an inner product space over F, and let $\lambda \in F$ be an eigenvalue of T. Then $|\lambda| = 1$. In particular, if $F = \mathbb{R}$ then $\lambda = 1$ or $\lambda = -1$.

Proof. Let $\mathbf{v} \neq \mathbf{0}$ satisfy $T\mathbf{v} = \lambda\mathbf{v}$ (Definition 8.2.1). Then $\|\mathbf{v}\| = \|T\mathbf{v}\| = \|\lambda\mathbf{v}\| = |\lambda|\,\|\mathbf{v}\|$ by Theorem 10.1.2 (b), and $\|\mathbf{v}\| \neq 0$, so dividing gives $|\lambda| = 1$. The only real numbers of modulus 1 are ± 1.

■

Example. (Isometries and Near-Isometries)

Decide which of the following linear maps are isometries, with the standard inner products.

(a) $T\colon \mathbb{R}^2 \to \mathbb{R}^3$, $T(x_1, x_2) = (x_1, x_2, 0)$.

(b) $T_{\mathbf{P}}\colon F^n \to F^n$ for a permutation matrix $\mathbf{P}$ (Definition 2.6.2).

(c) $T\colon \mathbb{C} \to \mathbb{C}$, $T(z) = \alpha z$, where $|\alpha| = 1$.

(d) $T\colon \mathbb{R}^2 \to \mathbb{R}^2$, $T(x_1, x_2) = (x_1 + x_2, x_2)$.

(e) The orthogonal projection P_U onto a subspace U with $\{\mathbf{0}\} \neq U \neq V$.

Solution.

(a) Yes: $\|T\mathbf{x}\|^2 = x_1^2 + x_2^2 + 0 = \|\mathbf{x}\|^2$. Note that T is not surjective, so an isometry need not be invertible.

(b) Yes. A permutation matrix has exactly one 1 in each row and column, so $\mathbf{Px}$ is the list $x_1, \dots, x_n$ in a different order, and $\|\mathbf{Px}\|^2 = \sum_i |x_{\sigma(i)}|^2 = \sum_i |x_i|^2$, the same sum reordered.

(c) Yes: $\|\alpha z\| = |\alpha z| = |\alpha||z| = |z|$.

(d) No: $\|T\mathbf{e}_2\| = \|(1,1)\| = \sqrt{2} \neq 1 = \|\mathbf{e}_2\|$. One vector is enough to refute.

(e) No: pick $\mathbf{v} \in U^{\perp}$ with $\mathbf{v} \neq \mathbf{0}$, which exists because $U \neq V$ (Theorem 10.3.2 (a)). Then $P_U\mathbf{v} = \mathbf{0}$ (Theorem 10.3.3 (a)), so $\|P_U\mathbf{v}\| = 0 \neq \|\mathbf{v}\|$. A projection destroys length by design.

10.7.2 Five ways to say the same thing

The definition mentions only norms, but norms and inner products determine each other. In one direction this is Definition 10.1.3. In the other it is the following identity, which reconstructs the inner product from lengths alone; it is the reason that preserving length automatically preserves angle.

Lemma 10.7.2 — Polarization Identities

Let V be an inner product space over F and let $\mathbf{u}, \mathbf{v} \in V$.

(a) If $F = \mathbb{R}$, then $\langle \mathbf{u}, \mathbf{v} \rangle = \frac{1}{4}\big(\|\mathbf{u}+\mathbf{v}\|^2 - \|\mathbf{u}-\mathbf{v}\|^2\big)$.

(b) If $F = \mathbb{C}$, then $\langle \mathbf{u}, \mathbf{v} \rangle = \frac{1}{4}\displaystyle\sum_{k=0}^{3} i^k \, \|\mathbf{u} + i^k \mathbf{v}\|^2$.

Idea. Expand every norm squared with $\|\mathbf{u}+\mathbf{w}\|^2 = \|\mathbf{u}\|^2 + 2\,\mathrm{Re}\langle \mathbf{u}, \mathbf{w}\rangle + \|\mathbf{w}\|^2$ (Theorem 10.1.2 (c)). In the real case the two expansions differ only in the middle term, which survives doubled. In the complex case the four terms $\|\mathbf{u}\|^2 + \|\mathbf{w}\|^2$ are the same in all four summands and are killed by $\sum_k i^k = 0$; what is left is a sum in which the $\langle \mathbf{u}, \mathbf{v}\rangle$ parts reinforce and the $\overline{\langle \mathbf{u}, \mathbf{v}\rangle}$ parts cancel.

Proof.

(a) By Theorem 10.1.2 (c), $\|\mathbf{u} \pm \mathbf{v}\|^2 = \|\mathbf{u}\|^2 \pm 2\langle \mathbf{u}, \mathbf{v}\rangle + \|\mathbf{v}\|^2$, since over $\mathbb{R}$ the inner product is its own real part. Subtracting, $\|\mathbf{u}+\mathbf{v}\|^2 - \|\mathbf{u}-\mathbf{v}\|^2 = 4\langle \mathbf{u}, \mathbf{v}\rangle$.

(b) Write $z = \langle \mathbf{u}, \mathbf{v}\rangle$. Since $|i^k| = 1$, Theorem 10.1.2 (b) and (c) give $\|i^k \mathbf{v}\| = \|\mathbf{v}\|$ and

$$\|\mathbf{u} + i^k \mathbf{v}\|^2 = \|\mathbf{u}\|^2 + \|\mathbf{v}\|^2 + 2\,\mathrm{Re}\langle \mathbf{u}, i^k \mathbf{v}\rangle = \|\mathbf{u}\|^2 + \|\mathbf{v}\|^2 + 2\,\mathrm{Re}\big(i^{-k} z\big),$$

where $\langle \mathbf{u}, i^k \mathbf{v}\rangle = \overline{i^k}\, z = i^{-k} z$ by conjugate-linearity in the second slot. Multiply by i^k and sum over $k = 0, 1, 2, 3$. The first two terms contribute $(\|\mathbf{u}\|^2 + \|\mathbf{v}\|^2)\sum_k i^k = 0$, because $1 + i - 1 - i = 0$. For the remaining terms use $2\,\mathrm{Re}(w) = w + \overline{w}$:

$$\sum_{k=0}^{3} i^k \cdot 2\,\mathrm{Re}\big(i^{-k} z\big) = \sum_{k=0}^{3} i^k \big(i^{-k} z + i^k \overline{z}\big) = \sum_{k=0}^{3} z + \overline{z} \sum_{k=0}^{3} i^{2k} = 4z + 0,$$

since $\sum_k i^{2k} = 1 - 1 + 1 - 1 = 0$. Dividing by 4 gives the identity.

■

Now the main theorem. It says that length, angle, the adjoint and orthonormal bases all detect the same class of maps, and it is the reason isometries are easy to work with: whichever of the five descriptions a problem hands you, you may switch to whichever one you want.

Theorem 10.7.3 — Characterizations of Isometries

Let V and W be finite-dimensional inner product spaces over F, and let $T \in \mathcal{L}(V, W)$. The following are equivalent.

(a) T is an isometry: $\|T\mathbf{v}\| = \|\mathbf{v}\|$ for every $\mathbf{v} \in V$.

(b) T preserves inner products: $\langle T\mathbf{u}, T\mathbf{v}\rangle = \langle \mathbf{u}, \mathbf{v}\rangle$ for all $\mathbf{u}, \mathbf{v} \in V$.

(c) $T^*T = \mathrm{id}_V$.

(d) T sends **every** orthonormal list in V to an orthonormal list in W.

(e) T sends **some** orthonormal basis of V to an orthonormal list in W.

(f) For one (equivalently every) pair of orthonormal bases $\mathcal{B}$ of V and $\mathcal{C}$ of W, the matrix $\mathbf{A} = [T]_{\mathcal{B}}^{\mathcal{C}} \in M_{m\times n}(F)$, where $n = \dim V$ and $m = \dim W$, satisfies $\mathbf{A}^*\mathbf{A} = \mathbf{I}_n$; that is, the n columns of $\mathbf{A}$ are orthonormal vectors of F^m.

If in addition $\dim W = \dim V$, then (a)–(f) are further equivalent to each of

(g1) T is invertible with $T^{-1} = T^*$;
(g2) $TT^* = \mathrm{id}_W$.

Idea. Run the cycle (a) $\Rightarrow$ (b) $\Rightarrow$ (c) $\Rightarrow$ (a). The first step is polarization: lengths are all we are given, and Lemma 10.7.2 converts them into an inner product. The second is the adjoint doing its job, $\langle T\mathbf{u}, T\mathbf{v}\rangle = \langle \mathbf{u}, T^*T\mathbf{v}\rangle$, plus non-degeneracy. The third is the same identity read backwards with $\mathbf{u} = \mathbf{v}$. Then (b) $\Rightarrow$ (d) $\Rightarrow$ (e) $\Rightarrow$ (b) is a second, shorter cycle, and (c) $\Leftrightarrow$ (f) is Theorem 10.6.3. The last two need a dimension count: $T^*T = \mathrm{id}$ makes T injective, and in equal dimensions injective means invertible.

Proof.

(a) $\Rightarrow$ (b). Suppose $\|T\mathbf{v}\| = \|\mathbf{v}\|$ for all $\mathbf{v}$. If $F = \mathbb{R}$, then by Lemma 10.7.2 (a) applied in W and then in V, and by the linearity of T,

$$\begin{aligned}\langle T\mathbf{u}, T\mathbf{v}\rangle &= \tfrac{1}{4}\big(\|T(\mathbf{u}+\mathbf{v})\|^2 - \|T(\mathbf{u}-\mathbf{v})\|^2\big)\\ &= \tfrac{1}{4}\big(\|\mathbf{u}+\mathbf{v}\|^2 - \|\mathbf{u}-\mathbf{v}\|^2\big) = \langle \mathbf{u}, \mathbf{v}\rangle.\end{aligned}$$

If $F = \mathbb{C}$, the same two lines work with Lemma 10.7.2 (b), since $T(\mathbf{u} + i^k\mathbf{v}) = T\mathbf{u} + i^kT\mathbf{v}$.

(b) $\Rightarrow$ (c). For all $\mathbf{u}, \mathbf{v} \in V$, Definition 10.6.1 gives $\langle \mathbf{u}, T^*T\mathbf{v}\rangle = \langle T\mathbf{u}, T\mathbf{v}\rangle = \langle \mathbf{u}, \mathbf{v}\rangle$, so $\langle \mathbf{u}, T^*T\mathbf{v} - \mathbf{v}\rangle = 0$ for every $\mathbf{u}$. Taking $\mathbf{u} = T^*T\mathbf{v} - \mathbf{v}$ makes its norm zero, so $T^*T\mathbf{v} = \mathbf{v}$ for every $\mathbf{v}$.

(c) $\Rightarrow$ (a). $\|T\mathbf{v}\|^2 = \langle T\mathbf{v}, T\mathbf{v}\rangle = \langle \mathbf{v}, T^*T\mathbf{v}\rangle = \langle \mathbf{v}, \mathbf{v}\rangle = \|\mathbf{v}\|^2$, and norms are non-negative, so $\|T\mathbf{v}\| = \|\mathbf{v}\|$.

(d) $\Rightarrow$ (d). Let $(\mathbf{u}_1, \dots, \mathbf{u}_k)$ be orthonormal in V, so $\langle \mathbf{u}_i, \mathbf{u}_j\rangle = \delta_{ij}$. Then $\langle T\mathbf{u}_i, T\mathbf{u}_j\rangle = \langle \mathbf{u}_i, \mathbf{u}_j\rangle = \delta_{ij}$, which is exactly what it means for $(T\mathbf{u}_1, \dots, T\mathbf{u}_k)$ to be orthonormal (Definition 10.2.1).

(e) $\Rightarrow$ (e). V is finite-dimensional, so it has an orthonormal basis by Theorem 10.2.2, and (d) applies to it.

(f) $\Rightarrow$ (b). Let $\mathcal{B} = (\mathbf{v}_1, \dots, \mathbf{v}_n)$ be an orthonormal basis of V with $(T\mathbf{v}_1, \dots, T\mathbf{v}_n)$ orthonormal. Given $\mathbf{u}, \mathbf{v} \in V$, expand them in $\mathcal{B}$ as $\mathbf{u} = \sum_i a_i\mathbf{v}_i$ and $\mathbf{v} = \sum_j b_j\mathbf{v}_j$. Expanding both slots and using orthonormality twice,

$$\langle T\mathbf{u}, T\mathbf{v}\rangle = \sum_{i,j} a_i\overline{b_j}\langle T\mathbf{v}_i, T\mathbf{v}_j\rangle = \sum_i a_i\overline{b_i} = \sum_{i,j} a_i\overline{b_j}\langle \mathbf{v}_i, \mathbf{v}_j\rangle = \langle \mathbf{u}, \mathbf{v}\rangle,$$

since in both double sums only the terms with $i = j$ survive.

(g) $\Leftrightarrow$ (f). Fix orthonormal bases $\mathcal{B}$ and $\mathcal{C}$ and put $\mathbf{A} = [T]_{\mathcal{B}}^{\mathcal{C}}$. By Theorem 10.6.3, $[T^*]_{\mathcal{C}}^{\mathcal{B}} = \mathbf{A}^*$, and by Theorem 3.6.2, $[T^*T]_{\mathcal{B}}^{\mathcal{B}} = \mathbf{A}^*\mathbf{A}$. Since a map is determined by its matrix in fixed bases, $T^*T = \mathrm{id}_V$ if and only if $\mathbf{A}^*\mathbf{A} = \mathbf{I}_n$. The (i, j) entry of $\mathbf{A}^*\mathbf{A}$ is the standard inner product of column j with column i, so this says the columns are orthonormal. As (c) does not mention the bases, the condition holds for one pair of orthonormal bases if and only if it holds for every pair.

Now assume $\dim W = \dim V$.

(c) $\Rightarrow$ (g1). By (c) and Theorem 3.2.3, T is injective, so $\operatorname{rank} T = \dim V = \dim W$

by Theorem 3.3.1, and T is surjective. Hence T is invertible, and multiplying $T^*T = \mathrm{id}_V$ on the right by T^{-1} gives $T^* = T^{-1}$.

(g1) $\Rightarrow$ (g2). $TT^* = TT^{-1} = \mathrm{id}_W$.

(g2) $\Rightarrow$ (c). $TT^* = \mathrm{id}_W$ makes T surjective, hence invertible by the equal dimensions and Theorem 3.3.1, and multiplying on the left by T^{-1} gives $T^* = T^{-1}$, so $T^*T = \mathrm{id}_V$. This proves the theorem.

■

Condition (f) is the one to use on a concrete matrix: **check that the columns are orthonormal**. Condition (c) is the one to use in a proof. Condition (e) is the cheapest to verify on an abstract map, since one basis suffices, and (d) is what you get out afterwards.

Warning. $T^*T = \mathrm{id}$ **does not give** $TT^* = \mathrm{id}$ **when the dimensions differ.** Let $T\colon \mathbb{R}^2 \to \mathbb{R}^3$ be $T(x_1, x_2) = (x_1, x_2, 0)$, with matrix $\mathbf{A} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \\ 0 & 0 \end{pmatrix}$. Then $\mathbf{A}^{\top}\mathbf{A} = \mathbf{I}_2$, so T is an isometry; but

$$\mathbf{A}\mathbf{A}^{\top} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \end{pmatrix} \neq \mathbf{I}_3.$$

Ask *identity on what?* The composite TT^* is the orthogonal projection of $\mathbb{R}^3$ onto $\operatorname{im} T$, the x_1x_2-plane, and it is the identity there and nowhere else. Only when T is surjective can both products be identities.

Quick check. Is $\begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}$ the matrix of an isometry of $\mathbb{R}^2$? If not, is some scalar multiple of it?

Solution. No: the first column has norm $\sqrt{2} \neq 1$, so the columns are not orthonormal and condition (f) of Theorem 10.7.3 fails. The columns are, however, orthogonal, so dividing by $\sqrt{2}$ normalizes both and $\frac{1}{\sqrt{2}}\begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}$ is an isometry.

10.7.3 Unitary and orthogonal maps

Conditions (g1) and (g2) describe the case that matters most, an isometry of a space with itself. It is the case with a name.

Definition 10.7.2 — Unitary and Orthogonal

Let V be a finite-dimensional inner product space over F. An operator $T \in \mathcal{L}(V)$ is **unitary** if

$$T^*T = TT^* = \mathrm{id}_V,$$

equivalently if T is an invertible isometry. When $F = \mathbb{R}$, such a T is also called **orthogonal**.

A matrix $\mathbf{A} \in M_n(\mathbb{C})$ with $\mathbf{A}^*\mathbf{A} = \mathbf{I}_n$ is a **unitary matrix**; a matrix $\mathbf{A} \in M_n(\mathbb{R})$ with $\mathbf{A}^\top\mathbf{A} = \mathbf{I}_n$ is an **orthogonal matrix**.

For a **square** matrix the one-sided condition $\mathbf{A}^*\mathbf{A} = \mathbf{I}$ already forces $\mathbf{A}\mathbf{A}^* = \mathbf{I}$, by part (g2) of Theorem 10.7.3, or directly by Theorem 2.4.5. The warning above shows that squareness is not a formality.

Definition 10.7.3 — The Unitary and Orthogonal Groups

For $n \geq 1$ set

$$\mathrm{U}(n) \coloneqq \{\mathbf{A} \in M_n(\mathbb{C}) : \mathbf{A}^*\mathbf{A} = \mathbf{I}_n\}, \qquad \mathrm{O}(n) \coloneqq \{\mathbf{A} \in M_n(\mathbb{R}) : \mathbf{A}^\top\mathbf{A} = \mathbf{I}_n\},$$

and $\mathrm{SO}(n) \coloneqq \{\mathbf{A} \in \mathrm{O}(n) : \det \mathbf{A} = 1\}$, the **special orthogonal group**.

Proposition 10.7.4 — The Groups and Their Determinants

(a) $\mathrm{U}(n)$ and $\mathrm{O}(n)$ are groups under matrix multiplication, and $\mathrm{O}(n) = \mathrm{U}(n) \cap M_n(\mathbb{R})$.

(b) If $\mathbf{A} \in \mathrm{U}(n)$ then $|\det \mathbf{A}| = 1$. If $\mathbf{A} \in \mathrm{O}(n)$ then $\det \mathbf{A} = 1$ or $\det \mathbf{A} = -1$.

(c) $\mathrm{SO}(n)$ is a subgroup of $\mathrm{O}(n)$.

Proof.

(a) $\mathbf{I}^*\mathbf{I} = \mathbf{I}$, so $\mathbf{I} \in \mathrm{U}(n)$. If $\mathbf{A}, \mathbf{B} \in \mathrm{U}(n)$ then $(\mathbf{AB})^*(\mathbf{AB}) = \mathbf{B}^*\mathbf{A}^*\mathbf{AB} = \mathbf{B}^*\mathbf{B} = \mathbf{I}$, so $\mathbf{AB} \in \mathrm{U}(n)$. Each $\mathbf{A} \in \mathrm{U}(n)$ is invertible with $\mathbf{A}^{-1} = \mathbf{A}^*$, and $(\mathbf{A}^*)^*\mathbf{A}^* = \mathbf{A}\mathbf{A}^* = \mathbf{I}$, so $\mathbf{A}^{-1} \in \mathrm{U}(n)$. Associativity is inherited from matrix multiplication. The same three lines prove the claim for $\mathrm{O}(n)$, with $\mathbf{A}^* = \mathbf{A}^\top$ for a real matrix, which is also the last assertion.

(b) The determinant is the sum $\sum_\sigma \operatorname{sgn}(\sigma) a_{\sigma(1)1} \cdots a_{\sigma(n)n}$ of Definition 6.4.1, and conjugation of complex numbers respects sums and products, so $\det \overline{\mathbf{A}} = \overline{\det \mathbf{A}}$. With Theorem 6.4.5 this gives $\det \mathbf{A}^* = \det\big(\overline{\mathbf{A}}^\top\big) = \det \overline{\mathbf{A}} = \overline{\det \mathbf{A}}$. Hence, by Theorem 6.5.4,

$$1 = \det \mathbf{I}_n = \det(\mathbf{A}^*\mathbf{A}) = \overline{\det \mathbf{A}}\, \det \mathbf{A} = |\det \mathbf{A}|^2.$$

For real $\mathbf{A}$ the determinant is real, and the real numbers of modulus 1 are ± 1.

(c) $\det \mathbf{I} = 1$, and det is multiplicative (Theorem 6.5.4), so $\det(\mathbf{AB}) = 1$ and $\det(\mathbf{A}^{-1}) = (\det \mathbf{A})^{-1} = 1$ whenever $\det \mathbf{A} = \det \mathbf{B} = 1$.

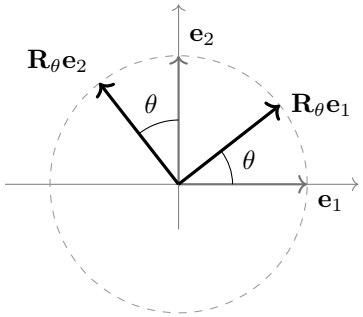
■

Warning. $|\lambda| = 1$ **does not mean** $\lambda = \pm 1$**, and** $\det \mathbf{A} = 1$ **does not mean "rotation".** The matrix $-\mathbf{I}_4 \in \mathrm{SO}(4)$ has determinant $(-1)^4 = 1$, but it fixes no non-zero vector, so it is not a rotation about an axis in any sense. Likewise $-\mathbf{I}_3 \in \mathrm{O}(3)$ has determinant -1 but is not a reflection in a plane: a reflection fixes a plane pointwise, and $-\mathbf{I}_3$ fixes only $\mathbf{0}$. The clean classification below is a feature of dimensions 2 and 3, not a general theorem.

10.7.4 Rotations and reflections of the plane

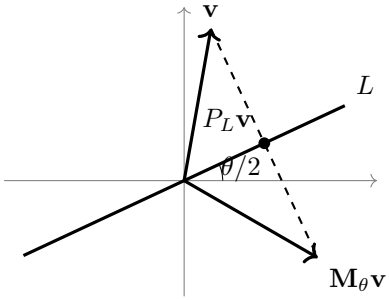
In dimension 2 the group $\mathrm{O}(2)$ can be written down completely, and the two determinant values split it into exactly the two families the words suggest. For $\theta \in \mathbb{R}$ put

$$\mathbf{R}_\theta := \begin{pmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{pmatrix}, \qquad \mathbf{M}_\theta := \begin{pmatrix} \cos\theta & \sin\theta \\ \sin\theta & -\cos\theta \end{pmatrix}.$$



the columns of $\mathbf{R}_\theta$ are the rotated axes

The first matrix rotates the plane by θ: its columns are $\mathbf{e}_1$ and $\mathbf{e}_2$ turned through θ. The second is a reflection, and the picture says in which mirror.



$\mathbf{M}_\theta$ reflects in the line L at angle $\theta/2$

Theorem 10.7.5 — Classification of the Plane Isometries

Let $\mathbf{A} \in \mathrm{O}(2)$.

(a) If $\det \mathbf{A} = 1$, then $\mathbf{A} = \mathbf{R}_\theta$ for a unique $\theta \in [0, 2\pi)$.

(b) If $\det \mathbf{A} = -1$, then $\mathbf{A} = \mathbf{M}_\theta$ for a unique $\theta \in [0, 2\pi)$. In this case $\mathbf{A}^2 = \mathbf{I}$, the eigenvalues of $\mathbf{A}$ are 1 and -1, and $\mathbf{A}$ is the reflection in the line $L = \mathrm{span}\big((\cos\frac{\theta}{2}, \sin\frac{\theta}{2})\big)$: it fixes L pointwise and negates $L^\perp$.

Consequently $\mathrm{O}(2) = \{\mathbf{R}_\theta\} \cup \{\mathbf{M}_\theta\}$, and $\mathrm{SO}(2) = \{\mathbf{R}_\theta : \theta \in [0, 2\pi)\}$.

Idea. Condition (f) of Theorem 10.7.3 says the two columns are orthonormal. A unit vector of $\mathbb{R}^2$ is $(\cos\theta, \sin\theta)$ for exactly one $\theta \in [0, 2\pi)$, and there are exactly two unit vectors orthogonal to it. So there are only two candidates once the first column is chosen,

and the determinant tells them apart. The geometric description of $\mathbf{M}_\theta$ is then a two-line verification: guess the fixed vector from the picture and check it.

Proof. Write $\mathbf{A} = \begin{pmatrix} a & c \\ b & d \end{pmatrix} \in \mathrm{O}(2)$. By Theorem 10.7.3 (f), the columns are orthonormal: $a^2 + b^2 = 1$, $c^2 + d^2 = 1$ and $ac + bd = 0$. Since (a, b) is a unit vector of $\mathbb{R}^2$, there is a unique $\theta \in [0, 2\pi)$ with $a = \cos\theta$ and $b = \sin\theta$. The vectors orthogonal to (a, b) form a line, spanned by $(-b, a)$, which is already a unit vector; so the unit vectors on that line are $\pm(-b, a)$, and $(c, d) = \pm(-\sin\theta, \cos\theta)$. The two choices give

$$\begin{pmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{pmatrix} = \mathbf{R}_\theta \quad \text{and} \quad \begin{pmatrix} \cos\theta & \sin\theta \\ \sin\theta & -\cos\theta \end{pmatrix} = \mathbf{M}_\theta,$$

with determinants $\cos^2\theta + \sin^2\theta = 1$ and $-\cos^2\theta - \sin^2\theta = -1$. This proves (a) and the first sentence of (b), and uniqueness of θ in both cases, since θ is already determined by the first column.

For the rest of (b), put $\mathbf{u} = (\cos\frac{\theta}{2}, \sin\frac{\theta}{2})$ and $\mathbf{w} = (-\sin\frac{\theta}{2}, \cos\frac{\theta}{2})$, two orthogonal unit vectors. Writing $\theta = \frac{\theta}{2} + \frac{\theta}{2}$ and using the subtraction formulas for cosine and sine,

$$\mathbf{M}_\theta \mathbf{u} = \begin{pmatrix} \cos\theta\cos\frac{\theta}{2} + \sin\theta\sin\frac{\theta}{2} \\ \sin\theta\cos\frac{\theta}{2} - \cos\theta\sin\frac{\theta}{2} \end{pmatrix} = \begin{pmatrix} \cos\frac{\theta}{2} \\ \sin\frac{\theta}{2} \end{pmatrix} = \mathbf{u},$$

$$\mathbf{M}_\theta \mathbf{w} = \begin{pmatrix} -\cos\theta\sin\frac{\theta}{2} + \sin\theta\cos\frac{\theta}{2} \\ -\sin\theta\sin\frac{\theta}{2} - \cos\theta\cos\frac{\theta}{2} \end{pmatrix} = \begin{pmatrix} \sin\frac{\theta}{2} \\ -\cos\frac{\theta}{2} \end{pmatrix} = -\mathbf{w}.$$

So $(\mathbf{u}, \mathbf{w})$ is an orthonormal basis of eigenvectors with eigenvalues 1 and -1, and $\mathbf{M}_\theta^2$ fixes both of them, hence $\mathbf{M}_\theta^2 = \mathbf{I}$. Since $L = \mathrm{span}(\mathbf{u})$, we have $L^\perp = \mathrm{span}(\mathbf{w})$, because $\mathbf{w} \perp \mathbf{u}$ and $\dim L^\perp = 1$ (Theorem 10.3.2 (c)), so $\mathbf{M}_\theta$ fixes L pointwise and negates $L^\perp$, which is the description of a reflection. This proves the theorem. ∎

So $\mathrm{SO}(2)$ is the circle of rotations, and the other half of $\mathrm{O}(2)$ is the circle of reflections. Multiplying two rotations adds the angles, $\mathbf{R}_\alpha \mathbf{R}_\beta = \mathbf{R}_{\alpha+\beta}$, so $\mathrm{SO}(2)$ is abelian; Exercise (C3: Two reflections make a rotation) shows what happens when two reflections are multiplied.

Example. (Naming Two Plane Isometries)

Classify each of the following as a rotation or a reflection, and give the angle or the mirror line.

(a) $\mathbf{A} = \frac{1}{2}\begin{pmatrix} 1 & -\sqrt{3} \\ \sqrt{3} & 1 \end{pmatrix}$.

(b) $\mathbf{B} = \frac{1}{5}\begin{pmatrix} 3 & 4 \\ 4 & -3 \end{pmatrix}$.

Solution.

(a) The columns $\frac{1}{2}(1, \sqrt{3})$ and $\frac{1}{2}(-\sqrt{3}, 1)$ have norm $\frac{1}{2}\sqrt{1+3} = 1$ and inner product $\frac{1}{4}(-\sqrt{3} + \sqrt{3}) = 0$, so $\mathbf{A} \in \mathrm{O}(2)$. Its determinant is $\frac{1}{4}(1 + 3) = 1$, so $\mathbf{A} = \mathbf{R}_\theta$ with

$\cos\theta = \frac{1}{2}$ and $\sin\theta = \frac{\sqrt{3}}{2}$: rotation by $\theta = \pi/3$.

(b) The columns $\frac{1}{5}(3,4)$ and $\frac{1}{5}(4,-3)$ are orthonormal, and $\det \mathbf{B} = \frac{1}{25}(-9-16) = -1$, so $\mathbf{B} = \mathbf{M}_\theta$ with $\cos\theta = \frac{3}{5}$ and $\sin\theta = \frac{4}{5}$. The mirror is $L = \operatorname{span}\big((\cos\frac{\theta}{2}, \sin\frac{\theta}{2})\big)$, and rather than halve the angle we find the fixed line directly: $\mathbf{Bx} = \mathbf{x}$ reads $3x_1 + 4x_2 = 5x_1$, that is $x_1 = 2x_2$. So $L = \operatorname{span}\big((2,1)\big)$. Check: $\mathbf{B}(2,1) = \frac{1}{5}(6+4, 8-3) = (2,1)$, and $\mathbf{B}(-1,2) = \frac{1}{5}(-3+8, -4-6) = (1,-2) = -(-1,2)$, as a reflection must do to $L^\perp$.

10.7.5 Rotations of space

In dimension 3 the answer is the one physics assumes: every orientation-preserving isometry of $\mathbb{R}^3$ is a rotation about a line. The proof is where Chapter 8 is needed, for one reason only: to produce an eigenvector.

Theorem 10.7.6 — Every Element of SO(3) Is a Rotation

Let $\mathbf{A} \in \mathrm{SO}(3)$. Then there is a unit vector $\mathbf{u} \in \mathbb{R}^3$ with $\mathbf{Au} = \mathbf{u}$, and an orthonormal basis $\mathcal{B} = (\mathbf{u}, \mathbf{w}_1, \mathbf{w}_2)$ of $\mathbb{R}^3$ in which

$$[T_{\mathbf{A}}]_{\mathcal{B}}^{\mathcal{B}} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos\theta & -\sin\theta \\ 0 & \sin\theta & \cos\theta \end{pmatrix}$$

for some θ. That is, $\mathbf{A}$ fixes the **axis** $\operatorname{span}(\mathbf{u})$ and rotates the plane $\operatorname{span}(\mathbf{u})^\perp$ by θ. Moreover $\operatorname{tr}\mathbf{A} = 1 + 2\cos\theta$.

Idea. Three steps. ① Get a real eigenvalue: the characteristic polynomial is real of degree 3, and an odd-degree real polynomial has a real root. ② That eigenvalue is ± 1, since $T_{\mathbf{A}}$ is an isometry. ③ Split off the eigenline: its orthogonal complement is invariant, the restriction there lies in $\mathrm{O}(2)$, and Theorem 10.7.5 finishes. If the eigenvalue was -1 the restriction has determinant -1, so it is a reflection and supplies a $+1$ eigenvector inside the plane; feed that back into step ③.

Proof. Write $T = T_{\mathbf{A}}$, an isometry of $\mathbb{R}^3$ by Theorem 10.7.3.

Step 1: a real eigenvalue exists. By Theorem 6.10.2, $p_{\mathbf{A}} \in \mathbb{R}[x]$ is monic of degree 3, which is odd, so $p_{\mathbf{A}}$ has a real root λ by Corollary 5.5.9, and λ is an eigenvalue of $\mathbf{A}$ by Theorem 8.2.1. By Proposition 10.7.1, $\lambda = 1$ or $\lambda = -1$. Fix a unit eigenvector $\mathbf{u}_0$ for λ, possible after dividing by its norm.

Step 2: the orthogonal complement of an invariant line is invariant.

Claim. If $U \subseteq \mathbb{R}^3$ is a subspace with $T(U) \subseteq U$, then $T(U^\perp) \subseteq U^\perp$.

Proof. $T|_U \colon U \to U$ is injective, because T is, so it is surjective by Theorem 3.5.7 applied on the finite-dimensional space U. Let $\mathbf{w} \in U^\perp$ and $\mathbf{u} \in U$. Write $\mathbf{u} = T\mathbf{u}'$ with $\mathbf{u}' \in U$. Then $\langle T\mathbf{w}, \mathbf{u}\rangle = \langle T\mathbf{w}, T\mathbf{u}'\rangle = \langle \mathbf{w}, \mathbf{u}'\rangle = 0$, the middle step by Theorem 10.7.3 (b) and the last because $\mathbf{u}' \in U$. So $T\mathbf{w} \in U^\perp$. ∎

Step 3: reduce to the plane. Put $U = \operatorname{span}(\mathbf{u}_0)$, which is T-invariant. By the claim, $P \coloneqq U^\perp$ is T-invariant, and $\dim P = 2$ by Theorem 10.3.2 (c). Choose an orthonormal basis $(\mathbf{w}_1, \mathbf{w}_2)$ of P (Theorem 10.2.2); then $\mathcal{B}_0 = (\mathbf{u}_0, \mathbf{w}_1, \mathbf{w}_2)$ is an orthonormal basis of $\mathbb{R}^3$, and in it

$$[T]^{\mathcal{B}_0}_{\mathcal{B}_0} = \begin{pmatrix} \lambda & 0 & 0 \\ 0 & c_{11} & c_{12} \\ 0 & c_{21} & c_{22} \end{pmatrix}, \qquad \mathbf{C} \coloneqq \begin{pmatrix} c_{11} & c_{12} \\ c_{21} & c_{22} \end{pmatrix},$$

the first column because $T\mathbf{u}_0 = \lambda\mathbf{u}_0$, and the two zeros in the first row because $T\mathbf{w}_1, T\mathbf{w}_2 \in P$ have no $\mathbf{u}_0$-component. This matrix is orthogonal, being the matrix of an isometry in orthonormal bases (Theorem 10.7.3 (f)), so its second and third columns are orthonormal, which says $\mathbf{C}^\top\mathbf{C} = \mathbf{I}_2$ and $\mathbf{C} \in \mathrm{O}(2)$; and $\mathbf{C}$ is the matrix of $T|_P$ in the basis $(\mathbf{w}_1, \mathbf{w}_2)$. Expanding the determinant along the first column, and using that similar matrices have equal determinants (Corollary 6.5.7, with Theorem 3.7.4 (a)), $1 = \det \mathbf{A} = \lambda \det \mathbf{C}$, so $\det \mathbf{C} = \lambda$.

Case $\lambda = 1$. Then $\det \mathbf{C} = 1$, so $\mathbf{C} = \mathbf{R}_\theta$ for some θ by Theorem 10.7.5 (a), and $\mathcal{B} = \mathcal{B}_0$ and $\mathbf{u} = \mathbf{u}_0$ are as required.

Case $\lambda = -1$. Then $\det \mathbf{C} = -1$, so by Theorem 10.7.5 (b) the restriction $T|_P$ is a reflection of the plane P and has 1 as an eigenvalue. Let $\mathbf{u} \in P$ be a unit eigenvector for 1, so $T\mathbf{u} = \mathbf{u}$. Now rerun Steps 2 and 3 with $\mathbf{u}$ in place of $\mathbf{u}_0$. Because $\mathbf{u}$ was chosen with $T\mathbf{u} = \mathbf{u}$, the eigenvalue this time is 1, so the rerun lands in the previous case and cannot return here.

Finally, $\mathbf{A}$ and $[T]^{\mathcal{B}}_{\mathcal{B}}$ are matrices of the same operator, hence similar (Theorem 3.7.4 (a)), and similar matrices have equal traces (Theorem 3.7.5), so $\operatorname{tr} \mathbf{A} = 1 + 2\cos\theta$. This proves the theorem. ∎

The angle is determined by $\mathbf{A}$ up to sign, since reversing the order of $\mathbf{w}_1, \mathbf{w}_2$ replaces θ by $-\theta$; the trace formula $\cos\theta = \frac{1}{2}(\operatorname{tr}\mathbf{A} - 1)$ gives $|\theta|$ with no computation at all. This settles O(3) as well: if $\det \mathbf{A} = -1$ then $-\mathbf{A} \in \mathrm{SO}(3)$, so $\mathbf{A}$ is a rotation composed with the antipodal map.

Example. (Axis and Angle of a Rotation)

Let $\mathbf{A} = \frac{1}{3}\begin{pmatrix} 2 & -2 & 1 \\ 1 & 2 & 2 \\ -2 & -1 & 2 \end{pmatrix}$. Verify that $\mathbf{A} \in \mathrm{SO}(3)$ and find its axis and angle.

Solution. *Orthogonality.* The three columns are $\frac{1}{3}(2,1,-2)$, $\frac{1}{3}(-2,2,-1)$ and $\frac{1}{3}(1,2,2)$. Their squared norms are $\frac{1}{9}(4+1+4)=1$, $\frac{1}{9}(4+4+1)=1$ and $\frac{1}{9}(1+4+4)=1$, and their pairwise inner products are $\frac{1}{9}(-4+2+2)=0$, $\frac{1}{9}(2+2-4)=0$ and $\frac{1}{9}(-2+4-2)=0$. So the columns are orthonormal and $\mathbf{A}\in\mathrm{O}(3)$ by Theorem 10.7.3 (f).

Determinant. Expanding along the first row, $27\det\mathbf{A}=2(4+2)-(-2)(2+4)+1(-1+4)=12+12+3=27$, so $\det\mathbf{A}=1$ and $\mathbf{A}\in\mathrm{SO}(3)$.

Axis. Solve $\mathbf{A}\mathbf{u}=\mathbf{u}$, that is $(3\mathbf{I}-3\mathbf{A})\mathbf{u}=\mathbf{0}$:

$$\begin{pmatrix} 1 & 2 & -1 \\ -1 & 1 & -2 \\ 2 & 1 & 1 \end{pmatrix}\mathbf{u}=\mathbf{0}.$$

Adding row one to row two gives $3u_2-3u_3=0$, so $u_2=u_3$; then row one gives $u_1=-u_2$. The axis is $\operatorname{span}\big((-1,1,1)\big)$, and indeed $\mathbf{A}(-1,1,1)=\frac{1}{3}(-2-2+1,-1+2+2,2-1+2)=(-1,1,1)$.

Angle. $\operatorname{tr}\mathbf{A}=\frac{1}{3}(2+2+2)=2$, so $\cos\theta=\frac{1}{2}(2-1)=\frac{1}{2}$ and $|\theta|=\pi/3$. The map is a rotation by 60° about the line through $(-1,1,1)$.

Quick check. A matrix $\mathbf{A}\in\mathrm{SO}(3)$ has $\operatorname{tr}\mathbf{A}=-1$. What is its angle, and what is $\mathbf{A}^2$?

Solution. $\cos\theta=\frac{1}{2}(-1-1)=-1$, so $\theta=\pi$: a half-turn about the axis. Then $\mathbf{A}^2$ is the rotation by 2π about the same axis, which is $\mathbf{I}_3$. (In the basis of Theorem 10.7.6 the matrix is $\operatorname{diag}(1,-1,-1)$, whose square is $\mathbf{I}_3$.)

10.7.6 Rigid motions

We assumed linearity from the start. It is worth knowing that we did not have to: for maps of $\mathbb{R}^n$ that fix the origin, preserving distance forces linearity.

Theorem 10.7.7 — Distance-Preserving Maps Are Affine

Let $f\colon\mathbb{R}^n\to\mathbb{R}^n$ be any function, not assumed linear, with

$$\|f(\mathbf{x})-f(\mathbf{y})\|=\|\mathbf{x}-\mathbf{y}\| \qquad \text{for all } \mathbf{x},\mathbf{y}\in\mathbb{R}^n.$$

(a) If $f(\mathbf{0})=\mathbf{0}$, then f is linear and orthogonal.

(b) In general, $f(\mathbf{x})=\mathbf{A}\mathbf{x}+\mathbf{b}$ for a unique $\mathbf{A}\in\mathrm{O}(n)$ and a unique $\mathbf{b}\in\mathbb{R}^n$.

Idea. Setting $\mathbf{y}=\mathbf{0}$ turns the hypothesis into "preserves norms", and expanding the squared distance then turns it into "preserves inner products" without any polarization at all. Once inner products are preserved, f sends the standard basis to an orthonormal basis, and Theorem 10.2.1 writes $f(\mathbf{x})$ as an explicit linear expression in the coordinates of $\mathbf{x}$. Part (b) is part (a) applied to $\mathbf{x}\mapsto f(\mathbf{x})-f(\mathbf{0})$.

Proof.

(a) Assume $f(\mathbf{0}) = \mathbf{0}$. Taking $\mathbf{y} = \mathbf{0}$ gives $\|f(\mathbf{x})\| = \|\mathbf{x}\|$ for all $\mathbf{x}$. Expanding both sides of the hypothesis with Theorem 10.1.2 (c),

$$\|f(\mathbf{x})\|^2 - 2\langle f(\mathbf{x}), f(\mathbf{y})\rangle + \|f(\mathbf{y})\|^2 = \|\mathbf{x}\|^2 - 2\langle \mathbf{x}, \mathbf{y}\rangle + \|\mathbf{y}\|^2,$$

and the four outer terms cancel in pairs, leaving

$$\langle f(\mathbf{x}), f(\mathbf{y})\rangle = \langle \mathbf{x}, \mathbf{y}\rangle \qquad \text{for all } \mathbf{x}, \mathbf{y}. \tag{$*$}$$

Put $\mathbf{f}_i \coloneqq f(\mathbf{e}_i)$. By $(*)$, $\langle \mathbf{f}_i, \mathbf{f}_j\rangle = \langle \mathbf{e}_i, \mathbf{e}_j\rangle = \delta_{ij}$, so $(\mathbf{f}_1, \dots, \mathbf{f}_n)$ is an orthonormal list of n vectors in $\mathbb{R}^n$, hence an orthonormal basis (it is independent by Theorem 10.1.4 and has $n = \dim \mathbb{R}^n$ elements). Now let $\mathbf{x} = (x_1, \dots, x_n)$ be arbitrary. By Theorem 10.2.1 applied to the basis $(\mathbf{f}_1, \dots, \mathbf{f}_n)$, and then by $(*)$,

$$f(\mathbf{x}) = \sum_{i=1}^{n} \langle f(\mathbf{x}), \mathbf{f}_i\rangle\, \mathbf{f}_i = \sum_{i=1}^{n} \langle f(\mathbf{x}), f(\mathbf{e}_i)\rangle\, \mathbf{f}_i = \sum_{i=1}^{n} \langle \mathbf{x}, \mathbf{e}_i\rangle\, \mathbf{f}_i = \sum_{i=1}^{n} x_i\, \mathbf{f}_i.$$

The right-hand side is linear in $\mathbf{x}$, so f is linear; and it preserves norms, so it is an isometry, hence orthogonal by Definition 10.7.2, since it maps $\mathbb{R}^n$ to $\mathbb{R}^n$.

(b) Put $\mathbf{b} \coloneqq f(\mathbf{0})$ and $g(\mathbf{x}) \coloneqq f(\mathbf{x}) - \mathbf{b}$. Then g preserves distances, since the translation cancels, and $g(\mathbf{0}) = \mathbf{0}$; by (a), g is orthogonal, say $g(\mathbf{x}) = \mathbf{A}\mathbf{x}$ with $\mathbf{A} \in \mathrm{O}(n)$, and $f(\mathbf{x}) = \mathbf{A}\mathbf{x} + \mathbf{b}$. For uniqueness, evaluating at $\mathbf{0}$ recovers $\mathbf{b}$, and then $\mathbf{A}\mathbf{x} = f(\mathbf{x}) - \mathbf{b}$ determines $\mathbf{A}$. This proves the theorem.

■

So the rigid motions of $\mathbb{R}^n$ are exactly the maps "rotate or reflect, then translate", and the linear ones are exactly the orthogonal maps. That is the sense in which $\mathrm{O}(n)$ is the symmetry group of Euclidean geometry, and it is why the same group reappears whenever a problem has a distance in it.

10.7.7 Exercises

10.7.7.1 A. Check your understanding

Exercise A1.

(a) Define an isometry $T \in \mathcal{L}(V, W)$, and state two conditions equivalent to it.

(b) What must be checked about a square matrix $\mathbf{A}$ to decide whether it is unitary? State the check in terms of its columns.

(c) True or false: every isometry is invertible. Justify your answer.

(d) True or false: if $\det \mathbf{A} = 1$ for $\mathbf{A} \in \mathrm{O}(n)$, then $\mathbf{A}$ fixes a non-zero vector. Justify your answer.

(e) Give the two families of matrices making up $\mathrm{O}(2)$, and say how the determinant distinguishes them.

(f) An operator T on a complex inner product space is unitary. Why must every eigenvalue of T lie on the unit circle?

Solution.

(a) $\|T\mathbf{v}\| = \|\mathbf{v}\|$ for every $\mathbf{v} \in V$ (Definition 10.7.1). Equivalent: $\langle T\mathbf{u}, T\mathbf{v}\rangle = \langle \mathbf{u}, \mathbf{v}\rangle$ for all $\mathbf{u}, \mathbf{v}$; and $T^*T = \mathrm{id}_V$ (Theorem 10.7.3).

(b) That its columns are orthonormal in F^n, that is $\mathbf{A}^*\mathbf{A} = \mathbf{I}_n$ (Theorem 10.7.3 (f)). For a square matrix this already gives $\mathbf{A}\mathbf{A}^* = \mathbf{I}_n$.

(c) False. $T\colon \mathbb{R}^2 \to \mathbb{R}^3$, $T(x_1, x_2) = (x_1, x_2, 0)$, is an isometry and is not surjective (Example (Isometries and Near-Isometries) (a)). An isometry is always injective, and it is invertible exactly when $\dim W = \dim V$.

(d) False for even n: $-\mathbf{I}_4 \in \mathrm{SO}(4)$ has determinant 1 and fixes only $\mathbf{0}$. It is true for odd n, though not by the argument of Theorem 10.7.6, which uses the $\mathrm{O}(2)$ classification of a 2-dimensional complement. The general reason is a count: the non-real eigenvalues of a real $\mathbf{A}$ come in conjugate pairs $\lambda, \overline{\lambda}$ with $\lambda\overline{\lambda} = |\lambda|^2 = 1$ for an isometry, so they contribute 1 to the determinant and an even number to the count. With n odd, an odd number of eigenvalues are real, each ± 1, and their product is $\det \mathbf{A} = 1$; an odd number of factors ± 1 with product 1 cannot all be -1, so 1 is an eigenvalue and some non-zero vector is fixed.

(e) The rotations $\mathbf{R}_\theta$, with determinant 1, and the reflections $\mathbf{M}_\theta$, with determinant -1 (Theorem 10.7.5).

(f) A unitary operator is an isometry, so Proposition 10.7.1 applies: $|\lambda| = 1$.

10.7.7.2 B. Practice

Exercise B1: Determine which are unitary.

Determine which of the following matrices are orthogonal or unitary. Justify your answer; for those that are not, name the failing condition.

(a) $\frac{1}{3}\begin{pmatrix} 2 & -2 & 1 \\ 1 & 2 & 2 \\ -2 & -1 & 2 \end{pmatrix}$ over $\mathbb{R}$.

(b) $\frac{1}{\sqrt{2}}\begin{pmatrix} 1 & i \\ i & 1 \end{pmatrix}$ over $\mathbb{C}$.

(c) $\begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$ over $\mathbb{R}$.

(d) $\frac{1}{5}\begin{pmatrix} 3 & 4 \\ 4 & 3 \end{pmatrix}$ over $\mathbb{R}$.

Solution.

(a) Orthogonal, as computed in Example (Axis and Angle of a Rotation): the three columns are orthonormal.

(b) Unitary. The columns are $\frac{1}{\sqrt{2}}(1, i)$ and $\frac{1}{\sqrt{2}}(i, 1)$, of norm $\frac{1}{\sqrt{2}}\sqrt{1+1} = 1$, and their inner product is

$$\tfrac{1}{2}\big(1 \cdot \overline{i} + i \cdot \overline{1}\big) = \tfrac{1}{2}(-i + i) = 0.$$

So $\mathbf{A}^*\mathbf{A} = \mathbf{I}_2$. (It is unitary but not orthogonal, since it is not real.)

(c) Not orthogonal. The second column $(1, 1)$ has norm $\sqrt{2} \neq 1$, so the columns are not orthonormal. Equivalently, the map stretches $\mathbf{e}_2$.

(d) Not orthogonal. Both columns are unit vectors, $\frac{1}{5}(3,4)$ and $\frac{1}{5}(4,3)$, but their inner product is $\frac{1}{25}(12+12) = \frac{24}{25} \neq 0$. Unit columns are not enough; they must also be orthogonal. (Its determinant is $\frac{1}{25}(9-16) = -\frac{7}{25}$, neither 1 nor -1, which confirms it by Proposition 10.7.4.)

Exercise B2: Name the plane isometry.

Each of the following lies in $\mathrm{O}(2)$. Decide whether it is a rotation or a reflection, and give the angle of rotation or the mirror line.

(a) $\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$.

(b) $\frac{1}{\sqrt{2}}\begin{pmatrix} 1 & 1 \\ -1 & 1 \end{pmatrix}$.

(c) $\frac{1}{13}\begin{pmatrix} 5 & 12 \\ 12 & -5 \end{pmatrix}$.

Solution.

(a) Determinant -1, so a reflection. $\mathbf{Ax} = \mathbf{x}$ reads $x_2 = x_1$, so the mirror is $L = \operatorname{span}\big((1,1)\big)$, the line $x_2 = x_1$. Check: $\mathbf{A}(1,-1) = (-1,1) = -(1,-1)$.

(b) Determinant $\frac{1}{2}(1+1) = 1$, so a rotation $\mathbf{R}_\theta$. Comparing with $\mathbf{R}_\theta$, $\cos\theta = \frac{1}{\sqrt{2}}$ and $\sin\theta = -\frac{1}{\sqrt{2}}$, so $\theta = -\pi/4$: a clockwise half of a right angle.

(c) Determinant $\frac{1}{169}(-25-144) = -1$, so a reflection. $\mathbf{Ax} = \mathbf{x}$ reads $5x_1+12x_2 = 13x_1$, that is $3x_2 = 2x_1$, so $L = \operatorname{span}\big((3,2)\big)$. Check: $\mathbf{A}(3,2) = \frac{1}{13}(15+24, 36-10) = (3,2)$.

Exercise B3: Permutations are orthogonal.

Let $\sigma \in S_n$ and let $\mathbf{P}_\sigma \in M_n(\mathbb{R})$ be its permutation matrix (Definition 2.6.2), whose j-th column is $\mathbf{e}_{\sigma(j)}$.

(a) Prove that $\mathbf{P}_\sigma \in \mathrm{O}(n)$.

(b) Deduce that $\det \mathbf{P}_\sigma = \pm 1$, and identify the sign.

(c) Show that $\mathbf{P}_\sigma^{-1} = \mathbf{P}_\sigma^{\top} = \mathbf{P}_{\sigma^{-1}}$.

Solution.

(a) Column j of $\mathbf{P}_\sigma$ is $\mathbf{e}_{\sigma(j)}$, by Definition 2.6.2. So each column is a unit vector, and for $i \neq j$ the columns $\mathbf{e}_{\sigma(i)}$ and $\mathbf{e}_{\sigma(j)}$ are distinct standard basis vectors, because σ is injective, hence orthogonal. By Theorem 10.7.3 (f), $\mathbf{P}_\sigma \in \mathrm{O}(n)$.

(b) By Proposition 10.7.4 (b), $\det \mathbf{P}_\sigma = \pm 1$. The sign is $\operatorname{sgn}(\sigma)$: permuting the columns of $\mathbf{I}_n$ by σ multiplies the determinant by $\operatorname{sgn}(\sigma)$ (Theorem 6.2.1), and $\det \mathbf{I}_n = 1$.

(c) $\mathbf{P}_\sigma^{-1} = \mathbf{P}_\sigma^{\top}$ holds because $\mathbf{P}_\sigma$ is orthogonal, by (a). For the second equality, $(\mathbf{P}_\sigma)_{ij} = 1$ exactly when $i = \sigma(j)$, so $(\mathbf{P}_\sigma^{\top})_{ij} = (\mathbf{P}_\sigma)_{ji} = 1$ exactly when $j = \sigma(i)$, that is when $i = \sigma^{-1}(j)$; and that is the defining condition for $(\mathbf{P}_{\sigma^{-1}})_{ij} = 1$.

10.7.7.3 C. Going deeper

Exercise C1: Determinant as a homomorphism.

(a) Prove that $\det\colon \mathrm{O}(n) \to \{1, -1\}$ is a surjective group homomorphism with kernel $\mathrm{SO}(n)$, and deduce that exactly half of $\mathrm{O}(n)$ has determinant -1, in the sense that $\mathrm{O}(n)$ is the disjoint union of $\mathrm{SO}(n)$ and one coset $\mathbf{A}_0\,\mathrm{SO}(n)$.

(b) Prove that $\det\colon \mathrm{U}(n) \to \{z \in \mathbb{C} : |z| = 1\}$ is a surjective group homomorphism.

(c) Describe $\mathrm{O}(1)$ and $\mathrm{U}(1)$ completely.

Solution.

(a) $\det$ is multiplicative (Theorem 6.5.4) and takes only the values ± 1 on $\mathrm{O}(n)$ (Proposition 10.7.4 (b)), so it is a homomorphism into $\{1, -1\}$. It is surjective: $\det \mathbf{I}_n = 1$, and $\mathbf{A}_0 := \mathrm{diag}(-1, 1, \dots, 1)$ is orthogonal, since its columns are $\pm\mathbf{e}_i$, with $\det \mathbf{A}_0 = -1$. Its kernel is $\{\mathbf{A} : \det \mathbf{A} = 1\} = \mathrm{SO}(n)$ by definition. If $\det \mathbf{A} = -1$ then $\det(\mathbf{A}_0^{-1}\mathbf{A}) = 1$, so $\mathbf{A} \in \mathbf{A}_0\,\mathrm{SO}(n)$; and no matrix has both determinants, so the union is disjoint.

(b) Multiplicativity again, and $|\det \mathbf{A}| = 1$ on $\mathrm{U}(n)$ by Proposition 10.7.4 (b). For surjectivity, given z with $|z| = 1$, the matrix $\mathrm{diag}(z, 1, \dots, 1)$ has orthonormal columns, hence lies in $\mathrm{U}(n)$, and its determinant is z (Theorem 6.4.6).

(c) A 1×1 matrix (a) satisfies $\overline{a}a = 1$ exactly when $|a| = 1$. So $\mathrm{U}(1)$ is the unit circle of $\mathbb{C}$ and $\mathrm{O}(1) = \{(1), (-1)\}$. Consistently, $\mathrm{SO}(1) = \{(1)\}$ is trivial.

Exercise C2: Linearity is a hypothesis, not a consequence.

(a) Let $c\colon \mathbb{C} \to \mathbb{C}$ be $c(z) = \overline{z}$, where $\mathbb{C}$ carries $\langle z, w\rangle = z\overline{w}$. Show that $\|c(z)\| = \|z\|$ for every z, that c is not linear over $\mathbb{C}$, and that c does not preserve the inner product. Which step of Theorem 10.7.3 fails?

(b) Let V be a **complex** inner product space and let $T \in \mathcal{L}(V)$ satisfy $\langle T\mathbf{v}, \mathbf{v}\rangle = 0$ for every $\mathbf{v} \in V$. Prove that $T = 0$.

(c) Show that (b) fails over $\mathbb{R}$ by exhibiting a non-zero $T \in \mathcal{L}(\mathbb{R}^2)$ with $\langle T\mathbf{v}, \mathbf{v}\rangle = 0$ for all $\mathbf{v}$.

Hint for (b): apply the hypothesis to $\mathbf{v} = \mathbf{u} + \mathbf{w}$ *and to* $\mathbf{v} = \mathbf{u} + i\mathbf{w}$.

Solution.

(a) $\|c(z)\| = |\overline{z}| = |z| = \|z\|$. But $c(iz) = \overline{iz} = -i\overline{z} = -ic(z) \neq ic(z)$ unless $z = 0$, so c is not $\mathbb{C}$-linear. And $\langle c(1), c(i)\rangle = \langle 1, -i\rangle = 1 \cdot \overline{-i} = i$, while $\langle 1, i\rangle = -i$. The proof of (a) $\Rightarrow$ (b) in Theorem 10.7.3 uses $T(\mathbf{u} + i^k\mathbf{v}) = T\mathbf{u} + i^k T\mathbf{v}$, which is exactly what c does not satisfy.

(b) Let $\mathbf{u}, \mathbf{w} \in V$. Applying the hypothesis to $\mathbf{u} + \mathbf{w}$ and expanding both slots,

$$\begin{aligned} 0 = \langle T(\mathbf{u} + \mathbf{w}), \mathbf{u} + \mathbf{w}\rangle &= \langle T\mathbf{u}, \mathbf{u}\rangle + \langle T\mathbf{u}, \mathbf{w}\rangle + \langle T\mathbf{w}, \mathbf{u}\rangle + \langle T\mathbf{w}, \mathbf{w}\rangle \\ &= \langle T\mathbf{u}, \mathbf{w}\rangle + \langle T\mathbf{w}, \mathbf{u}\rangle. \end{aligned} \tag{1}$$

Applying it to $\mathbf{u} + i\mathbf{w}$, and using $\langle T\mathbf{u}, i\mathbf{w}\rangle = -i\langle T\mathbf{u}, \mathbf{w}\rangle$, $\langle T(i\mathbf{w}), \mathbf{u}\rangle = i\langle T\mathbf{w}, \mathbf{u}\rangle$

and $\langle T(i\mathbf{w}), i\mathbf{w}\rangle = i\bar{i}\langle T\mathbf{w}, \mathbf{w}\rangle = 0$,

$$0 = -i\langle T\mathbf{u}, \mathbf{w}\rangle + i\langle T\mathbf{w}, \mathbf{u}\rangle.$$

Multiplying by i gives

$$\langle T\mathbf{u}, \mathbf{w}\rangle - \langle T\mathbf{w}, \mathbf{u}\rangle = 0. \tag{2}$$

Adding (1) and (2), $2\langle T\mathbf{u}, \mathbf{w}\rangle = 0$, so $\langle T\mathbf{u}, \mathbf{w}\rangle = 0$ for all $\mathbf{u}, \mathbf{w}$. Taking $\mathbf{w} = T\mathbf{u}$ gives $\|T\mathbf{u}\|^2 = 0$, so $T\mathbf{u} = \mathbf{0}$ for every $\mathbf{u}$, that is $T = 0$.

(c) Let T be the rotation $\mathbf{R}_{\pi/2}$, that is $T(x_1, x_2) = (-x_2, x_1)$. Then $\langle T\mathbf{x}, \mathbf{x}\rangle = -x_2x_1 + x_1x_2 = 0$ for every $\mathbf{x}$, and $T \neq 0$. The complex proof breaks down because the second equation is unavailable: there is no i to substitute.

Exercise C3: Two reflections make a rotation.

Let $\alpha, \beta \in \mathbb{R}$ and let $\mathbf{M}_\alpha, \mathbf{M}_\beta \in \mathrm{O}(2)$ be the reflections of Theorem 10.7.5, in the lines L_α and L_β at angles $\alpha/2$ and $\beta/2$.

(a) Prove that $\mathbf{M}_\alpha\mathbf{M}_\beta = \mathbf{R}_{\alpha-\beta}$.

(b) Deduce that the composite of the reflections in two lines through the origin is the rotation by **twice** the angle from the second line to the first, and that every rotation of the plane is a product of two reflections.

(c) Deduce that $\mathrm{O}(2)$ is not abelian, by computing $\mathbf{M}_\beta\mathbf{M}_\alpha$.

Solution.

(a) Multiplying out,

$$\mathbf{M}_\alpha\mathbf{M}_\beta = \begin{pmatrix} \cos\alpha & \sin\alpha \\ \sin\alpha & -\cos\alpha \end{pmatrix}\begin{pmatrix} \cos\beta & \sin\beta \\ \sin\beta & -\cos\beta \end{pmatrix} = \begin{pmatrix} c & -s \\ s & c \end{pmatrix},$$

where $c = \cos\alpha\cos\beta + \sin\alpha\sin\beta = \cos(\alpha-\beta)$ and $s = \sin\alpha\cos\beta - \cos\alpha\sin\beta = \sin(\alpha-\beta)$, by the subtraction formulas. The top-right entry is $\cos\alpha\sin\beta - \sin\alpha\cos\beta = -\sin(\alpha-\beta)$, as displayed. So $\mathbf{M}_\alpha\mathbf{M}_\beta = \mathbf{R}_{\alpha-\beta}$.

(b) The angle from L_β to L_α is $\frac{\alpha}{2} - \frac{\beta}{2}$, and (a) says the composite is the rotation by $\alpha-\beta$, twice that. Conversely, given θ, choose $\alpha = \theta$ and $\beta = 0$; then $\mathbf{R}_\theta = \mathbf{M}_\theta\mathbf{M}_0$, a product of two reflections.

(c) By (a) with the roles exchanged, $\mathbf{M}_\beta\mathbf{M}_\alpha = \mathbf{R}_{\beta-\alpha} = \mathbf{R}_{\alpha-\beta}^{-1}$. These two agree only when $\mathbf{R}_{\alpha-\beta}^2 = \mathbf{I}$, that is when $\alpha-\beta$ is a multiple of π. Taking $\alpha = \pi/2$ and $\beta = 0$ gives $\mathbf{M}_{\pi/2}\mathbf{M}_0 = \mathbf{R}_{\pi/2} \neq \mathbf{R}_{-\pi/2} = \mathbf{M}_0\mathbf{M}_{\pi/2}$, so $\mathrm{O}(2)$ is not abelian.

10.8 QR, Householder and Hessenberg

Section 2 turned a basis into an orthonormal basis one vector at a time, and every step was bookkeeping: each new vector recorded in terms of those already produced. Collect that bookkeeping into a matrix and the Gram–Schmidt process becomes a **factorization A = QR** — an orthogonal counterpart of the **LU** factorization of Definition 2.6.1. This section proves it and

its uniqueness, then builds it a second time out of reflections, a route that survives dependent columns. The same reflections, applied on **both** sides, bring any square matrix to an almost-triangular form by a unitary similarity. Throughout, F is $\mathbb{R}$ or $\mathbb{C}$, and F^m carries the standard inner product, linear in the first slot.

10.8.1 Gram–Schmidt in matrix form

Let $\mathbf{A} \in M_{m\times n}(F)$ have columns $\mathbf{a}_1, \dots, \mathbf{a}_n$, and suppose they are linearly independent. Apply Theorem 10.2.2 to the list $(\mathbf{a}_1, \dots, \mathbf{a}_n)$. It returns an orthonormal list $(\mathbf{q}_1, \dots, \mathbf{q}_n)$ in F^m with

$$\operatorname{span}(\mathbf{q}_1, \dots, \mathbf{q}_k) = \operatorname{span}(\mathbf{a}_1, \dots, \mathbf{a}_k)$$

for every k. In particular $\mathbf{a}_k$ lies in $\operatorname{span}(\mathbf{q}_1, \dots, \mathbf{q}_k)$, and Theorem 10.2.1 (a), applied inside that subspace, expands it:

$$\mathbf{a}_k = \sum_{i=1}^{k} \langle \mathbf{a}_k, \mathbf{q}_i \rangle \, \mathbf{q}_i \qquad (k = 1, \dots, n). \tag{$*$}$$

Now read $(*)$ as a matrix product. Put $\mathbf{Q} = (\mathbf{q}_1 \mid \cdots \mid \mathbf{q}_n) \in M_{m\times n}(F)$ and let $\mathbf{R} \in M_n(F)$ have entries

$$r_{ik} = \begin{cases} \langle \mathbf{a}_k, \mathbf{q}_i \rangle, & i \le k, \\ 0, & i > k. \end{cases}$$

Then $\mathbf{R}$ is upper triangular (Definition 0.9.5), and $(*)$ says that the k-th column of $\mathbf{A}$ equals $\mathbf{Q}$ times the k-th column of $\mathbf{R}$. That is exactly $\mathbf{A} = \mathbf{QR}$. **Nothing has been computed; the factorization is the Gram–Schmidt output, rewritten.**

Two features of the rewriting matter later. First the diagonal: in the notation of Theorem 10.2.2, $\mathbf{q}_k = \mathbf{w}_k / \|\mathbf{w}_k\|$ with $\mathbf{w}_k = \mathbf{a}_k - \sum_{i<k} \langle \mathbf{a}_k, \mathbf{q}_i \rangle \mathbf{q}_i$, so comparing with $(*)$ gives

$$r_{kk} = \langle \mathbf{a}_k, \mathbf{q}_k \rangle = \|\mathbf{w}_k\| > 0,$$

strictly positive because $\mathbf{w}_k \neq \mathbf{0}$. Second, $\mathbf{R}$ is recoverable from $\mathbf{Q}$ and $\mathbf{A}$: since the columns of $\mathbf{Q}$ are orthonormal,

$$(\mathbf{Q}^*\mathbf{Q})_{ij} = \sum_{p=1}^{m} \overline{q_{pi}}\, q_{pj} = \langle \mathbf{q}_j, \mathbf{q}_i \rangle = \delta_{ij},$$

by Definition 10.1.2, so $\mathbf{Q}^*\mathbf{Q} = \mathbf{I}_n$ and $\mathbf{R} = \mathbf{Q}^*\mathbf{A}$.

Theorem 10.8.1 — QR Factorization

Let $\mathbf{A} \in M_{m\times n}(F)$ have **linearly independent** columns. Then there are matrices $\mathbf{Q} \in M_{m\times n}(F)$ and $\mathbf{R} \in M_n(F)$ with

(a) the columns of $\mathbf{Q}$ orthonormal, equivalently $\mathbf{Q}^*\mathbf{Q} = \mathbf{I}_n$;

(b) $\mathbf{R}$ upper triangular with **positive real** diagonal entries;

(c) $\mathbf{A} = \mathbf{QR}$.

Moreover $\mathbf{Q}$ and $\mathbf{R}$ are **unique**: any pair satisfying (a), (b), (c) is this one. The pair $(\mathbf{Q}, \mathbf{R})$ is the **QR factorization** of $\mathbf{A}$.

Idea. Existence is the paragraph above: run Gram–Schmidt and read off the coefficients. For uniqueness, suppose $\mathbf{Q}_1\mathbf{R}_1 = \mathbf{Q}_2\mathbf{R}_2$. We cannot cancel $\mathbf{Q}$, which is not square, but $\mathbf{Q}^*\mathbf{Q} = \mathbf{I}$ turns $\mathbf{A}^*\mathbf{A}$ into $\mathbf{R}^*\mathbf{R}$ and makes the $\mathbf{Q}$'s vanish. That leaves $\mathbf{R}_1^*\mathbf{R}_1 = \mathbf{R}_2^*\mathbf{R}_2$, so the matrix $\mathbf{S}$ carrying $\mathbf{R}_1$ to $\mathbf{R}_2$ is upper triangular with positive diagonal and satisfies $\mathbf{S}^*\mathbf{S} = \mathbf{I}$. Such a matrix has no room to be anything but $\mathbf{I}$: column by column, orthogonality to the earlier columns kills every entry above the diagonal.

Proof. Existence. Apply Theorem 10.2.2 to the columns of $\mathbf{A}$, which is legitimate because they are independent, and define $\mathbf{Q}$ and $\mathbf{R}$ as above. Then (a) holds by orthonormality of the output, (b) holds because $r_{kk} = \|\mathbf{w}_k\| > 0$, and (c) is $(*)$.

Uniqueness. Suppose $\mathbf{A} = \mathbf{Q}_1\mathbf{R}_1 = \mathbf{Q}_2\mathbf{R}_2$ with both pairs satisfying (a) and (b). Each $\mathbf{R}_t$ has non-zero diagonal entries, hence is invertible by Lemma 2.6.2. Using $\mathbf{Q}_t^*\mathbf{Q}_t = \mathbf{I}_n$ twice,

$$\mathbf{R}_1^*\mathbf{R}_1 = \mathbf{R}_1^*\mathbf{Q}_1^*\mathbf{Q}_1\mathbf{R}_1 = \mathbf{A}^*\mathbf{A} = \mathbf{R}_2^*\mathbf{Q}_2^*\mathbf{Q}_2\mathbf{R}_2 = \mathbf{R}_2^*\mathbf{R}_2.$$

Put $\mathbf{S} = \mathbf{R}_2\mathbf{R}_1^{-1}$, so that $\mathbf{R}_2 = \mathbf{S}\mathbf{R}_1$. The matrix $\mathbf{R}_1^{-1}$ is upper triangular: its j-th column is the solution $\mathbf{x}$ of $\mathbf{R}_1\mathbf{x} = \mathbf{e}_j$, and solving from the bottom row upward gives $x_i = 0$ for every $i > j$, exactly as in the proof of Lemma 2.6.2. Hence $\mathbf{S}$ is upper triangular, being a product of upper triangular matrices: in $(\mathbf{S})_{ij} = \sum_k (\mathbf{R}_2)_{ik}(\mathbf{R}_1^{-1})_{kj}$ a term can be non-zero only when $i \le k$ and $k \le j$, which is impossible for $i > j$, and for $i = j$ only the term $k = i$ survives. So its diagonal entries are $(\mathbf{S})_{kk} = (\mathbf{R}_2)_{kk}(\mathbf{R}_1)_{kk}^{-1} > 0$, a quotient of positive reals. Substituting $\mathbf{R}_2 = \mathbf{S}\mathbf{R}_1$ into the display gives $\mathbf{R}_1^*\mathbf{R}_1 = \mathbf{R}_1^*\mathbf{S}^*\mathbf{S}\mathbf{R}_1$, and multiplying by $(\mathbf{R}_1^*)^{-1} = (\mathbf{R}_1^{-1})^*$ on the left and $\mathbf{R}_1^{-1}$ on the right leaves

$$\mathbf{S}^*\mathbf{S} = \mathbf{I}_n.$$

Claim. An upper triangular $\mathbf{S} \in M_n(F)$ with $\mathbf{S}^*\mathbf{S} = \mathbf{I}_n$ and positive real diagonal entries is $\mathbf{I}_n$.

Proof. Write $\mathbf{s}_1, \dots, \mathbf{s}_n$ for the columns of $\mathbf{S}$. As computed before the theorem, $\mathbf{S}^*\mathbf{S} = \mathbf{I}_n$ says $\langle \mathbf{s}_j, \mathbf{s}_i \rangle = \delta_{ij}$. We show $\mathbf{s}_j = \mathbf{e}_j$ by induction on j. Let $1 \le j \le n$ and suppose $\mathbf{s}_i = \mathbf{e}_i$ for every $i < j$ (no assumption when $j = 1$). For $i < j$,

$$0 = \langle \mathbf{s}_j, \mathbf{s}_i \rangle = \langle \mathbf{s}_j, \mathbf{e}_i \rangle = s_{ij},$$

so every entry of $\mathbf{s}_j$ above the diagonal vanishes; and $s_{ij} = 0$ for $i > j$ because $\mathbf{S}$ is upper triangular. Hence $\mathbf{s}_j = s_{jj}\mathbf{e}_j$, and $1 = \langle \mathbf{s}_j, \mathbf{s}_j \rangle = |s_{jj}|^2$ forces $|s_{jj}| = 1$. Since $s_{jj} > 0$, this gives $s_{jj} = 1$ and $\mathbf{s}_j = \mathbf{e}_j$.

■

By the Claim, $\mathbf{S} = \mathbf{I}_n$, so $\mathbf{R}_2 = \mathbf{R}_1$ and therefore $\mathbf{Q}_2 = \mathbf{A}\mathbf{R}_2^{-1} = \mathbf{A}\mathbf{R}_1^{-1} = \mathbf{Q}_1$. This proves uniqueness.

■

The positivity in (b) is a normalization and nothing deeper: without it, scaling $\mathbf{q}_k$ by any c of modulus 1 and row k of $\mathbf{R}$ by $\bar{c}$ gives another factorization. Exercise (C1: All the QR factorizations of a matrix) describes all of them.

Warning. **In $\mathbf{A} = \mathbf{QR}$ the matrix $\mathbf{Q}$ is usually not square, and $\mathbf{QQ}^* \neq \mathbf{I}$.** Only $\mathbf{Q}^*\mathbf{Q} = \mathbf{I}_n$ holds. For the 3×2 matrix of Example (A 3×2 QR, and a least-squares problem) below,

$$\mathbf{QQ}^* = \tfrac{1}{18}\begin{pmatrix} 2 & 4 & 4 \\ 4 & 17 & -1 \\ 4 & -1 & 17 \end{pmatrix},$$

whose trace is 2, not 3. This is the "identity on what?" trap of Theorem 10.7.3: the columns of $\mathbf{Q}$ are an orthonormal basis of a **plane**, and $\mathbf{QQ}^*$ is the orthogonal projection onto it (Theorem 10.3.3).

Quick check. Each factor of a QR factorization is recoverable from the other: $\mathbf{R} = \mathbf{Q}^*\mathbf{A}$ and $\mathbf{Q} = \mathbf{AR}^{-1}$. One of the two recoveries needs an invertibility hypothesis and the other does not. Which, and why?

Solution. The second. Multiplying $\mathbf{A} = \mathbf{QR}$ on the left by $\mathbf{Q}^*$ gives $\mathbf{Q}^*\mathbf{QR} = \mathbf{R}$, which uses only $\mathbf{Q}^*\mathbf{Q} = \mathbf{I}_n$: nothing is inverted, and $\mathbf{Q}$ is not even square. Multiplying on the right by $\mathbf{R}^{-1}$ presupposes that $\mathbf{R}$ is invertible — true by Lemma 2.6.2, but only because clause (b) makes the diagonal positive.

10.8.2 Least squares through QR

An inconsistent system $\mathbf{Ax} = \mathbf{b}$ was handled in Section 4 by the normal equations $\mathbf{A}^*\mathbf{Ax} = \mathbf{A}^*\mathbf{b}$ (Theorem 10.4.2). When the columns of $\mathbf{A}$ are independent, the QR factorization simplifies those equations to a triangular system.

Substituting $\mathbf{A} = \mathbf{QR}$ and using $\mathbf{Q}^*\mathbf{Q} = \mathbf{I}_n$,

$$\mathbf{A}^*\mathbf{A} = \mathbf{R}^*\mathbf{Q}^*\mathbf{QR} = \mathbf{R}^*\mathbf{R}, \qquad \mathbf{A}^*\mathbf{b} = \mathbf{R}^*\mathbf{Q}^*\mathbf{b},$$

so the normal equations read $\mathbf{R}^*\mathbf{Rx} = \mathbf{R}^*\mathbf{Q}^*\mathbf{b}$. Now $\mathbf{R}$ is invertible by Lemma 2.6.2, hence so is $\mathbf{R}^*$, with $(\mathbf{R}^*)^{-1} = (\mathbf{R}^{-1})^*$ — conjugate-transpose $\mathbf{RR}^{-1} = \mathbf{I}_n$. So $\mathbf{R}^*$ cancels:

$$\mathbf{Rx} = \mathbf{Q}^*\mathbf{b}. \tag{$\dagger$}$$

By Corollary 10.4.4 the least-squares solution is unique here, and ($\dagger$) is a triangular system, solved by back substitution. The deeper reason to prefer it is not the operation count: forming $\mathbf{A}^*\mathbf{A}$ squares the sensitivity of the problem to rounding, while ($\dagger$) never forms that product at all. Chapter 23 makes "sensitivity" precise and proves the comparison; here we record only the practice.

Example. (A 3×2 QR, and a least-squares problem)

Let

$$\mathbf{A} = \begin{pmatrix} 1 & 1 \\ 2 & 1 \\ 2 & 3 \end{pmatrix}, \qquad \mathbf{b} = \begin{pmatrix} 1 \\ 1 \\ 1 \end{pmatrix}.$$

(a) Find the QR factorization of $\mathbf{A}$.

(b) Find the $\mathbf{x} \in \mathbb{R}^2$ minimizing $\|\mathbf{Ax} - \mathbf{b}\|$, using (a).

Solution.

(a) Write $\mathbf{a}_1 = (1,2,2)$ and $\mathbf{a}_2 = (1,1,3)$. They are independent, since neither is a multiple of the other.
Step 1. $\|\mathbf{a}_1\|^2 = 1+4+4 = 9$, so $r_{11} = 3$ and $\mathbf{q}_1 = \tfrac{1}{3}(1,2,2)$.
Step 2. $r_{12} = \langle \mathbf{a}_2, \mathbf{q}_1 \rangle = \tfrac{1}{3}(1+2+6) = 3$, so

$$\mathbf{w}_2 = (1,1,3) - 3 \cdot \tfrac{1}{3}(1,2,2) = (0,-1,1),$$

with $\|\mathbf{w}_2\| = \sqrt{2} = r_{22}$ and $\mathbf{q}_2 = \tfrac{1}{\sqrt{2}}(0,-1,1)$. Hence

$$\mathbf{Q} = \begin{pmatrix} \tfrac{1}{3} & 0 \\ \tfrac{2}{3} & -\tfrac{1}{\sqrt{2}} \\ \tfrac{2}{3} & \tfrac{1}{\sqrt{2}} \end{pmatrix}, \qquad \mathbf{R} = \begin{pmatrix} 3 & 3 \\ 0 & \sqrt{2} \end{pmatrix}.$$

Check. $\mathbf{QR}$ has first column $3\mathbf{q}_1 = (1,2,2)$ and second column $3\mathbf{q}_1 + \sqrt{2}\,\mathbf{q}_2 = (1,2,2) + (0,-1,1) = (1,1,3)$, which is $\mathbf{A}$.

(b) By (†) we need $\mathbf{Q}^*\mathbf{b}$. Here $\langle \mathbf{b}, \mathbf{q}_1 \rangle = \tfrac{1}{3}(1+2+2) = \tfrac{5}{3}$ and $\langle \mathbf{b}, \mathbf{q}_2 \rangle = \tfrac{1}{\sqrt{2}}(0-1+1) = 0$, so the system is

$$\begin{pmatrix} 3 & 3 \\ 0 & \sqrt{2} \end{pmatrix} \mathbf{x} = \begin{pmatrix} \tfrac{5}{3} \\ 0 \end{pmatrix}.$$

Back substitution gives $\sqrt{2}\,x_2 = 0$, so $x_2 = 0$, and then $3x_1 = \tfrac{5}{3}$, so $x_1 = \tfrac{5}{9}$. The minimizer is $\mathbf{x} = (\tfrac{5}{9}, 0)$.

Check against the normal equations. $\mathbf{A}^{\top}\mathbf{A} = \begin{pmatrix} 9 & 9 \\ 9 & 11 \end{pmatrix}$ and $\mathbf{A}^{\top}\mathbf{b} = (5,5)$. Subtracting the first equation from the second gives $2x_2 = 0$, and then $9x_1 = 5$. The same answer, with the same arithmetic done in a worse order.

10.8.3 Reflections

Gram–Schmidt builds $\mathbf{Q}$ out of the columns of $\mathbf{A}$. There is an entirely different route to a triangular $\mathbf{R}$, modeled on elimination: hit $\mathbf{A}$ on the left with simple matrices that create zeros, one column at a time, and collect the inverses. Chapter 2 used shears and got $\mathbf{A} = \mathbf{LU}$; if every matrix we hit $\mathbf{A}$ with is **unitary** instead, the collected product is unitary and we get $\mathbf{A} = \mathbf{QR}$. Which unitary matrices are simple enough? A rotation in the plane of two coordinates is one answer, taken up below. The more efficient answer is a reflection, because one reflection can flatten an entire column at once.

A reflection in a hyperplane sends a vector to its mirror image: keep the part perpendicular to $\mathbf{w}$*, and reverse the part along* $\mathbf{w}$*.*

Definition 10.8.1 — Householder Reflection

Let $\mathbf{w} \in F^m$ be **non-zero**. The **Householder reflection** determined by $\mathbf{w}$ is

$$\mathbf{H}_{\mathbf{w}} = \mathbf{I}_m - \frac{2\,\mathbf{w}\mathbf{w}^*}{\|\mathbf{w}\|^2} \in M_m(F).$$

In words: $\mathbf{w}\mathbf{w}^*$ is an $m \times m$ matrix (a column times a row), and for any $\mathbf{v} \in F^m$ the product $\mathbf{w}^*\mathbf{v}$ is the scalar $\sum_p \overline{w_p} v_p = \langle \mathbf{v}, \mathbf{w} \rangle$. So the definition says

$$\mathbf{H}_\mathbf{w}\mathbf{v} = \mathbf{v} - 2\,\frac{\langle \mathbf{v}, \mathbf{w} \rangle}{\|\mathbf{w}\|^2}\,\mathbf{w} = \mathbf{v} - 2P_{\mathrm{span}(\mathbf{w})}\mathbf{v}, \tag{‡}$$

where the last equality is Theorem 10.3.3 with the orthonormal basis $(\mathbf{w}/\|\mathbf{w}\|)$ of the line $\mathrm{span}(\mathbf{w})$. Writing $\mathbf{v} = P_{\mathrm{span}(\mathbf{w})}\mathbf{v} + (\mathbf{v} - P_{\mathrm{span}(\mathbf{w})}\mathbf{v})$ as in Theorem 10.3.2, we see that $\mathbf{H}_\mathbf{w}$ keeps the component of $\mathbf{v}$ in $\mathrm{span}(\mathbf{w})^\perp$ and reverses the component along $\mathbf{w}$. That is a mirror reflection in the hyperplane $\mathrm{span}(\mathbf{w})^\perp$.

Note at once that $\mathbf{H}_{c\mathbf{w}} = \mathbf{H}_\mathbf{w}$ for every non-zero scalar c, since $(c\mathbf{w})(c\mathbf{w})^* = |c|^2\mathbf{w}\mathbf{w}^*$ and $\|c\mathbf{w}\|^2 = |c|^2\|\mathbf{w}\|^2$. **Only the line through $\mathbf{w}$ matters.**

Examples.

- **The smallest case.** In F^1 take $\mathbf{w} = 1$: then $\mathbf{H}_\mathbf{w} = -1$, the map $x \mapsto -x$. The "hyperplane" is $\{0\}$, and this is the only non-trivial isometry of the line.
- **A coordinate reflection.** In $\mathbb{R}^2$ take $\mathbf{w} = \mathbf{e}_2$, so $\mathbf{w}\mathbf{w}^\top = \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix}$ and $\mathbf{H}_\mathbf{w} = \mathrm{diag}(1, -1)$: the reflection in the x-axis.
- **A diagonal reflection.** In $\mathbb{R}^2$ take $\mathbf{w} = (1, -1)$, so $\|\mathbf{w}\|^2 = 2$ and $\mathbf{H}_\mathbf{w} = \mathbf{I}_2 - \begin{pmatrix} 1 & -1 \\ -1 & 1 \end{pmatrix} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$, which swaps the coordinates. It is the reflection in the line $y = x$, and $\mathrm{span}(\mathbf{w})^\perp$ is that line.
- **A complex one.** In $\mathbb{C}^m$ take $\mathbf{w} = \mathbf{e}_1$: then $\mathbf{H}_\mathbf{w} = \mathrm{diag}(-1, 1, \ldots, 1)$, over either field.

Non-example by minimal change. Drop the factor 2: the matrix $\mathbf{I}_m - \mathbf{w}\mathbf{w}^*/\|\mathbf{w}\|^2$ is $\mathbf{I}_m - P_{\mathrm{span}(\mathbf{w})}$, the orthogonal projection onto $\mathrm{span}(\mathbf{w})^\perp$. It is Hermitian, as $\mathbf{H}_\mathbf{w}$ is, but **not** unitary and not invertible: it sends $\mathbf{w}$ to $\mathbf{0}$. Halving the coefficient turns "reverse the component along $\mathbf{w}$" into "delete it", an isometry into a shadow.

Proposition 10.8.2 — Properties of a Householder Reflection

Let $\mathbf{w} \in F^m$ be non-zero and $\mathbf{H} = \mathbf{H}_\mathbf{w}$. Then

(a) $\mathbf{H}^* = \mathbf{H}$ ($\mathbf{H}$ is Hermitian);
(b) $\mathbf{H}^2 = \mathbf{I}_m$, so $\mathbf{H}^{-1} = \mathbf{H}$;
(c) $\mathbf{H}$ is unitary;
(d) $\mathbf{H}\mathbf{w} = -\mathbf{w}$, and $\mathbf{H}\mathbf{v} = \mathbf{v}$ for every $\mathbf{v} \perp \mathbf{w}$;
(e) $\det \mathbf{H} = -1$.

Proof.

(a) By Definition 10.1.2, $(\mathbf{w}\mathbf{w}^*)^* = \mathbf{w}^{**}\mathbf{w}^* = \mathbf{w}\mathbf{w}^*$, and $\|\mathbf{w}\|^2$ is a real number (Theorem 10.1.1 (a)), so $\mathbf{H}^* = \mathbf{I}_m - 2\mathbf{w}\mathbf{w}^*/\|\mathbf{w}\|^2 = \mathbf{H}$.

(b) Since $\mathbf{w}^*\mathbf{w} = \langle \mathbf{w}, \mathbf{w} \rangle = \|\mathbf{w}\|^2$,

$$\mathbf{H}^2 = \mathbf{I}_m - \frac{4\mathbf{w}\mathbf{w}^*}{\|\mathbf{w}\|^2} + \frac{4\,\mathbf{w}(\mathbf{w}^*\mathbf{w})\mathbf{w}^*}{\|\mathbf{w}\|^4} = \mathbf{I}_m,$$

because the last two terms cancel.

(c) By (a) and (b), $\mathbf{H}^*\mathbf{H} = \mathbf{H}^2 = \mathbf{I}_m$, which is the criterion of Definition 10.7.2.

(d) Both statements are read off (‡): $P_{\mathrm{span}(\mathbf{w})}\mathbf{w} = \mathbf{w}$ gives $\mathbf{H}\mathbf{w} = \mathbf{w} - 2\mathbf{w} = -\mathbf{w}$, and $\langle \mathbf{v}, \mathbf{w}\rangle = 0$ gives $\mathbf{H}\mathbf{v} = \mathbf{v}$.

(e) Extend the unit vector $\mathbf{w}/\|\mathbf{w}\|$ to an orthonormal basis $(\mathbf{f}_1, \dots, \mathbf{f}_m)$ of F^m with $\mathbf{f}_1 = \mathbf{w}/\|\mathbf{w}\|$, which is possible by Corollary 10.2.3, and let $\mathbf{P} = (\mathbf{f}_1 \mid \cdots \mid \mathbf{f}_m)$. By (d), $\mathbf{H}\mathbf{f}_1 = -\mathbf{f}_1$ and $\mathbf{H}\mathbf{f}_i = \mathbf{f}_i$ for $i \geq 2$, that is, $\mathbf{HP} = \mathbf{PD}$ with $\mathbf{D} = \mathrm{diag}(-1, 1, \dots, 1)$. The matrix $\mathbf{P}$ is unitary, hence invertible, so $\mathbf{H} = \mathbf{PDP}^{-1}$. Taking determinants, $\det \mathbf{H} = \det \mathbf{D}$ by Theorem 6.5.4 and Corollary 6.5.6, and $\det \mathbf{D} = -1$ by Theorem 6.4.6.

■

So a Householder reflection is a unitary involution of determinant -1: cheap to store (one vector) and cheap to apply, by (‡). What makes it useful is the following choice of $\mathbf{w}$.

Theorem 10.8.3 — A Reflection Flattening a Vector

Let $\mathbf{x} \in F^m$ be non-zero, and let

$$\alpha = \begin{cases} x_1/|x_1|, & x_1 \neq 0, \\ 1, & x_1 = 0, \end{cases} \qquad \mathbf{w} = \mathbf{x} + \alpha\|\mathbf{x}\|\,\mathbf{e}_1.$$

Then $\mathbf{w} \neq \mathbf{0}$ and

$$\mathbf{H}_{\mathbf{w}}\,\mathbf{x} = -\alpha\|\mathbf{x}\|\,\mathbf{e}_1.$$

In particular $\mathbf{H}_{\mathbf{w}}\mathbf{x}$ is a multiple of $\mathbf{e}_1$ of length $\|\mathbf{x}\|$. Over $\mathbb{R}$, α is the sign of x_1 (or 1 if $x_1 = 0$), and $\mathbf{H}_{\mathbf{w}}\mathbf{x} = \mp\|\mathbf{x}\|\mathbf{e}_1$ according to that sign.

Idea. Picture the real plane. We want a mirror line taking $\mathbf{x}$ to a point on the first axis at the same distance from the origin. There are two such points, $\pm\|\mathbf{x}\|\mathbf{e}_1$, and for each the mirror is the perpendicular bisector of the segment joining $\mathbf{x}$ to it — whose normal direction is the **difference** $\mathbf{x} \mp \|\mathbf{x}\|\mathbf{e}_1$. So the vector $\mathbf{w}$ is forced, up to which of the two targets we aim at, and all that remains is to check that the coefficient $2\langle \mathbf{x}, \mathbf{w}\rangle/\|\mathbf{w}\|^2$ in (‡) comes out exactly 1, so that $\mathbf{H}_{\mathbf{w}}\mathbf{x} = \mathbf{x} - \mathbf{w}$. The role of α is to choose the target on the far side from $\mathbf{x}$.

Proof. Note first that $\overline{\alpha}x_1 = |x_1|$ in both cases, and $|\alpha| = 1$. Expanding with (IP1) and Theorem 10.1.1 (b),

$$\begin{aligned} \|\mathbf{w}\|^2 &= \|\mathbf{x}\|^2 + \overline{\alpha}\|\mathbf{x}\|\langle \mathbf{x}, \mathbf{e}_1\rangle + \alpha\|\mathbf{x}\|\langle \mathbf{e}_1, \mathbf{x}\rangle + |\alpha|^2\|\mathbf{x}\|^2 \\ &= 2\|\mathbf{x}\|^2 + 2\|\mathbf{x}\|\,|x_1|, \end{aligned}$$

where the second line uses $\langle \mathbf{x}, \mathbf{e}_1\rangle = x_1$, $\langle \mathbf{e}_1, \mathbf{x}\rangle = \overline{x_1}$ and $\overline{\alpha}x_1 + \alpha\overline{x_1} = 2|x_1|$. Since $\mathbf{x} \neq \mathbf{0}$ we have $\|\mathbf{x}\| > 0$, so $\|\mathbf{w}\|^2 > 0$ and $\mathbf{w} \neq \mathbf{0}$. Likewise

$$\langle \mathbf{x}, \mathbf{w}\rangle = \|\mathbf{x}\|^2 + \overline{\alpha}\|\mathbf{x}\|\,x_1 = \|\mathbf{x}\|^2 + \|\mathbf{x}\||x_1|,$$

so that $2\langle \mathbf{x}, \mathbf{w}\rangle = \|\mathbf{w}\|^2$. Hence by (‡),

$$\mathbf{H}_{\mathbf{w}}\mathbf{x} = \mathbf{x} - \frac{2\langle \mathbf{x}, \mathbf{w}\rangle}{\|\mathbf{w}\|^2}\,\mathbf{w} = \mathbf{x} - \mathbf{w} = -\alpha\|\mathbf{x}\|\,\mathbf{e}_1.$$

Finally $\|-\alpha\|\mathbf{x}\|\mathbf{e}_1\| = |\alpha|\|\mathbf{x}\| = \|\mathbf{x}\|$ by Theorem 10.1.2 (b), as it must be, since $\mathbf{H_w}$ is unitary. This proves the theorem.

■

Why that sign. The opposite choice $\mathbf{w}' = \mathbf{x} - \alpha\|\mathbf{x}\|\mathbf{e}_1$ also works whenever $\mathbf{w}' \neq \mathbf{0}$, giving $\mathbf{H}_{\mathbf{w}'}\mathbf{x} = +\alpha\|\mathbf{x}\|\mathbf{e}_1$; in exact arithmetic the two are equally good, and in floating point they are not. The first entry of $\mathbf{w}'$ is $x_1 - \alpha\|\mathbf{x}\|$, a difference of two numbers of modulus $|x_1|$ and $\|\mathbf{x}\|$ — and when $\mathbf{x}$ is close to a multiple of $\mathbf{e}_1$ those two are nearly equal, so the leading digits cancel and the computed first entry keeps only the few digits they did not share. The other entries of $\mathbf{w}'$ are copied from $\mathbf{x}$ and stay exact, so the computed $\mathbf{w}'$ points in a noticeably wrong direction, and so does the reflection built from it. With $\mathbf{w} = \mathbf{x} + \alpha\|\mathbf{x}\|\mathbf{e}_1$ the first entry has modulus $|x_1| + \|\mathbf{x}\|$: like-signed quantities, nothing to cancel. (The same computation shows $\mathbf{w} \neq \mathbf{0}$ always, whereas $\mathbf{w}' = \mathbf{0}$ exactly when $\mathbf{x} = \alpha\|\mathbf{x}\|\mathbf{e}_1$, the extreme case of that cancellation.) Chapter 23 quantifies the loss; the summary here is that both signs are correct mathematics and only one is correct arithmetic.

Warning. **Do not build the matrix $\mathbf{H_w}$ in order to use it.** Forming it and multiplying costs m^2 operations per column, while (‡) applies the same reflection with one inner product and one scaled subtraction, about $4m$. Every "multiply by $\mathbf{H}$" below is really an instance of (‡); the matrix is a proof device.

Quick check. Let $\mathbf{x} = (0, 3, 4) \in \mathbb{R}^3$. Find $\mathbf{w}$ and $\mathbf{H_w x}$ as in Theorem 10.8.3, and say why the sign question does not arise here.

Solution. $\|\mathbf{x}\| = 5$ and $x_1 = 0$, so $\alpha = 1$ and $\mathbf{w} = (0, 3, 4) + 5(1, 0, 0) = (5, 3, 4)$. Then $\mathbf{H_w x} = -5\mathbf{e}_1 = (-5, 0, 0)$. With $x_1 = 0$ there is no cancellation to avoid: the first entry of $\mathbf{w}$ is 0 ± 5 either way, and both choices are equally accurate. The convention $\alpha = 1$ is only a convention.

10.8.4 QR by reflections

One reflection makes the first column a multiple of $\mathbf{e}_1$ — exactly the zeros an upper triangular matrix needs in column 1. Repeating on the trailing submatrix triangularizes everything.

Theorem 10.8.4 — QR by Householder Reflections

Let $\mathbf{A} \in M_{m\times n}(F)$. Then there are a **unitary** $\mathbf{Q} \in M_m(F)$ and an $\mathbf{R} \in M_{m\times n}(F)$ with $r_{ij} = 0$ whenever $i > j$, such that

$$\mathbf{A} = \mathbf{QR}.$$

Moreover $\mathbf{Q}$ can be taken to be a product of at most $\min(n, m-1)$ Householder reflections. **No hypothesis on the columns of A is needed.**

Idea. Induction on the number of columns. Step one is Theorem 10.8.3 applied to the first column: after it, the first column is $\rho\mathbf{e}_1$ and what is left to triangularize is the trailing $(m-1)\times(n-1)$ block. Feed that block to the induction hypothesis, and lift the unitary matrix it returns to F^m by putting a 1 in the top-left corner — a block matrix of that shape does not touch the first row or the first column, so it cannot spoil the zeros

just created.

Proof. We induct on n, the statement being asserted for every $m \geq 1$ at once.

If $m = 1$, then $\mathbf{A}$ has no entries below its diagonal, so $\mathbf{Q} = \mathbf{I}_1$ and $\mathbf{R} = \mathbf{A}$ work. Assume from now on that $m \geq 2$.

Let $\mathbf{a}$ be the first column of $\mathbf{A}$. If $\mathbf{a} = \mathbf{0}$, put $\mathbf{H} = \mathbf{I}_m$ and $\rho = 0$; otherwise let $\mathbf{H} = \mathbf{H}_{\mathbf{w}}$ be the reflection of Theorem 10.8.3 for $\mathbf{x} = \mathbf{a}$, and $\rho = -\alpha\|\mathbf{a}\|$. In both cases $\mathbf{H}$ is unitary and Hermitian with $\mathbf{H}^{-1} = \mathbf{H}$ — by Proposition 10.8.2 (a)–(c) for a reflection, and because $\mathbf{I}_m^* = \mathbf{I}_m = \mathbf{I}_m^{-1}$ in the degenerate case — and $\mathbf{H}\mathbf{a} = \rho\mathbf{e}_1$. Hence, by Theorem 7.1.1,

$$\mathbf{H}\mathbf{A} = \begin{pmatrix} \rho & \mathbf{b}^* \\ \mathbf{0} & \mathbf{A}' \end{pmatrix}$$

for some $\mathbf{b} \in F^{n-1}$ and $\mathbf{A}' \in M_{(m-1)\times(n-1)}(F)$, where the $\mathbf{0}$ is a column of $m-1$ zeros.

Base case $n = 1$. There is no block $\mathbf{A}'$, and $\mathbf{H}\mathbf{A} = \rho\mathbf{e}_1$ already has $r_{i1} = 0$ for $i > 1$. So $\mathbf{A} = \mathbf{H}(\mathbf{H}\mathbf{A})$ is of the required form with $\mathbf{Q} = \mathbf{H}$.

Induction step. Let $n \geq 2$ and assume the statement for $n-1$ columns. Applied to $\mathbf{A}'$, which has $m - 1 \geq 1$ rows, it gives a unitary $\mathbf{Q}' \in M_{m-1}(F)$ and an $\mathbf{R}'$ with zeros below the diagonal and $\mathbf{A}' = \mathbf{Q}'\mathbf{R}'$. Put

$$\mathbf{U} = \begin{pmatrix} 1 & \mathbf{0}^* \\ \mathbf{0} & \mathbf{Q}' \end{pmatrix}, \qquad \mathbf{R} = \begin{pmatrix} \rho & \mathbf{b}^* \\ \mathbf{0} & \mathbf{R}' \end{pmatrix}.$$

Then $\mathbf{U}^*\mathbf{U} = \mathbf{I}_m$ by Theorem 7.1.1, so $\mathbf{U}$ is unitary, and $\mathbf{U}\mathbf{R} = \mathbf{H}\mathbf{A}$ by the same computation. Also $\mathbf{R}$ has zeros below its diagonal: in column 1 this is the block $\mathbf{0}$; and for $j \geq 2$ and $i > j$, the (i, j)-entry of $\mathbf{R}$ is the $(i-1, j-1)$-entry of $\mathbf{R}'$, which vanishes because $i - 1 > j - 1$.

Therefore $\mathbf{A} = \mathbf{H}\mathbf{U}\mathbf{R}$, and $\mathbf{Q} = \mathbf{H}\mathbf{U}$ is unitary as a product of unitary matrices (Proposition 10.7.4). Unwinding the induction, $\mathbf{Q}$ is a product of one reflection (or $\mathbf{I}_m$) for each of the columns $1, \dots, \min(n, m-1)$, since the recursion stops once one row is left. This proves the theorem.

■

Example. (A 3×3 QR by reflections)

Triangularize

$$\mathbf{A} = \begin{pmatrix} 2 & 0 & 1 \\ 1 & 5 & 2 \\ 2 & 5 & 4 \end{pmatrix}$$

by Householder reflections, and read off $\mathbf{Q}$ and $\mathbf{R}$.

Solution. Step 1. The first column is $\mathbf{a} = (2, 1, 2)$ with $\|\mathbf{a}\| = 3$ and $a_1 = 2 > 0$, so $\alpha = 1$ and

$$\mathbf{w}_1 = (2, 1, 2) + 3(1, 0, 0) = (5, 1, 2), \qquad \|\mathbf{w}_1\|^2 = 30.$$

Apply (‡) to each column: $\mathbf{H}_1\mathbf{v} = \mathbf{v} - \frac{1}{15}\langle \mathbf{v}, \mathbf{w}_1 \rangle \mathbf{w}_1$. All three columns pair with $\mathbf{w}_1$ to

give 15, so each loses exactly one copy of $\mathbf{w}_1$:

$$\mathbf{H}_1\mathbf{A} = \begin{pmatrix} -3 & -5 & -4 \\ 0 & 4 & 1 \\ 0 & 3 & 2 \end{pmatrix}.$$

(As predicted, the first column is $-\|\mathbf{a}\|\mathbf{e}_1$.)

Step 2. Work now in the trailing 2×2 block, whose first column is $\mathbf{y} = (4, 3)$ with $\|\mathbf{y}\| = 5$ and $y_1 > 0$. So $\mathbf{w}_2 = (9, 3)$, and inside $\mathbb{R}^3$ we reflect in $\widetilde{\mathbf{w}}_2 = (0, 9, 3)$, which fixes $\mathbf{e}_1$ and so leaves column 1 alone; here $\mathbf{H}_2\mathbf{v} = \mathbf{v} - \frac{1}{45}\langle \mathbf{v}, \widetilde{\mathbf{w}}_2\rangle \widetilde{\mathbf{w}}_2$. The second and third columns of $\mathbf{H}_1\mathbf{A}$ pair with $\widetilde{\mathbf{w}}_2$ to give $36 + 9 = 45$ and $9 + 6 = 15$, so they lose one copy and a third of a copy respectively:

$$\mathbf{R} = \mathbf{H}_2\mathbf{H}_1\mathbf{A} = \begin{pmatrix} -3 & -5 & -4 \\ 0 & -5 & -2 \\ 0 & 0 & 1 \end{pmatrix}.$$

The unitary factor. By Proposition 10.8.2 (b), $\mathbf{A} = \mathbf{H}_1\mathbf{H}_2\mathbf{R}$, so $\mathbf{Q} = \mathbf{H}_1\mathbf{H}_2$. Computing the product,

$$\mathbf{Q} = \tfrac{1}{3}\begin{pmatrix} -2 & 2 & -1 \\ -1 & -2 & -2 \\ -2 & -1 & 2 \end{pmatrix},$$

whose columns have length 1 and are pairwise orthogonal, as one checks from the integer entries: for instance $(-2)(2) + (-1)(-2) + (-2)(-1) = 0$.

Check. $\det \mathbf{A} = 15$ by expansion along the first row, and $\det \mathbf{R} = (-3)(-5)(1) = 15$ by Theorem 6.4.6, consistent with $\det \mathbf{Q} = (-1)(-1) = 1$ from Proposition 10.8.2 (e).

The diagonal of $\mathbf{R}$ here is $(-3, -5, 1)$, not positive: the reflection route produces **a** factorization, not **the** one of Theorem 10.8.1. The two are related by flipping the sign of each row of $\mathbf{R}$ with a negative diagonal entry, and of the matching column of $\mathbf{Q}$; Exercise (B2: The same matrix by reflections) carries this out on the matrix of Example (A 3×2 QR, and a least-squares problem).

Warning. **"The QR factorization" is definite only with the positivity normalization.** Theorem 10.8.1 pins the pair down by demanding $r_{kk} > 0$; the reflection algorithm ignores that demand and chooses signs for stability instead. So two correct computations of "the QR factorization of $\mathbf{A}$" can differ by signs. Compare $|r_{kk}|$, and the lines spanned by the columns of $\mathbf{Q}$.

Where Gram–Schmidt cannot follow. Theorem 10.8.4 assumed nothing about the columns, and that is a genuine gain. Let the columns of $\mathbf{A}$ be dependent, and let k be the first index with $\mathbf{a}_k \in \operatorname{span}(\mathbf{a}_1, \dots, \mathbf{a}_{k-1})$. The Gram–Schmidt recursion then produces $\mathbf{w}_k = \mathbf{0}$ and stops, because the next step divides by $\|\mathbf{w}_k\|$; Exercise (C2: Gram–Schmidt on a dependent list) works this out. Nor is the failure an artifact of the method: if $\mathbf{A} = \mathbf{Q}\mathbf{R}$ with $\mathbf{Q}^*\mathbf{Q} = \mathbf{I}_n$ and $\mathbf{R}$ upper triangular with positive diagonal, then $\mathbf{R}$ is invertible by Lemma 2.6.2, so $\operatorname{rank} \mathbf{A} = \operatorname{rank} \mathbf{Q} = n$ and the columns were independent after all. **A QR factorization in the sense of Theorem 10.8.1 exists exactly for matrices of full column rank.** The reflection route is untroubled: a dependent column simply puts a zero on the diagonal of $\mathbf{R}$ where the dependence appears, and the algorithm continues (Exercise (C2: Reflections do not mind dependence)).

10.8.5 Givens rotations

A reflection zeroes a whole column at once. Sometimes that is too much: if $\mathbf{A}$ is nearly triangular already, we would rather kill the few offending entries one at a time and leave the rest alone.

Definition 10.8.2 — Givens Rotation

Let $1 \le i < j \le m$ and let $c, s \in \mathbb{R}$ with $c^2+s^2 = 1$. The **Givens rotation** $\mathbf{G}(i, j; c, s) \in M_m(\mathbb{R})$ is the identity matrix with the four entries in rows and columns i, j replaced by

$$\begin{pmatrix} g_{ii} & g_{ij} \\ g_{ji} & g_{jj} \end{pmatrix} = \begin{pmatrix} c & s \\ -s & c \end{pmatrix}.$$

The two columns involved are orthonormal, since $c^2 + s^2 = 1$ and $cs - sc = 0$, and every other column of $\mathbf{G}$ is a standard basis vector, orthogonal to both; so $\mathbf{G}^{\top}\mathbf{G} = \mathbf{I}_m$ and $\mathbf{G}$ is orthogonal, with $\det \mathbf{G} = c^2 + s^2 = 1$ by expansion along those other columns (Theorem 6.6.1). Moreover $\mathbf{G}$ acts as the identity on every coordinate other than i and j. Given a vector $\mathbf{v}$ with $(v_i, v_j) \neq (0, 0)$, set

$$r = \sqrt{v_i^2 + v_j^2}, \qquad c = \frac{v_i}{r}, \qquad s = \frac{v_j}{r}.$$

Then the i-th entry of $\mathbf{Gv}$ is $(v_i^2 + v_j^2)/r = r$ and the j-th is $(-v_j v_i + v_i v_j)/r = 0$, while every other entry is unchanged. **One rotation, one new zero.**

Here is one rotation at work. To clear the $(3, 1)$-entry of the matrix $\mathbf{A}$ below, take $i = 1$, $j = 3$ and for $\mathbf{v}$ its first column, so that $(v_1, v_3) = (3, 4)$ and $r = 5$, $c = \frac{3}{5}$, $s = \frac{4}{5}$. Then $\mathbf{G} = \mathbf{G}(1, 3; \frac{3}{5}, \frac{4}{5})$ replaces row 1 by $\frac{3}{5}$(row 1) $+ \frac{4}{5}$(row 3) and row 3 by $-\frac{4}{5}$(row 1) $+ \frac{3}{5}$(row 3), and leaves row 2 alone:

$$\mathbf{A} = \begin{pmatrix} 3 & 5 & 0 \\ 0 & 2 & 1 \\ 4 & 0 & 5 \end{pmatrix}, \qquad \mathbf{GA} = \begin{pmatrix} 5 & 3 & 4 \\ 0 & 2 & 1 \\ 0 & -4 & 3 \end{pmatrix}.$$

The new $(1, 1)$-entry is $\frac{1}{5}(3 \cdot 3 + 4 \cdot 4) = 5 = r$ and the new $(3, 1)$-entry is $\frac{1}{5}(-4 \cdot 3 + 3 \cdot 4) = 0$, as designed; the zero already sitting in position $(2, 1)$ survives because row 2 was never touched. A reflection would have flattened the whole first column in one step, at the price of rewriting row 2 as well.

Applied in a suitable order, rotations triangularize any real matrix, which is a second proof of Theorem 10.8.4 over $\mathbb{R}$ at the cost of more steps: a full $m \times n$ matrix needs about mn rotations where reflections need n. For a nearly triangular matrix the count reverses, which is why the Hessenberg matrices below are handled with rotations in practice. Over $\mathbb{C}$ one takes $c \in \mathbb{R}$, $s \in \mathbb{C}$ with $c^2 + |s|^2 = 1$, and $-\overline{s}$ in place of $-s$; to zero the j-th entry of $\mathbf{v}$ one puts $r = \sqrt{|v_i|^2 + |v_j|^2}$ and takes $c = |v_i|/r$ and $s = (v_i/|v_i|)\overline{v_j}/r$ when $v_i \neq 0$, and $c = 0$, $s = 1$ when $v_i = 0$.

10.8.6 Hessenberg form

So far the unitary matrices acted on one side. A similarity needs both: to preserve eigenvalues we must pass from $\mathbf{A}$ to $\mathbf{Q}^*\mathbf{AQ}$, not to $\mathbf{Q}^*\mathbf{A}$. What can reflections achieve under that constraint?

Not triangularity, and the reason is worth seeing before the theorem. Suppose we reflect so that the first column becomes $\rho\mathbf{e}_1$. Multiplying on the right must not disturb column 1, so the right

factor must fix $\mathbf{e}_1$ — and so must the left factor, since they are the same matrix. But a reflection fixing $\mathbf{e}_1$ acts only on the coordinates $2, \dots, n$, so in column 1 the best it can do is compress rows $2, \dots, n$ into row 2. **The entry just below the diagonal survives, by necessity.** That is exactly the pattern we can reach.

Theorem 10.8.5 — Reduction to Hessenberg Form

Let $\mathbf{A} \in M_n(F)$, $n \geq 1$. Then there is a unitary $\mathbf{Q} \in M_n(F)$ such that $\mathbf{Z} = \mathbf{Q}^*\mathbf{A}\mathbf{Q}$ is **upper Hessenberg**, that is,

$$z_{ij} = 0 \qquad \text{whenever } i > j + 1.$$

The matrix $\mathbf{Q}$ can be taken to be a product of $n-2$ factors, each a Householder reflection or an identity matrix (and $\mathbf{Q} = \mathbf{I}_n$ when $n \leq 2$). For $n = 4$ the pattern is

$$\mathbf{Z} = \begin{pmatrix} * & * & * & * \\ * & * & * & * \\ 0 & * & * & * \\ 0 & 0 & * & * \end{pmatrix}.$$

Idea. Work column by column, as in Theorem 10.8.4, but apply each reflection on both sides. At step k it is chosen to fix $\mathbf{e}_1, \dots, \mathbf{e}_k$ and to flatten the part of column k in rows $k+1, \dots, n$. Two observations do the bookkeeping. On the **left** it only recombines rows $k+1, \dots, n$, and in the earlier columns those rows are already zero, so a combination of them is still zero. On the **right** it only recombines columns $k+1, \dots, n$, so the columns already in shape are untouched.

Proof. For $0 \leq k \leq n-2$ say that $\mathbf{B} \in M_n(F)$ satisfies $(*_k)$ if $b_{ij} = 0$ whenever $j \leq k$ and $i \geq j+2$. Every matrix satisfies $(*_0)$ vacuously, and $(*_{n-2})$ says precisely that $\mathbf{B}$ is upper Hessenberg, since the conditions with $j = n-1$ and $j = n$ are empty.

Put $\mathbf{A}_0 = \mathbf{A}$. Let $1 \leq k \leq n-2$ and suppose $\mathbf{A}_{k-1}$ satisfies $(*_{k-1})$. Let $\mathbf{a} \in F^{n-k}$ be the vector of entries in rows $k+1, \dots, n$ of column k of $\mathbf{A}_{k-1}$. If $\mathbf{a} = \mathbf{0}$, put $\mathbf{H}_k = \mathbf{I}_{n-k}$; otherwise let $\mathbf{H}_k \in M_{n-k}(F)$ be the reflection of Theorem 10.8.3 with $\mathbf{H}_k\mathbf{a} = \rho\mathbf{e}_1$, where $\rho = -\alpha\|\mathbf{a}\|$. Set

$$\mathbf{Q}_k = \begin{pmatrix} \mathbf{I}_k & \mathbf{0} \\ \mathbf{0} & \mathbf{H}_k \end{pmatrix} \in M_n(F), \qquad \mathbf{A}_k = \mathbf{Q}_k\mathbf{A}_{k-1}\mathbf{Q}_k.$$

The block $\mathbf{H}_k$ is unitary and Hermitian with $\mathbf{H}_k^{-1} = \mathbf{H}_k$ — by Proposition 10.8.2 (a)–(c) for a reflection, and because $\mathbf{I}_{n-k}^* = \mathbf{I}_{n-k} = \mathbf{I}_{n-k}^{-1}$ otherwise — so by Theorem 7.1.1 $\mathbf{Q}_k$ is unitary and Hermitian with $\mathbf{Q}_k^{-1} = \mathbf{Q}_k$, and $\mathbf{Q}_k\mathbf{e}_j = \mathbf{e}_j$ for every $j \leq k$.

Claim 1. $\mathbf{Q}_k\mathbf{A}_{k-1}$ satisfies $(*_{k-1})$, and its entries in rows $i \geq k+2$ of column k are 0.

Proof. By Theorem 7.1.1, the rows $1,\dots,k$ of $\mathbf{Q}_k\mathbf{A}_{k-1}$ are those of $\mathbf{A}_{k-1}$, and each of the rows $k+1,\dots,n$ is a linear combination of the rows $k+1,\dots,n$ of $\mathbf{A}_{k-1}$. Fix a column $j \le k-1$. By $(*_{k-1})$, the entries of that column in rows $i \ge j+2$ vanish, and $k+1 \ge j+2$, so all the entries being combined are 0 and the combination is 0. Hence $(*_{k-1})$ survives. In column k, the entries in rows $k+1,\dots,n$ form the vector $\mathbf{H}_k\mathbf{a} = \rho\mathbf{e}_1$, whose entries after the first are 0; these sit in rows $k+2,\dots,n$.

■

Claim 2. $\mathbf{A}_k = (\mathbf{Q}_k\mathbf{A}_{k-1})\mathbf{Q}_k$ has the same first k columns as $\mathbf{Q}_k\mathbf{A}_{k-1}$.

Proof. For $j \le k$, the j-th column of $\mathbf{B}\mathbf{Q}_k$ is $\mathbf{B}(\mathbf{Q}_k\mathbf{e}_j) = \mathbf{B}\mathbf{e}_j$, the j-th column of $\mathbf{B}$.

■

Combining the two claims, $\mathbf{A}_k$ satisfies $(*_k)$: columns $1,\dots,k-1$ keep the zeros guaranteed by Claim 1, and column k has zeros in rows $k+2,\dots,n$, also by Claim 1, and both survive the right multiplication by Claim 2.

Running $k = 1,\dots,n-2$ produces $\mathbf{A}_{n-2}$ satisfying $(*_{n-2})$, that is, upper Hessenberg. Put $\mathbf{Q} = \mathbf{Q}_1\mathbf{Q}_2\cdots\mathbf{Q}_{n-2}$, unitary as a product of unitary matrices (Proposition 10.7.4). Since each $\mathbf{Q}_k^* = \mathbf{Q}_k$,

$$\mathbf{Q}^*\mathbf{A}\mathbf{Q} = \mathbf{Q}_{n-2}\cdots\mathbf{Q}_1\,\mathbf{A}\,\mathbf{Q}_1\cdots\mathbf{Q}_{n-2} = \mathbf{A}_{n-2},$$

which proves the theorem. (For $n \le 2$ there are no steps and every matrix is already Hessenberg.)

■

Because $\mathbf{Q}^{-1} = \mathbf{Q}^*$, the matrices $\mathbf{A}$ and $\mathbf{Z}$ are similar (Definition 3.7.2), so they share their characteristic polynomial, their eigenvalues and their trace. The reduction is not merely tidying: it removes $\binom{n-1}{2}$ entries and keeps **the whole spectrum**.

Example. (Hessenberg form of a 3×3 matrix)

Reduce

$$\mathbf{A} = \begin{pmatrix} 2 & 1 & 0 \\ 0 & 3 & 1 \\ 1 & 0 & 4 \end{pmatrix}$$

to upper Hessenberg form by a unitary similarity.

Solution. Only $k = 1$ occurs, and only the entry a_{31} has to be killed. The relevant vector is $\mathbf{a} = (a_{21}, a_{31}) = (0,1) \in \mathbb{R}^2$, with $\|\mathbf{a}\| = 1$ and $a_1 = 0$, so $\alpha = 1$ and

$$\mathbf{w} = (0,1) + (1,0) = (1,1), \qquad \|\mathbf{w}\|^2 = 2.$$

Hence $\mathbf{H}_1 = \mathbf{I}_2 - \mathbf{w}\mathbf{w}^\top = \begin{pmatrix} 0 & -1 \\ -1 & 0 \end{pmatrix}$, and

$$\mathbf{Q}_1 = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & -1 \\ 0 & -1 & 0 \end{pmatrix}.$$

Left multiplication by $\mathbf{Q}_1$ exchanges rows 2 and 3 and negates them, and right multiplication does the same to columns 2 and 3:

$$\mathbf{Q}_1\mathbf{A} = \begin{pmatrix} 2 & 1 & 0 \\ -1 & 0 & -4 \\ 0 & -3 & -1 \end{pmatrix}, \qquad \mathbf{Q}_1\mathbf{A}\mathbf{Q}_1 = \begin{pmatrix} 2 & 0 & -1 \\ -1 & 4 & 0 \\ 0 & 1 & 3 \end{pmatrix}.$$

Entry $(3,1)$ is 0 and entry $(2,1)$ is $-1 = -\|\mathbf{a}\|$, as Theorem 10.8.3 predicts. Watch column 1 through the second multiplication: it is untouched, because $\mathbf{Q}_1\mathbf{e}_1 = \mathbf{e}_1$. Both matrices have trace 9, as similarity requires.

Warning. **Hessenberg form is not one small step from triangular form.** A few more reflections will not clear the subdiagonal, and not merely because the argument above breaks. The diagonal of a triangular matrix similar to $\mathbf{A}$ lists the eigenvalues of $\mathbf{A}$ (Theorem 8.7.4), so a finite procedure using only arithmetic and square roots that always produced one would extract the roots of an arbitrary polynomial from its coefficients by those operations alone. No such procedure exists: from degree five on, the roots of a general polynomial cannot be written with arithmetic and radicals at all. That is a theorem of Abel and Ruffini, which this book does not prove and which nothing later depends on; we quote it only to explain why the algorithms of Chapter 23 iterate instead of terminating. Over $\mathbb{C}$ a triangularizing unitary does exist (Theorem 8.7.2); what does not exist is a finite algorithm of this kind producing it. Over $\mathbb{R}$ even the existence fails: a rotation in $\mathrm{O}(2)$ with no real eigenvalue is already Hessenberg and is orthogonally similar to no real triangular matrix.

Hessenberg form is where the practical computation of eigenvalues begins. One applies the reduction once, then iterates a cheap step that preserves the pattern: factor $\mathbf{Z} = \mathbf{Q}\mathbf{R}$ and replace $\mathbf{Z}$ by $\mathbf{R}\mathbf{Q} = \mathbf{Q}^*\mathbf{Z}\mathbf{Q}$, again a unitary similarity. Chapter 23 develops that iteration and explains why every implementation starts with the reduction proved here.

Quick check. In the reduction of a 5×5 matrix, how many reflections are used, and how many entries does the second one set to zero?

Solution. Three, namely $k = 1, 2, 3$. The step $k = 2$ chooses a reflection acting on the coordinates $3, 4, 5$ and sets the entries in rows 4 and 5 of column 2 to zero: two entries. (Step 1 sets three, step 3 sets one, for $\binom{4}{2} = 6$ in total.)

10.8.7 Exercises

10.8.7.1 A. Check your understanding

Exercise A1.

(a) State Theorem 10.8.1 in full, including the two normalizations that make $\mathbf{Q}$ and $\mathbf{R}$ unique.

(b) Which hypothesis on $\mathbf{A}$ does Theorem 10.8.1 need, and which does Theorem 10.8.4 need? Explain the difference in one sentence.

(c) Write down the Householder reflection determined by $\mathbf{w}$, and list three of its properties.

(d) In Theorem 10.8.3, which of the two possible targets $\pm\|\mathbf{x}\|\mathbf{e}_1$ is chosen, and why?

(e) True or false: applying reflections on both sides, as in Theorem 10.8.5, can be pushed to make every complex matrix unitarily similar to an upper triangular one. Justify your answer.

(f) Why must the reflection used at step k of Theorem 10.8.5 fix $\mathbf{e}_1, \dots, \mathbf{e}_k$?

Solution.

(a) If the columns of $\mathbf{A} \in M_{m\times n}(F)$ are independent, then $\mathbf{A} = \mathbf{QR}$ with $\mathbf{R}$ upper triangular; the normalizations are that the columns of $\mathbf{Q}$ are **orthonormal** and that the diagonal of $\mathbf{R}$ is **positive real**. With both, the pair is unique.

(b) Theorem 10.8.1 needs independent columns; Theorem 10.8.4 needs nothing. A positive diagonal forces $\mathbf{R}$ to be invertible and hence rank $\mathbf{A} = n$, while the reflection route is content to put a zero on the diagonal where a dependence occurs.

(c) $\mathbf{H}_{\mathbf{w}} = \mathbf{I}_m - 2\mathbf{w}\mathbf{w}^*/\|\mathbf{w}\|^2$ (Definition 10.8.1); it is Hermitian, unitary, equal to its own inverse, and has determinant -1 (Proposition 10.8.2).

(d) The target $-\alpha\|\mathbf{x}\|\mathbf{e}_1$, where α is the phase (over $\mathbb{R}$, the sign) of x_1 — that is, the target on the **opposite** side from x_1. The reason is arithmetic: this makes the first entry of $\mathbf{w} = \mathbf{x} + \alpha\|\mathbf{x}\|\mathbf{e}_1$ a sum of like-signed quantities, with no cancellation of leading digits.

(e) False. A reflection preserving the zeros already created must fix $\mathbf{e}_1, \dots, \mathbf{e}_k$, and then it cannot touch the entry in row $k+1$ of column k. More decisively, such a finite procedure would compute the roots of an arbitrary polynomial by arithmetic and square roots alone, which the theorem of Abel and Ruffini quoted in the warning rules out.

(f) Because the same matrix multiplies on the right, and right multiplication by $\mathbf{Q}_k$ changes column j only if $\mathbf{Q}_k\mathbf{e}_j \neq \mathbf{e}_j$. Fixing $\mathbf{e}_1, \dots, \mathbf{e}_k$ is exactly what leaves columns $1, \dots, k$, and the zeros in them, alone.

10.8.7.2 B. Practice

Exercise B1: QR by Gram–Schmidt.

Find the QR factorization of

$$\mathbf{A} = \begin{pmatrix} 1 & 1 & 1 \\ 1 & 1 & 0 \\ 1 & 0 & 0 \end{pmatrix}$$

in the sense of Theorem 10.8.1, and verify that $\mathbf{R} = \mathbf{Q}^{\top}\mathbf{A}$ for the top-left 2×2 entries.

Solution. Step 1. $\mathbf{a}_1 = (1,1,1)$ has $\|\mathbf{a}_1\| = \sqrt{3}$, so $r_{11} = \sqrt{3}$ and $\mathbf{q}_1 = \frac{1}{\sqrt{3}}(1,1,1)$.

Step 2. $r_{12} = \langle \mathbf{a}_2, \mathbf{q}_1 \rangle = \frac{2}{\sqrt{3}}$, so

$$\mathbf{w}_2 = (1,1,0) - \tfrac{2}{3}(1,1,1) = \tfrac{1}{3}(1,1,-2),$$

with $\|\mathbf{w}_2\|^2 = \frac{1}{9} \cdot 6 = \frac{2}{3}$. Hence $r_{22} = \sqrt{2/3}$ and $\mathbf{q}_2 = \frac{1}{\sqrt{6}}(1,1,-2)$.

Step 3. $r_{13} = \langle \mathbf{a}_3, \mathbf{q}_1 \rangle = \frac{1}{\sqrt{3}}$ and $r_{23} = \langle \mathbf{a}_3, \mathbf{q}_2 \rangle = \frac{1}{\sqrt{6}}$, so

$$\mathbf{w}_3 = (1,0,0) - \tfrac{1}{3}(1,1,1) - \tfrac{1}{6}(1,1,-2) = \left(\tfrac{1}{2}, -\tfrac{1}{2}, 0\right),$$

with $\|\mathbf{w}_3\| = \frac{1}{\sqrt{2}} = r_{33}$ and $\mathbf{q}_3 = \frac{1}{\sqrt{2}}(1,-1,0)$. Therefore

$$\mathbf{Q} = \begin{pmatrix} \frac{1}{\sqrt{3}} & \frac{1}{\sqrt{6}} & \frac{1}{\sqrt{2}} \\ \frac{1}{\sqrt{3}} & \frac{1}{\sqrt{6}} & -\frac{1}{\sqrt{2}} \\ \frac{1}{\sqrt{3}} & -\frac{2}{\sqrt{6}} & 0 \end{pmatrix}, \qquad \mathbf{R} = \begin{pmatrix} \sqrt{3} & \frac{2}{\sqrt{3}} & \frac{1}{\sqrt{3}} \\ 0 & \frac{2}{\sqrt{6}} & \frac{1}{\sqrt{6}} \\ 0 & 0 & \frac{1}{\sqrt{2}} \end{pmatrix},$$

where $r_{22} = \sqrt{2/3} = 2/\sqrt{6}$. All three diagonal entries are positive, as required.

For the verification, $(\mathbf{Q}^{\top}\mathbf{A})_{11} = \langle \mathbf{a}_1, \mathbf{q}_1 \rangle = 3/\sqrt{3} = \sqrt{3} = r_{11}$ and $(\mathbf{Q}^{\top}\mathbf{A})_{12} = \langle \mathbf{a}_2, \mathbf{q}_1 \rangle = 2/\sqrt{3} = r_{12}$; also $(\mathbf{Q}^{\top}\mathbf{A})_{21} = \langle \mathbf{a}_1, \mathbf{q}_2 \rangle = (1+1-2)/\sqrt{6} = 0 = r_{21}$ and $(\mathbf{Q}^{\top}\mathbf{A})_{22} = \langle \mathbf{a}_2, \mathbf{q}_2 \rangle = 2/\sqrt{6} = r_{22}$.

Exercise B2: The same matrix by reflections.

Let $\mathbf{A} = \begin{pmatrix} 1 & 1 \\ 2 & 1 \\ 2 & 3 \end{pmatrix}$, the matrix of Example (A 3×2 QR, and a least-squares problem).

(a) Find $\mathbf{w}_1$ and the reflection $\mathbf{H}_1$ of Theorem 10.8.3 for the first column of $\mathbf{A}$, and compute $\mathbf{H}_1\mathbf{A}$.

(b) Find the second reflection and hence a factorization $\mathbf{A} = \mathbf{QR}$ with $\mathbf{Q} \in M_3(\mathbb{R})$ orthogonal and $\mathbf{R} \in M_{3\times 2}(\mathbb{R})$ upper triangular.

(c) Compare the $\mathbf{R}$ of (b) with the $\mathbf{R}$ of Example (A 3×2 QR, and a least-squares problem), and say exactly how the two factorizations differ.

Solution.

(a) The first column is $\mathbf{a} = (1,2,2)$ with $\|\mathbf{a}\| = 3$ and $a_1 = 1 > 0$, so $\alpha = 1$ and $\mathbf{w}_1 = (1,2,2) + 3\mathbf{e}_1 = (4,2,2)$, with $\|\mathbf{w}_1\|^2 = 24$. By (‡), $\mathbf{H}_1\mathbf{v} = \mathbf{v} - \frac{1}{12}\langle \mathbf{v}, \mathbf{w}_1 \rangle \mathbf{w}_1$. Since $\langle \mathbf{a}, \mathbf{w}_1 \rangle = 4+4+4 = 12$ and $\langle (1,1,3), \mathbf{w}_1 \rangle = 4+2+6 = 12$, each column loses one copy of $\mathbf{w}_1$:

$$\mathbf{H}_1\mathbf{A} = \begin{pmatrix} -3 & -3 \\ 0 & -1 \\ 0 & 1 \end{pmatrix}.$$

(b) The trailing vector is $\mathbf{y} = (-1,1)$, with $\|\mathbf{y}\| = \sqrt{2}$ and $y_1 = -1 < 0$, so $\alpha = -1$ and $\mathbf{w}_2 = (-1,1) - \sqrt{2}(1,0) = (-1-\sqrt{2}, 1)$. By Theorem 10.8.3, the reflection

sends $\mathbf{y}$ to $+\sqrt{2}\,\mathbf{e}_1$. Embedding it as $\mathbf{H}_2 = \mathbf{I}_1 \oplus \mathbf{H}_{\mathbf{w}_2}$, we get

$$\mathbf{R} = \mathbf{H}_2\mathbf{H}_1\mathbf{A} = \begin{pmatrix} -3 & -3 \\ 0 & \sqrt{2} \\ 0 & 0 \end{pmatrix}, \qquad \mathbf{Q} = \mathbf{H}_1\mathbf{H}_2,$$

and $\mathbf{A} = \mathbf{QR}$ because each $\mathbf{H}_i$ is its own inverse (Proposition 10.8.2 (b)).

(c) In Example (A 3×2 QR, and a least-squares problem), $\mathbf{R}_0 = \begin{pmatrix} 3 & 3 \\ 0 & \sqrt{2} \end{pmatrix}$. Deleting the zero row of $\mathbf{R}$ leaves $\mathbf{R}_0$ with its **first row negated**, and correspondingly the first column of $\mathbf{Q}$ is $-\mathbf{q}_1$ while the second is $\mathbf{q}_2$. The reflection route did not aim for a positive diagonal, and by the uniqueness in Theorem 10.8.1 signs are the only discrepancy possible.

Exercise B3: A least-squares fit through QR.

Fit a line $y = c_0 + c_1 t$ to the data $(t, y) = (0, 1), (1, 3), (2, 2)$ in the least-squares sense, by finding the QR factorization of the design matrix and solving $\mathbf{Rx} = \mathbf{Q}^{\top}\mathbf{b}$. Compute the residual and check the answer against the normal equations.

Solution. The system is $\mathbf{Ax} = \mathbf{b}$ with

$$\mathbf{A} = \begin{pmatrix} 1 & 0 \\ 1 & 1 \\ 1 & 2 \end{pmatrix}, \qquad \mathbf{b} = \begin{pmatrix} 1 \\ 3 \\ 2 \end{pmatrix}, \qquad \mathbf{x} = (c_0, c_1).$$

Gram–Schmidt: $\|\mathbf{a}_1\| = \sqrt{3}$, so $r_{11} = \sqrt{3}$ and $\mathbf{q}_1 = \frac{1}{\sqrt{3}}(1, 1, 1)$. Then $r_{12} = \langle \mathbf{a}_2, \mathbf{q}_1 \rangle = 3/\sqrt{3} = \sqrt{3}$ and

$$\mathbf{w}_2 = (0, 1, 2) - (1, 1, 1) = (-1, 0, 1),$$

so $r_{22} = \sqrt{2}$ and $\mathbf{q}_2 = \frac{1}{\sqrt{2}}(-1, 0, 1)$. Now $\langle \mathbf{b}, \mathbf{q}_1 \rangle = 6/\sqrt{3} = 2\sqrt{3}$ and $\langle \mathbf{b}, \mathbf{q}_2 \rangle = (-1 + 0 + 2)/\sqrt{2} = 1/\sqrt{2}$, so (†) reads

$$\begin{pmatrix} \sqrt{3} & \sqrt{3} \\ 0 & \sqrt{2} \end{pmatrix} \mathbf{x} = \begin{pmatrix} 2\sqrt{3} \\ 1/\sqrt{2} \end{pmatrix}.$$

Back substitution gives $c_1 = \frac{1}{2}$ and then $\sqrt{3}(c_0 + \frac{1}{2}) = 2\sqrt{3}$, so $c_0 = \frac{3}{2}$. The fitted line is $y = \frac{3}{2} + \frac{1}{2}t$, with residual $\mathbf{Ax} - \mathbf{b} = (\frac{1}{2}, -1, \frac{1}{2})$ and $\|\mathbf{Ax} - \mathbf{b}\|^2 = \frac{3}{2}$.

Check. $\mathbf{A}^{\top}\mathbf{A} = \begin{pmatrix} 3 & 3 \\ 3 & 5 \end{pmatrix}$ and $\mathbf{A}^{\top}\mathbf{b} = (6, 7)$. Subtracting the first normal equation from the second gives $2c_1 = 1$, and then $3c_0 + \frac{3}{2} = 6$, so $c_0 = \frac{3}{2}$. The residual is orthogonal to both columns of $\mathbf{A}$: $\frac{1}{2} - 1 + \frac{1}{2} = 0$ and $0 \cdot \frac{1}{2} - 1 \cdot 1 + 2 \cdot \frac{1}{2} = 0$, which is what the normal equations of Theorem 10.4.2 say.

Exercise B4: Determine which are QR factorizations.

Determine which of the following are QR factorizations of the matrix on the left in the sense of Theorem 10.8.1. Justify your answer; for those that are not, name the clause that fails and repair it if possible.

(a) $\begin{pmatrix} 3 & 1 \\ 4 & 7 \end{pmatrix} = \frac{1}{5}\begin{pmatrix} 3 & -4 \\ 4 & 3 \end{pmatrix}\begin{pmatrix} 5 & \frac{31}{5} \\ 0 & \frac{17}{5} \end{pmatrix}$.

(b) $\begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix} = \begin{pmatrix} 1 & -1 \\ 1 & 1 \end{pmatrix}\begin{pmatrix} 1 & \frac{1}{2} \\ 0 & \frac{1}{2} \end{pmatrix}$.

(c) $\begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}\begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix}$.

Solution.

(a) Yes. The product is

$$\frac{1}{5}\begin{pmatrix} 15 & \frac{93}{5} - \frac{68}{5} \\ 20 & \frac{124}{5} + \frac{51}{5} \end{pmatrix} = \frac{1}{5}\begin{pmatrix} 15 & 5 \\ 20 & 35 \end{pmatrix} = \begin{pmatrix} 3 & 1 \\ 4 & 7 \end{pmatrix},$$

the columns of the left factor are $\frac{1}{5}(3,4)$ and $\frac{1}{5}(-4,3)$, both of length 1 and orthogonal, and the diagonal entries 5 and $\frac{17}{5}$ are positive. All three clauses hold, so by the uniqueness in Theorem 10.8.1 this is **the** QR factorization.

(b) No. The identity is correct, and $\mathbf{R}$ is upper triangular with positive diagonal, but the columns of the left factor have length $\sqrt{2}$, not 1, so clause (a) of Theorem 10.8.1 fails. Repair it by dividing each column of $\mathbf{Q}$ by $\sqrt{2}$ and multiplying the matching row of $\mathbf{R}$ by $\sqrt{2}$:

$$\mathbf{Q} = \frac{1}{\sqrt{2}}\begin{pmatrix} 1 & -1 \\ 1 & 1 \end{pmatrix}, \qquad \mathbf{R} = \begin{pmatrix} \sqrt{2} & \frac{1}{\sqrt{2}} \\ 0 & \frac{1}{\sqrt{2}} \end{pmatrix}.$$

(c) No. The identity is correct and the columns of $\mathbf{Q} = \mathbf{I}_2$ are orthonormal, but $r_{11} = -1 < 0$, so clause (b) fails. Repair it by moving the sign across: $\mathbf{Q} = \operatorname{diag}(-1, 1)$, whose columns are still orthonormal, and $\mathbf{R} = \mathbf{I}_2$, whose diagonal is positive. This is the move described in Exercise (C1: All the QR factorizations of a matrix) with $\mathbf{D} = \operatorname{diag}(-1, 1)$.

10.8.7.3 C. Going deeper

Exercise C1: All the QR factorizations of a matrix.

Let $\mathbf{A} \in M_{m\times n}(F)$ have independent columns, with QR factorization $\mathbf{A} = \mathbf{QR}$ as in Theorem 10.8.1.

(a) Prove that an upper triangular $\mathbf{S} \in M_n(F)$ with $\mathbf{S}^*\mathbf{S} = \mathbf{I}_n$ is diagonal, with diagonal entries of modulus 1.

(b) Deduce that the pairs $(\mathbf{Q}_1, \mathbf{R}_1)$ with $\mathbf{Q}_1^*\mathbf{Q}_1 = \mathbf{I}_n$, $\mathbf{R}_1$ upper triangular and invertible, and $\mathbf{A} = \mathbf{Q}_1\mathbf{R}_1$, are exactly the pairs $(\mathbf{QD}^{-1}, \mathbf{DR})$ for $\mathbf{D} = \operatorname{diag}(d_1, \dots, d_n)$ with $|d_k| = 1$.

(c) Hence give a second proof of the uniqueness statement of Theorem 10.8.1.

Solution.

(a) Let $\mathbf{s}_1, \dots, \mathbf{s}_n$ be the columns of $\mathbf{S}$; as in the proof of Theorem 10.8.1, $\mathbf{S}^*\mathbf{S} = \mathbf{I}_n$ says $\langle \mathbf{s}_j, \mathbf{s}_i \rangle = \delta_{ij}$. We show $\mathbf{s}_j = s_{jj}\mathbf{e}_j$ with $|s_{jj}| = 1$, by induction on j. Suppose

this holds for every $i < j$. For such i,

$$0 = \langle \mathbf{s}_j, \mathbf{s}_i \rangle = \overline{s_{ii}} \langle \mathbf{s}_j, \mathbf{e}_i \rangle = \overline{s_{ii}}\, s_{ij},$$

and $s_{ii} \neq 0$, so $s_{ij} = 0$. Together with upper triangularity this gives $\mathbf{s}_j = s_{jj}\mathbf{e}_j$, and $\|\mathbf{s}_j\| = 1$ gives $|s_{jj}| = 1$.

(b) ($\Leftarrow$) If $|d_k| = 1$ for all k, then $\mathbf{D}^*\mathbf{D} = \mathbf{I}_n$, so $(\mathbf{Q}\mathbf{D}^{-1})^*(\mathbf{Q}\mathbf{D}^{-1}) = (\mathbf{D}^{-1})^*\mathbf{Q}^*\mathbf{Q}\mathbf{D}^{-1} = (\mathbf{D}\mathbf{D}^*)^{-1} = \mathbf{I}_n$; the matrix $\mathbf{D}\mathbf{R}$ is upper triangular and invertible; and $(\mathbf{Q}\mathbf{D}^{-1})(\mathbf{D}\mathbf{R}) = \mathbf{Q}\mathbf{R} = \mathbf{A}$.
($\Rightarrow$) Suppose $\mathbf{A} = \mathbf{Q}_1\mathbf{R}_1$ as stated. Exactly as in the proof of Theorem 10.8.1, $\mathbf{R}_1^*\mathbf{R}_1 = \mathbf{A}^*\mathbf{A} = \mathbf{R}^*\mathbf{R}$, and $\mathbf{S} = \mathbf{R}_1\mathbf{R}^{-1}$ is upper triangular with $\mathbf{S}^*\mathbf{S} = \mathbf{I}_n$. By (a), $\mathbf{S} = \mathbf{D}$ is diagonal with $|d_k| = 1$. Then $\mathbf{R}_1 = \mathbf{D}\mathbf{R}$ and $\mathbf{Q}_1 = \mathbf{A}\mathbf{R}_1^{-1} = \mathbf{Q}\mathbf{R}\mathbf{R}^{-1}\mathbf{D}^{-1} = \mathbf{Q}\mathbf{D}^{-1}$.

(c) If in addition both $\mathbf{R}$ and $\mathbf{R}_1 = \mathbf{D}\mathbf{R}$ have positive real diagonal entries, then $d_k = (\mathbf{R}_1)_{kk}/(\mathbf{R})_{kk}$ is a positive real number of modulus 1, so $d_k = 1$ for every k. Hence $\mathbf{D} = \mathbf{I}_n$, $\mathbf{R}_1 = \mathbf{R}$ and $\mathbf{Q}_1 = \mathbf{Q}$.

Exercise C2: Reflections do not mind dependence.

Let

$$\mathbf{A} = \begin{pmatrix} 1 & 1 & 2 \\ 2 & 1 & 3 \\ 2 & 3 & 5 \end{pmatrix},$$

whose third column is the sum of the first two.

(a) Run the Gram–Schmidt process of Theorem 10.2.2 on the columns of $\mathbf{A}$ and say precisely which step fails.

(b) Carry out the Householder reduction of Theorem 10.8.4 on $\mathbf{A}$ and exhibit $\mathbf{R}$.

(c) Explain, using Theorem 10.8.1, why no factorization $\mathbf{A} = \mathbf{Q}\mathbf{R}$ with $\mathbf{Q}^*\mathbf{Q} = \mathbf{I}_3$ and $\mathbf{R}$ upper triangular with positive diagonal can exist.

Solution.

(a) Steps 1 and 2 go through: $\mathbf{q}_1 = \frac{1}{3}(1,2,2)$ and, since $\langle \mathbf{a}_2, \mathbf{q}_1 \rangle = \frac{1}{3}(1+2+6) = 3$, $\mathbf{w}_2 = (1,1,3) - (1,2,2) = (0,-1,1)$ and $\mathbf{q}_2 = \frac{1}{\sqrt{2}}(0,-1,1)$. At step 3, $\mathbf{a}_3 = \mathbf{a}_1 + \mathbf{a}_2$ lies in $\operatorname{span}(\mathbf{a}_1, \mathbf{a}_2) = \operatorname{span}(\mathbf{q}_1, \mathbf{q}_2)$, so by Theorem 10.2.1 (a) the vector subtracted from $\mathbf{a}_3$ is $\mathbf{a}_3$ itself and $\mathbf{w}_3 = \mathbf{0}$. The normalization $\mathbf{q}_3 = \mathbf{w}_3/\|\mathbf{w}_3\|$ divides by 0 and fails. This is the situation of Exercise (C2: Gram–Schmidt on a dependent list).

(b) The first column is $(1,2,2)$, so as in Exercise (B2: The same matrix by reflections) we take $\mathbf{w}_1 = (4,2,2)$ with $\|\mathbf{w}_1\|^2 = 24$, and $\mathbf{H}_1\mathbf{v} = \mathbf{v} - \frac{1}{12}\langle \mathbf{v}, \mathbf{w}_1 \rangle \mathbf{w}_1$. The inner products of the three columns with $\mathbf{w}_1$ are 12, 12 and 24, so

$$\mathbf{H}_1\mathbf{A} = \begin{pmatrix} -3 & -3 & -6 \\ 0 & -1 & -1 \\ 0 & 1 & 1 \end{pmatrix}.$$

The trailing vector of column 2 is $(-1,1)$, which by Exercise (B2: The same matrix by reflections) (b) the second reflection sends to $\sqrt{2}\,\mathbf{e}_1$; it sends the trailing vector

of column 3, which is the same vector $(-1, 1)$, to the same place. Hence

$$\mathbf{R} = \begin{pmatrix} -3 & -3 & -6 \\ 0 & \sqrt{2} & \sqrt{2} \\ 0 & 0 & 0 \end{pmatrix},$$

upper triangular, with a zero in position $(3, 3)$ exactly where the dependence sits. No step of the algorithm divided by zero.

(c) Such an $\mathbf{R}$ would be invertible by Lemma 2.6.2, so $\operatorname{rank} \mathbf{A} = \operatorname{rank}(\mathbf{QR}) = \operatorname{rank} \mathbf{Q} = 3$. But $\mathbf{a}_3 = \mathbf{a}_1 + \mathbf{a}_2$, so the columns are dependent and $\operatorname{rank} \mathbf{A} \leq 2$, a contradiction. The positive-diagonal factorization exists precisely for matrices of full column rank.

Exercise C3: Triangularizing with rotations.

(a) Let $(a, b) \in \mathbb{R}^2$ be non-zero and $r = \sqrt{a^2 + b^2}$. Verify that the Givens rotation $\mathbf{G}$ of Definition 10.8.2 with $c = a/r$ and $s = b/r$ satisfies $\mathbf{G}(a, b) = (r, 0)$, and that $\mathbf{G} \in \mathrm{SO}(2)$.

(b) Use (a) to write $\mathbf{A} = \begin{pmatrix} 3 & 1 \\ 4 & 2 \end{pmatrix}$ as $\mathbf{QR}$ with $\mathbf{Q} \in \mathrm{SO}(2)$ and $\mathbf{R}$ upper triangular with positive diagonal.

(c) How many Givens rotations does it take to triangularize a general 3×3 real matrix, and which entries does each one kill? Compare with the number of Householder reflections.

Solution.

(a) $\mathbf{G}(a, b) = (ca + sb,\ -sa + cb) = \big((a^2 + b^2)/r,\ (-ab + ab)/r\big) = (r, 0)$. Also $c^2 + s^2 = 1$, so the columns of $\mathbf{G}$ are orthonormal and $\det \mathbf{G} = c^2 + s^2 = 1$; hence $\mathbf{G} \in \mathrm{SO}(2)$.

(b) The first column is $(3, 4)$, so $r = 5$, $c = \frac{3}{5}$, $s = \frac{4}{5}$ and $\mathbf{G} = \frac{1}{5}\begin{pmatrix} 3 & 4 \\ -4 & 3 \end{pmatrix}$. Then

$$\mathbf{GA} = \tfrac{1}{5}\begin{pmatrix} 9 + 16 & 3 + 8 \\ -12 + 12 & -4 + 6 \end{pmatrix} = \begin{pmatrix} 5 & \frac{11}{5} \\ 0 & \frac{2}{5} \end{pmatrix} =: \mathbf{R},$$

whose diagonal entries 5 and $\frac{2}{5}$ are positive. Since $\mathbf{G}^{-1} = \mathbf{G}^{\top} \in \mathrm{SO}(2)$, we get $\mathbf{A} = \mathbf{QR}$ with $\mathbf{Q} = \mathbf{G}^{\top} = \frac{1}{5}\begin{pmatrix} 3 & -4 \\ 4 & 3 \end{pmatrix}$. As a check, $\det \mathbf{A} = 2 = 5 \cdot \frac{2}{5} = \det \mathbf{R}$.

(c) Three: one for a_{21} (rows $1, 2$), one for a_{31} (rows $1, 3$), and one for the new $(3, 2)$-entry (rows $2, 3$). The last acts on rows 2 and 3, which by then have zeros in column 1, so it does not undo the earlier work. Householder needs two reflections, one per column, since each clears a whole column at once.

10.9 Bessel, Parseval and Fourier Series

Section 3 measured a vector against a finite-dimensional subspace and produced the nearest point in it. Read that answer coefficient by coefficient and it becomes an inequality: the numbers $\langle \mathbf{v}, \mathbf{e}_i \rangle$ collected against an orthonormal list can never carry more squared length than $\mathbf{v}$ itself

has. That is Bessel's inequality. It costs nothing in dimension, it holds in spaces far too large for Chapter 1's machinery, and its equality case is Parseval's identity. This section proves both, applies them to the sines and cosines, and then stops at the exact place where linear algebra stops and analysis begins.

Throughout, V is an inner product space over $F = \mathbb{R}$ or $F = \mathbb{C}$, with inner product $\langle \cdot, \cdot \rangle$ (Definition 10.1.1) and induced norm $\|\cdot\|$ (Definition 10.1.3). **We do not assume that V is finite-dimensional.** What we assume each time is that the *list* we compute against is finite.

10.9.1 Coefficients against an orthonormal list

In Theorem 10.2.1 the list was an orthonormal **basis**, and the coefficients $\langle \mathbf{v}, \mathbf{e}_i \rangle$ recovered $\mathbf{v}$ exactly. Suppose now the list is only a list: too short to be a basis, or sitting inside a space that has no finite basis at all, like the continuous functions on an interval. The numbers $\langle \mathbf{v}, \mathbf{e}_i \rangle$ are still there. What can be said about them when they no longer determine $\mathbf{v}$?

Against a shorter list you can only lose length, never gain it.

Definition 10.9.1 — Fourier Coefficients With Respect to an Orthonormal List

Let $(\mathbf{e}_1, \dots, \mathbf{e}_k)$ be an orthonormal list in an inner product space V and let $\mathbf{v} \in V$. The scalars

$$\langle \mathbf{v}, \mathbf{e}_1 \rangle, \ \dots, \ \langle \mathbf{v}, \mathbf{e}_k \rangle \in F$$

are the **Fourier coefficients** of $\mathbf{v}$ with respect to the list.

The name is borrowed from the classical case below, where the $\mathbf{e}_i$ are sines and cosines; nothing in the definition mentions trigonometry. When the list happens to be a basis, these are exactly the coordinates of $\mathbf{v}$, by Theorem 10.2.1 (a). When it is not, they are the coordinates of a *shadow* of $\mathbf{v}$, and the next theorem measures that shadow.

Theorem 10.9.1 — Bessel's Inequality

Let V be an inner product space over F, **not assumed finite-dimensional**, and let $(\mathbf{e}_1, \dots, \mathbf{e}_k)$ be an orthonormal list in V. Then for **every** $\mathbf{v} \in V$,

$$\sum_{i=1}^{k} |\langle \mathbf{v}, \mathbf{e}_i \rangle|^2 \ \leq \ \|\mathbf{v}\|^2.$$

Idea. The left-hand side is not a quantity out of nowhere. Let U be the span of the list. By the projection formula, $P_U \mathbf{v}$ is exactly $\sum_i \langle \mathbf{v}, \mathbf{e}_i \rangle \mathbf{e}_i$, and its summands are pairwise orthogonal, so Pythagoras turns its squared length into precisely that sum. The inequality then says no more than "a shadow is no longer than what casts it", which we already proved. The one point needing care is that V may be infinite-dimensional; it does not matter, because Section 3 only ever asked the **subspace** to be finite-dimensional.

Proof. Put $U = \operatorname{span}(\mathbf{e}_1, \dots, \mathbf{e}_k)$. The vectors $\mathbf{e}_i$ are orthogonal and non-zero, so the list is linearly independent by Theorem 10.1.4; being a spanning list of U as well, it is

an orthonormal basis of U, and $\dim U = k$ is finite. Hence Theorem 10.3.3 applies to U even though V need not be finite-dimensional, and part (a) of it gives

$$P_U\mathbf{v} = \sum_{i=1}^{k} \langle \mathbf{v}, \mathbf{e}_i \rangle \, \mathbf{e}_i .$$

The summands $\langle \mathbf{v}, \mathbf{e}_i \rangle \mathbf{e}_i$ are pairwise orthogonal, since $\mathbf{e}_i \perp \mathbf{e}_j$ for $i \neq j$ and scalars come out of both slots. So Theorem 10.1.3 and Theorem 10.1.2 (b) give

$$\|P_U\mathbf{v}\|^2 = \sum_{i=1}^{k} |\langle \mathbf{v}, \mathbf{e}_i \rangle|^2 \|\mathbf{e}_i\|^2 = \sum_{i=1}^{k} |\langle \mathbf{v}, \mathbf{e}_i \rangle|^2 ,$$

using $\|\mathbf{e}_i\| = 1$. By Theorem 10.3.3 (c), $\|P_U\mathbf{v}\| \leq \|\mathbf{v}\|$. Both sides are non-negative, so squaring preserves the inequality, and this proves the theorem.

■

The proof gives more than the inequality, and the surplus is worth recording. The vector $\mathbf{v} - P_U\mathbf{v}$ lies in $U^{\perp}$ by Theorem 10.3.2, so it is orthogonal to $P_U\mathbf{v} \in U$, and Theorem 10.1.3 turns $\mathbf{v} = P_U\mathbf{v} + (\mathbf{v} - P_U\mathbf{v})$ into $\|\mathbf{v}\|^2 = \|P_U\mathbf{v}\|^2 + \|\mathbf{v} - P_U\mathbf{v}\|^2$. Rearranging, and substituting $\|P_U\mathbf{v}\|^2 = \sum_{i=1}^{k} |\langle \mathbf{v}, \mathbf{e}_i \rangle|^2$ from the proof above,

$$\|\mathbf{v} - P_U\mathbf{v}\|^2 = \|\mathbf{v}\|^2 - \sum_{i=1}^{k} |\langle \mathbf{v}, \mathbf{e}_i \rangle|^2 . \tag{$*$}$$

In words: **the deficit in Bessel's inequality is the squared distance from $\mathbf{v}$ to the span of the list** (Definition 10.3.3). An inequality with a known defect is much more useful than an inequality, and we will read $(*)$ from both sides.

Remark. For an infinite orthonormal list $(\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3, \dots)$, apply the theorem to the first k terms for each k. The partial sums $\sum_{i \leq k} |\langle \mathbf{v}, \mathbf{e}_i \rangle|^2$ increase with k and are all bounded above by $\|\mathbf{v}\|^2$, so they converge, and $\sum_{i=1}^{\infty} |\langle \mathbf{v}, \mathbf{e}_i \rangle|^2 \leq \|\mathbf{v}\|^2$. This is the only fact from analysis used in the present paragraph: a bounded increasing sequence of real numbers converges.

Now the equality case, which is where the word *basis* returns.

Theorem 10.9.2 — Parseval's Identity

Let $(\mathbf{e}_1, \dots, \mathbf{e}_k)$ be an orthonormal list in an inner product space V and let $\mathbf{v} \in V$. Then

$$\sum_{i=1}^{k} |\langle \mathbf{v}, \mathbf{e}_i \rangle|^2 = \|\mathbf{v}\|^2 \quad \text{if and only if} \quad \mathbf{v} \in \operatorname{span}(\mathbf{e}_1, \dots, \mathbf{e}_k).$$

In particular, if $(\mathbf{e}_1, \dots, \mathbf{e}_k)$ is an orthonormal **basis** of V, the identity holds for every $\mathbf{v} \in V$.

Proof. Keep the notation of the proof of Theorem 10.9.1, where we showed $\sum_i |\langle \mathbf{v}, \mathbf{e}_i \rangle|^2 = \|P_U\mathbf{v}\|^2$ with $U = \operatorname{span}(\mathbf{e}_1, \dots, \mathbf{e}_k)$. So the stated equality says $\|P_U\mathbf{v}\| = \|\mathbf{v}\|$, and by Theorem 10.3.3 (c) this holds if and only if $\mathbf{v} \in U$. If the list is a basis of V, then $U = V$ and every $\mathbf{v} \in V$ lies in U.

■

For an orthonormal basis of a finite-dimensional space this is Theorem 10.2.1 (c) again; what is new is the equality **case**, which identifies exactly the vectors for which no length is lost. Keep the two statements apart:

- **Bessel** is about an orthonormal **list**, in **any** inner product space, and it is an inequality.
- **Parseval** is the equality, and it holds exactly for the vectors the list already spans.

The whole difference is whether the list reaches $\mathbf{v}$.

Warning. **An orthonormal list is not an orthonormal basis, and the deficit in Bessel can be everything.** In $C[-\pi,\pi]$ below, the list $(\cos x, \sin x)$ is orthonormal, and for the constant function $f = 1$ both coefficients are 0, so the left-hand side of Bessel is 0 while $\|f\|^2 = 2$. Nothing at all is captured. A short orthonormal list is not a bad basis; it is not a basis.

Quick check. In $\mathbb{R}^4$ with the dot product, let $\mathbf{e}_1 = \frac{1}{2}(1,1,1,1)$ and $\mathbf{e}_2 = \frac{1}{2}(1,1,-1,-1)$, and let $\mathbf{v} = (1,2,3,4)$. Check that $(\mathbf{e}_1, \mathbf{e}_2)$ is orthonormal, compute both sides of Bessel's inequality, and say what the deficit equals.

Solution. Each has norm $\frac{1}{2}\sqrt{4} = 1$, and $\langle \mathbf{e}_1, \mathbf{e}_2 \rangle = \frac{1}{4}(1+1-1-1) = 0$, so the list is orthonormal. The coefficients are $\langle \mathbf{v}, \mathbf{e}_1 \rangle = \frac{1}{2}(1+2+3+4) = 5$ and $\langle \mathbf{v}, \mathbf{e}_2 \rangle = \frac{1}{2}(1+2-3-4) = -2$, so the left-hand side is $25+4 = 29$, while $\|\mathbf{v}\|^2 = 1+4+9+16 = 30$. The inequality is strict, and by $(*)$ the deficit 1 is the squared distance from $\mathbf{v}$ to $\operatorname{span}(\mathbf{e}_1, \mathbf{e}_2)$. Indeed $P_U\mathbf{v} = 5\mathbf{e}_1 - 2\mathbf{e}_2 = \left(\frac{3}{2}, \frac{3}{2}, \frac{7}{2}, \frac{7}{2}\right)$ and $\mathbf{v} - P_U\mathbf{v} = \frac{1}{2}(-1,1,-1,1)$, whose squared norm is $4 \cdot \frac{1}{4} = 1$.

10.9.2 The trigonometric system

The classical home of these two statements is a space of functions, and the first thing to fix is the inner product, constant included.

Let $V = C[-\pi,\pi]$ be the space of continuous functions $f\colon [-\pi,\pi] \to \mathbb{R}$, a real vector space, and define

$$\langle f, g \rangle = \frac{1}{\pi} \int_{-\pi}^{\pi} f(t)\, g(t)\, \mathrm{d}t.$$

This is the continuous-function inner product of Definition 10.1.1 on a different interval and rescaled by the positive constant $1/\pi$; rescaling by a positive constant preserves all three axioms, and positive definiteness is the argument given there. The constant is chosen for one reason only: it makes the sines and cosines unit vectors. With $1/(2\pi)$ in front they would have norm $1/\sqrt{2}$, and with no constant at all, norm $\sqrt{\pi}$.

Warning. **Always state the normalizing constant before computing.** Formulas for Fourier coefficients differ between books by exactly such a factor, and a misplaced π or 2 changes every number below. In this section $\langle f, g \rangle = \frac{1}{\pi}\int_{-\pi}^{\pi} fg$, and every coefficient, norm and inequality is written for that choice.

Here are the facts we assume. From calculus: the integral of a finite sum is the sum of the integrals; $\int_{-\pi}^{\pi} \mathrm{d}t = 2\pi$; $\int_{-\pi}^{\pi} \sin(mt)\,\mathrm{d}t = 0$ for every integer m and $\int_{-\pi}^{\pi} \cos(mt)\,\mathrm{d}t = 0$ for

every **non-zero** integer m (for $m \neq 0$ evaluate the antiderivative $-\cos(mt)/m$, respectively $\sin(mt)/m$, each of which takes the same value at $t = -\pi$ as at $t = \pi$; for $m = 0$ the sine integrand is 0); integration by parts, and the substitution $t \mapsto -t$, both of which we use later in the section when computing particular Fourier coefficients. From trigonometry: the product-to-sum identities. **No theorem about convergence is used anywhere in this section**; every integral we compute is the integral of a finite sum of sines and cosines.

Example. (The Trigonometric System Is Orthonormal)

Fix $n \geq 1$. Show that the list of $2n+1$ functions

$$\frac{1}{\sqrt{2}},\ \cos x,\ \sin x,\ \cos 2x,\ \sin 2x,\ \ldots,\ \cos nx,\ \sin nx$$

is orthonormal in $V = C[-\pi, \pi]$ with $\langle f, g\rangle = \frac{1}{\pi}\int_{-\pi}^{\pi} fg$.

Solution. There are five kinds of pair. Write j, k for indices in $\{1, \ldots, n\}$.

The constant with itself. $\|1/\sqrt{2}\|^2 = \frac{1}{\pi}\int_{-\pi}^{\pi} \frac{1}{2}\,\mathrm{d}t = \frac{1}{\pi}\cdot\pi = 1$.

The constant against $\cos kx$ *or* $\sin kx$. These are $\frac{1}{\pi\sqrt{2}}\int_{-\pi}^{\pi}\cos(kt)\,\mathrm{d}t = 0$ and $\frac{1}{\pi\sqrt{2}}\int_{-\pi}^{\pi}\sin(kt)\,\mathrm{d}t = 0$, since $k \neq 0$.

Two cosines. By $\cos A\cos B = \frac{1}{2}[\cos(A-B)+\cos(A+B)]$,

$$\langle \cos jx, \cos kx\rangle = \frac{1}{2\pi}\int_{-\pi}^{\pi}\big[\cos((j-k)t)+\cos((j+k)t)\big]\mathrm{d}t.$$

If $j \neq k$, both $j-k$ and $j+k$ are non-zero integers, so both integrals vanish and the value is 0. If $j = k$, the first integrand is the constant 1 and the second has non-zero frequency $2k$, so the value is $\frac{1}{2\pi}(2\pi + 0) = 1$.

Two sines. By $\sin A\sin B = \frac{1}{2}[\cos(A-B)-\cos(A+B)]$, the same two integrals appear with a minus sign, giving 0 for $j \neq k$ and $\frac{1}{2\pi}(2\pi - 0) = 1$ for $j = k$.

A sine against a cosine. By $\sin A\cos B = \frac{1}{2}[\sin(A+B)+\sin(A-B)]$,

$$\langle \sin jx, \cos kx\rangle = \frac{1}{2\pi}\int_{-\pi}^{\pi}\big[\sin((j+k)t)+\sin((j-k)t)\big]\mathrm{d}t = 0,$$

because every integral of a sine over $[-\pi, \pi]$ vanishes, including the case $j = k$ where the second integrand is $\sin 0 = 0$.

So each of the $2n+1$ functions is a unit vector and distinct ones are orthogonal, which is Definition 10.2.1.

Write $W_n = \operatorname{span}(1, \cos x, \sin x, \ldots, \cos nx, \sin nx)$, the space of **trigonometric polynomials of degree at most** n. The list above is an orthonormal list, hence independent (Theorem 10.1.4), and it spans W_n, since $1 = \sqrt{2}\cdot\frac{1}{\sqrt{2}}$. So it is an orthonormal basis of W_n and $\dim W_n = 2n+1$.

For $f \in V$ the classical **Fourier coefficients** of f are

$$a_k = \frac{1}{\pi}\int_{-\pi}^{\pi} f(t)\cos(kt)\,\mathrm{d}t, \qquad b_k = \frac{1}{\pi}\int_{-\pi}^{\pi} f(t)\sin(kt)\,\mathrm{d}t,$$

for $k \geq 0$ and $k \geq 1$ respectively. Comparing with the inner product, $a_k = \langle f, \cos kx\rangle$ and $b_k = \langle f, \sin kx\rangle$, while the coefficient against the constant of the orthonormal list is $\langle f, 1/\sqrt{2}\rangle = a_0/\sqrt{2}$. These are exactly the Fourier coefficients of Definition 10.9.1 for this list.

Theorem 10.9.3 — Fourier Partial Sums Are Best Approximations

Let $f \in C[-\pi, \pi]$, let $n \geq 1$, and let a_k, b_k be the Fourier coefficients of f. Put

$$S_n f = \frac{a_0}{2} + \sum_{k=1}^{n} \big(a_k \cos kx + b_k \sin kx\big).$$

Then, with $\langle f, g\rangle = \frac{1}{\pi}\int_{-\pi}^{\pi} fg$:

(a) $S_n f = P_{W_n} f$;

(b) $\|f - S_n f\| \leq \|f - g\|$ for every $g \in W_n$, with equality **only** for $g = S_n f$;

(c) $\dfrac{a_0^2}{2} + \displaystyle\sum_{k=1}^{n} \big(a_k^2 + b_k^2\big) \leq \frac{1}{\pi}\int_{-\pi}^{\pi} f(t)^2 \, \mathrm{d}t.$

Idea. Nothing new happens here. The subspace W_n is finite-dimensional and we have an orthonormal basis of it, so Section 3 answers the approximation question and Theorem 10.9.1 answers the coefficient question; the work is only to match the classical notation to ours. The one thing to watch is the factor $\frac{1}{2}$ in front of a_0: it is not a convention pulled from the air, it is what $\langle f, 1/\sqrt{2}\rangle \cdot \frac{1}{\sqrt{2}}$ equals.

Proof.

(a) By Example (The Trigonometric System Is Orthonormal) the list $\big(\frac{1}{\sqrt{2}}, \cos x, \sin x, \ldots, \cos nx, \sin nx\big)$ is an orthonormal basis of W_n. By Theorem 10.3.3 (a),

$$P_{W_n} f = \Big\langle f, \tfrac{1}{\sqrt{2}}\Big\rangle \tfrac{1}{\sqrt{2}} + \sum_{k=1}^{n} \big(\langle f, \cos kx\rangle \cos kx + \langle f, \sin kx\rangle \sin kx\big).$$

The first term is $\frac{a_0}{\sqrt{2}} \cdot \frac{1}{\sqrt{2}} = \frac{a_0}{2}$, and the remaining terms are $a_k \cos kx + b_k \sin kx$. Hence $P_{W_n} f = S_n f$.

(b) This is Theorem 10.3.5 applied to the subspace $U = W_n$, which is legitimate because $\dim W_n = 2n + 1$ is finite, together with (a).

(c) This is Theorem 10.9.1 for the same orthonormal list, since $|\langle f, 1/\sqrt{2}\rangle|^2 = a_0^2/2$ and $\|f\|^2 = \frac{1}{\pi}\int_{-\pi}^{\pi} f^2$.

■

So the Fourier partial sum is not a guess at f that happens to work: it **is** the orthogonal projection of f onto the trigonometric polynomials of degree at most n, and by Theorem 10.3.5 it is the unique trigonometric polynomial of that degree closest to f in this norm. The mysterious $a_0/2$ of the classical formula is an artifact of normalizing the constant function.

10.9.3 A worked computation

Example. (The Fourier Coefficients of $f(x) = x$)

In $C[-\pi, \pi]$ with $\langle f, g\rangle = \frac{1}{\pi}\int_{-\pi}^{\pi} fg$, let $f(x) = x$. Find all a_k and b_k, write down $S_n f$, and say what Theorem 10.9.3 (c) gives.

Solution. We use one further calculus fact: a continuous **odd** function integrates to 0 over $[-\pi, \pi]$, and a continuous **even** one integrates to twice its integral over $[0, \pi]$. Both come from the substitution $t \mapsto -t$.

The cosine coefficients. For every $k \geq 0$ the function $t\cos(kt)$ is odd, so $a_k = 0$. In particular $a_0 = 0$.

The sine coefficients. The function $t\sin(kt)$ is even, so for $k \geq 1$,

$$b_k = \frac{1}{\pi}\int_{-\pi}^{\pi} t\sin(kt)\,\mathrm{d}t = \frac{2}{\pi}\int_{0}^{\pi} t\sin(kt)\,\mathrm{d}t.$$

Integrating by parts, with $\mathrm{d}(-\cos(kt)/k) = \sin(kt)\,\mathrm{d}t$,

$$\int_0^{\pi} t\sin(kt)\,\mathrm{d}t = \Big[\frac{-t\cos(kt)}{k}\Big]_0^{\pi} + \frac{1}{k}\int_0^{\pi}\cos(kt)\,\mathrm{d}t = \frac{-\pi\cos(k\pi)}{k},$$

since the last integral is $[\sin(kt)/k^2]_0^{\pi} = 0$. As $\cos(k\pi) = (-1)^k$, this equals $\pi(-1)^{k+1}/k$, and therefore

$$b_k = \frac{2(-1)^{k+1}}{k}.$$

The partial sums. Hence

$$S_n f = \sum_{k=1}^{n} \frac{2(-1)^{k+1}}{k}\sin kx = 2\sin x - \sin 2x + \tfrac{2}{3}\sin 3x - \dots,$$

and by Theorem 10.9.3 (b) this is the closest trigonometric polynomial of degree at most n to the function x in this norm.

What Bessel's inequality (Theorem 10.9.1) gives. First $\|f\|^2 = \frac{1}{\pi}\int_{-\pi}^{\pi} t^2\,\mathrm{d}t = \frac{1}{\pi}\cdot\frac{2\pi^3}{3} = \frac{2\pi^2}{3}$. Since $a_k = 0$ and $b_k^2 = 4/k^2$, part (c) of Theorem 10.9.3 reads

$$\sum_{k=1}^{n}\frac{4}{k^2} \leq \frac{2\pi^2}{3}, \qquad \text{that is} \qquad \sum_{k=1}^{n}\frac{1}{k^2} \leq \frac{\pi^2}{6}$$

for **every** n. The partial sums on the left increase and are bounded above, so they converge, and $\sum_{k=1}^{\infty} 1/k^2 \leq \pi^2/6$.

That bound is sharp: the true value of the sum is $\pi^2/6$. But sharpness is not something Bessel can deliver. By Theorem 10.9.2, equality for a fixed finite list holds only when f lies in the span of that list, and the function x lies in no W_n — it is not a trigonometric polynomial, since every element of W_n takes the same value at $-\pi$ and at π. Getting the equality requires a statement about the **infinite** system, and that statement is an input from analysis; Exercise (C1: Parseval for the full trigonometric system) carries it out and flags it.

Quick check. Let $g(x) = \cos^2 x$ in $C[-\pi, \pi]$. Using $\cos^2 x = \frac{1}{2} + \frac{1}{2}\cos 2x$, write down all Fourier coefficients of g, find $S_1 g$, and compute the deficit in Bessel's inequality for $n = 1$.

Solution. The right-hand side $\frac{1}{2} + \frac{1}{2}\cos 2x$ already lies in W_2, and coefficients against an orthonormal basis are unique (Theorem 10.2.1 (a)), so, applying that result inside W_2 and reading the coefficients off: $a_0 = 1$, $a_2 = \frac{1}{2}$, and all other a_k and all b_k are 0. Hence $S_1 g = a_0/2 = \frac{1}{2}$, a constant. For the deficit, $\|g\|^2 = \frac{1}{\pi}\int_{-\pi}^{\pi} \cos^4 t \, dt = \frac{1}{\pi} \cdot \frac{3\pi}{4} = \frac{3}{4}$, while the Bessel sum for $n = 1$ is $a_0^2/2 = \frac{1}{2}$. The deficit is $\frac{1}{4}$, and by $(*)$ it should be $\|g - S_1 g\|^2 = \left\|\frac{1}{2}\cos 2x\right\|^2 = \frac{1}{4} \cdot 1 = \frac{1}{4}$. It is.

10.9.4 What best approximation does and does not say

It is worth being exact about the boundary here, because it is easy to read more into Theorem 10.9.3 than it contains.

Identity $(*)$ applied to $U = W_n$ says

$$\|f - S_n f\|^2 = \|f\|^2 - \frac{a_0^2}{2} - \sum_{k=1}^{n} (a_k^2 + b_k^2).$$

The subtracted sum never decreases as n grows, so the numbers $\|f - S_n f\|^2$ never increase, and they are bounded below by 0. Hence they converge to some limit $L \geq 0$. Everything up to this sentence is linear algebra plus one fact about monotone bounded sequences.

Whether $L = 0$ is a different kind of question. It asks whether the trigonometric polynomials come arbitrarily close, in this norm, to every continuous function, and no argument in this book decides it. The statement is true, and it is the analytic content of the theory of Fourier series; it is what makes the *infinite* trigonometric system behave like an orthonormal basis even though it is not a basis in the sense of Chapter 1.

And even $L = 0$ would not be a statement about individual points. Our norm averages the error over the whole interval, so it tolerates a large error on a short interval. The function $f(x) = x$ shows this at once:

$$S_n f(\pi) = \sum_{k=1}^{n} \frac{2(-1)^{k+1}}{k} \sin(k\pi) = 0$$

for every n, while $f(\pi) = \pi$. The error at the single point $x = \pi$ never shrinks at all.

Warning. **Mean-square best approximation is not pointwise approximation.** Theorem 10.9.3 says that $S_n f$ minimizes $\int_{-\pi}^{\pi}(f - g)^2$ over $g \in W_n$. It does not say that $S_n f(x)$ is close to $f(x)$ for a given x, and for $f(x) = x$ at $x = \pi$ it is not. Whether a Fourier series converges at a point is a question in analysis with a delicate answer; it is not decided by anything in this chapter, and a projection theorem cannot decide it.

10.9.5 Legendre and Chebyshev

Two families of orthogonal polynomials show the same two theorems at work with a different weight.

Legendre. Example (Gram–Schmidt on $1, x, x^2$) ran Gram–Schmidt on $(1, x, x^2)$ in $\mathbb{R}[x]_{\le 2}$ with $\langle p, q\rangle = \int_{-1}^{1} pq$, producing the orthogonal list $1,\ x,\ x^2 - \frac{1}{3}$ and, after normalizing, the orthonormal basis

$$\mathbf{e}_1 = \tfrac{1}{\sqrt{2}}, \qquad \mathbf{e}_2 = \sqrt{3/2}\,x, \qquad \mathbf{e}_3 = \tfrac{\sqrt{10}}{4}\big(3x^2 - 1\big).$$

Inside $\mathbb{R}[x]_{\le 2}$ this is a **basis**, so Theorem 10.9.2 gives $\|p\|^2 = \sum_{i=1}^{3} |\langle p, \mathbf{e}_i\rangle|^2$ for every quadratic p. Viewed inside the larger space $C[-1,1]$ of continuous functions, the same three vectors are only a **list**, and for an f outside $\mathbb{R}[x]_{\le 2}$ Theorem 10.9.1 is strict, the deficit being the squared distance from f to $\mathbb{R}[x]_{\le 2}$ by $(*)$. That deficit is what Example (The best quadratic approximation to a cubic) computed for $f = x^3$. One list, two readings, and which reading applies depends on the ambient space, not on the list. In practice one projects with the orthogonal list $1,\ x,\ x^2 - \frac{1}{3}$ through Corollary 10.3.4 and avoids the square roots entirely.

Chebyshev. Change the weight. On $\mathbb{R}[x]$ define

$$\langle p, q\rangle_w = \int_{-1}^{1} \frac{p(t)\,q(t)}{\sqrt{1-t^2}}\,\mathrm{d}t.$$

The integrand is unbounded at $t = \pm 1$, so this is an improper integral; it converges for polynomials, because $|pq|$ is bounded on $[-1,1]$ and $\int_{-1}^{1} \mathrm{d}t/\sqrt{1-t^2} = \pi$. The three axioms are checked as in Definition 10.1.1, positivity because $1/\sqrt{1-t^2} > 0$ on $(-1,1)$.

The **Chebyshev polynomials** are defined by the requirement

$$T_n(\cos\theta) = \cos n\theta \qquad \text{for all } \theta,$$

which does determine a polynomial of degree n, and determines it uniquely, since $\cos\theta$ runs over the whole of $[-1,1]$ and two polynomials agreeing on an infinite set are equal (Corollary 5.1.4). The first few are $T_0 = 1$, $T_1 = x$, $T_2 = 2x^2 - 1$ (from $\cos 2\theta = 2\cos^2\theta - 1$), and Exercise (C2: Chebyshev orthogonality by substitution) handles the general case. They are orthogonal for $\langle\cdot,\cdot\rangle_w$:

$$\langle T_m, T_n\rangle_w = 0 \quad (m \neq n), \qquad \langle T_n, T_n\rangle_w = \begin{cases} \pi, & n = 0, \\ \pi/2, & n \ge 1. \end{cases}$$

For $m, n \le 2$ this can be checked by hand, using $\int_{-1}^{1} \mathrm{d}t/\sqrt{1-t^2} = \pi$ and $\int_{-1}^{1} t^2\,\mathrm{d}t/\sqrt{1-t^2} = \pi/2$ (both come from $t = \cos\theta$). The pairs (T_0, T_1) and (T_1, T_2) have odd integrands on a symmetric interval, so those integrals are 0 by the substitution $t \mapsto -t$. For the remaining pair,

$$\langle T_0, T_2\rangle_w = \int_{-1}^{1} \frac{2t^2 - 1}{\sqrt{1-t^2}}\,\mathrm{d}t = 2 \cdot \frac{\pi}{2} - \pi = 0.$$

Why should such a weight produce orthogonality? Because it is the trigonometric system in disguise. Substituting $t = \cos\theta$ turns $\langle p, q\rangle_w$ into $\int_0^{\pi} p(\cos\theta) q(\cos\theta)\,\mathrm{d}\theta$, and on the Chebyshev polynomials that integrand is $\cos m\theta \cos n\theta$ — the very product whose integral we computed in Example (The Trigonometric System Is Orthonormal). Exercise (C2: Chebyshev orthogonality by substitution) asks for this in full.

Since the T_n are orthogonal but not normalized, projections onto their span are computed with Corollary 10.3.4 rather than Theorem 10.3.3. Section 10 of this chapter takes up orthogonal polynomials as a subject in their own right, including the recurrence that generates the T_n and the quadrature rules they produce.

10.9.6 Exercises

10.9.6.1 A. Check your understanding

Exercise A1.

(a) State Bessel's inequality, saying exactly what is assumed about the space and what is assumed about the list.

(b) State Parseval's identity, including the condition under which equality holds for a given vector.

(c) True or false: Bessel's inequality requires the ambient space to be finite-dimensional. Justify your answer.

(d) Write down the inner product used on $C[-\pi,\pi]$ in this section, including its normalizing constant, and say what the constant is for.

(e) State what Theorem 10.9.3 gives about $S_n f$, and name one thing it does not give.

(f) True or false: if $(\mathbf{e}_1,\dots,\mathbf{e}_k)$ is an orthonormal list and $\sum_i |\langle \mathbf{v},\mathbf{e}_i\rangle|^2 = \|\mathbf{v}\|^2$ for one particular $\mathbf{v}\neq\mathbf{0}$, then the list is an orthonormal basis of V. Justify your answer.

Solution.

(a) If $(\mathbf{e}_1,\dots,\mathbf{e}_k)$ is an orthonormal list in an inner product space V over $\mathbb{R}$ or $\mathbb{C}$, then $\sum_{i=1}^{k}|\langle \mathbf{v},\mathbf{e}_i\rangle|^2 \le \|\mathbf{v}\|^2$ for every $\mathbf{v}\in V$ (Theorem 10.9.1). The list is assumed **finite and orthonormal**; the space is assumed only to be an inner product space, with no dimension hypothesis.

(b) Equality $\sum_i |\langle \mathbf{v},\mathbf{e}_i\rangle|^2 = \|\mathbf{v}\|^2$ holds if and only if $\mathbf{v}\in\operatorname{span}(\mathbf{e}_1,\dots,\mathbf{e}_k)$; in particular it holds for every $\mathbf{v}$ when the list is an orthonormal basis of V (Theorem 10.9.2).

(c) False. Only the span of the list has to be finite-dimensional, and it automatically is, being spanned by k vectors. The proof uses Theorem 10.3.3, whose hypothesis is that the **subspace** projected onto is finite-dimensional. The application to $C[-\pi,\pi]$ is exactly a case where V is not finite-dimensional.

(d) $\langle f,g\rangle = \frac{1}{\pi}\int_{-\pi}^{\pi} f(t)g(t)\,dt$. The constant $1/\pi$ makes $\cos kx$ and $\sin kx$ unit vectors for every $k\ge 1$; without it their norms would be $\sqrt{\pi}$.

(e) It gives that $S_n f$ is the orthogonal projection of f onto W_n, hence the unique element of W_n minimizing $\|f-g\|$, and it gives Bessel's inequality for the coefficients. It does **not** give that $S_n f(x)\to f(x)$ at any particular x, nor even that $\|f-S_n f\|\to 0$.

(f) False. Equality for one $\mathbf{v}$ says only that $\mathbf{v}\in\operatorname{span}(\mathbf{e}_1,\dots,\mathbf{e}_k)$ (Theorem 10.9.2). In $\mathbb{R}^3$ take the list $(\mathbf{e}_1)$ and $\mathbf{v}=\mathbf{e}_1$: equality holds, and the list is not a basis.

10.9.6.2 B. Practice

Exercise B1: Fourier coefficients.

Work in $C[-\pi,\pi]$ with $\langle f,g\rangle = \frac{1}{\pi}\int_{-\pi}^{\pi} fg$. Find all Fourier coefficients a_k and b_k of each of the following, and in each case write down $S_2 f$.

(a) $f(x) = |x|$.
(b) $f(x) = x^2$.
(c) $f(x) = 3 - 2\sin x + \sin 3x$.

Solution.

(a) $|t|\sin(kt)$ is odd, so $b_k = 0$ for all k. For the cosines, $|t|\cos(kt)$ is even, so $a_k = \frac{2}{\pi}\int_0^{\pi} t\cos(kt)\,\mathrm{d}t$. For $k = 0$ this is $\frac{2}{\pi}\cdot\frac{\pi^2}{2} = \pi$. For $k \geq 1$, integrating by parts,

$$\int_0^{\pi} t\cos(kt)\,\mathrm{d}t = \Big[\frac{t\sin(kt)}{k}\Big]_0^{\pi} - \frac{1}{k}\int_0^{\pi}\sin(kt)\,\mathrm{d}t = \frac{(-1)^k - 1}{k^2},$$

since the bracket vanishes and $\int_0^{\pi}\sin(kt)\,\mathrm{d}t = (1-(-1)^k)/k$. Hence

$$a_k = \frac{2\big((-1)^k - 1\big)}{\pi k^2} = \begin{cases} -\dfrac{4}{\pi k^2}, & k \text{ odd},\\ 0, & k \text{ even}, \end{cases}$$

and $S_2 f = \dfrac{\pi}{2} - \dfrac{4}{\pi}\cos x$.

(b) $t^2\sin(kt)$ is odd, so $b_k = 0$. Also $a_0 = \frac{2}{\pi}\int_0^{\pi} t^2\,\mathrm{d}t = \frac{2\pi^2}{3}$. For $k \geq 1$, integrating by parts twice gives

$$\int_0^{\pi} t^2\cos(kt)\,\mathrm{d}t = \Big[\frac{t^2\sin(kt)}{k}\Big]_0^{\pi} - \frac{2}{k}\int_0^{\pi} t\sin(kt)\,\mathrm{d}t = \frac{2\pi(-1)^k}{k^2},$$

using $\int_0^{\pi} t\sin(kt)\,\mathrm{d}t = \pi(-1)^{k+1}/k$ from Example (The Fourier Coefficients of $f(x) = x$). Hence $a_k = \frac{2}{\pi}\cdot\frac{2\pi(-1)^k}{k^2} = \frac{4(-1)^k}{k^2}$, so $a_1 = -4$, $a_2 = 1$, and

$$S_2 f = \frac{\pi^2}{3} - 4\cos x + \cos 2x.$$

(c) The function already lies in W_3. Coefficients against an orthonormal basis are unique (Theorem 10.2.1 (a)), so, applying that result inside W_3, we may read them off: $a_0/2 = 3$, that is $a_0 = 6$, together with $b_1 = -2$ and $b_3 = 1$; every other coefficient is 0. Hence $S_2 f = 3 - 2\sin x$, which is **not** f: the term $\sin 3x$ lies outside W_2 and is discarded by the projection. (From $n = 3$ on, $S_n f = f$, as Theorem 10.3.3 (a) predicts, since $f \in W_3$ and a projection fixes its own subspace.)

Exercise B2: Verifying Bessel for a truncation.

(a) In $\mathbb{R}^4$ with the dot product let $\mathbf{e}_1 = \frac{1}{2}(1,1,1,1)$, $\mathbf{e}_2 = \frac{1}{2}(1,-1,1,-1)$ and $\mathbf{v} = (2,0,0,2)$. Verify Theorem 10.9.1 for $\mathbf{v}$ and this list, compute the deficit, and check against $(*)$ by computing $\|\mathbf{v} - P_U\mathbf{v}\|$ directly, where $U = \operatorname{span}(\mathbf{e}_1,\mathbf{e}_2)$.
(b) For $f(x) = |x|$ and $n = 1$, write out both sides of Theorem 10.9.3 (c) using Exercise

(B1: Fourier coefficients) (a), and show that the resulting inequality is equivalent to $96 \le \pi^4$.

Solution.

(a) Both vectors have norm $\frac{1}{2}\sqrt{4} = 1$ and $\langle \mathbf{e}_1, \mathbf{e}_2 \rangle = \frac{1}{4}(1 - 1 + 1 - 1) = 0$, so the list is orthonormal. The coefficients are $\langle \mathbf{v}, \mathbf{e}_1 \rangle = \frac{1}{2}(2 + 0 + 0 + 2) = 2$ and $\langle \mathbf{v}, \mathbf{e}_2 \rangle = \frac{1}{2}(2 - 0 + 0 - 2) = 0$, so the left-hand side of Bessel is 4, while $\|\mathbf{v}\|^2 = 4 + 4 = 8$. The inequality $4 \le 8$ holds, with deficit 4. By Theorem 10.3.3 (a), $P_U\mathbf{v} = 2\mathbf{e}_1 = (1, 1, 1, 1)$, so $\mathbf{v} - P_U\mathbf{v} = (1, -1, -1, 1)$ and $\|\mathbf{v} - P_U\mathbf{v}\|^2 = 4$, matching $(*)$.

(b) With $a_0 = \pi$ and $a_1 = -4/\pi$, and $b_1 = 0$, the left-hand side of (c) for $n = 1$ is

$$\frac{a_0^2}{2} + a_1^2 = \frac{\pi^2}{2} + \frac{16}{\pi^2}.$$

The right-hand side is $\|f\|^2 = \frac{1}{\pi}\int_{-\pi}^{\pi} t^2 \, dt = \frac{2\pi^2}{3}$. So the inequality reads

$$\frac{\pi^2}{2} + \frac{16}{\pi^2} \le \frac{2\pi^2}{3},$$

that is $16/\pi^2 \le 2\pi^2/3 - \pi^2/2 = \pi^2/6$, that is $96 \le \pi^4$. Since $\pi > 3.14$ and $3.14^4 > 97$, the inequality is true, and it is tight: the deficit is $\pi^2/6 - 16/\pi^2 \approx 0.024$, so the single cosine $\cos x$ already captures almost all of $|x|$.

Exercise B3: The best approximation by $\operatorname{span}(1, \cos x)$**.**

In $C[-\pi, \pi]$ with $\langle f, g \rangle = \frac{1}{\pi}\int_{-\pi}^{\pi} fg$, let $U = \operatorname{span}(1, \cos x)$ and $f(x) = x^2$. Find $P_U f$ and $d(f, U)^2$. *Hint: the list* $(1, \cos x)$ *is orthogonal but not orthonormal.*

Solution. The two functions are orthogonal, since $\langle 1, \cos x \rangle = \frac{1}{\pi}\int_{-\pi}^{\pi} \cos t \, dt = 0$, and both are non-zero, with $\langle 1, 1 \rangle = 2$ and $\langle \cos x, \cos x \rangle = 1$ by Example (The Trigonometric System Is Orthonormal). So $(1, \cos x)$ is an orthogonal basis of U, and Corollary 10.3.4 gives

$$P_U f = \frac{\langle f, 1 \rangle}{2} \cdot 1 + \frac{\langle f, \cos x \rangle}{1} \cdot \cos x.$$

By Exercise (B1: Fourier coefficients) (b), $\langle f, 1 \rangle = a_0 = 2\pi^2/3$ and $\langle f, \cos x \rangle = a_1 = -4$. Hence

$$P_U f = \frac{\pi^2}{3} - 4\cos x.$$

For the distance, normalize: $(1/\sqrt{2}, \cos x)$ is an orthonormal basis of the same U, with coefficients $\langle f, 1/\sqrt{2} \rangle = a_0/\sqrt{2}$ and $\langle f, \cos x \rangle = a_1$. Now $\|f\|^2 = \frac{1}{\pi}\int_{-\pi}^{\pi} t^4 \, dt = \frac{1}{\pi} \cdot \frac{2\pi^5}{5} = \frac{2\pi^4}{5}$ and the Bessel sum is $a_0^2/2 + a_1^2 = 2\pi^4/9 + 16$, so $(*)$ gives

$$d(f, U)^2 = \frac{2\pi^4}{5} - \frac{2\pi^4}{9} - 16 = \frac{8\pi^4}{45} - 16 \approx 1.32.$$

It is positive, as it must be, since $x^2 \notin U$.

10.9.6.3 C. Going deeper

Exercise C1: Parseval for the full trigonometric system.

This exercise uses an **input from analysis that this book does not prove**: the trigonometric system is *complete* in $C[-\pi,\pi]$, meaning that for every $f \in C[-\pi,\pi]$,

$$\frac{a_0^2}{2} + \sum_{k=1}^{\infty} \left(a_k^2 + b_k^2\right) = \frac{1}{\pi} \int_{-\pi}^{\pi} f(t)^2 \, \mathrm{d}t.$$

(a) Apply this to $f(x) = x$ and deduce that $\sum_{k=1}^{\infty} 1/k^2 = \pi^2/6$.
(b) Hence deduce that $\sum_{k=1}^{\infty} 1/(2k-1)^2 = \pi^2/8$.
(c) Say precisely which step used the analysis input, and explain why no result of this section can supply it.

Solution.

(a) By Example (The Fourier Coefficients of $f(x) = x$), $a_k = 0$ for all k and $b_k = 2(-1)^{k+1}/k$, so $b_k^2 = 4/k^2$; and $\|f\|^2 = 2\pi^2/3$. The stated identity becomes

$$\sum_{k=1}^{\infty} \frac{4}{k^2} = \frac{2\pi^2}{3},$$

so $\sum_{k=1}^{\infty} 1/k^2 = \pi^2/6$.

(b) All terms are positive and the series converges, so it may be split into its even-index and odd-index parts. The even part is

$$\sum_{j=1}^{\infty} \frac{1}{(2j)^2} = \frac{1}{4} \sum_{j=1}^{\infty} \frac{1}{j^2} = \frac{\pi^2}{24}.$$

Hence the odd part is $\pi^2/6 - \pi^2/24 = (4\pi^2 - \pi^2)/24 = \pi^2/8$, which is the claim.

(c) The analysis input is used exactly once, at the equality sign in (a). This section proves only the inequality $\sum_{k \le n} 4/k^2 \le 2\pi^2/3$ for each n (Theorem 10.9.1), and Theorem 10.9.2 turns that inequality into an equality only when f lies in the span of the finitely many functions used. The function x lies in no W_n, since every element of W_n takes equal values at $-\pi$ and π while $f(-\pi) = -\pi \neq \pi = f(\pi)$. Passing to the infinite system is a statement about a limit of functions, and nothing in this book proves such a statement.

Remark. The classical route to $\sum 1/(2k-1)^2 = \pi^2/8$ applies the same identity to the square wave, the function equal to -1 on $[-\pi, 0)$ and 1 on $[0, \pi]$, whose coefficients are $b_k = 4/(\pi k)$ for odd k and 0 otherwise. That function is not continuous, so it does not live in the space $C[-\pi,\pi]$ of this section, and enlarging the space to all integrable functions destroys positive definiteness, as the third non-example of Section 1 shows. Working with $f(x) = x$ keeps everything inside a genuine inner product space.

Exercise C2: Chebyshev orthogonality by substitution.

Let $\langle p, q \rangle_w = \int_{-1}^{1} p(t)q(t)(1-t^2)^{-1/2} \, \mathrm{d}t$ on $\mathbb{R}[x]$, the Chebyshev inner product of the text.

(a) Prove that for every $n \geq 0$ there is a polynomial T_n of degree n with $T_n(\cos\theta) = \cos n\theta$ for all θ, and find T_0, T_1, T_2, T_3.

(b) Prove that $\langle p, q\rangle_w = \int_0^\pi p(\cos\theta)\, q(\cos\theta)\, \mathrm{d}\theta$ for all polynomials p, q.

(c) Deduce that $\langle T_m, T_n\rangle_w = 0$ for $m \neq n$, and compute $\langle T_n, T_n\rangle_w$.

Hint for (a): the identity $\cos((n+1)\theta) + \cos((n-1)\theta) = 2\cos\theta\cos n\theta$.

Solution.

(a) Induction on n. Take $T_0 = 1$ and $T_1 = x$, which satisfy $T_0(\cos\theta) = 1 = \cos 0\theta$ and $T_1(\cos\theta) = \cos\theta$, of degrees 0 and 1. Suppose T_{n-1} and T_n exist, of degrees $n-1$ and n. Put $T_{n+1} = 2xT_n - T_{n-1}$. Then for every θ,

$$T_{n+1}(\cos\theta) = 2\cos\theta\cos n\theta - \cos((n-1)\theta) = \cos((n+1)\theta)$$

by the stated identity. Its degree is $n+1$, since the leading term of $2xT_n$ has degree $n+1$ and T_{n-1} has degree $n-1$. This completes the induction, and the recurrence gives $T_2 = 2x^2 - 1$ and $T_3 = 2x(2x^2-1) - x = 4x^3 - 3x$.

(b) The integral is improper at both endpoints, so it means the limit as $\delta \to 0^+$ of the integrals over $[-1+\delta,\ 1-\delta]$. On each such interval the integrand is continuous, and $t = \cos\theta$ is a continuously differentiable bijection from the corresponding θ-interval, so the change-of-variables rule applies there. With $t = \cos\theta$, θ running from π down to 0, we have $\mathrm{d}t = -\sin\theta\,\mathrm{d}\theta$ and $\sqrt{1-t^2} = \sin\theta$, which is ≥ 0 on $[0,\pi]$. The two minus signs cancel when the limits are reversed, and letting $\delta \to 0^+$,

$$\int_{-1}^{1} \frac{p(t)q(t)}{\sqrt{1-t^2}}\,\mathrm{d}t = \int_0^\pi p(\cos\theta)\, q(\cos\theta)\,\mathrm{d}\theta.$$

The right-hand side is a proper integral of a continuous function, so both sides converge, and the limits agree.

(c) By (a) and (b), $\langle T_m, T_n\rangle_w = \int_0^\pi \cos m\theta\cos n\theta\,\mathrm{d}\theta$. Using $\cos A\cos B = \tfrac{1}{2}[\cos(A-B) + \cos(A+B)]$ and $\int_0^\pi \cos(p\theta)\,\mathrm{d}\theta = [\sin(p\theta)/p]_0^\pi = 0$ for every non-zero integer p:

if $m \neq n$, then $m-n \neq 0$, and $m+n \geq 1$ because the two indices differ, so both integrals vanish and the value is 0;

if $m = n \geq 1$, the value is $\tfrac{1}{2}\big(\int_0^\pi 1\,\mathrm{d}\theta + 0\big) = \pi/2$;

if $m = n = 0$, the integrand is 1 and the value is π.

So the T_n are orthogonal for $\langle\cdot,\cdot\rangle_w$, with $\langle T_0, T_0\rangle_w = \pi$ and $\langle T_n, T_n\rangle_w = \pi/2$ for $n \geq 1$. Consequently $\big(T_0/\sqrt{\pi},\ T_1\sqrt{2/\pi},\ \ldots,\ T_n\sqrt{2/\pi}\big)$ is an orthonormal list, and Theorem 10.9.1 applies to it verbatim.

10.10 Orthogonal Polynomials

Section 2 ran Gram–Schmidt on $(1, x, x^2)$ with $\langle p, q\rangle = \int_{-1}^{1} pq$, and stopped at degree 2 only because the space did (Example (Gram–Schmidt on $1, x, x^2$)). Nothing in the process cared.

Feed it $(1, x, x^2, x^3, \dots)$ and it returns an infinite orthogonal sequence, one polynomial of each degree. Three things make such sequences worth a section. Each member is computable from the two before it. Each member of degree k has k distinct real roots inside the interval. And those roots are the best possible points at which to sample a function to estimate its integral. The first fact rests on one small identity; the other two rest on the first.

Throughout this section the field is $\mathbb{R}$.

10.10.1 Two ways to make an inner product on polynomials

Both constructions we need appeared in Section 1.

From a weight. Fix an interval with endpoints $-\infty \le a < b \le \infty$ and a **weight** w: a function continuous and **strictly positive** on the open interval (a, b), with $\int_a^b |t|^k w(t)\,\mathrm{d}t$ finite for every $k \in \mathbb{N}$. Define

$$\langle p, q \rangle = \int_a^b p(t)\, q(t)\, w(t)\,\mathrm{d}t.$$

Finiteness of the moments makes this a real number for all $p, q \in \mathbb{R}[x]$, and bilinearity and symmetry come from linearity of the integral. For positivity, let $p \neq 0$. Then $p^2 w$ is continuous and ≥ 0 on (a, b), and > 0 off the finitely many roots of p (Corollary 5.1.4), so $\langle p, p \rangle > 0$. That last step is the one calculus fact this section leans on: a continuous non-negative function on an interval whose integral is 0 vanishes identically. As in Definition 10.1.1 it follows from the local fact that a continuous function non-zero at a point stays bounded away from 0 on a small interval around it, which then contributes a positive amount to the integral.

From nodes. Fix distinct $c_0 < \cdots < c_n$ in $\mathbb{R}$ and put $\langle p, q \rangle = \sum_{i=0}^{n} p(c_i) q(c_i)$. Section 1 checked that this is an inner product **on** $\mathbb{R}[x]_{\le n}$, positivity coming from the root bound. It is not one on $\mathbb{R}[x]$: the polynomial $(x - c_0) \cdots (x - c_n)$ is non-zero and pairs with itself to give 0. So in the node case everything below stops at degree n.

The two constructions share one property, and it is the engine of the section.

Proposition 10.10.1 — Multiplication by x is symmetric

Let $\langle \cdot, \cdot \rangle$ be an inner product on $\mathbb{R}[x]$ coming from a weight, or the node inner product on $\mathbb{R}[x]_{\le n}$. Then

$$\langle xp, q \rangle = \langle p, xq \rangle$$

for all polynomials p, q in the space (in the node case, for all p, q of degree at most $n-1$, so that xp and xq still lie in it).

Proof. In the weight case both sides equal $\int_a^b t\, p(t) q(t) w(t)\,\mathrm{d}t$, and in the node case both sides equal $\sum_{i=0}^{n} c_i\, p(c_i) q(c_i)$.

■

The proof is one line, but the statement is not a triviality: multiplication by x moves from one slot to the other for free. That is exactly the identity $\langle T\mathbf{u}, \mathbf{v} \rangle = \langle \mathbf{u}, T\mathbf{v} \rangle$ defining a **self-adjoint** operator (Definition 10.6.2), and it is the reason the recurrence below has three terms instead

of $k+2$.

Warning. **Multiplication by x is not an operator on $\mathbb{R}[x]_{\le n}$.** It raises degree, so it maps that space out of itself; on $\mathbb{R}[x]$ it is an operator, but there the space is infinite-dimensional, and Definition 10.6.2 was stated for a finite-dimensional one. "Self-adjoint" is here a name for Proposition 10.10.1, not a literal application of the definition. It is the identity, not the name, that the proofs use.

10.10.2 Orthogonal polynomial sequences

Applied to the independent list $(1, x, x^2, \dots)$, Gram–Schmidt never stalls. What comes out is one polynomial of each degree, pairwise orthogonal, and that combination deserves a name.

An orthogonal polynomial sequence is one polynomial of every degree, no two of them pairing to anything but zero.

Definition 10.10.1 — Orthogonal Polynomial Sequence

Let $\langle \cdot, \cdot \rangle$ be an inner product on $\mathbb{R}[x]$, or on $\mathbb{R}[x]_{\le n}$. An **orthogonal polynomial sequence** for it is a sequence $p_0, p_1, p_2, \dots$ of polynomials (a finite list $p_0, \dots, p_n$ in the second case) such that

(OP1) $\deg p_k = k$ for **every** index k;
(OP2) $\langle p_j, p_k \rangle = 0$ whenever $j \neq k$.

The sequence is **monic** if every p_k has leading coefficient 1.

In words. (OP1) says one polynomial of each degree: no gaps, no repeats, no accidental drop in degree. (OP2) says the members are pairwise orthogonal. Together they say more than either alone, because by (OP1) the list $(p_0, \dots, p_{k-1})$ is a basis of $\mathbb{R}[x]_{\le k-1}$, so (OP2) upgrades to

$$\langle p_k, q \rangle = 0 \qquad \text{for every } q \in \mathbb{R}[x]_{\le k-1},$$

and that is the form in which the condition always gets used.

Two things need checking: that such a sequence exists, and that fixing the scale pins it down.

Proposition 10.10.2 — Existence and uniqueness of the monic sequence

Let $\langle \cdot, \cdot \rangle$ be an inner product on $\mathbb{R}[x]$. For each $k \in \mathbb{N}$ there is **exactly one** monic p_k of degree k with $\langle p_k, q \rangle = 0$ for every $q \in \mathbb{R}[x]_{\le k-1}$. These p_k form the unique monic orthogonal polynomial sequence, and $(p_0, \dots, p_k)$ is an orthogonal basis of $\mathbb{R}[x]_{\le k}$ for every k. The same holds on $\mathbb{R}[x]_{\le n}$ for $k \le n$.

Idea. Existence is Gram–Schmidt, once we know the k-th output really has degree k; it does, because it lies in $\mathbb{R}[x]_{\le k}$ but not in the span of its predecessors, which is $\mathbb{R}[x]_{\le k-1}$. Uniqueness is the standard move: two candidates differ by a polynomial of lower degree that is orthogonal to everything of lower degree, hence to itself.

Proof. Existence. The list $(1, x, \dots, x^k)$ is independent, so Theorem 10.2.2 applies and returns an orthonormal list $(\mathbf{e}_0, \dots, \mathbf{e}_k)$ with $\operatorname{span}(\mathbf{e}_0, \dots, \mathbf{e}_j) = \operatorname{span}(1, x, \dots, x^j) = \mathbb{R}[x]_{\le j}$ for every $j \le k$. Fix j. Then $\mathbf{e}_j \in \mathbb{R}[x]_{\le j}$, and $\mathbf{e}_j \notin \mathbb{R}[x]_{\le j-1} = \operatorname{span}(\mathbf{e}_0, \dots, \mathbf{e}_{j-1})$, since an orthonormal list is independent (Theorem 10.1.4). Hence $\deg \mathbf{e}_j = j$ exactly. Let $a_j \neq 0$ be its leading coefficient and put $p_j = \mathbf{e}_j / a_j$, monic of degree j. For $q \in \mathbb{R}[x]_{\le j-1} = \operatorname{span}(\mathbf{e}_0, \dots, \mathbf{e}_{j-1})$ we get $\langle p_j, q \rangle = 0$ by orthogonality of the list.

Uniqueness. Suppose p and p' are both monic of degree k and orthogonal to every element of $\mathbb{R}[x]_{\le k-1}$. Their leading terms cancel, so $p - p' \in \mathbb{R}[x]_{\le k-1}$. Therefore $\langle p - p', p - p' \rangle = \langle p, p - p' \rangle - \langle p', p - p' \rangle = 0$, and positive definiteness gives $p = p'$.

Finally, $(p_0, \dots, p_k)$ is an orthogonal list of non-zero vectors, hence independent (Theorem 10.1.4), with $k + 1 = \dim \mathbb{R}[x]_{\le k}$ members, hence a basis (Theorem 1.6.4).

■

Examples. For $\langle p, q \rangle = \int_{-1}^{1} pq$ the first three monic members are 1, x, $x^2 - \frac{1}{3}$ (Example (Gram–Schmidt on $1, x, x^2$)); these are the monic **Legendre polynomials**. For the node inner product with nodes $-1, 0, 1$ on $\mathbb{R}[x]_{\le 2}$ we have $\langle 1, 1 \rangle = 3$, $\langle x, 1 \rangle = 0$, $\langle x, x \rangle = 2$, $\langle x^2, 1 \rangle = 2$, $\langle x^2, x \rangle = 0$, so $p_0 = 1$, $p_1 = x$, $p_2 = x^2 - \frac{2}{3}$ — and there the sequence ends, since $\mathbb{R}[x]_{\le 2}$ holds nothing of degree 3. The degenerate member is always $p_0 = 1$, the only monic polynomial of degree 0, with an empty condition on it.

A non-example by minimal change. Replace the Legendre $p_2 = x^2 - \frac{1}{3}$ by $\tilde{p}_2 = x^2 + x - \frac{1}{3}$. Still monic of degree 2, so (OP1) survives; but $\langle \tilde{p}_2, x \rangle = \langle x, x \rangle = \frac{2}{3} \neq 0$, so (OP2) fails. Adding a multiple of a lower member is exactly the freedom orthogonality removes.

Why monic? Rescaling each p_k by a non-zero λ_k gives another orthogonal polynomial sequence, so a normalization has to be chosen, and traditions differ: the classical Legendre polynomials P_k are fixed by $P_k(1) = 1$, and Gram–Schmidt as run in Section 2 fixes $\|p_k\| = 1$. Monic is the convenient choice here, because it is the one for which the recurrence below needs no extra factor.

Warning. **The sequence belongs to the inner product, not to the polynomials.** "The orthogonal polynomials" is meaningless without a weight and an interval. Exercise B2 of Section 2 (Exercise (B2: Gram–Schmidt on polynomials)) ran the same process with $\int_0^1$ instead of $\int_{-1}^1$ and got 1, $x - \frac{1}{2}$, $x^2 - x + \frac{1}{6}$: same degrees, different polynomials.

Quick check. For $\langle p, q \rangle = \int_{-1}^{1} pq$, how many polynomials of degree 2 with $\|p\| = 1$ are orthogonal to $\mathbb{R}[x]_{\le 1}$? Write them down.

Solution. Exactly two. If p has degree 2 and $p \perp \mathbb{R}[x]_{\le 1}$, let $\lambda \neq 0$ be its leading coefficient; then p/λ is monic of degree 2 and still orthogonal to $\mathbb{R}[x]_{\le 1}$, so $p/\lambda = x^2 - \frac{1}{3}$ by Proposition 10.10.2. Thus $p = \lambda(x^2 - \frac{1}{3})$, and $\|p\| = 1$ leaves $\lambda = \pm 1/\|x^2 - \frac{1}{3}\|$. Since Example (Gram–Schmidt on $1, x, x^2$) computed $\|x^2 - \frac{1}{3}\|^2 = \frac{8}{45}$, the two answers are $\pm\frac{\sqrt{10}}{4}(3x^2 - 1)$. Fixing the scale by the norm leaves a sign; fixing it by "monic" leaves nothing.

10.10.3 The three-term recurrence

Computing p_n by Gram–Schmidt costs one inner product for every earlier member, so reaching degree n costs about $n^2/2$ integrals. Almost all of them return 0. The next theorem says which ones do not, and reduces the cost to two integrals per step.

Theorem 10.10.3 — Three-Term Recurrence

Let (p_k) be the monic orthogonal polynomial sequence of Proposition 10.10.2, for an inner product satisfying Proposition 10.10.1. For a weight on an interval this covers every k; for the node inner product on n nodes, where Proposition 10.10.1 holds only up to degree $n-1$, read the statement for $k+1 \le n$. Put $p_{-1} = 0$ and, for $k \ge 0$,

$$a_k = \frac{\langle x p_k, p_k \rangle}{\langle p_k, p_k \rangle}, \qquad b_k = \frac{\langle p_k, p_k \rangle}{\langle p_{k-1}, p_{k-1} \rangle} \quad (k \ge 1).$$

Then $p_0 = 1$, $p_1 = x - a_0$, and

$$p_{k+1} = (x - a_k)\, p_k - b_k\, p_{k-1} \qquad \text{for every } k \ge 1.$$

Moreover $b_k > 0$ for every $k \ge 1$.

Idea. The polynomial $x p_k$ is monic of degree $k+1$, so it is p_{k+1} plus something of degree at most k, and that something expands in the orthogonal basis $(p_0, \dots, p_k)$ with coefficients $\langle x p_k, p_j \rangle / \langle p_j, p_j \rangle$ (Corollary 10.3.4). The point is that almost every coefficient is 0: move the x across with Proposition 10.10.1, and the coefficient becomes $\langle p_k, x p_j \rangle$, which vanishes as soon as $\deg(x p_j) = j+1$ is still below k. Only $j = k$ and $j = k-1$ can survive.

Proof. $p_0 = 1$ is the unique monic polynomial of degree 0, and $p_1 = x - a_0$ is the unique monic polynomial of degree 1 with $\langle p_1, p_0 \rangle = 0$, since $\langle x - a_0, 1 \rangle = \langle x, 1 \rangle - a_0 \langle 1, 1 \rangle = 0$ exactly for $a_0 = \langle x \cdot 1, 1 \rangle / \langle 1, 1 \rangle$.

Now fix $k \ge 1$. By Proposition 10.10.2, $(p_0, \dots, p_{k+1})$ is an orthogonal basis of $\mathbb{R}[x]_{\le k+1}$, and $x p_k$ lies in that space. By Corollary 10.3.4 applied inside $\mathbb{R}[x]_{\le k+1}$,

$$x p_k = \sum_{j=0}^{k+1} c_j\, p_j, \qquad c_j = \frac{\langle x p_k, p_j \rangle}{\langle p_j, p_j \rangle}.$$

Both $x p_k$ and p_{k+1} are monic of degree $k+1$, and every other term of the sum has degree at most k; comparing coefficients of x^{k+1} gives $c_{k+1} = 1$.

Let $j \le k-2$. By Proposition 10.10.1, $\langle x p_k, p_j \rangle = \langle p_k, x p_j \rangle$, and $\deg(x p_j) = j+1 \le k-1$, so $x p_j \in \mathbb{R}[x]_{\le k-1}$ and the pairing is 0 by Proposition 10.10.2. Hence $c_j = 0$ for every $j \le k-2$, and

$$x p_k = p_{k+1} + c_k\, p_k + c_{k-1}\, p_{k-1},$$

which rearranges to $p_{k+1} = (x - c_k) p_k - c_{k-1} p_{k-1}$.

It remains to identify the two coefficients. By definition $c_k = \langle x p_k, p_k \rangle / \langle p_k, p_k \rangle = a_k$. For the other, $x p_{k-1}$ is monic of degree k, so $x p_{k-1} - p_k$ has degree at most $k-1$ and

therefore pairs to 0 with p_k. Hence, using Proposition 10.10.1 again,

$$\langle xp_k, p_{k-1}\rangle = \langle p_k, xp_{k-1}\rangle = \langle p_k, p_k\rangle,$$

so $c_{k-1} = \langle p_k, p_k\rangle / \langle p_{k-1}, p_{k-1}\rangle = b_k$. Finally b_k is a quotient of $\|p_k\|^2$ by $\|p_{k-1}\|^2$, both strictly positive because p_k and p_{k-1} are non-zero, so $b_k > 0$.

■

Two inner products per step generate the whole sequence. The positivity of b_k is not decoration either: it is the sign that drives the interlacing argument of Exercise (C1: Interlacing roots).

Remark. If the interval is symmetric, $(a, b) = (-c, c)$, and the weight is even, $w(-t) = w(t)$, then $a_k = 0$ for every k and $p_k(-x) = (-1)^k p_k(x)$. Induct on k: $p_0 = 1$ is even, and $a_0 = \langle x, 1\rangle / \langle 1, 1\rangle = 0$ because $t\,w(t)$ is odd, so $p_1 = x$ is odd. If p_{k-1} and p_k have parities $(-1)^{k-1}$ and $(-1)^k$, then $t\,p_k(t)^2 w(t)$ is odd, so $a_k = 0$, and $p_{k+1} = xp_k - b_k p_{k-1}$ is a combination of two polynomials of parity $(-1)^{k+1}$.

Example. (The monic Legendre polynomials, continued)

For $\langle p, q\rangle = \int_{-1}^{1} pq$, Example (Gram–Schmidt on $1, x, x^2$) gave $p_0 = 1$, $p_1 = x$, $p_2 = x^2 - \frac{1}{3}$, with $\langle p_0, p_0\rangle = 2$, $\langle p_1, p_1\rangle = \frac{2}{3}$ and $\langle p_2, p_2\rangle = \frac{8}{45}$. Use Theorem 10.10.3 to obtain p_3, and check the recurrence reproduces p_2.

Solution. The weight $w = 1$ is even on $(-1, 1)$, so every $a_k = 0$ by the remark above. Then

$$b_1 = \frac{\langle p_1, p_1\rangle}{\langle p_0, p_0\rangle} = \frac{2/3}{2} = \frac{1}{3}, \qquad b_2 = \frac{\langle p_2, p_2\rangle}{\langle p_1, p_1\rangle} = \frac{8/45}{2/3} = \frac{4}{15}.$$

The recurrence at $k = 1$ gives $p_2 = x \cdot x - \frac{1}{3} \cdot 1 = x^2 - \frac{1}{3}$, which is what Gram–Schmidt produced. At $k = 2$,

$$p_3 = x\left(x^2 - \tfrac{1}{3}\right) - \tfrac{4}{15}\, x = x^3 - \tfrac{3}{5}x.$$

Check. $\langle p_3, 1\rangle = \langle p_3, x^2\rangle = 0$ because the integrands are odd, and

$$\langle p_3, x\rangle = \int_{-1}^{1} \left(t^4 - \tfrac{3}{5}t^2\right) \mathrm{d}t = \tfrac{2}{5} - \tfrac{3}{5} \cdot \tfrac{2}{3} = 0.$$

So $p_3 \perp \mathbb{R}[x]_{\le 2}$, as it should be. Two integrals produced a polynomial that Gram–Schmidt would have charged three for, and the saving grows with the degree.

10.10.4 Where the roots are

The roots of $p_2 = x^2 - \frac{1}{3}$ are $\pm 1/\sqrt{3} \approx \pm 0.577$, and those of $p_3 = x^3 - \frac{3}{5}x$ are 0 and $\pm\sqrt{3/5} \approx \pm 0.775$. All five lie inside $(-1, 1)$, where the weight lives. No coincidence. The argument first needs one fact about real polynomials, in which $\mathrm{mult}_r(f)$ is the multiplicity of r as a root of f (Definition 5.4.1).

Lemma 10.10.4 — Even multiplicities mean no sign change

Let $I \subseteq \mathbb{R}$ be an open interval and let $f \in \mathbb{R}[x]$ be non-zero. If $\mathrm{mult}_r(f)$ is even for every $r \in I$, then $f \geq 0$ throughout I, or $f \leq 0$ throughout I.

Proof. By Theorem 5.4.3 over $\mathbb{R}$, write $f = (x-d_1)^{m_1} \cdots (x-d_l)^{m_l}\, g$, where $d_1, \ldots, d_l$ are the distinct real roots of f, $m_i = \mathrm{mult}_{d_i}(f)$, and g has no real root. Separate the factors according to whether $d_i \in I$:

$$f = h \cdot \Big(\textstyle\prod_{d_i \in I} (x-d_i)^{m_i} \Big), \qquad h = g \cdot \textstyle\prod_{d_i \notin I} (x-d_i)^{m_i}.$$

Each m_i with $d_i \in I$ is even by hypothesis, so the second factor is the square of a real polynomial and is ≥ 0 everywhere. The polynomial h has no root in I: its roots are the d_i outside I, and g has none. Being continuous and nowhere zero on the interval I, h has constant sign there by the intermediate value theorem. Hence f has that same sign throughout I, weakly, with equality only at the d_i inside I.

■

Theorem 10.10.5 — Roots of an Orthogonal Polynomial

Let w be a weight on (a,b), let $\langle p, q \rangle = \int_a^b pqw$, and let (p_k) be the monic orthogonal polynomial sequence. For every $k \geq 1$, the polynomial p_k has k **distinct real** roots, and every one of them lies in the **open** interval (a,b).

Idea. Suppose p_k changed sign at only a few points $c_1, \ldots, c_m$ of (a,b), with $m < k$. Build the polynomial $q = (x-c_1)\cdots(x-c_m)$. It is cheap — degree at most $k-1$ — so p_k is orthogonal to it. But q was designed to change sign at exactly the points where p_k does, so the product $p_k q$ changes sign nowhere, and a function of one sign that is not identically zero cannot integrate to zero against a positive weight. The contradiction forces $m \geq k$, and k distinct roots is all a polynomial of degree k can hold.

Proof. Fix $k \geq 1$. Let $c_1 < \cdots < c_m$ be the roots of p_k in (a,b) whose multiplicity is **odd** (possibly $m = 0$), and set $q = (x-c_1)\cdots(x-c_m)$, with $q = 1$ when $m = 0$.

Suppose, for contradiction, that $m \leq k-1$. Then $q \in \mathbb{R}[x]_{\leq k-1}$, so $\langle p_k, q \rangle = 0$ by Proposition 10.10.2.

Put $f = p_k q$, a non-zero polynomial (Theorem 0.8.3). Let $r \in (a,b)$ be a root of f. By Theorem 5.4.2, $\mathrm{mult}_r(f) = \mathrm{mult}_r(p_k) + \mathrm{mult}_r(q)$. If $r = c_i$ for some i, then $\mathrm{mult}_r(q) = 1$ and $\mathrm{mult}_r(p_k)$ is odd by the choice of the c_i, so the sum is even. If r is none of the c_i, then $q(r) \neq 0$, so $\mathrm{mult}_r(q) = 0$ and $\mathrm{mult}_r(p_k)$ is even, again by the choice of the c_i. Either way $\mathrm{mult}_r(f)$ is even.

By Lemma 10.10.4, $f \geq 0$ throughout (a,b) or $f \leq 0$ throughout (a,b); replacing q by $-q$ if necessary, which changes neither $\langle p_k, q \rangle = 0$ nor $\deg q$, we may assume $f \geq 0$ there. Then fw is continuous and ≥ 0 on (a,b), and it is > 0 off the finitely many roots of f, because $w > 0$. By the calculus fact recalled when the inner product was set up — a continuous non-negative function with integral 0 vanishes identically — an integrand of

that shape cannot integrate to 0. Therefore

$$\langle p_k, q\rangle = \int_a^b f(t)\,w(t)\,\mathrm{d}t > 0,$$

contradicting $\langle p_k, q\rangle = 0$.

Hence $m \geq k$. Each c_i is a root of p_k, and p_k is non-zero of degree k, so $m \leq k$ by Corollary 5.1.4; thus $m = k$ and p_k has k distinct roots $c_1, \ldots, c_k$, all in (a, b). By Corollary 5.1.4 again, $(x - c_1)\cdots(x - c_k)$ divides p_k, and both are monic of degree k, so $p_k = (x - c_1)\cdots(x - c_k)$. In particular each root is simple and p_k has no roots outside (a, b), real or complex. This proves the theorem.

■

So the weight hands us k points inside its interval, chosen by the inner product rather than by us. The next subsection says what they are good for.

Quick check. The monic Laguerre polynomial of degree 2 for the weight $w(t) = e^{-t}$ on $(0, \infty)$ is $p_2 = x^2 - 4x + 2$. Check that Theorem 10.10.5 is not lying.

Solution. The roots are $2 \pm \sqrt{2}$, that is ≈ 0.586 and ≈ 3.414: real, distinct, and both in $(0, \infty)$. An unbounded interval is no obstacle, since the theorem asks only that the weight be positive with finite moments, and $\int_0^\infty t^k e^{-t}\,\mathrm{d}t = k!$.

10.10.5 Gaussian quadrature

Chapter 5 wrote $\int_0^1 p$ as a fixed combination of $p(0)$, $p(\frac{1}{2})$ and $p(1)$, valid for every $p \in \mathbb{R}[x]_{\leq 2}$ (Example (Integrals and Slopes from Values)). The construction works for any prescribed nodes: integrate the Lagrange interpolation formula (Theorem 5.6.1) and k distinct nodes give a rule exact on $\mathbb{R}[x]_{\leq k-1}$.

But a k-point rule has $2k$ numbers at its disposal, k nodes and k coefficients, and only k of them were spent. Spending the nodes too should buy degree $2k - 1$. Where to put them is the question, and the answer is the one place we have not chosen: the roots of p_k.

Theorem 10.10.6 — Gaussian Quadrature

Let w be a weight on (a, b) with $\langle p, q\rangle = \int_a^b pqw$, let $k \geq 1$, and let $t_1 < \cdots < t_k$ be the roots of the monic orthogonal polynomial p_k, which lie in (a, b) by Theorem 10.10.5. Let $\ell_1, \ldots, \ell_k \in \mathbb{R}[x]_{\leq k-1}$ be the Lagrange polynomials for these nodes (Definition 5.6.1) and set

$$\alpha_i = \int_a^b \ell_i(t)\,w(t)\,\mathrm{d}t \qquad (i = 1, \ldots, k).$$

Then every α_i is **strictly positive**, and

$$\int_a^b f(t)\,w(t)\,\mathrm{d}t = \sum_{i=1}^{k} \alpha_i\, f(t_i)$$

for **every** $f \in \mathbb{R}[x]_{\le 2k-1}$.

Idea. Two moves, one for each side of the identity. On the left, divide f by p_k: $f = qp_k + r$. The degree bookkeeping — $\deg f \le 2k-1$ against $\deg p_k = k$ — forces $\deg q \le k-1$, which is exactly the condition under which $\int qp_k w = \langle p_k, q\rangle$ vanishes. So the integral of f is the integral of its remainder. On the right, p_k vanishes at every node, so the sum also only sees the remainder. And the remainder has degree at most $k-1$, which is precisely the range on which k nodes reproduce a polynomial exactly. The two sides meet there.

Proof. Let $f \in \mathbb{R}[x]_{\le 2k-1}$. Since $p_k \neq 0$, Theorem 5.1.1 gives $q, r \in \mathbb{R}[x]$ with

$$f = qp_k + r, \qquad \deg r < k.$$

If $q = 0$ then $q \in \mathbb{R}[x]_{\le k-1}$ trivially. Otherwise $qp_k = f - r$ has degree at most $2k-1$, while $\deg(qp_k) = \deg q + k$ by Theorem 0.8.3; hence $\deg q \le k-1$. Either way $q \in \mathbb{R}[x]_{\le k-1}$, so Proposition 10.10.2 gives $\langle p_k, q\rangle = 0$, that is, $\int_a^b qp_k w = 0$. Therefore

$$\int_a^b fw = \int_a^b qp_k w + \int_a^b rw = \int_a^b rw. \tag{$*$}$$

At each node, $p_k(t_i) = 0$, so

$$f(t_i) = q(t_i)p_k(t_i) + r(t_i) = r(t_i) \qquad (i = 1, \dots, k). \tag{$**$}$$

Since $\deg r \le k-1$ and $t_1, \dots, t_k$ are k distinct points, Theorem 5.6.1 (b) gives $r = \sum_i r(t_i)\ell_i$. Integrating against w and using the definition of α_i,

$$\int_a^b rw = \sum_{i=1}^{k} r(t_i)\,\alpha_i = \sum_{i=1}^{k} \alpha_i f(t_i),$$

the last step by $(**)$. Combining with $(*)$ proves the quadrature identity.

For positivity, fix j and apply the identity to $f = \ell_j^2$, which is legitimate because $\deg \ell_j^2 = 2k-2 \le 2k-1$. By Theorem 5.6.1 (a), $\ell_j(t_i) = \delta_{ij}$, so the right-hand side collapses to α_j, while the left-hand side is $\langle \ell_j, \ell_j\rangle = \|\ell_j\|^2$. Since $\ell_j \neq 0$, positive definiteness gives $\alpha_j = \|\ell_j\|^2 > 0$.

■

Each hypothesis did one job. Orthogonality to lower degrees killed the quotient on the left; the nodes being roots of p_k killed it again on the right. That is also why the nodes cannot be moved: shift one and the second cancellation fails. Exercise (C2: The ceiling is 2k − 1) shows $2k-1$ is a ceiling, not just what this proof happens to reach.

Example. (Two-point Gauss–Legendre)

Take $w = 1$ on $(-1, 1)$ and $k = 2$. Find the nodes and weights, and test the resulting rule on $f = 1 + 2x + 3x^2 + 4x^3$ and on $f = x^4$.

Solution. The monic p_2 is $x^2 - \frac{1}{3}$ (Example (Gram–Schmidt on $1, x, x^2$)), so the nodes are $t_1 = -1/\sqrt{3}$ and $t_2 = 1/\sqrt{3}$. The Lagrange polynomials are $\ell_1 = (x - t_2)/(t_1 - t_2)$ and $\ell_2 = (x - t_1)/(t_2 - t_1)$, with $t_1 - t_2 = -2/\sqrt{3}$. Since $\int_{-1}^{1} t\,\mathrm{d}t = 0$ and $\int_{-1}^{1} 1\,\mathrm{d}t = 2$,

$$\alpha_1 = \frac{0 - 2t_2}{t_1 - t_2} = \frac{-2/\sqrt{3}}{-2/\sqrt{3}} = 1,$$

and $\alpha_2 = 1$ by the same computation with the roles swapped. The rule is

$$\int_{-1}^{1} f(t)\,\mathrm{d}t = f\Big(-\tfrac{1}{\sqrt{3}}\Big) + f\Big(\tfrac{1}{\sqrt{3}}\Big) \qquad \text{for } f \in \mathbb{R}[x]_{\le 3}.$$

Two evaluations, no coefficients to remember, every cubic exactly.

The cubic test. Exactly, $\int_{-1}^{1}(1 + 2t + 3t^2 + 4t^3)\mathrm{d}t = 2 + 0 + 3 \cdot \frac{2}{3} + 0 = 4$. By the rule, $f(-1/\sqrt{3}) = 2 - \frac{10\sqrt{3}}{9}$ and $f(1/\sqrt{3}) = 2 + \frac{10\sqrt{3}}{9}$, whose sum is 4. The odd parts cancel and the constant and quadratic parts contribute $1 + 1$ and $1 + 1$.

The quartic test. Exactly, $\int_{-1}^{1} t^4\,\mathrm{d}t = \frac{2}{5}$. By the rule, $(1/\sqrt{3})^4 + (1/\sqrt{3})^4 = \frac{2}{9}$. These differ, so degree $4 = 2k$ is already out of reach. Compare Example (Integrals and Slopes from Values), where the nodes were fixed in advance and **three** of them guaranteed exactness only up to degree 2 — guaranteed by the construction, that is; that particular symmetric rule happens to integrate cubics exactly as well, which is luck of the symmetry and not something the construction promises.

Warning. **"Exact" means exact on polynomials.** Theorem 10.10.6 says nothing about $\int_a^b fw$ for a general f, and nothing about what happens as k grows; on a non-polynomial the rule returns an approximation whose error is a question for analysis. What linear algebra delivers is exactness on a subspace, and the reason that subspace is the largest available.

10.10.6 The classical families

Four weights account for most of the orthogonal polynomials that occur in practice. The table records them; the entries are statements, and Exercise (B2: Two rows of the table) asks you to verify two of the rows by integration.

Family	Interval	Weight $w(t)$	p_1	p_2
Legendre	$(-1, 1)$	1	x	$x^2 - \frac{1}{3}$
Chebyshev	$(-1, 1)$	$(1 - t^2)^{-1/2}$	x	$x^2 - \frac{1}{2}$
Hermite	$(-\infty, \infty)$	e^{-t^2}	x	$x^2 - \frac{1}{2}$
Laguerre	$(0, \infty)$	e^{-t}	$x - 1$	$x^2 - 4x + 2$

The last two columns give the monic members of degrees 1 and 2; $p_0 = 1$ in every row. The Chebyshev weight is unbounded at ± 1 and the Hermite and Laguerre intervals are unbounded, so in those three rows the integrals defining the inner product are improper; they converge, which is the finiteness condition our definition of a weight demanded. The first three weights are even on symmetric intervals, so their a_k all vanish and their members alternate in parity; the Laguerre weight is not, and $a_0 = 1$ there. Section 9 of this chapter meets the Chebyshev

family again from the Fourier side, where the substitution $t = \cos\theta$ turns its awkward weight into $\mathrm{d}\theta$.

10.10.7 Exercises

10.10.7.1 A. Check your understanding

Exercise A1.

(a) Define what it means for $p_0, p_1, p_2, \dots$ to be a **monic orthogonal polynomial sequence** for an inner product on $\mathbb{R}[x]$.

(b) State the three-term recurrence, including the formulas for a_k and b_k and the starting values.

(c) True or false: $b_k > 0$ for every $k \geq 1$. Justify your answer.

(d) For $\langle p, q\rangle = \int_{-1}^{1} pq$, how many roots does p_7 have, of what kind, and where?

(e) True or false: for **every** inner product on $\mathbb{R}[x]$ one has $\langle xp, q\rangle = \langle p, xq\rangle$. Justify your answer.

(f) How many nodes does a Gaussian rule need in order to integrate every polynomial of degree at most 11 exactly?

Solution.

(a) A sequence with $\deg p_k = k$ and leading coefficient 1 for every k, and $\langle p_j, p_k\rangle = 0$ whenever $j \neq k$ (Definition 10.10.1).

(b) With $p_{-1} = 0$, $p_0 = 1$ and $p_1 = x - a_0$, one has $p_{k+1} = (x - a_k)p_k - b_k p_{k-1}$ for $k \geq 1$, where $a_k = \langle xp_k, p_k\rangle / \langle p_k, p_k\rangle$ and $b_k = \langle p_k, p_k\rangle / \langle p_{k-1}, p_{k-1}\rangle$ (Theorem 10.10.3).

(c) True. Both $\langle p_k, p_k\rangle = \|p_k\|^2$ and $\langle p_{k-1}, p_{k-1}\rangle = \|p_{k-1}\|^2$ are strictly positive, since p_k and p_{k-1} are non-zero and the inner product is positive definite.

(d) Seven roots, all real, all distinct, all in the open interval $(-1, 1)$ (Theorem 10.10.5). In particular p_7 has no complex roots and no repeated ones.

(e) False. Take the coefficient inner product $\langle p, q\rangle = \sum_k u_k v_k$ on $\mathbb{R}[x]$, where $p = \sum_k u_k x^k$ and $q = \sum_k v_k x^k$ (Example (A functional with no Riesz vector)). Then $\langle x \cdot 1, x\rangle = \langle x, x\rangle = 1$, while $\langle 1, x \cdot x\rangle = \langle 1, x^2\rangle = 0$. The identity is a property of the weight and node constructions (Proposition 10.10.1), not of inner products in general.

(f) Six. A k-point rule is exact up to degree $2k - 1$, and $2 \cdot 6 - 1 = 11$.

10.10.7.2 B. Practice

Exercise B1: A weighted interval.

On $\mathbb{R}[x]$ put $\langle p, q\rangle = \int_0^1 p(t)q(t)\, t\, \mathrm{d}t$. Compute the monic p_0, p_1 and p_2, and verify directly that $p_2 \perp \mathbb{R}[x]_{\leq 1}$.

Solution. The moments are $\langle x^k, 1\rangle = \int_0^1 t^{k+1}\mathrm{d}t = 1/(k+2)$, so $\frac{1}{2}, \frac{1}{3}, \frac{1}{4}, \frac{1}{5}$ for $k = 0, 1, 2, 3$.

$p_0 = 1$. Then $a_0 = \langle x, 1\rangle/\langle 1, 1\rangle = (1/3)/(1/2) = \frac{2}{3}$, so $p_1 = x - \frac{2}{3}$, and

$$\langle p_1, p_1\rangle = \tfrac{1}{4} - \tfrac{4}{3}\cdot\tfrac{1}{3} + \tfrac{4}{9}\cdot\tfrac{1}{2} = \tfrac{1}{4} - \tfrac{2}{9} = \tfrac{1}{36}.$$

Next $\langle xp_1, p_1\rangle = \int_0^1 (t^4 - \frac{4}{3}t^3 + \frac{4}{9}t^2)\mathrm{d}t = \frac{1}{5} - \frac{1}{3} + \frac{4}{27} = \frac{2}{135}$, so

$$a_1 = \frac{2/135}{1/36} = \frac{8}{15}, \qquad b_1 = \frac{1/36}{1/2} = \frac{1}{18},$$

and Theorem 10.10.3 gives

$$p_2 = \left(x - \tfrac{8}{15}\right)\left(x - \tfrac{2}{3}\right) - \tfrac{1}{18} = x^2 - \tfrac{6}{5}x + \tfrac{3}{10}.$$

Verification. $\langle p_2, 1\rangle = \int_0^1 (t^3 - \frac{6}{5}t^2 + \frac{3}{10}t)\mathrm{d}t = \frac{1}{4} - \frac{2}{5} + \frac{3}{20} = 0$, and $\langle p_2, x\rangle = \int_0^1 (t^4 - \frac{6}{5}t^3 + \frac{3}{10}t^2)\mathrm{d}t = \frac{1}{5} - \frac{3}{10} + \frac{1}{10} = 0$. Since $(1, x)$ spans $\mathbb{R}[x]_{\le 1}$, this is the whole check.

Exercise B2: Two rows of the table.

Verify the degree-1 and degree-2 entries of the table for two of the classical families.

(a) Chebyshev: $w(t) = (1 - t^2)^{-1/2}$ on $(-1, 1)$. You may use, without proof, that $\int_{-1}^1 (1 - t^2)^{-1/2}\mathrm{d}t = \pi$ and $\int_{-1}^1 t^2(1 - t^2)^{-1/2}\mathrm{d}t = \pi/2$.

(b) Laguerre: $w(t) = e^{-t}$ on $(0, \infty)$. You may use, without proof, that $\int_0^\infty t^k e^{-t}\,\mathrm{d}t = k!$.

Solution.

(a) The weight is even, so $\langle x^j, x^i\rangle = 0$ whenever $i + j$ is odd. Hence $\langle x, 1\rangle = 0$, and x is monic of degree 1 and orthogonal to $\mathbb{R}[x]_{\le 0}$, so $p_1 = x$ by Proposition 10.10.2. Write $p_2 = x^2 + \beta x + \gamma$. Then $\langle p_2, x\rangle = \langle x^2, x\rangle + \beta\langle x, x\rangle + \gamma\langle 1, x\rangle = 0 + \beta\cdot\frac{\pi}{2} + 0$, forcing $\beta = 0$; and $\langle p_2, 1\rangle = \frac{\pi}{2} + 0 + \gamma\pi = 0$, forcing $\gamma = -\frac{1}{2}$. So $p_2 = x^2 - \frac{1}{2}$.

(b) The moments are $\langle x^k, 1\rangle = k!$, so $1, 1, 2, 6$ for $k = 0, 1, 2, 3$. For $p_1 = x + \beta$: $\langle p_1, 1\rangle = 1 + \beta = 0$, so $p_1 = x - 1$. For $p_2 = x^2 + \beta x + \gamma$, the two conditions $\langle p_2, 1\rangle = 0$ and $\langle p_2, x\rangle = 0$ read

$$2 + \beta + \gamma = 0, \qquad 6 + 2\beta + \gamma = 0.$$

Subtracting gives $\beta = -4$, then $\gamma = 2$. So $p_2 = x^2 - 4x + 2$, whose roots $2 \pm \sqrt{2}$ we already located in the Quick check above.

Exercise B3: One more Legendre polynomial.

Continue Example (The monic Legendre polynomials, continued): compute $\langle p_3, p_3\rangle$ for $p_3 = x^3 - \frac{3}{5}x$, then use Theorem 10.10.3 to find p_4. Verify that $\langle p_4, 1\rangle = \langle p_4, x^2\rangle = 0$.

Solution.

$$\langle p_3, p_3\rangle = \int_{-1}^1 \left(t^6 - \tfrac{6}{5}t^4 + \tfrac{9}{25}t^2\right)\mathrm{d}t = \tfrac{2}{7} - \tfrac{6}{5}\cdot\tfrac{2}{5} + \tfrac{9}{25}\cdot\tfrac{2}{3} = \tfrac{2}{7} - \tfrac{6}{25} = \tfrac{8}{175}.$$

Since the weight is even, $a_3 = 0$, and $b_3 = \langle p_3, p_3\rangle / \langle p_2, p_2\rangle = (8/175)/(8/45) = \frac{9}{35}$. Hence

$$p_4 = x\Big(x^3 - \tfrac{3}{5}x\Big) - \tfrac{9}{35}\Big(x^2 - \tfrac{1}{3}\Big) = x^4 - \tfrac{6}{7}x^2 + \tfrac{3}{35}.$$

Verification. $\langle p_4, 1\rangle = \frac{2}{5} - \frac{6}{7}\cdot\frac{2}{3} + \frac{3}{35}\cdot 2 = \frac{14-20+6}{35} = 0$, and

$$\langle p_4, x^2\rangle = \tfrac{2}{7} - \tfrac{6}{7}\cdot\tfrac{2}{5} + \tfrac{3}{35}\cdot\tfrac{2}{3} = \tfrac{10-12+2}{35} = 0.$$

Orthogonality to x and x^3 is automatic by parity.

Exercise B4: A two-point rule on the unit interval.

Work on $(0,1)$ with $w = 1$. Exercise B2 of Section 2 (Exercise (B2: Gram–Schmidt on polynomials)) found the monic orthogonal polynomials 1, $x - \frac{1}{2}$, $x^2 - x + \frac{1}{6}$.

(a) Write down the two-point Gaussian rule for $\int_0^1 f$.
(b) Check it on $f = x^3$, and show that it fails on $f = x^4$.

Solution.

(a) The nodes are the roots of $x^2 - x + \frac{1}{6}$, namely

$$t_{1,2} = \tfrac{1}{2} \mp \tfrac{\sqrt{3}}{6}, \qquad t_2 - t_1 = \tfrac{\sqrt{3}}{3},$$

both in $(0,1)$, as Theorem 10.10.5 promises. With $\ell_1 = (x - t_2)/(t_1 - t_2)$ and $\int_0^1 t\,\mathrm{d}t = \frac{1}{2}$,

$$\alpha_1 = \frac{\frac{1}{2} - t_2}{t_1 - t_2} = \frac{-\sqrt{3}/6}{-\sqrt{3}/3} = \tfrac{1}{2},$$

and $\alpha_2 = \frac{1}{2}$ likewise. So $\int_0^1 f = \frac{1}{2}\big(f(t_1) + f(t_2)\big)$ for $f \in \mathbb{R}[x]_{\le 3}$.

(b) Write $t_{1,2} = \frac{1}{2} \mp u$ with $u = \sqrt{3}/6$, so $u^2 = \frac{1}{12}$. The odd powers of u cancel in a sum over t_1 and t_2, so

$$t_1^3 + t_2^3 = 2\Big(\tfrac{1}{8} + 3\cdot\tfrac{1}{2}\cdot\tfrac{1}{12}\Big) = 2\cdot\tfrac{1}{4} = \tfrac{1}{2},$$

and half of that is $\frac{1}{4} = \int_0^1 t^3\,\mathrm{d}t$. For the quartic,

$$t_1^4 + t_2^4 = 2\Big(\tfrac{1}{16} + 6\cdot\tfrac{1}{4}\cdot\tfrac{1}{12} + \tfrac{1}{144}\Big) = 2\cdot\tfrac{28}{144} = \tfrac{7}{18},$$

so the rule returns $\frac{7}{36}$, whereas $\int_0^1 t^4\,\mathrm{d}t = \frac{1}{5}$. The rule is exact to degree $3 = 2k-1$ and no further.

10.10.7.3 C. Going deeper

Exercise C1: Interlacing roots.

Let w be a weight on (a,b) and let (p_k) be its monic orthogonal polynomial sequence. The roots of p_k are said to **interlace** those of p_{k+1} when exactly one root of p_k lies strictly between each pair of consecutive roots of p_{k+1}. This is true for every k; prove the first two cases by hand.

(a) Let r be the root of p_1 and $s_1 < s_2$ the roots of p_2. Prove that $s_1 < r < s_2$.

(b) Let $u_1 < u_2 < u_3$ be the roots of p_3. Prove that $u_1 < s_1 < u_2 < s_2 < u_3$.

Hint: evaluate the three-term recurrence at a root.

Solution.

(a) By Theorem 10.10.3 with $k = 1$, $p_2 = (x - a_1)p_1 - b_1 p_0 = (x - a_1)(x - r) - b_1$. Evaluating at r gives $p_2(r) = -b_1 < 0$, since $b_1 > 0$. By Theorem 10.10.5, $p_2 = (x - s_1)(x - s_2)$ with $s_1 < s_2$ real, and this product is negative exactly on (s_1, s_2). Hence $s_1 < r < s_2$.

(b) By Theorem 10.10.3 with $k = 2$, $p_3 = (x - a_2)p_2 - b_2 p_1$. At a root of p_2 the first term dies, so

$$p_3(s_i) = -b_2\, p_1(s_i) = -b_2(s_i - r) \qquad (i = 1, 2).$$

By (a), $s_1 - r < 0$ and $s_2 - r > 0$, and $b_2 > 0$, so $p_3(s_1) > 0$ and $p_3(s_2) < 0$.

By Theorem 10.10.5, $p_3 = (x-u_1)(x-u_2)(x-u_3)$ with $u_1 < u_2 < u_3$. Such a product is negative on $(-\infty, u_1)$, positive on (u_1, u_2), negative on (u_2, u_3), and positive on (u_3, ∞). So $p_3(s_1) > 0$ puts s_1 in (u_1, u_2) or in (u_3, ∞), and $p_3(s_2) < 0$ puts s_2 in $(-\infty, u_1)$ or in (u_2, u_3). The option $s_1 > u_3$ is impossible: it would give $s_2 > s_1 > u_3$, where p_3 is positive, contradicting $p_3(s_2) < 0$. The option $s_2 < u_1$ is impossible too: it would give $s_1 < s_2 < u_1$, where p_3 is negative, contradicting $p_3(s_1) > 0$. Hence $u_1 < s_1 < u_2$ and $u_2 < s_2 < u_3$, which is the assertion.

The general case is not proved this way. The coefficients a_k and b_k assemble into a symmetric tridiagonal matrix whose characteristic polynomial is p_k, and the interlacing then follows from the interlacing theorem for the eigenvalues of a symmetric matrix and its leading submatrices, which is Chapter 16's business.

Exercise C2: The ceiling is 2k − 1.

Let w be a weight on (a, b) and let $k \geq 1$.

(a) Let $t_1, \ldots, t_k$ be **any** k distinct real numbers and $\alpha_1, \ldots, \alpha_k$ **any** real numbers. Prove that there is an $f \in \mathbb{R}[x]_{\leq 2k}$ with $\int_a^b f w \neq \sum_i \alpha_i f(t_i)$.

(b) Hence deduce that the Gaussian rule of Theorem 10.10.6 is exact on $\mathbb{R}[x]_{\leq 2k-1}$ and on no larger space $\mathbb{R}[x]_{\leq d}$.

Solution.

(a) Put $g = (x - t_1) \cdots (x - t_k)$ and $f = g^2$, a polynomial of degree $2k$. Every node is a root of g, so $f(t_i) = 0$ for every i and the right-hand side is 0, whatever the α_i are. The left-hand side is $\int_a^b g^2 w = \langle g, g \rangle$, and $g \neq 0$, so $\langle g, g \rangle > 0$ by positive definiteness. The two sides differ.

(b) Exactness on $\mathbb{R}[x]_{\leq 2k-1}$ is Theorem 10.10.6. Suppose the rule were exact on $\mathbb{R}[x]_{\leq d}$ for some $d \geq 2k$. Since $\mathbb{R}[x]_{\leq 2k} \subseteq \mathbb{R}[x]_{\leq d}$, it would then be exact on every polynomial of degree at most $2k$. But its nodes are k distinct real numbers (Theorem 10.10.5), so (a) supplies a polynomial of degree $2k$ on which it is not. Hence no such d exists, and $2k - 1$ is the largest degree for which the rule is exact. The concrete instance $k = 2$, $f = x^4$ is the failure computed in Example (Two-point

Gauss–Legendre).

Chapter 11

Spectral Theory

Take the unit circle of $\mathbb{R}^2$ and push it through a linear map. What comes out is an ellipse. The ellipse has two axes, at right angles to each other, and it is natural to ask whether those axes sit along directions that the map merely stretches — whether, in other words, the map's eigenvectors are perpendicular. Usually they are not. Chapter 8 found eigenvectors and asked only that they be independent; a basis of eigenvectors can be as skewed as it likes, and for a matrix like $\begin{pmatrix} 1 & 1 \\ 0 & 2 \end{pmatrix}$ it is. Perpendicular eigenvectors are a strictly stronger demand, and it is the demand that matters in practice: coordinates in an orthonormal basis are read off by one inner product each, the change of basis is an isometry, and nothing is distorted along the way.

This chapter answers the question completely. There is an orthonormal basis of eigenvectors exactly when the operator commutes with its adjoint over $\mathbb{C}$, and exactly when it equals its adjoint over $\mathbb{R}$. Those two statements are the **spectral theorems**, and they are the most used theorems in applied linear algebra. Everything else here grows out of them: the triangular form that every complex matrix has in an orthonormal basis (Schur), the shape of a rotation in three dimensions, several commuting operators diagonalized at once, functions of an operator computed on its spectrum, the discrete Fourier transform as one instance of the whole picture, and finally a number that measures how far a matrix is from being normal. **The field is $\mathbb{R}$ or $\mathbb{C}$ throughout**, as in Chapter 10, and every statement says which one it needs. The difference between the two is not cosmetic: the Fundamental Theorem of Algebra hands $\mathbb{C}$ an eigenvalue for free, and over $\mathbb{R}$ each eigenvalue has to be earned.

What you need. From Chapter 5, the Fundamental Theorem of Algebra and the splitting it gives (Theorem 5.5.1, Corollary 5.5.5), together with Lagrange interpolation (Theorem 5.6.1). From Chapter 8, eigenvalues and eigenspaces, the characteristic polynomial and multiplicities, the existence of an eigenvalue over $\mathbb{C}$ (Definition 8.2.1, Theorem 8.2.1, Theorem 8.2.4), triangularization and what its diagonal records (Theorem 8.7.2, Corollary 8.7.3, Theorem 8.7.4, Theorem 8.3.3), the conjugate-pair behavior of real matrices (Theorem 8.2.5), and the two results on commuting operators (Theorem 8.9.3, Theorem 8.9.5). From Chapter 1, the complexification of a real vector space (Definition 1.9.2, Theorem 1.9.3). From Chapter 9, the Jordan form and the rotation-scaling block (Theorem 9.3.1, Definition 9.4.1). From Chapter 7, the Kronecker product and the vec operator (Definition 7.4.1, Theorem 7.4.1, Definition 7.4.2, Theorem 7.4.4). Above all, from Chapter 10: orthonormal bases and Gram–Schmidt (Theorem 10.2.2, Corollary 10.2.3, Theorem 10.2.1), orthogonal complements and projections (Theorem 10.3.2, Definition 10.3.2, Theorem 10.3.3), the adjoint with its arithmetic and its matrix (Definition 10.6.1, Theorem 10.6.2, Theorem 10.6.3, Theorem 10.6.5), the two classes of operators it singles out

(Definition 10.6.2, Definition 10.6.3, Proposition 10.6.7), and isometries (Definition 10.7.1, Theorem 10.7.3, Definition 10.7.2, Definition 10.7.3).

11.0.1 Roadmap

- **Schur's unitary triangularization.** Every complex matrix is upper triangular in some orthonormal basis; the workhorse the rest of the chapter runs on, and the real block version alongside it.
- **Self-adjoint operators.** Real eigenvalues over both fields, orthogonal eigenspaces, invariant complements, and the test $\langle T\mathbf{v}, \mathbf{v}\rangle = 0$ that forces $T = 0$.
- **Normal operators.** The weakest hypothesis that works over $\mathbb{C}$: four equivalent descriptions, $\ker T = \ker T^*$, and why a normal operator has no Jordan blocks.
- **The complex spectral theorem.** Normal is exactly the same as having an orthonormal eigenbasis; Schur plus one entry-by-entry computation.
- **The real spectral theorem.** Self-adjoint is exactly the same as having an orthonormal eigenbasis over $\mathbb{R}$; the principal axis theorem, and the rotation that shows why "normal" is not enough here.
- **The shape of an orthogonal matrix.** Blocks $[1]$, $[-1]$ and plane rotations; every element of SO(3) is a turn about an axis, and reflections generate.
- **Commuting families.** One orthonormal basis that diagonalizes every member of a commuting family of normal operators at once.
- **Spectral resolutions and functions of a normal operator.** Writing $T = \sum \lambda_i P_i$ with orthogonal projections, and defining $f(T)$ by applying f to the spectrum.
- **Circulants and the discrete Fourier transform.** One unitary matrix diagonalizes every circulant, and multiplication becomes convolution.
- **The Sylvester equation and block diagonalization.** When $\mathbf{X} \mapsto \mathbf{AX} - \mathbf{XB}$ is invertible, and what that buys for block triangular matrices.
- **How far from normal?** Schur's inequality turns normality from a yes-or-no property into a measurement.

11.0.2 Named moves

- **Take one eigenvector, then pass to its orthogonal complement.** As soon as the operator is normal or self-adjoint, that complement is invariant, so the induction on dimension runs inside the space instead of in a quotient. This replaces Chapter 8's "extend a basis and pass to the quotient".
- **Compute $\langle T\mathbf{v}, \mathbf{v}\rangle$ two ways.** Once with the eigenvalue equation, once by moving T across to T^*. Comparing the two is almost the whole of the elementary theory.
- **Work with $\|T\mathbf{v}\|^2 = \langle T^*T\mathbf{v}, \mathbf{v}\rangle$.** A statement about lengths becomes a statement about the single operator T^*T, and a difference of two such operators is tested by the zero test.
- **Triangular plus normal forces diagonal.** Compare one diagonal entry of $\mathbf{A}^*\mathbf{A}$ with the same entry of $\mathbf{AA}^*$, and a row of off-diagonal entries has to vanish.
- **Split into real and imaginary parts.** Write $T = A + iB$ with A and B self-adjoint; then T is normal exactly when A and B commute, and questions about T become questions about a commuting pair.
- **Diagonalize, then read the answer off the diagonal.** Powers, square roots, exponentials and the whole functional calculus are one line once an orthonormal eigenbasis is in hand.

11.1 Schur Triangularization

Chapter 8 proved that every operator on a non-zero complex vector space has an upper triangular matrix in **some** basis (Corollary 8.7.3). That basis was built by extending an eigenvector and passing to a quotient, and it came out as skewed as the operator happened to be. Now we have lengths and angles, so we can be fussier and ask for an **orthonormal** basis. The remarkable thing is that the answer is still yes, at no extra cost in hypotheses, and the proof is the same induction run inside an orthogonal complement rather than in a quotient. This section proves it, reads off the first consequences, and gives the real version, where a conjugate pair of eigenvalues costs one 2×2 block.

Throughout, V is a finite-dimensional inner product space over $F = \mathbb{R}$ or $F = \mathbb{C}$, and every matrix statement uses the standard inner product on F^n.

11.1.1 Why the obvious route fails

Here is the natural first attempt, and it is worth watching it fail, because the repair is the whole idea of the proof.

We want an orthonormal basis $\mathcal{B} = (\mathbf{v}_1, \dots, \mathbf{v}_n)$ with $[T]_{\mathcal{B}}^{\mathcal{B}}$ upper triangular, that is, with

$$T\mathbf{v}_j \in \operatorname{span}(\mathbf{v}_1, \dots, \mathbf{v}_j) \qquad \text{for every } j.$$

For $j = 1$ this says $\mathbf{v}_1$ is an eigenvector of T, and over $\mathbb{C}$ one exists (Theorem 8.2.4). Normalize it, set $U = (\operatorname{span}(\mathbf{v}_1))^{\perp}$, and try to finish by induction on U. The attempt stops at once: to speak of T restricted to U we need U to be T-invariant, and it need not be.

Example. (An Eigenline Whose Complement Is Not Invariant)

Let $\mathbf{A} = \begin{pmatrix} 1 & 1 \\ 0 & 2 \end{pmatrix}$ act on $\mathbb{C}^2$. Check that $\mathbf{e}_1$ is an eigenvector and decide whether $(\operatorname{span}(\mathbf{e}_1))^{\perp}$ is invariant.

Solution. $\mathbf{A}\mathbf{e}_1 = (1, 0) = \mathbf{e}_1$, so $\mathbf{e}_1$ is an eigenvector for the eigenvalue 1. The orthogonal complement of $\operatorname{span}(\mathbf{e}_1)$ is $\operatorname{span}(\mathbf{e}_2)$, and $\mathbf{A}\mathbf{e}_2 = (1, 2)$, which is not a multiple of $\mathbf{e}_2$. So $(\operatorname{span}(\mathbf{e}_1))^{\perp}$ is **not** invariant, and the induction has nothing to run on.

So the first basis vector is the wrong end to start from. Look at the target instead. Suppose $\mathcal{B}$ is orthonormal and $[T]_{\mathcal{B}}^{\mathcal{B}} = \mathbf{T}$ is upper triangular. By Theorem 10.6.3 the matrix of T^* in the same basis is $\mathbf{T}^*$, which is **lower** triangular; and the last column of a lower triangular matrix has only its bottom entry. Reading that column off,

$$T^*\mathbf{v}_n = \overline{t_{nn}}\,\mathbf{v}_n.$$

In the basis we are trying to build, the last vector is an eigenvector of T^* — not of T.

That is the vector to produce first, and it is exactly the one whose orthogonal complement behaves.

Lemma 11.1.1 — Eigenvectors of the Adjoint Cut Out Invariant Subspaces

Let V be a finite-dimensional inner product space over F, let $T \in \mathcal{L}(V)$, and let $W \subseteq V$ be a T^*-invariant subspace. Then $W^\perp$ is T-invariant.

Proof. Let $\mathbf{u} \in W^\perp$ and $\mathbf{w} \in W$. Since W is T^*-invariant, $T^*\mathbf{w} \in W$, so by Definition 10.6.1

$$\langle T\mathbf{u}, \mathbf{w}\rangle = \langle \mathbf{u}, T^*\mathbf{w}\rangle = 0.$$

As $\mathbf{w} \in W$ was arbitrary, $T\mathbf{u} \in W^\perp$. Hence $T(W^\perp) \subseteq W^\perp$.

■

The special case we need is $W = \operatorname{span}(\mathbf{v})$ with $T^*\mathbf{v} = \mu\mathbf{v}$: one vector, one line, and an invariant complement of dimension $n-1$ to recurse into. And over $\mathbb{C}$ such a $\mathbf{v}$ always exists, because T^* is an operator on a non-zero complex space and the Fundamental Theorem of Algebra gives it an eigenvalue. That is where the field enters, and it is the only place it enters.

11.1.2 The theorem

Theorem 11.1.2 — Schur's Unitary Triangularization

Let V be a finite-dimensional inner product space over $\mathbb{C}$ with $\dim V = n \geq 1$, and let $T \in \mathcal{L}(V)$.

(a) There is an **orthonormal** basis $\mathcal{B}$ of V such that $[T]_{\mathcal{B}}^{\mathcal{B}}$ is upper triangular.

(b) More precisely, let $\lambda_1, \ldots, \lambda_n$ be the eigenvalues of T, each listed as often as its algebraic multiplicity, in **any** order we please. Then $\mathcal{B}$ can be chosen so that the i-th diagonal entry of $[T]_{\mathcal{B}}^{\mathcal{B}}$ is λ_i.

Idea. Induction on $\dim V$, building the basis from its **last** vector backwards. ① Pick the eigenvalue λ_n we want in the bottom-right corner; the conjugate $\overline{\lambda_n}$ is then an eigenvalue of T^*, because starring turns a non-invertible operator into a non-invertible operator. ② Take a unit eigenvector $\mathbf{e}$ of T^* for $\overline{\lambda_n}$ and put $U = (\operatorname{span}(\mathbf{e}))^\perp$; by Lemma 11.1.1 it is T-invariant, so $T|_U$ exists and lives on a space of dimension $n-1$. ③ Check that the characteristic polynomial of $T|_U$ is p_T with the factor $x - \lambda_n$ removed, so the inductive hypothesis may be applied with the shortened list. ④ Append $\mathbf{e}$ to the basis it returns.

Proof. We induct on $n = \dim V$. Since $\mathbb{C}$ is algebraically closed, p_T splits (Corollary 5.5.5), so a list $\lambda_1, \ldots, \lambda_n$ as in (b) exists and $p_T = (x-\lambda_1)\cdots(x-\lambda_n)$; proving (b) proves (a).

For $n = 1$, any unit vector $\mathbf{v}_1$ is a basis, every 1×1 matrix is upper triangular, and its single entry is the single eigenvalue λ_1.

Let $n \geq 2$ and assume the statement for all inner product spaces of dimension $n-1$. Fix a list $\lambda_1, \ldots, \lambda_n$ as in (b).

$\overline{\lambda_n}$ is an eigenvalue of T^*. Since λ_n is an eigenvalue of T, the operator $T - \lambda_n \operatorname{id}_V$ is not invertible (Theorem 8.2.1). By Theorem 10.6.2 (a), (b) and (d), its adjoint is $T^* - \overline{\lambda_n} \operatorname{id}_V$, and the adjoint of that is $T - \lambda_n \operatorname{id}_V$ again. If $T^* - \overline{\lambda_n} \operatorname{id}_V$ were invertible, then Theorem 10.6.2 (e) would make its adjoint $T - \lambda_n \operatorname{id}_V$ invertible too. So $T^* - \overline{\lambda_n} \operatorname{id}_V$ is not invertible, and $\overline{\lambda_n} \in \operatorname{spec}(T^*)$.

Choose an eigenvector of T^* for $\overline{\lambda_n}$; it is non-zero, so dividing by its norm gives a unit vector $\mathbf{e}$ with $T^*\mathbf{e} = \overline{\lambda_n}\mathbf{e}$. Put $U = (\operatorname{span}(\mathbf{e}))^\perp$. By Theorem 10.3.2 (c), $\dim U = n - 1 \geq 1$, and U is T-invariant by Lemma 11.1.1. Write $S = T|_U \in \mathcal{L}(U)$, where U carries the inner product of V.

The bottom-right entry is λ_n. Using Definition 10.6.1 and conjugate-linearity in the second slot,

$$\langle T\mathbf{e}, \mathbf{e}\rangle = \langle \mathbf{e}, T^*\mathbf{e}\rangle = \langle \mathbf{e}, \overline{\lambda_n}\mathbf{e}\rangle = \lambda_n \|\mathbf{e}\|^2 = \lambda_n.$$

The shortened list belongs to S. Take any orthonormal basis $(\mathbf{f}_1, \dots, \mathbf{f}_{n-1})$ of U (Theorem 10.2.2) and set $\mathcal{C} = (\mathbf{f}_1, \dots, \mathbf{f}_{n-1}, \mathbf{e})$, an orthonormal list of n vectors, hence an orthonormal basis of V by Theorem 10.1.4 and Theorem 1.6.4. Since U is T-invariant, Theorem 8.1.3 (b) applies with the basis $\mathcal{C}$ and gives $p_T = p_S\, p_{\bar{T}}$, where $\bar{T}$ is the induced operator on the one-dimensional quotient V/U. Its matrix is the single bottom-right entry of $[T]_{\mathcal{C}}^{\mathcal{C}}$, which is $\langle T\mathbf{e}, \mathbf{e}\rangle = \lambda_n$ by Theorem 10.2.1; so $p_{\bar{T}} = x - \lambda_n$. Canceling that factor in $\mathbb{C}[x]$,

$$p_S = (x - \lambda_1) \cdots (x - \lambda_{n-1}).$$

So $\lambda_1, \dots, \lambda_{n-1}$ is a list of the eigenvalues of S with their algebraic multiplicities.

Induct. By the inductive hypothesis there is an orthonormal basis $(\mathbf{v}_1, \dots, \mathbf{v}_{n-1})$ of U in which the matrix of S is upper triangular with diagonal $\lambda_1, \dots, \lambda_{n-1}$. Put $\mathcal{B} = (\mathbf{v}_1, \dots, \mathbf{v}_{n-1}, \mathbf{e})$, again an orthonormal basis of V for the reason given above. For $j \leq n - 1$ we have $T\mathbf{v}_j = S\mathbf{v}_j \in \operatorname{span}(\mathbf{v}_1, \dots, \mathbf{v}_j)$, so the j-th column of $[T]_{\mathcal{B}}^{\mathcal{B}}$ vanishes below row j and has λ_j in row j. The n-th column has nothing below row n, and its entry there is $\langle T\mathbf{e}, \mathbf{e}\rangle = \lambda_n$. Hence $[T]_{\mathcal{B}}^{\mathcal{B}}$ is upper triangular with diagonal $\lambda_1, \dots, \lambda_n$. This proves the theorem.

■

Two hypotheses did all the work, and it is worth naming which. **Complex** produced the eigenvalue of T^*, through the Fundamental Theorem of Algebra; over $\mathbb{R}$ the theorem is false as stated, and the last part of this section says what survives. **Inner product** produced the invariant complement, through Lemma 11.1.1; without one we would be back in Chapter 8's quotient. Notice also what the theorem does **not** claim: nothing was assumed about T, and nothing beyond triangularity is promised. Diagonal is a different and much stronger request, and Sections 4 and 5 say exactly which operators grant it.

11.1.3 The matrix form

Translating through an orthonormal basis turns the theorem into a factorization. Recall that a square complex matrix is **unitary** when $\mathbf{U}^*\mathbf{U} = \mathbf{I}$ (Definition 10.7.2), and call two matrices **unitarily similar** when $\mathbf{B} = \mathbf{U}^*\mathbf{A}\mathbf{U}$ for some unitary $\mathbf{U}$; this is similarity by a matrix that is also an isometry, so it preserves the inner product as well as the operator.

Corollary 11.1.3 — Schur Factorization

Let $\mathbf{A} \in M_n(\mathbb{C})$ with $n \geq 1$, and let $\lambda_1, \dots, \lambda_n$ be the eigenvalues of $\mathbf{A}$, each listed as often as its algebraic multiplicity, in any prescribed order. Then there are a unitary $\mathbf{U} \in M_n(\mathbb{C})$ and an upper triangular $\mathbf{T} \in M_n(\mathbb{C})$ with

$$\mathbf{A} = \mathbf{U}\mathbf{T}\mathbf{U}^*, \qquad t_{ii} = \lambda_i \quad (1 \leq i \leq n).$$

Proof. Apply Theorem 11.1.2 to $T_{\mathbf{A}}$ on $\mathbb{C}^n$ with the standard inner product and the given list: there is an orthonormal basis $\mathcal{B} = (\mathbf{u}_1, \dots, \mathbf{u}_n)$ of $\mathbb{C}^n$ with $\mathbf{T} := [T_{\mathbf{A}}]_{\mathcal{B}}^{\mathcal{B}}$ upper triangular and $t_{ii} = \lambda_i$. Let $\mathbf{U}$ be the matrix whose j-th column is $\mathbf{u}_j$. Its columns are orthonormal, so $\mathbf{U}$ is unitary (Theorem 10.7.3 (f), Definition 10.7.2), and $\mathbf{U} = [\mathrm{id}]_{\mathcal{B}}^{\mathcal{E}}$ for the standard basis $\mathcal{E}$ (Definition 3.7.1). Since $[T_{\mathbf{A}}]_{\mathcal{E}}^{\mathcal{E}} = \mathbf{A}$, Theorem 3.7.3 gives $\mathbf{T} = \mathbf{U}^{-1}\mathbf{A}\mathbf{U} = \mathbf{U}^*\mathbf{A}\mathbf{U}$, the last step because $\mathbf{U}^{-1} = \mathbf{U}^*$ for a unitary matrix. Rearranging gives $\mathbf{A} = \mathbf{U}\mathbf{T}\mathbf{U}^*$. ∎

The order of the diagonal is free because at each step of the induction we chose which eigenvalue to send to the bottom-right corner, and any of them was available. That freedom is used constantly: it lets us put a distinguished eigenvalue first, or collect equal eigenvalues into a block.

Remark. **How to compute one.** The induction above runs from the bottom-right corner, because that is the corner where an operator on a subspace is available. For a **matrix** there is a second route, running from the top-left, and it is the one to use by hand. Let $\mathbf{q}_1$ be a unit eigenvector of $\mathbf{A}$ for an eigenvalue λ, extend it to an orthonormal basis of $\mathbb{C}^n$ (Corollary 10.2.3) and let $\mathbf{Q}$ be the unitary matrix with those columns. Then $\mathbf{Q}^*\mathbf{A}\mathbf{q}_1 = \lambda\mathbf{Q}^*\mathbf{q}_1 = \lambda\mathbf{e}_1$, so

$$\mathbf{Q}^*\mathbf{A}\mathbf{Q} = \begin{pmatrix} \lambda & \mathbf{b}^* \\ \mathbf{0} & \mathbf{A}_1 \end{pmatrix}$$

for some $\mathbf{b} \in \mathbb{C}^{n-1}$ and $\mathbf{A}_1 \in M_{n-1}(\mathbb{C})$. Triangularize $\mathbf{A}_1 = \mathbf{V}\mathbf{T}_1\mathbf{V}^*$ and put $\mathbf{U} = \mathbf{Q}(1 \oplus \mathbf{V})$; the product is unitary and $\mathbf{U}^*\mathbf{A}\mathbf{U}$ is upper triangular. This is legitimate for matrices precisely because we may replace $\mathbf{A}$ by the compressed block $\mathbf{A}_1$, which is not the restriction of any operator: $(\mathrm{span}(\mathbf{q}_1))^{\perp}$ is not invariant, as Example (An Eigenline Whose Complement Is Not Invariant) showed.

Example. (A Two-by-Two Schur Factorization)

Find a unitary $\mathbf{U}$ and an upper triangular $\mathbf{T}$ with $\mathbf{U}^*\mathbf{A}\mathbf{U} = \mathbf{T}$, as in Corollary 11.1.3, for

$$\mathbf{A} = \begin{pmatrix} 2 & -1 \\ 1 & 4 \end{pmatrix}.$$

Solution. Here $\operatorname{tr}\mathbf{A} = 6$ and $\det\mathbf{A} = 8 + 1 = 9$, so $p_{\mathbf{A}} = x^2 - 6x + 9 = (x-3)^2$ and the only eigenvalue is 3, with algebraic multiplicity 2.

Solving $(\mathbf{A} - 3\mathbf{I})\mathbf{x} = \mathbf{0}$ with $\mathbf{A} - 3\mathbf{I} = \begin{pmatrix} -1 & -1 \\ 1 & 1 \end{pmatrix}$ gives the single eigenline $\mathrm{span}\big((1,-1)\big)$.

Take $\mathbf{q}_1 = \frac{1}{\sqrt{2}}(1,-1)$ and complete with $\mathbf{q}_2 = \frac{1}{\sqrt{2}}(1,1)$, a unit vector orthogonal to $\mathbf{q}_1$.

With $\mathbf{U}$ the matrix of those columns,

$$\mathbf{U} = \tfrac{1}{\sqrt{2}}\begin{pmatrix} 1 & 1 \\ -1 & 1 \end{pmatrix}, \qquad \mathbf{U}^*\mathbf{A}\mathbf{U} = \begin{pmatrix} 3 & -2 \\ 0 & 3 \end{pmatrix}.$$

Both diagonal entries are 3, as they must be. The off-diagonal -2 cannot be removed: a matrix unitarily similar to $\operatorname{diag}(3,3) = 3\mathbf{I}$ would equal $\mathbf{U}(3\mathbf{I})\mathbf{U}^* = 3\mathbf{I}$, and $\mathbf{A} \neq 3\mathbf{I}$.

Example. (A Three-by-Three Schur Factorization)

Find a unitary $\mathbf{U}$ and an upper triangular $\mathbf{T}$ with $\mathbf{U}^*\mathbf{A}\mathbf{U} = \mathbf{T}$, as in Corollary 11.1.3, for

$$\mathbf{A} = \begin{pmatrix} 1 & 0 & 1 \\ 0 & 1 & -2 \\ 4 & -3 & -2 \end{pmatrix}.$$

Solution. Step 1: peel off one eigenvector. Expanding $\det(x\mathbf{I} - \mathbf{A})$ gives $p_{\mathbf{A}} = (x-1)(x-3)(x+4)$, so 1 is an eigenvalue. Solving $(\mathbf{A} - \mathbf{I})\mathbf{x} = \mathbf{0}$ by row reduction gives the eigenline spanned by $(3,4,0)$, of norm 5. Put

$$\mathbf{q}_1 = \tfrac{1}{5}(3,4,0), \quad \mathbf{q}_2 = \tfrac{1}{5}(4,-3,0), \quad \mathbf{q}_3 = (0,0,1),$$

an orthonormal basis of $\mathbb{C}^3$ (each has norm 1 and the three pairwise inner products are 0; the entries are real, so no conjugates intrude). With $\mathbf{Q} = \begin{pmatrix} \mathbf{q}_1 & \mathbf{q}_2 & \mathbf{q}_3 \end{pmatrix}$,

$$\mathbf{Q}^*\mathbf{A}\mathbf{Q} = \begin{pmatrix} 1 & 0 & -1 \\ 0 & 1 & 2 \\ 0 & 5 & -2 \end{pmatrix}, \qquad \mathbf{A}_1 = \begin{pmatrix} 1 & 2 \\ 5 & -2 \end{pmatrix}.$$

Step 2: triangularize the block. Here $\operatorname{tr}\mathbf{A}_1 = -1$ and $\det\mathbf{A}_1 = -12$, so $p_{\mathbf{A}_1} = x^2 + x - 12 = (x-3)(x+4)$. For the eigenvalue 3, $\mathbf{A}_1 - 3\mathbf{I} = \begin{pmatrix} -2 & 2 \\ 5 & -5 \end{pmatrix}$ gives the eigenvector $(1,1)$. Take $\mathbf{p}_1 = \frac{1}{\sqrt{2}}(1,1)$ and $\mathbf{p}_2 = \frac{1}{\sqrt{2}}(1,-1)$, and let $\mathbf{V}$ be the matrix of those columns. Then

$$\mathbf{V}^*\mathbf{A}_1\mathbf{V} = \begin{pmatrix} 3 & 3 \\ 0 & -4 \end{pmatrix}.$$

Step 3: assemble. Put $\mathbf{U} = \mathbf{Q}(1 \oplus \mathbf{V})$, whose columns are $\mathbf{q}_1$, $(\mathbf{q}_2 + \mathbf{q}_3)/\sqrt{2}$ and $(\mathbf{q}_2 - \mathbf{q}_3)/\sqrt{2}$:

$$\mathbf{U} = \tfrac{1}{5\sqrt{2}}\begin{pmatrix} 3\sqrt{2} & 4 & 4 \\ 4\sqrt{2} & -3 & -3 \\ 0 & 5 & -5 \end{pmatrix}, \qquad \mathbf{U}^*\mathbf{A}\mathbf{U} = \begin{pmatrix} 1 & -\frac{1}{\sqrt{2}} & \frac{1}{\sqrt{2}} \\ 0 & 3 & 3 \\ 0 & 0 & -4 \end{pmatrix}.$$

The diagonal reads $1, 3, -4$, and indeed $p_{\mathbf{A}} = (x-1)(x-3)(x+4)$, with trace $0 = 1+3-4$ and determinant $-12 = 1 \cdot 3 \cdot (-4)$.

Quick check. Why does Theorem 11.1.2 not prove that every complex matrix is unitarily similar to a **diagonal** matrix?

Solution. Because the proof controls only the entries below the diagonal. The entries above it are whatever they happen to be, and Example (A Two-by-Two Schur Factorization) shows they need not vanish: the matrix there has a -2 in the corner, and no unitary can remove it. A matrix unitarily similar to a diagonal one satisfies strong conditions — Section 4 identifies them exactly — and most matrices do not.

11.1.4 Reading the diagonal

A triangular form with an explicit factorization makes two Chapter 8 facts fall out in a line each.

Corollary 11.1.4 — Trace Is the Sum of the Eigenvalues

Let $\mathbf{A} \in M_n(\mathbb{C})$ have eigenvalues $\lambda_1, \dots, \lambda_n$, listed with algebraic multiplicity. Then $\operatorname{tr} \mathbf{A} = \lambda_1 + \cdots + \lambda_n$.

Proof. Write $\mathbf{A} = \mathbf{U}\mathbf{T}\mathbf{U}^*$ as in Corollary 11.1.3. By Theorem 0.9.6 (3) applied to the pair $\mathbf{U}$ and $\mathbf{T}\mathbf{U}^*$,

$$\operatorname{tr} \mathbf{A} = \operatorname{tr}\big(\mathbf{U}(\mathbf{T}\mathbf{U}^*)\big) = \operatorname{tr}\big((\mathbf{T}\mathbf{U}^*)\mathbf{U}\big) = \operatorname{tr} \mathbf{T},$$

since $\mathbf{U}^*\mathbf{U} = \mathbf{I}$. The diagonal of $\mathbf{T}$ is the list $\lambda_1, \dots, \lambda_n$.

■

Corollary 11.1.5 — Determinant Is the Product of the Eigenvalues

Let $\mathbf{A} \in M_n(\mathbb{C})$ have eigenvalues $\lambda_1, \dots, \lambda_n$, listed with algebraic multiplicity. Then $\det \mathbf{A} = \lambda_1 \cdots \lambda_n$.

Proof. With $\mathbf{A} = \mathbf{U}\mathbf{T}\mathbf{U}^*$ as above, Theorem 6.5.4 gives $\det \mathbf{A} = \det \mathbf{U} \det \mathbf{T} \det \mathbf{U}^*$, and $\det \mathbf{U} \det \mathbf{U}^* = \det(\mathbf{U}\mathbf{U}^*) = \det \mathbf{I} = 1$. So $\det \mathbf{A} = \det \mathbf{T}$, which is the product of the diagonal entries by Theorem 6.4.6.

■

Both statements are Theorem 8.3.3 over $\mathbb{C}$, recovered from the diagonal of $\mathbf{T}$ instead of from the coefficients of $p_{\mathbf{A}}$. Nothing is new; what is new is how short the argument became once a triangular form was available in hand.

The next consequence is not a restatement of anything. It says that the matrices we know how to handle sit arbitrarily close to the ones we do not.

Corollary 11.1.6 — Diagonalizable Matrices Are Everywhere

Let $\mathbf{A} \in M_n(\mathbb{C})$ and let $\varepsilon > 0$. Then there is a **diagonalizable** $\mathbf{A}' \in M_n(\mathbb{C})$ with

$$|a_{ij} - a'_{ij}| < \varepsilon \qquad \text{for all } i, j.$$

In this sense every complex square matrix is a limit of diagonalizable ones.

Idea. Diagonalizability is hard to arrange directly, but n distinct eigenvalues force it (Corollary 8.4.2), and in a triangular form the eigenvalues are sitting on the diagonal where we can nudge them apart. The only thing to check is that a small nudge inside the triangular form is still a small nudge after conjugating back by $\mathbf{U}$, and that is Cauchy–Schwarz on the rows of a unitary matrix.

Proof. Write $\mathbf{A} = \mathbf{UTU}^*$ as in Corollary 11.1.3. Choose $\delta_1, \dots, \delta_n \in \mathbb{C}$ with $|\delta_k| < \varepsilon$ and with $t_{11} + \delta_1, \dots, t_{nn} + \delta_n$ pairwise distinct. This is possible one index at a time: having chosen $\delta_1, \dots, \delta_{k-1}$, the forbidden values of δ_k are the $k-1$ numbers $t_{jj} + \delta_j - t_{kk}$, and the disc $\{|z| < \varepsilon\}$ has infinitely many points.

Put $\mathbf{D} = \operatorname{diag}(\delta_1, \dots, \delta_n)$ and $\mathbf{A}' = \mathbf{U}(\mathbf{T}+\mathbf{D})\mathbf{U}^*$. The matrix $\mathbf{T}+\mathbf{D}$ is upper triangular with n distinct diagonal entries, so by Theorem 8.7.4 (b) it has n distinct eigenvalues; $\mathbf{A}'$ is similar to it, hence has the same eigenvalues, and is diagonalizable by Corollary 8.4.2.

For the entries, $\mathbf{A} - \mathbf{A}' = -\mathbf{UDU}^*$, whose (i,j) entry is $-\sum_k u_{ik}\delta_k\overline{u_{jk}}$. Hence

$$|a_{ij} - a'_{ij}| \le \max_k |\delta_k| \sum_{k=1}^{n} |u_{ik}|\,|u_{jk}| \le \max_k |\delta_k| < \varepsilon,$$

where the middle inequality is Theorem 10.1.5 applied to the vectors of moduli, together with the fact that the rows of $\mathbf{U}$ are unit vectors, which is $\mathbf{UU}^* = \mathbf{I}$. This proves the corollary.

■

This is the tool behind a standard strategy: *prove it for diagonalizable matrices, then take a limit.* Chapter 15, where matrices acquire norms and limits can be spoken of properly, runs arguments of exactly this shape; and Exercise (C1: Cayley–Hamilton from the triangular factors) uses the triangular form directly, with no limits at all, to reprove the Cayley–Hamilton theorem over $\mathbb{C}$.

11.1.5 The real version

Over $\mathbb{R}$ the theorem fails, and it fails for the reason it always does: a rotation has no real eigenvector, so no real basis makes its matrix triangular (Theorem 8.7.2). The most one can hope for is to let a conjugate pair occupy a 2×2 block, and that much is true.

Theorem 11.1.7 — Real Schur Form

Let $\mathbf{A} \in M_n(\mathbb{R})$ with $n \ge 1$. Then there are an orthogonal $\mathbf{Q} \in \mathrm{O}(n)$ and a matrix $\mathbf{T} \in M_n(\mathbb{R})$ with

$$\mathbf{A} = \mathbf{QTQ}^{\top},$$

where $\mathbf{T}$ is **block** upper triangular with diagonal blocks of size 1×1 and 2×2, and every 2×2 diagonal block has a conjugate pair of non-real eigenvalues.

Idea. The same induction, with one change. The eigenvector of T^* may fail to exist over $\mathbb{R}$, but an invariant subspace of dimension 1 or 2 always does — that is Exercise

(C2: Real operators have small invariant subspaces), proved in Chapter 8 from a complex eigenvector $\mathbf{x}+i\mathbf{y}$ by taking $\operatorname{span}(\mathbf{x},\mathbf{y})$. Apply it to T^*, take the orthogonal complement, and induct. Dimension 1 occurs exactly when T^* has a real eigenvalue, and that is what keeps the 2×2 blocks honest.

Proof. Let $T = T_{\mathbf{A}}$ on $\mathbb{R}^n$ with the standard inner product, so that $T^* = T_{\mathbf{A}^\top}$ by Theorem 10.6.3. We induct on n.

Choose a T^*-invariant subspace W as follows. If T^* has a real eigenvalue, let W be a corresponding eigenline, so $d := \dim W = 1$. If it does not, take a complex eigenvalue $\mu = a + bi$ of $\mathbf{A}^\top$ with $b \neq 0$, which exists by Theorem 8.2.4 applied to $\mathbf{A}^\top$ over $\mathbb{C}$, and a complex eigenvector $\mathbf{x} + i\mathbf{y}$ with $\mathbf{x},\mathbf{y} \in \mathbb{R}^n$. Comparing real and imaginary parts of $\mathbf{A}^\top(\mathbf{x}+i\mathbf{y}) = \mu(\mathbf{x}+i\mathbf{y})$ gives $\mathbf{A}^\top\mathbf{x} = a\mathbf{x}-b\mathbf{y}$ and $\mathbf{A}^\top\mathbf{y} = b\mathbf{x}+a\mathbf{y}$, so $W := \operatorname{span}(\mathbf{x},\mathbf{y})$ is T^*-invariant. It has dimension 2: were $\mathbf{x},\mathbf{y}$ dependent, W would be a T^*-invariant line and T^* would have a real eigenvalue, contrary to the case we are in. So $d = 2$. (Exercise (C2: Real operators have small invariant subspaces) runs the same argument in Chapter 8.)

Put $U = W^\perp$, which is T-invariant by Lemma 11.1.1 and has dimension $n-d$ (Theorem 10.3.2 (c)). Pick an orthonormal basis $(\mathbf{v}_1,\dots,\mathbf{v}_{n-d})$ of U and one $(\mathbf{v}_{n-d+1},\dots,\mathbf{v}_n)$ of W (Theorem 10.2.2); together they form an orthonormal basis $\mathcal{B}$ of $\mathbb{R}^n$, since the two blocks are orthogonal to each other. Because $T(U) \subseteq U$,

$$[T]^{\mathcal{B}}_{\mathcal{B}} = \begin{pmatrix} \mathbf{C} & * \\ \mathbf{0} & \mathbf{B} \end{pmatrix}$$

with $\mathbf{C} \in M_{n-d}(\mathbb{R})$ the matrix of $T|_U$ and $\mathbf{B} \in M_d(\mathbb{R})$. Writing $\mathbf{Q}_{\mathcal{B}}$ for the matrix whose columns are the vectors of $\mathcal{B}$, which is orthogonal because those columns are orthonormal, Theorem 3.7.3 gives $\mathbf{Q}_{\mathcal{B}}^\top\mathbf{A}\mathbf{Q}_{\mathcal{B}} = [T]^{\mathcal{B}}_{\mathcal{B}}$.

The block $\mathbf{B}$ is of the allowed kind. If $d = 1$ it is 1×1. If $d = 2$, then by Theorem 10.6.3 the matrix of T^* in $\mathcal{B}$ is the transpose of the display, whose bottom-right block is $\mathbf{B}^\top$; as W is T^*-invariant, $\mathbf{B}^\top$ is the matrix of $T^*|_W$. A real eigenvalue of $\mathbf{B}^\top$ would be a real eigenvalue of T^*, which this case excludes. So $p_{\mathbf{B}} = p_{\mathbf{B}^\top}$ has no real root, and its two complex roots form a conjugate pair by Theorem 8.2.5.

Close the induction. If $U = \{\mathbf{0}\}$ then $n = d \leq 2$, the list $\mathcal{B}$ is a basis of W, and $\mathbf{Q}_{\mathcal{B}}^\top\mathbf{A}\mathbf{Q}_{\mathcal{B}} = \mathbf{B}$ is already a single allowed block; take $\mathbf{Q} = \mathbf{Q}_{\mathcal{B}}$. Otherwise $1 \leq n-d < n$, and by the inductive hypothesis $\mathbf{C} = \mathbf{Q}_1\mathbf{T}_1\mathbf{Q}_1^\top$ with $\mathbf{Q}_1 \in \mathrm{O}(n-d)$ and $\mathbf{T}_1$ of the required shape. Put $\mathbf{Q} = \mathbf{Q}_{\mathcal{B}}(\mathbf{Q}_1 \oplus \mathbf{I}_d)$, a product of orthogonal matrices and so orthogonal (Proposition 10.7.4 (a)). Then

$$\mathbf{Q}^\top\mathbf{A}\mathbf{Q} = (\mathbf{Q}_1 \oplus \mathbf{I}_d)^\top \begin{pmatrix} \mathbf{C} & * \\ \mathbf{0} & \mathbf{B} \end{pmatrix} (\mathbf{Q}_1 \oplus \mathbf{I}_d) = \begin{pmatrix} \mathbf{T}_1 & * \\ \mathbf{0} & \mathbf{B} \end{pmatrix},$$

which is block upper triangular with diagonal blocks those of $\mathbf{T}_1$ followed by $\mathbf{B}$. This proves the theorem.

■

Two remarks on the shape. The 1×1 blocks carry the real eigenvalues of $\mathbf{A}$ and the 2×2 blocks carry the non-real ones in conjugate pairs, so the block sizes are forced by the spectrum, even though the blocks themselves are not. And when all the eigenvalues of $\mathbf{A}$ are real, every block

is 1×1 and the real Schur form is an honest orthogonal triangularization.

Warning. **Neither T nor U is unique; only the diagonal multiset is.** For $\mathbf{A} = \begin{pmatrix} 1 & 1 \\ 0 & 2 \end{pmatrix}$, taking $\mathbf{U} = \mathbf{I}$ gives $\mathbf{T} = \mathbf{A}$, with diagonal $(1, 2)$. Taking instead $\mathbf{U} = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}$ gives

$$\mathbf{U}^* \mathbf{A} \mathbf{U} = \begin{pmatrix} 2 & -1 \\ 0 & 1 \end{pmatrix},$$

with diagonal $(2, 1)$ and a different corner entry. So a Schur form is **not** a canonical form: it does not decide similarity, and two matrices can have the same triangular form without being equal. The canonical form for similarity is Jordan's (Theorem 9.3.1), and Jordan's cannot in general be reached unitarily — Example (A Two-by-Two Schur Factorization) is already a Jordan block in disguise whose off-diagonal entry is -2, not 1. What the Schur form gives up in uniqueness it buys back in stability: the change of basis is an isometry.

11.1.6 Exercises

11.1.6.1 A. Check your understanding

Exercise A1.

(a) State Theorem 11.1.2, including the field and every hypothesis.

(b) In the proof, an eigenvector of T^* is taken rather than one of T. Say why, in one sentence, and name the property of $(\operatorname{span}(\mathbf{v}))^{\perp}$ that is wanted.

(c) True or false: if $\mathbf{A} \in M_n(\mathbb{C})$ is upper triangular in some orthonormal basis, then its eigenvalues are the diagonal entries of that triangular matrix. Justify your answer.

(d) Which step of the proof of Theorem 11.1.2 fails over $\mathbb{R}$?

(e) Give a matrix in $M_2(\mathbb{C})$ that is upper triangular in an orthonormal basis but is **not** diagonal in any.

Solution.

(a) Let V be a finite-dimensional inner product space over $\mathbb{C}$ with $\dim V \geq 1$ and let $T \in \mathcal{L}(V)$. Then V has an orthonormal basis $\mathcal{B}$ with $[T]_{\mathcal{B}}^{\mathcal{B}}$ upper triangular, and the diagonal may be made to read the eigenvalues of T, with algebraic multiplicity, in any prescribed order.

(b) Because the induction needs $(\operatorname{span}(\mathbf{v}))^{\perp}$ to be **T-invariant**, and Lemma 11.1.1 gives that exactly when $\operatorname{span}(\mathbf{v})$ is T^*-invariant, that is, when $\mathbf{v}$ is an eigenvector of T^*.

(c) True. The matrix of T in **any** basis has the same characteristic polynomial (Theorem 6.10.3), and for a triangular matrix that polynomial is the product of $x - t_{ii}$ (Theorem 8.7.4 (a)). Orthonormality is irrelevant to this particular point.

(d) The Fundamental Theorem of Algebra, twice: once so that p_T splits into the list of n roots the statement speaks of (Corollary 5.5.5), and once for the existence of an eigenvalue of T^* at each stage of the induction. It came from Theorem 8.2.4,

whose proof rests on the Fundamental Theorem of Algebra (Theorem 5.5.1); over $\mathbb{R}$ the rotation $\begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$ has no eigenvalue at all. Every other step is valid over $\mathbb{R}$.

(e) $\mathbf{A} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$. It is already upper triangular in the standard orthonormal basis. It is not diagonal in any basis, orthonormal or not: its only eigenvalue is 0, so a diagonal form would be the zero matrix, and $\mathbf{A} \neq 0$.

11.1.6.2 B. Practice

Exercise B1: A Schur form with complex entries.

Let $\mathbf{A} = \begin{pmatrix} 1 & 2 \\ -1 & 3 \end{pmatrix}$, regarded as a complex matrix.

(a) Find the eigenvalues of $\mathbf{A}$.

(b) Find a unitary $\mathbf{U} \in M_2(\mathbb{C})$ with $\mathbf{U}^*\mathbf{A}\mathbf{U}$ upper triangular, and compute that triangular matrix.

(c) Explain why no **real** orthogonal $\mathbf{Q}$ makes $\mathbf{Q}^\top\mathbf{A}\mathbf{Q}$ upper triangular.

Solution.

(a) $\operatorname{tr}\mathbf{A} = 4$ and $\det\mathbf{A} = 3 + 2 = 5$, so $p_{\mathbf{A}} = x^2 - 4x + 5 = (x-2)^2 + 1$, with roots $2 + i$ and $2 - i$.

(b) For $\lambda = 2 + i$,

$$\mathbf{A} - \lambda\mathbf{I} = \begin{pmatrix} -1 - i & 2 \\ -1 & 1 - i \end{pmatrix}.$$

The second row gives $-x + (1-i)y = 0$, so $(1-i, 1)$ is an eigenvector; its norm is $\sqrt{2+1} = \sqrt{3}$. Put $\mathbf{q}_1 = \frac{1}{\sqrt{3}}(1-i, 1)$. A unit vector orthogonal to it is $\mathbf{q}_2 = \frac{1}{\sqrt{3}}(1, -1-i)$, since

$$\langle \mathbf{q}_2, \mathbf{q}_1 \rangle = \tfrac{1}{3}\big(1 \cdot \overline{1-i} + (-1-i)\cdot\overline{1}\big) = \tfrac{1}{3}\big((1+i) - (1+i)\big) = 0$$

and $\|\mathbf{q}_2\|^2 = \frac{1}{3}(1+2) = 1$. With $\mathbf{U} = \begin{pmatrix} \mathbf{q}_1 & \mathbf{q}_2 \end{pmatrix}$,

$$\mathbf{U}^*\mathbf{A}\mathbf{U} = \begin{pmatrix} 2 + i & -1 - 2i \\ 0 & 2 - i \end{pmatrix}.$$

(c) A real upper triangular matrix has its diagonal entries as eigenvalues (Theorem 8.7.4), and those entries are real. But $\mathbf{Q}^\top\mathbf{A}\mathbf{Q}$ is similar to $\mathbf{A}$, whose eigenvalues $2 \pm i$ are not real. So no such $\mathbf{Q}$ exists. (This is Theorem 11.1.7 doing the only thing it can: here $\mathbf{T}$ is a single 2×2 block, and $\mathbf{Q} = \mathbf{I}$ already works.)

Exercise B2: A three-by-three Schur form.

Let $\mathbf{A} = \begin{pmatrix} 2 & 1 & 1 \\ 1 & 2 & 3 \\ 0 & 0 & 4 \end{pmatrix}$.

(a) Verify that $(1,-1,0)$ is an eigenvector and find the corresponding eigenvalue.
(b) Extend it to an orthonormal basis of $\mathbb{R}^3$ and compute $\mathbf{Q}^\top\mathbf{A}\mathbf{Q}$ for the resulting $\mathbf{Q}$.
(c) Hence write down the eigenvalues of $\mathbf{A}$ with their algebraic multiplicities.

Solution.

(a) $\mathbf{A}(1,-1,0) = (2-1,\ 1-2,\ 0) = (1,-1,0)$, so the eigenvalue is 1.
(b) Take $\mathbf{q}_1 = \frac{1}{\sqrt{2}}(1,-1,0)$, $\mathbf{q}_2 = \frac{1}{\sqrt{2}}(1,1,0)$ and $\mathbf{q}_3 = (0,0,1)$. These are pairwise orthogonal unit vectors, hence an orthonormal basis of $\mathbb{R}^3$. With $\mathbf{Q} = \begin{pmatrix}\mathbf{q}_1 & \mathbf{q}_2 & \mathbf{q}_3\end{pmatrix}$,

$$\mathbf{Q}^\top\mathbf{A}\mathbf{Q} = \begin{pmatrix} 1 & 0 & -\sqrt{2} \\ 0 & 3 & 2\sqrt{2} \\ 0 & 0 & 4 \end{pmatrix}.$$

This is already upper triangular, so a single step sufficed and $\mathbf{U} = \mathbf{Q}$. (In general the lower-right 2×2 block would need a second step, as in Example (A Three-by-Three Schur Factorization).)
(c) The diagonal is $1, 3, 4$, so by Theorem 8.7.4 these are the eigenvalues, each of algebraic multiplicity 1. As a check, $\operatorname{tr}\mathbf{A} = 8 = 1+3+4$ and $\det\mathbf{A} = 4(4-1) = 12 = 1\cdot 3\cdot 4$.

Exercise B3: The field matters.

Let $\mathbf{A} = \begin{pmatrix} a & -b \\ b & a \end{pmatrix} \in M_2(\mathbb{R})$ with $b \neq 0$.

(a) Find the eigenvalues of $\mathbf{A}$ over $\mathbb{C}$ and show that $\mathbf{A}$ is unitarily similar to a diagonal matrix in $M_2(\mathbb{C})$.
(b) Prove that there is no invertible $\mathbf{P} \in M_2(\mathbb{R})$ at all, orthogonal or otherwise, with $\mathbf{P}^{-1}\mathbf{A}\mathbf{P}$ upper triangular.
(c) Say what Theorem 11.1.7 produces for this $\mathbf{A}$.

Solution.

(a) $\operatorname{tr}\mathbf{A} = 2a$ and $\det\mathbf{A} = a^2+b^2$, so $p_{\mathbf{A}} = x^2 - 2ax + a^2 + b^2$ with roots $a \pm bi$, distinct because $b \neq 0$. For $\lambda = a+bi$, $\mathbf{A}(1,-i) = (a+bi,\ b-ai) = (a+bi)(1,-i)$, so $\mathbf{q}_1 = \frac{1}{\sqrt{2}}(1,-i)$ is a unit eigenvector; likewise $\mathbf{q}_2 = \frac{1}{\sqrt{2}}(1,i)$ is a unit eigenvector for $a-bi$, and

$$\langle \mathbf{q}_1, \mathbf{q}_2\rangle = \tfrac{1}{2}\big(1\cdot 1 + (-i)\bar{i}\big) = \tfrac{1}{2}(1-1) = 0.$$

So $\mathbf{U} = \begin{pmatrix}\mathbf{q}_1 & \mathbf{q}_2\end{pmatrix}$ is unitary and $\mathbf{U}^*\mathbf{A}\mathbf{U} = \operatorname{diag}(a+bi,\ a-bi)$.
(b) Suppose $\mathbf{P}^{-1}\mathbf{A}\mathbf{P} = \mathbf{T}$ were upper triangular with $\mathbf{P} \in M_2(\mathbb{R})$ invertible. Then $\mathbf{T} \in M_2(\mathbb{R})$ is similar to $\mathbf{A}$, so $p_{\mathbf{T}} = p_{\mathbf{A}}$ (Theorem 6.10.3); but $p_{\mathbf{T}} = (x-t_{11})(x-t_{22})$ has the real roots t_{11}, t_{22}, while $p_{\mathbf{A}}$ has none. Contradiction.
(c) Since $\mathbf{A}$ has no real eigenvalue, the real Schur form of $\mathbf{A}$ is a single 2×2 diagonal block; $\mathbf{Q} = \mathbf{I}_2$ and $\mathbf{T} = \mathbf{A}$ already work. There is nothing to simplify: over $\mathbb{R}$ this matrix is as reduced as it gets.

11.1.6.3 C. Going deeper

Exercise C1: Cayley–Hamilton from the triangular factors.

Let $\mathbf{T} \in M_n(\mathbb{C})$ be upper triangular with diagonal entries $\lambda_1, \dots, \lambda_n$, and set $\mathbf{N}_k = (\mathbf{T} - \lambda_1 \mathbf{I})(\mathbf{T} - \lambda_2 \mathbf{I}) \cdots (\mathbf{T} - \lambda_k \mathbf{I})$ for $1 \le k \le n$.

(a) Prove by induction on k that the first k columns of $\mathbf{N}_k$ are zero.

(b) Deduce that $p_{\mathbf{T}}(\mathbf{T}) = 0$.

(c) Deduce the Cayley–Hamilton Theorem (Theorem 8.6.1) for every $\mathbf{A} \in M_n(\mathbb{C})$, using Corollary 11.1.3.

Hint for (a): the j-th column of $\mathbf{T} - \lambda_j \mathbf{I}$ has its only possibly non-zero entries in rows $1, \dots, j-1$.

Solution.

(a) For $k = 1$: the first column of $\mathbf{T} - \lambda_1 \mathbf{I}$ is $(\lambda_1 - \lambda_1, 0, \dots, 0) = \mathbf{0}$, since $\mathbf{T}$ is upper triangular.
Assume the first $k-1$ columns of $\mathbf{N}_{k-1}$ are zero, where $2 \le k \le n$. Then $\mathbf{N}_k = \mathbf{N}_{k-1}(\mathbf{T} - \lambda_k \mathbf{I})$, so the j-th column of $\mathbf{N}_k$ is $\mathbf{N}_{k-1}\mathbf{c}_j$ with $\mathbf{c}_j$ the j-th column of $\mathbf{T} - \lambda_k \mathbf{I}$. For $j \le k-1$ we get $\mathbf{N}_k \mathbf{e}_j = \mathbf{N}_{k-1}(\mathbf{T} - \lambda_k \mathbf{I})\mathbf{e}_j$, and since $(\mathbf{T} - \lambda_k \mathbf{I})\mathbf{e}_j \in \operatorname{span}(\mathbf{e}_1, \dots, \mathbf{e}_j)$ by upper triangularity, this is a combination of the first $j \le k-1$ columns of $\mathbf{N}_{k-1}$, all zero. For $j = k$ the column $\mathbf{c}_k$ of $\mathbf{T} - \lambda_k \mathbf{I}$ has its (k,k) entry equal to $\lambda_k - \lambda_k = 0$ and zeros below, so $\mathbf{c}_k \in \operatorname{span}(\mathbf{e}_1, \dots, \mathbf{e}_{k-1})$, and $\mathbf{N}_{k-1}\mathbf{c}_k$ is a combination of the first $k-1$ columns of $\mathbf{N}_{k-1}$, again zero. So all of the first k columns of $\mathbf{N}_k$ vanish.

(b) By Theorem 8.7.4 (a), $p_{\mathbf{T}} = (x - \lambda_1) \cdots (x - \lambda_n)$, so $p_{\mathbf{T}}(\mathbf{T}) = \mathbf{N}_n$. By (a) with $k = n$, all n columns of $\mathbf{N}_n$ are zero, that is $p_{\mathbf{T}}(\mathbf{T}) = 0$.

(c) Write $\mathbf{A} = \mathbf{U}\mathbf{T}\mathbf{U}^*$ by Corollary 11.1.3. Similar matrices have the same characteristic polynomial (Theorem 6.10.3), so $p_{\mathbf{A}} = p_{\mathbf{T}}$, and $\mathbf{A}^k = \mathbf{U}\mathbf{T}^k\mathbf{U}^*$ for every $k \ge 0$ because the inner factors $\mathbf{U}^*\mathbf{U}$ cancel. Hence

$$p_{\mathbf{A}}(\mathbf{A}) = \mathbf{U}\, p_{\mathbf{T}}(\mathbf{T})\, \mathbf{U}^* = \mathbf{U}\, 0\, \mathbf{U}^* = 0.$$

Chapter 8 reached the same conclusion from the flag of invariant subspaces (Exercise (C1: A second proof of Cayley–Hamilton)); here the whole argument happens inside one matrix product.

Exercise C2: The Frobenius norm is unitarily invariant.

For $\mathbf{A} \in M_{m \times n}(\mathbb{C})$ write $\|\mathbf{A}\|_F^2 := \sum_{i,j} |a_{ij}|^2$; this is the norm induced by the Frobenius inner product $\langle \mathbf{A}, \mathbf{B} \rangle = \operatorname{tr}(\mathbf{B}^*\mathbf{A})$ of Chapter 10, Section 1.

(a) Prove that $\|\mathbf{A}\|_F^2 = \operatorname{tr}(\mathbf{A}^*\mathbf{A})$.

(b) Prove that $\|\mathbf{U}\mathbf{A}\|_F = \|\mathbf{A}\|_F = \|\mathbf{A}\mathbf{V}\|_F$ whenever $\mathbf{U} \in M_m(\mathbb{C})$ and $\mathbf{V} \in M_n(\mathbb{C})$ are unitary.

(c) Deduce that if $\mathbf{A} = \mathbf{U}\mathbf{T}\mathbf{U}^*$ is a Schur factorization (Corollary 11.1.3), then $\|\mathbf{A}\|_F = \|\mathbf{T}\|_F$.

Solution.

(a) The (j,j) entry of $\mathbf{A}^*\mathbf{A}$ is $\sum_i \overline{a_{ij}}a_{ij} = \sum_i |a_{ij}|^2$. Summing over j gives $\operatorname{tr}(\mathbf{A}^*\mathbf{A}) = \sum_{i,j}|a_{ij}|^2 = \|\mathbf{A}\|_F^2$.

(b) By (a) and $\mathbf{U}^*\mathbf{U} = \mathbf{I}_m$,

$$\|\mathbf{UA}\|_F^2 = \operatorname{tr}\big((\mathbf{UA})^*(\mathbf{UA})\big) = \operatorname{tr}(\mathbf{A}^*\mathbf{U}^*\mathbf{UA}) = \operatorname{tr}(\mathbf{A}^*\mathbf{A}) = \|\mathbf{A}\|_F^2.$$

For the other side, use $\operatorname{tr}(\mathbf{BC}) = \operatorname{tr}(\mathbf{CB})$ (Theorem 0.9.6 (3)) and $\mathbf{VV}^* = \mathbf{I}_n$:

$$\|\mathbf{AV}\|_F^2 = \operatorname{tr}(\mathbf{V}^*\mathbf{A}^*\mathbf{AV}) = \operatorname{tr}(\mathbf{A}^*\mathbf{AVV}^*) = \operatorname{tr}(\mathbf{A}^*\mathbf{A}) = \|\mathbf{A}\|_F^2.$$

Norms are non-negative, so the squares being equal gives the norms equal.

(c) Apply (b) twice: $\|\mathbf{A}\|_F = \|\mathbf{UTU}^*\|_F = \|\mathbf{TU}^*\|_F = \|\mathbf{T}\|_F$, using that $\mathbf{U}^*$ is unitary as well. So a Schur factorization redistributes the size of $\mathbf{A}$ between the diagonal and the strictly upper triangle without changing the total. Section 11 turns that observation into a measurement.

Exercise C3: Distinct eigenvalues are dense, but not over the reals.

(a) Sharpen Corollary 11.1.6: prove that for every $\mathbf{A} \in M_n(\mathbb{C})$ and every $\varepsilon > 0$ there is $\mathbf{A}'$ with n **distinct** eigenvalues and $|a_{ij} - a'_{ij}| < \varepsilon$ for all i, j.

(b) Show that the analogous statement fails over $\mathbb{R}$: for $\mathbf{R} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$ there is an $\varepsilon > 0$ such that **no** real matrix within ε of $\mathbf{R}$, entry by entry, has a real eigenvalue at all.

Hint for (b): a real 2×2 matrix with entries a, b, c, d has real eigenvalues exactly when $(a-d)^2 + 4bc \geq 0$.

Solution.

(a) This is exactly what the proof of Corollary 11.1.6 produced, before the conclusion was weakened. There the δ_k were chosen so that the diagonal entries of $\mathbf{T} + \mathbf{D}$ are pairwise distinct, and by Theorem 8.7.4 (b) those n distinct numbers are the eigenvalues of $\mathbf{T}+\mathbf{D}$, hence of the similar matrix $\mathbf{A}' = \mathbf{U}(\mathbf{T}+\mathbf{D})\mathbf{U}^*$. The entrywise estimate is unchanged.

(b) The characteristic polynomial of $\begin{pmatrix} a & b \\ c & d \end{pmatrix}$ is $x^2 - (a+d)x + (ad - bc)$, whose discriminant is

$$(a+d)^2 - 4(ad - bc) = (a-d)^2 + 4bc,$$

so the eigenvalues are real exactly when this is ≥ 0. Take $\varepsilon = \frac{1}{4}$ and let $\mathbf{A}'$ have entries within ε of those of $\mathbf{R}$, so $|a|, |d| \leq \frac{1}{4}$, $b \in [-\frac{5}{4}, -\frac{3}{4}]$ and $c \in [\frac{3}{4}, \frac{5}{4}]$. Then $(a-d)^2 \leq \frac{1}{4}$ and $bc \leq -\frac{9}{16}$, so

$$(a-d)^2 + 4bc \leq \tfrac{1}{4} - \tfrac{9}{4} = -2 < 0.$$

Hence $\mathbf{A}'$ has no real eigenvalue, let alone two distinct ones. The reason is the one this section keeps meeting: over $\mathbb{C}$ the eigenvalues move continuously and can

always be separated, while over $\mathbb{R}$ a conjugate pair cannot be pushed onto the real line by a small change.

11.2 Self-Adjoint Operators

Among complex numbers, the real ones are those fixed by conjugation: $\overline{z} = z$. Among operators on an inner product space, conjugation is replaced by the adjoint, and the operators fixed by it are the **self-adjoint** ones, $T^* = T$. The analogy is not decoration. Self-adjoint operators have real eigenvalues, they come with a real-valued quantity $\langle T\mathbf{v}, \mathbf{v}\rangle$ attached to every vector, they can be compared and ordered, and over $\mathbb{R}$ they are exactly the operators the spectral theorem applies to. This section collects everything about them that does not need a spectral theorem, and in doing so assembles every ingredient the real spectral theorem of Section 5 will use.

Throughout, V is a finite-dimensional inner product space over $F = \mathbb{R}$ or $F = \mathbb{C}$, and $T \in \mathcal{L}(V)$.

11.2.1 The operators fixed by starring

Chapter 10 already made the definition, so we only recall it: $T \in \mathcal{L}(V)$ is **self-adjoint** when $T^* = T$, equivalently when

$$\langle T\mathbf{u}, \mathbf{v}\rangle = \langle \mathbf{u}, T\mathbf{v}\rangle \qquad \text{for all } \mathbf{u}, \mathbf{v} \in V$$

(Definition 10.6.2). In an orthonormal basis this says the matrix is **Hermitian**, $\mathbf{A}^* = \mathbf{A}$, which over $\mathbb{R}$ is **symmetric**, $\mathbf{A}^\top = \mathbf{A}$ (Theorem 10.6.3). Three facts were proved there and will be used without further comment: $\langle T\mathbf{v}, \mathbf{v}\rangle$ is real for every $\mathbf{v}$, even over $\mathbb{C}$; the diagonal entries of the matrix in an orthonormal basis are real; and every self-adjoint operator is normal (Proposition 10.6.7).

Deciding self-adjointness is always the same job — compute T^*, or check the displayed identity on a basis — but the traps differ by example.

Example. (Four Tests)

Determine which of the following are self-adjoint. Justify your answer; for those that are not, name the failing pair of vectors.

(a) $T_{\mathbf{A}}$ on $\mathbb{C}^2$ with the standard inner product, $\mathbf{A} = \begin{pmatrix} 2 & 1-i \\ 1+i & 3 \end{pmatrix}$.

(b) $T_{\mathbf{B}}$ on $\mathbb{C}^2$ with the standard inner product, $\mathbf{B} = \begin{pmatrix} 1 & i \\ i & 1 \end{pmatrix}$.

(c) Differentiation D on $V = \mathbb{R}[x]_{\le 2}$ with $\langle p, q\rangle = \int_0^1 pq$.

(d) The orthogonal projection P_U onto a subspace U of any V.

Solution.

(a) Self-adjoint. Transposing swaps the off-diagonal entries and conjugating swaps them back, while the diagonal entries 2 and 3 are real; so $\mathbf{A}^* = \mathbf{A}$. The standard basis of $\mathbb{C}^2$ is orthonormal, so Theorem 10.6.3 turns this into $T_{\mathbf{A}}^* = T_{\mathbf{A}}$.

(b) Not self-adjoint. It is **symmetric**, $\mathbf{B}^\top = \mathbf{B}$, but $\mathbf{B}^* = \begin{pmatrix} 1 & -i \\ -i & 1 \end{pmatrix} \neq \mathbf{B}$. The failing pair is $\mathbf{e}_1, \mathbf{e}_2$: $\langle \mathbf{B}\mathbf{e}_1, \mathbf{e}_2 \rangle = i$, while $\langle \mathbf{e}_1, \mathbf{B}\mathbf{e}_2 \rangle = \bar{i} = -i$.

(c) Not self-adjoint. Take $p = x$ and $q = 1$. Then $Dp = 1$ and $Dq = 0$, so

$$\langle Dp, q \rangle = \int_0^1 1 \, \mathrm{d}x = 1, \qquad \langle p, Dq \rangle = 0.$$

The obstruction is visible in general: integration by parts gives

$$\langle Dp, q \rangle + \langle p, Dq \rangle = p(1)q(1) - p(0)q(0),$$

so D is as far from self-adjoint as it could be — the two sides add up rather than agreeing, apart from boundary terms.

(d) Self-adjoint, for every U. By Theorem 10.3.3 (b), $\langle P_U \mathbf{u}, \mathbf{v} \rangle = \langle \mathbf{u}, P_U \mathbf{v} \rangle$ for all $\mathbf{u}, \mathbf{v}$, which is the displayed identity.

Warning. **Over $\mathbb{C}$, symmetric is not the right notion; Hermitian is.** Part (b) above is symmetric and its eigenvalues are not even real: $\operatorname{tr} \mathbf{B} = 2$ and $\det \mathbf{B} = 1 - i^2 = 2$, so $p_{\mathbf{B}} = x^2 - 2x + 2$ and the eigenvalues are $1 + i$ and $1 - i$. Every theorem in this section would fail for it. The word "symmetric matrix" belongs to the **real** case, where conjugation does nothing and $\mathbf{A}^* = \mathbf{A}^\top$; over $\mathbb{C}$ always write, and check, $\mathbf{A}^* = \mathbf{A}$.

11.2.2 Eigenvalues are real

The first theorem is the operator version of "a number equal to its own conjugate is real", and its proof is the move that runs this whole chapter: compute one inner product two different ways.

Theorem 11.2.1 — Self-adjoint Operators Have Real Eigenvalues

Let V be a finite-dimensional inner product space over $F = \mathbb{R}$ or $F = \mathbb{C}$ and let $T \in \mathcal{L}(V)$ be self-adjoint. Then every eigenvalue of T is real.

Idea. Take $T\mathbf{v} = \lambda \mathbf{v}$ with $\mathbf{v} \neq \mathbf{0}$ and pair it with $\mathbf{v}$. Computing $\langle T\mathbf{v}, \mathbf{v} \rangle$ straight off the eigenvalue equation produces λ; computing it by pushing T into the second slot produces $\overline{\lambda}$, because a scalar leaving the second slot picks up a conjugate. The two answers must agree, and $\|\mathbf{v}\|^2 \neq 0$ lets us cancel.

Proof. Let λ be an eigenvalue of T, with eigenvector $\mathbf{v} \neq \mathbf{0}$. On one side,

$$\langle T\mathbf{v}, \mathbf{v} \rangle = \langle \lambda \mathbf{v}, \mathbf{v} \rangle = \lambda \|\mathbf{v}\|^2,$$

by linearity in the first slot. On the other, using Definition 10.6.2 and then conjugate-linearity in the second slot,

$$\langle T\mathbf{v}, \mathbf{v} \rangle = \langle \mathbf{v}, T\mathbf{v} \rangle = \langle \mathbf{v}, \lambda \mathbf{v} \rangle = \overline{\lambda} \|\mathbf{v}\|^2.$$

So $\lambda\|\mathbf{v}\|^2 = \overline{\lambda}\|\mathbf{v}\|^2$. Since $\mathbf{v} \neq \mathbf{0}$ we have $\|\mathbf{v}\|^2 \neq 0$ by positive definiteness (Definition 10.1.1), and dividing gives $\lambda = \overline{\lambda}$. A scalar equal to its own conjugate is real.

■

Chapter 10 already proved this, in the remark after Proposition 10.6.7. It is promoted to a theorem here because Sections 3 to 5 lean on it constantly, and a result cited that often should have a number. Over $\mathbb{R}$ the conclusion sounds empty, because the eigenvalues of a real operator are real by definition. What is not empty over $\mathbb{R}$ is the corresponding statement about the **roots of the characteristic polynomial**, and that is the next theorem: it says the roots do not escape into $\mathbb{C}$, which is exactly what guarantees that a real self-adjoint operator has an eigenvector at all.

11.2.3 Existence over the real numbers

Over $\mathbb{C}$ an eigenvalue is free (Theorem 8.2.4). Over $\mathbb{R}$ it is not, and the rotation of $\mathbb{R}^2$ by a quarter turn has none. Self-adjointness is what rules that out.

Theorem 11.2.2 — Real Self-adjoint Operators Have an Eigenvalue

Let $V \neq \{\mathbf{0}\}$ be a finite-dimensional inner product space over $\mathbb{R}$ and let $T \in \mathcal{L}(V)$ be self-adjoint. Then:

(a) every root of p_T in $\mathbb{C}$ is real, so p_T splits over $\mathbb{R}$;
(b) T has an eigenvalue.

Idea. There is no complex number in sight, so we put one there. Fix an orthonormal basis; the matrix $\mathbf{A}$ of T is real symmetric. The same array of numbers, read as a complex matrix, is Hermitian, and it acts on $\mathbb{C}^n$, which is the complexification of $\mathbb{R}^n$ (Definition 1.9.2, Example (The Complexification of $\mathbb{R}^n$ Is $\mathbb{C}^n$)) — the arena Chapter 1 built, and Chapter 8 put to work, precisely so that a real matrix could borrow complex eigenvalues. Over $\mathbb{C}$ an eigenvalue exists, and Theorem 11.2.1 says it is real. A real root of p_T is an eigenvalue of T itself, and we are back where we started, one eigenvalue richer.

Proof. Let $n = \dim V \geq 1$. By Theorem 10.2.2, V has an orthonormal basis $\mathcal{B}$; put $\mathbf{A} = [T]_{\mathcal{B}}^{\mathcal{B}} \in M_n(\mathbb{R})$. By Theorem 10.6.3 and Definition 10.6.2, $\mathbf{A}^* = \mathbf{A}$, and since $\mathbf{A}$ is real this says $\mathbf{A}^\top = \mathbf{A}$.

Now read $\mathbf{A}$ as an element of $M_n(\mathbb{C})$, acting on $\mathbb{C}^n$ with the standard inner product; this is the extension of the real map $T_{\mathbf{A}}$ to the complexification $(\mathbb{R}^n)_{\mathbb{C}} = \mathbb{C}^n$, which acts on $\mathbf{x} + i\mathbf{y}$ by $\mathbf{A}\mathbf{x} + i\mathbf{A}\mathbf{y}$ (Chapter 8, Section 2). Because $\mathbf{A}$ is real and symmetric, $\mathbf{A}^* = \overline{\mathbf{A}}^\top = \mathbf{A}^\top = \mathbf{A}$, so $T_{\mathbf{A}}$ is self-adjoint as an operator on $\mathbb{C}^n$ (Theorem 10.6.3 again, the standard basis of $\mathbb{C}^n$ being orthonormal).

(a) By Definition 6.10.2, $p_T = p_{\mathbf{A}}$, and the entries of $x\mathbf{I} - \mathbf{A}$ are real, so this is the same polynomial whether the determinant is expanded over $\mathbb{R}$ or over $\mathbb{C}$; it lies in $\mathbb{R}[x] \subseteq \mathbb{C}[x]$. Let $\lambda \in \mathbb{C}$ be a root of $p_{\mathbf{A}}$. By Theorem 8.2.1, λ is an eigenvalue of

$\mathbf{A}$ over $\mathbb{C}$, and $\mathbf{A}$ is self-adjoint there, so $\lambda \in \mathbb{R}$ by Theorem 11.2.1. Since every root of p_T in $\mathbb{C}$ lies in $\mathbb{R}$, and p_T splits over $\mathbb{C}$ by Corollary 5.5.5, it splits over $\mathbb{R}$.

(b) p_T is monic of degree $n \geq 1$ (Theorem 6.10.2), so by (a) it has a root $\lambda \in \mathbb{R}$. By Theorem 8.2.1 ((e) $\Rightarrow$ (a)), λ is an eigenvalue of T. This proves the theorem.

■

Remark. There is a second, very different route to (b): the function $\mathbf{v} \mapsto \langle T\mathbf{v}, \mathbf{v}\rangle$ is real-valued and continuous on the unit sphere of V, which is closed and bounded, so it attains a maximum, and a vector where it does so turns out to be an eigenvector for the largest eigenvalue. That argument is shorter to state but it is analysis, not algebra, and it needs the extreme value theorem; we keep to the algebraic route so that nothing in this chapter depends on it. The maximization picture returns in Chapter 16, where the Rayleigh quotient and the Courant–Fischer theorem describe every eigenvalue of a self-adjoint operator by optimization.

Quick check. The rotation $\mathbf{R} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$ on $\mathbb{R}^2$ has no eigenvalue, and over $\mathbb{C}$ its eigenvalues $\pm i$ are not real. Which hypothesis of Theorem 11.2.2 does it fail, and how do you see it in one line?

Solution. Self-adjointness. In the standard orthonormal basis the matrix of $\mathbf{R}^*$ is $\mathbf{R}^\top = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} = -\mathbf{R}$, which is not $\mathbf{R}$. So $\mathbf{R}$ is skew-adjoint, not self-adjoint, and neither theorem applies. (It is, however, normal, since $\mathbf{R}^\top\mathbf{R} = \mathbf{R}\mathbf{R}^\top = \mathbf{I}$ — which is why Section 5 has to insist on self-adjoint rather than normal over $\mathbb{R}$.)

11.2.4 Eigenvectors for different eigenvalues are orthogonal

The second theorem is the same move with two vectors instead of one, and it is the geometric half of the spectral theorem: the eigenspaces are not merely independent, as in Chapter 8, but perpendicular.

Theorem 11.2.3 — Distinct Eigenvalues Give Orthogonal Eigenvectors

Let $T \in \mathcal{L}(V)$ be self-adjoint, and let $\mathbf{u}, \mathbf{v} \in V$ satisfy $T\mathbf{u} = \lambda\mathbf{u}$ and $T\mathbf{v} = \mu\mathbf{v}$ with $\lambda \neq \mu$. Then $\langle \mathbf{u}, \mathbf{v}\rangle = 0$. Consequently $E_\lambda(T) \perp E_\mu(T)$ for distinct eigenvalues λ, μ.

Proof. Compute $\langle T\mathbf{u}, \mathbf{v}\rangle$ two ways. First, $\langle T\mathbf{u}, \mathbf{v}\rangle = \langle \lambda\mathbf{u}, \mathbf{v}\rangle = \lambda\langle \mathbf{u}, \mathbf{v}\rangle$. Second, by Definition 10.6.2 and conjugate-linearity in the second slot,

$$\langle T\mathbf{u}, \mathbf{v}\rangle = \langle \mathbf{u}, T\mathbf{v}\rangle = \langle \mathbf{u}, \mu\mathbf{v}\rangle = \overline{\mu}\langle \mathbf{u}, \mathbf{v}\rangle = \mu\langle \mathbf{u}, \mathbf{v}\rangle,$$

the last step because μ is real by Theorem 11.2.1. Subtracting, $(\lambda - \mu)\langle \mathbf{u}, \mathbf{v}\rangle = 0$, and $\lambda - \mu \neq 0$, so $\langle \mathbf{u}, \mathbf{v}\rangle = 0$. Since every element of $E_\lambda(T)$ is such a $\mathbf{u}$ and every element of

$E_\mu(T)$ such a $\mathbf{v}$, the two eigenspaces are orthogonal.

■

Note where the previous theorem was spent: it made $\overline{\mu} = \mu$, so that the conjugation which appears on the way out of the second slot does no damage. Without real eigenvalues the computation would end at $\lambda\langle \mathbf{u}, \mathbf{v}\rangle = \overline{\mu}\langle \mathbf{u}, \mathbf{v}\rangle$, which says nothing when $\lambda = \overline{\mu}$.

Example. (A Hermitian Two-by-Two)

For $\mathbf{A} = \begin{pmatrix} 2 & 1-i \\ 1+i & 3 \end{pmatrix}$ on $\mathbb{C}^2$, find the eigenvalues and an eigenvector for each, and verify that the two eigenvectors are orthogonal.

Solution. Here $\operatorname{tr}\mathbf{A} = 5$ and $\det\mathbf{A} = 6 - (1-i)(1+i) = 6 - 2 = 4$, so

$$p_{\mathbf{A}} = x^2 - 5x + 4 = (x-1)(x-4).$$

Both eigenvalues are real, as Theorem 11.2.1 promised.

For $\lambda = 1$: $\mathbf{A} - \mathbf{I} = \begin{pmatrix} 1 & 1-i \\ 1+i & 2 \end{pmatrix}$, and the first row gives $x + (1-i)y = 0$, so $\mathbf{u} = (-1+i, 1)$. Check the second row: $(1+i)(-1+i)+2 = (-1+i-i+i^2)+2 = -2+2 = 0$.

For $\lambda = 4$: $\mathbf{A} - 4\mathbf{I} = \begin{pmatrix} -2 & 1-i \\ 1+i & -1 \end{pmatrix}$, and the first row gives $-2x + (1-i)y = 0$, so $\mathbf{v} = (1-i, 2)$.

Finally

$$\langle \mathbf{u}, \mathbf{v}\rangle = (-1+i)\overline{(1-i)} + 1\cdot\overline{2} = (-1+i)(1+i) + 2 = -2 + 2 = 0,$$

so $\mathbf{u} \perp \mathbf{v}$, as Theorem 11.2.3 requires. Normalizing, $\|\mathbf{u}\|^2 = 2+1 = 3$ and $\|\mathbf{v}\|^2 = 2+4 = 6$, so

$$\left(\tfrac{1}{\sqrt{3}}(-1+i, 1),\ \tfrac{1}{\sqrt{6}}(1-i, 2)\right)$$

is an orthonormal basis of $\mathbb{C}^2$ consisting of eigenvectors of $\mathbf{A}$. Section 4 proves that this always happens, for exactly the operators it happens for.

11.2.5 Invariant complements

Section 5 will prove the real spectral theorem by the move named at the front of the chapter: find one eigenvector, pass to its orthogonal complement, induct. For that to work the complement must be invariant, and the restriction must again be self-adjoint so that the induction can be applied to it. Both hold, and neither needs an eigenvector — the statement is about any invariant subspace.

Theorem 11.2.4 — Self-adjointness Passes to Orthogonal Complements

Let $T \in \mathcal{L}(V)$ be self-adjoint and let $U \subseteq V$ be a T-invariant subspace. Then:

(a) $U^{\perp}$ is T-invariant;

(b) $T|_U \in \mathcal{L}(U)$ and $T|_{U^{\perp}} \in \mathcal{L}(U^{\perp})$ are self-adjoint, for the inner products inherited from V.

Proof.

(a) Since T is self-adjoint, $T^* = T$, so U is T^*-invariant. By Lemma 11.1.1, $U^{\perp}$ is T-invariant.

(b) U is T-invariant, so $T|_U$ maps U to U and is an operator on U. For $\mathbf{u}_1, \mathbf{u}_2 \in U$,

$$\langle T|_U \mathbf{u}_1, \mathbf{u}_2 \rangle = \langle T\mathbf{u}_1, \mathbf{u}_2 \rangle = \langle \mathbf{u}_1, T\mathbf{u}_2 \rangle = \langle \mathbf{u}_1, T|_U \mathbf{u}_2 \rangle,$$

where the inner products are those of V, which is what U inherits. By Definition 10.6.2, $T|_U$ is self-adjoint. The same three equalities with $U^{\perp}$ in place of U give the second claim, using (a) to know that $T|_{U^{\perp}}$ is an operator on $U^{\perp}$.

■

So the pair $(U, U^{\perp})$ splits a self-adjoint operator into two self-adjoint operators on smaller spaces, and nothing is lost: $V = U \oplus U^{\perp}$ by Theorem 10.3.2 (a). Combined with Theorem 11.2.2, which guarantees that a non-zero space always offers an eigenvector to start from, this is a complete induction, and Section 5 will do no more than write it out.

11.2.6 Two zero tests, and the gap between the fields

An operator carries the function $\mathbf{v} \mapsto \langle T\mathbf{v}, \mathbf{v} \rangle$, sometimes called its quadratic form. How much of T does that one function remember? The answer depends on the field, and the difference is the sharpest illustration in this book of why $\mathbb{C}$ is the easier place to work.

Theorem 11.2.5 — The Zero Test for Self-adjoint Operators

Let V be a finite-dimensional inner product space over $F = \mathbb{R}$ or $F = \mathbb{C}$ and let $T \in \mathcal{L}(V)$ be **self-adjoint**. If $\langle T\mathbf{v}, \mathbf{v} \rangle = 0$ for every $\mathbf{v} \in V$, then $T = 0$.

Idea. The hypothesis only ever feeds T one vector, while the conclusion is about $\langle T\mathbf{u}, \mathbf{w} \rangle$ for **two**. So manufacture two out of one: apply the hypothesis to $\mathbf{u} + \mathbf{w}$ and expand. The diagonal terms die by hypothesis and what is left is a statement about the cross terms, which self-adjointness turns into a statement about $\langle T\mathbf{u}, \mathbf{w} \rangle$ alone.

Proof. Let $\mathbf{u}, \mathbf{w} \in V$. Expanding $\langle T(\mathbf{u} + \mathbf{w}), \mathbf{u} + \mathbf{w} \rangle$ in both slots,

$$\begin{aligned} 0 &= \langle T\mathbf{u}, \mathbf{u} \rangle + \langle T\mathbf{u}, \mathbf{w} \rangle + \langle T\mathbf{w}, \mathbf{u} \rangle + \langle T\mathbf{w}, \mathbf{w} \rangle \\ &= \langle T\mathbf{u}, \mathbf{w} \rangle + \langle T\mathbf{w}, \mathbf{u} \rangle, \end{aligned}$$

the two outer terms vanishing by hypothesis. Since T is self-adjoint, $\langle T\mathbf{w}, \mathbf{u} \rangle = \langle \mathbf{w}, T\mathbf{u} \rangle =$

$\overline{\langle T\mathbf{u}, \mathbf{w}\rangle}$ by conjugate symmetry. Writing $z = \langle T\mathbf{u}, \mathbf{w}\rangle$, the display says $z + \overline{z} = 0$, that is

$$\mathrm{Re}\langle T\mathbf{u}, \mathbf{w}\rangle = 0 \qquad \text{for all } \mathbf{u}, \mathbf{w} \in V. \tag{$*$}$$

If $F = \mathbb{R}$ this already says $\langle T\mathbf{u}, \mathbf{w}\rangle = 0$ for all $\mathbf{u}, \mathbf{w}$. If $F = \mathbb{C}$, apply $(*)$ with $i\mathbf{w}$ in place of $\mathbf{w}$: since $\langle T\mathbf{u}, i\mathbf{w}\rangle = \overline{i}\, z = -iz$ and $\mathrm{Re}(-iz) = \mathrm{Im}(z)$, we also get $\mathrm{Im}\langle T\mathbf{u}, \mathbf{w}\rangle = 0$. Either way $\langle T\mathbf{u}, \mathbf{w}\rangle = 0$ for all $\mathbf{u}, \mathbf{w}$.

Taking $\mathbf{w} = T\mathbf{u}$ gives $\|T\mathbf{u}\|^2 = 0$, so $T\mathbf{u} = \mathbf{0}$ for every $\mathbf{u}$, that is $T = 0$. This proves the theorem.

■

Now drop the hypothesis. Over $\mathbb{C}$ nothing is lost.

Theorem 11.2.6 — The Zero Test over the Complex Numbers

Let V be a finite-dimensional **complex** inner product space and let $T \in \mathcal{L}(V)$ be any operator. If $\langle T\mathbf{v}, \mathbf{v}\rangle = 0$ for every $\mathbf{v} \in V$, then $T = 0$.

Idea. The previous proof used self-adjointness in exactly one place: to convert $\langle T\mathbf{w}, \mathbf{u}\rangle$ into $\overline{\langle T\mathbf{u}, \mathbf{w}\rangle}$, which gave the real part only. Without it we must extract the imaginary part some other way, and over $\mathbb{C}$ there is another way — substitute $\mathbf{u} + i\mathbf{w}$ as well as $\mathbf{u} + \mathbf{w}$, and take a combination of the two identities. There is no third substitution available over $\mathbb{R}$, which is precisely why the real statement is false.

Proof. Let $\mathbf{u}, \mathbf{w} \in V$. Applying the hypothesis to $\mathbf{u} + \mathbf{w}$ and expanding as before,

$$\langle T\mathbf{u}, \mathbf{w}\rangle + \langle T\mathbf{w}, \mathbf{u}\rangle = 0. \tag{1}$$

Applying it to $\mathbf{u} + i\mathbf{w}$ and using $\langle T\mathbf{u}, i\mathbf{w}\rangle = -i\langle T\mathbf{u}, \mathbf{w}\rangle$, $\langle T(i\mathbf{w}), \mathbf{u}\rangle = i\langle T\mathbf{w}, \mathbf{u}\rangle$ and $\langle T(i\mathbf{w}), i\mathbf{w}\rangle = i\overline{i}\langle T\mathbf{w}, \mathbf{w}\rangle = 0$,

$$-i\langle T\mathbf{u}, \mathbf{w}\rangle + i\langle T\mathbf{w}, \mathbf{u}\rangle = 0.$$

Multiplying that by i gives

$$\langle T\mathbf{u}, \mathbf{w}\rangle - \langle T\mathbf{w}, \mathbf{u}\rangle = 0. \tag{2}$$

Adding (1) and (2), $2\langle T\mathbf{u}, \mathbf{w}\rangle = 0$, so $\langle T\mathbf{u}, \mathbf{w}\rangle = 0$ for all $\mathbf{u}, \mathbf{w}$. Taking $\mathbf{w} = T\mathbf{u}$ gives $\|T\mathbf{u}\|^2 = 0$, hence $T = 0$.

■

This statement appeared once already, as Exercise (C2: Linearity is a hypothesis, not a consequence) (b), where it was an exercise in the arithmetic of complex inner products. It is restated and proved here because Section 3 needs to cite it as a theorem: the four characterizations of a normal operator all come from applying it to $T^*T - TT^*$. The proof is the same one; what is new is the company it now keeps.

Warning. **Over $\mathbb{R}$, the quadratic form does not determine the operator.** Let T

be the quarter turn of $\mathbb{R}^2$, $T(x_1, x_2) = (-x_2, x_1)$. Then

$$\langle T\mathbf{x}, \mathbf{x}\rangle = -x_2x_1 + x_1x_2 = 0 \qquad \text{for every } \mathbf{x} \in \mathbb{R}^2,$$

and yet $T \neq 0$. So Theorem 11.2.6 genuinely fails over $\mathbb{R}$, and Theorem 11.2.5 genuinely needs its hypothesis: this T is not self-adjoint, since $T^* = -T$. The general real statement is that $\langle T\mathbf{v}, \mathbf{v}\rangle = 0$ for all $\mathbf{v}$ forces $T^* = -T$ and no more — Exercise (C3: What the real quadratic form does determine).

Quick check. Over $\mathbb{C}$, suppose $\langle T\mathbf{v}, \mathbf{v}\rangle$ is **real** for every $\mathbf{v} \in V$. Must T be self-adjoint?

Solution. Yes. Put $S = T - T^*$. For every $\mathbf{v}$, $\langle T^*\mathbf{v}, \mathbf{v}\rangle = \langle \mathbf{v}, T\mathbf{v}\rangle = \overline{\langle T\mathbf{v}, \mathbf{v}\rangle} = \langle T\mathbf{v}, \mathbf{v}\rangle$, the last step because the number is real. Hence $\langle S\mathbf{v}, \mathbf{v}\rangle = 0$ for all $\mathbf{v}$, and Theorem 11.2.6 gives $S = 0$, that is $T^* = T$. Combined with Proposition 10.6.7 (a), this says that over $\mathbb{C}$ "self-adjoint" and "$\langle T\mathbf{v}, \mathbf{v}\rangle$ always real" are the same condition. Over $\mathbb{R}$ the criterion is useless, since $\langle T\mathbf{v}, \mathbf{v}\rangle$ is automatically real for every operator.

11.2.7 Exercises

11.2.7.1 A. Check your understanding

Exercise A1.

(a) State what it means for $T \in \mathcal{L}(V)$ to be self-adjoint, in terms of T^* and in terms of inner products, and say what the matrix condition is and in which bases it may be used.

(b) True or false: a symmetric matrix in $M_2(\mathbb{C})$ has real eigenvalues. Justify your answer.

(c) Which field does Theorem 11.2.2 concern, and which earlier theorem supplies the eigenvalue it borrows?

(d) True or false: if T is self-adjoint and U is any subspace, then $U^\perp$ is T-invariant. Justify your answer.

(e) State the difference between Theorem 11.2.5 and Theorem 11.2.6, and give the standard example showing the second has no real analogue.

(f) Give a normal operator on $\mathbb{R}^2$ that is not self-adjoint.

Solution.

(a) $T^* = T$; equivalently $\langle T\mathbf{u}, \mathbf{v}\rangle = \langle \mathbf{u}, T\mathbf{v}\rangle$ for **all** $\mathbf{u}, \mathbf{v} \in V$ (Definition 10.6.2). The matrix condition is $\mathbf{A}^* = \mathbf{A}$, and by Theorem 10.6.3 it may be used only in an **orthonormal** basis.

(b) False. $\mathbf{B} = \begin{pmatrix} 1 & i \\ i & 1 \end{pmatrix}$ is symmetric with eigenvalues $1 \pm i$ (Example (Four Tests) (b) and the warning after it). Over $\mathbb{C}$ the relevant condition is $\mathbf{A}^* = \mathbf{A}$, not $\mathbf{A}^\top = \mathbf{A}$.

(c) The real field: it says a self-adjoint operator on a non-zero **real** inner product space has an eigenvalue. The eigenvalue is borrowed from Theorem 8.2.4, applied to the matrix read as a complex matrix on the complexification $\mathbb{C}^n$ of $\mathbb{R}^n$, and is

then shown to be real by Theorem 11.2.1.

(d) False as stated: U must be **T-invariant** (Theorem 11.2.4). For example, $T = T_{\mathbf{A}}$ on $\mathbb{R}^2$ with $\mathbf{A} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$ is self-adjoint, and $U = \operatorname{span}(\mathbf{e}_1)$ has $U^\perp = \operatorname{span}(\mathbf{e}_2)$ with $T\mathbf{e}_2 = \mathbf{e}_1 \notin U^\perp$. Here U was not invariant either, since $T\mathbf{e}_1 = \mathbf{e}_2$.

(e) Theorem 11.2.5 holds over $\mathbb{R}$ and $\mathbb{C}$ but assumes T self-adjoint; Theorem 11.2.6 drops that assumption but holds only over $\mathbb{C}$. The quarter turn $T(x_1, x_2) = (-x_2, x_1)$ of $\mathbb{R}^2$ satisfies $\langle T\mathbf{x}, \mathbf{x}\rangle = 0$ for every $\mathbf{x}$ and is not zero.

(f) The same quarter turn: $T^* = -T$, so $T^*T = TT^* = \mathrm{id}$ and T is normal, while $T^* \neq T$.

11.2.7.2 B. Practice

Exercise B1: Determine which are self-adjoint.

Determine which of the following operators are self-adjoint. Justify your answer; for those that are not, exhibit a pair $\mathbf{u}, \mathbf{v}$ with $\langle T\mathbf{u}, \mathbf{v}\rangle \neq \langle \mathbf{u}, T\mathbf{v}\rangle$, or compute T^*.

(a) $T_{\mathbf{A}}$ on $\mathbb{C}^2$, $\mathbf{A} = \begin{pmatrix} 1 & 2+i \\ 2-i & -5 \end{pmatrix}$, standard inner product.

(b) $T_{\mathbf{B}}$ on $\mathbb{C}^2$, $\mathbf{B} = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}$, standard inner product.

(c) $T_{\mathbf{C}}$ on $\mathbb{R}^3$, $\mathbf{C} = \begin{pmatrix} 1 & 2 & 0 \\ 2 & 1 & 3 \\ 0 & 3 & 1 \end{pmatrix}$, standard inner product.

(d) S^*S, for an arbitrary $S \in \mathcal{L}(V, W)$ between finite-dimensional inner product spaces.

(e) $P_U - P_{U^\perp}$, for a subspace U of a finite-dimensional V.

(f) $T(x_1, x_2) = (x_2, x_1)$ on $\mathbb{R}^2$ with the standard inner product, whose matrix in the basis $\mathcal{C} = ((1,0),(1,2))$ is $\begin{pmatrix} -\frac{1}{2} & \frac{3}{2} \\ \frac{1}{2} & \frac{1}{2} \end{pmatrix}$, which is not symmetric.

Solution.

(a) Self-adjoint. The diagonal entries 1 and -5 are real and the off-diagonal pair $2+i$, $2-i$ are conjugates, so $\mathbf{A}^* = \mathbf{A}$; the standard basis is orthonormal, so Theorem 10.6.3 applies.

(b) Not self-adjoint. $\mathbf{B}^* = \mathbf{B}^\top = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} = -\mathbf{B}$, so $T_{\mathbf{B}}$ is skew-adjoint. Concretely $\langle \mathbf{B}\mathbf{e}_1, \mathbf{e}_2\rangle = -1$ while $\langle \mathbf{e}_1, \mathbf{B}\mathbf{e}_2\rangle = 1$.

(c) Self-adjoint. $\mathbf{C}$ is real and $\mathbf{C}^\top = \mathbf{C}$, and the standard basis of $\mathbb{R}^3$ is orthonormal.

(d) Self-adjoint, for every S. By Theorem 10.6.2 (c) and (d), $(S^*S)^* = S^*S^{**} = S^*S$.

(e) Self-adjoint. Each of P_U and $P_{U^\perp}$ is self-adjoint (Example (Four Tests) (d)), and by Theorem 10.6.2 (a) and (b) the difference of self-adjoint operators is self-adjoint: $(P_U - P_{U^\perp})^* = P_U^* - P_{U^\perp}^* = P_U - P_{U^\perp}$.

(f) Self-adjoint, in spite of the non-symmetric matrix. The basis $\mathcal{C}$ is **not** orthonormal — $\langle (1,0),(1,2)\rangle = 1 \neq 0$ — so Theorem 10.6.3 does not apply to it, and the shape

of $[T]_{\mathcal{C}}^{\mathcal{C}}$ says nothing either way. Test the definition instead: for $\mathbf{x}, \mathbf{y} \in \mathbb{R}^2$,

$$\langle T\mathbf{x}, \mathbf{y}\rangle = x_2 y_1 + x_1 y_2 = \langle \mathbf{x}, T\mathbf{y}\rangle,$$

so $T^* = T$. In the standard basis, which *is* orthonormal, the matrix is $\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$, symmetric as it must be. The moral is the one Chapter 10, Section 6 closes with: self-adjointness is a property of the operator and the inner product, never of a matrix taken on its own.

Exercise B2: Eigenvalues and orthogonality.

(a) For $\mathbf{A} = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix} \in M_2(\mathbb{C})$, check that $\mathbf{A}$ is Hermitian, find its eigenvalues and an eigenvector for each, and verify that the eigenvectors are orthogonal.

(b) For $\mathbf{S} = \begin{pmatrix} 3 & 1 & 1 \\ 1 & 3 & 1 \\ 1 & 1 & 3 \end{pmatrix} \in M_3(\mathbb{R})$, find the eigenvalues with their multiplicities and bases of the eigenspaces, and verify that the two eigenspaces are orthogonal.

(c) Hence write down an orthonormal basis of $\mathbb{R}^3$ consisting of eigenvectors of $\mathbf{S}$.

Solution.

(a) $\mathbf{A}^* = \overline{\mathbf{A}}^{\top} = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix} = \mathbf{A}$, so $\mathbf{A}$ is Hermitian. Then $\operatorname{tr}\mathbf{A} = 0$ and $\det\mathbf{A} = 0 - (-i)(i) = -1$, so $p_{\mathbf{A}} = x^2 - 1$ and the eigenvalues are 1 and -1, both real. $\mathbf{A}(1, i) = (-i \cdot i,\ i \cdot 1) = (1, i)$, so $\mathbf{u} = (1, i)$ works for $\lambda = 1$. $\mathbf{A}(1, -i) = (-1,\ i) = -(1, -i)$, so $\mathbf{v} = (1, -i)$ works for $\lambda = -1$. Finally

$$\langle \mathbf{u}, \mathbf{v}\rangle = 1 \cdot \overline{1} + i\,\overline{(-i)} = 1 + i \cdot i = 0.$$

(b) Expanding the determinant gives $p_{\mathbf{S}} = (x - 5)(x - 2)^2$, so $\operatorname{spec}(\mathbf{S}) = \{5, 2\}$ with algebraic multiplicities 1 and 2. The eigenspaces are read off from $\mathbf{S} = 2\mathbf{I} + \mathbf{J}$, where $\mathbf{J}$ is the all-ones matrix: since $\mathbf{J}(1,1,1) = (3,3,3)$ and $\mathbf{J}\mathbf{x} = \mathbf{0}$ exactly when $x_1 + x_2 + x_3 = 0$,

$$E_5(\mathbf{S}) = \operatorname{span}\big((1,1,1)\big), \quad E_2(\mathbf{S}) = \operatorname{span}\big((1,-1,0), (1,0,-1)\big),$$

of dimensions 1 and 2. Orthogonality: $(1,1,1)\cdot(1,-1,0) = 0$ and $(1,1,1)\cdot(1,0,-1) = 0$, so $E_5(\mathbf{S}) \perp E_2(\mathbf{S})$, as Theorem 11.2.3 requires.

(c) The two vectors spanning $E_2(\mathbf{S})$ are not orthogonal to each other, so run Gram–Schmidt inside that eigenspace (Theorem 10.2.2). With $\mathbf{w}_1 = (1, -1, 0)$,

$$(1, 0, -1) - \tfrac{1}{2}(1, -1, 0) = \tfrac{1}{2}(1, 1, -2).$$

Normalizing all three vectors gives the orthonormal eigenbasis

$$\tfrac{1}{\sqrt{3}}(1,1,1), \quad \tfrac{1}{\sqrt{2}}(1,-1,0), \quad \tfrac{1}{\sqrt{6}}(1,1,-2).$$

The eigenvalues are $5, 2, 2$ in that order.

Exercise B3: A self-adjoint square root of zero.

Let $T \in \mathcal{L}(V)$ be self-adjoint with $T^2 = 0$. Prove that $T = 0$. Deduce that a self-adjoint T with $T^k = 0$ for some $k \geq 1$ is zero.

Solution. For every $\mathbf{v} \in V$, by Definition 10.6.2,

$$\|T\mathbf{v}\|^2 = \langle T\mathbf{v}, T\mathbf{v}\rangle = \langle T^2\mathbf{v}, \mathbf{v}\rangle = \langle \mathbf{0}, \mathbf{v}\rangle = 0,$$

so $T\mathbf{v} = \mathbf{0}$. As $\mathbf{v}$ was arbitrary, $T = 0$.

For the deduction, use strong induction on k (Theorem 0.2.10). If $k = 1$ there is nothing to prove. Let $k \geq 2$ with $T^k = 0$, and put $m = \lceil k/2 \rceil$, so that $1 \leq m < k$ and $2m \geq k$. Then $(T^m)^2 = T^{2m} = T^{2m-k}T^k = 0$, and T^m is self-adjoint, since $(T^m)^* = (T^*)^m = T^m$ by Theorem 10.6.2 (c). By the first part, $T^m = 0$, and the inductive hypothesis applied to the exponent m gives $T = 0$.

11.2.7.3 C. Going deeper

Exercise C1: The operator S^*S.

Let $S \in \mathcal{L}(V, W)$ between finite-dimensional inner product spaces over F, and set $T = S^*S \in \mathcal{L}(V)$.

(a) Prove that T is self-adjoint and that $\langle T\mathbf{v}, \mathbf{v}\rangle \geq 0$ for every $\mathbf{v} \in V$, with equality if and only if $S\mathbf{v} = \mathbf{0}$.

(b) Deduce that every eigenvalue of T is a non-negative real number.

(c) Prove that T is invertible if and only if S is injective.

Hint for (a): the quantity $\langle T\mathbf{v}, \mathbf{v}\rangle$ is a norm squared in disguise.

Solution.

(a) $T^* = (S^*S)^* = S^*S^{**} = S^*S = T$, by Theorem 10.6.2 (c) and (d). For the second claim, use conjugate symmetry and then Definition 10.6.1:

$$\langle T\mathbf{v}, \mathbf{v}\rangle = \overline{\langle \mathbf{v}, S^*S\mathbf{v}\rangle} = \overline{\langle S\mathbf{v}, S\mathbf{v}\rangle} = \|S\mathbf{v}\|^2,$$

the last step because a norm squared is a non-negative real number and is its own conjugate. So $\langle T\mathbf{v}, \mathbf{v}\rangle \geq 0$, with equality exactly when $\|S\mathbf{v}\| = 0$, that is $S\mathbf{v} = \mathbf{0}$ (Definition 10.1.1).

(b) Let $T\mathbf{v} = \lambda\mathbf{v}$ with $\mathbf{v} \neq \mathbf{0}$. By Theorem 11.2.1, $\lambda \in \mathbb{R}$. By (a), $0 \leq \langle T\mathbf{v}, \mathbf{v}\rangle = \lambda\|\mathbf{v}\|^2$, and $\|\mathbf{v}\|^2 > 0$, so $\lambda \geq 0$.

(c) ($\Rightarrow$) If $S\mathbf{v} = \mathbf{0}$ then $T\mathbf{v} = \mathbf{0}$, so injectivity of T forces $\mathbf{v} = \mathbf{0}$; and an invertible operator is injective. ($\Leftarrow$) If S is injective and $T\mathbf{v} = \mathbf{0}$, then by (a) $\|S\mathbf{v}\|^2 = \langle T\mathbf{v}, \mathbf{v}\rangle = 0$, so $S\mathbf{v} = \mathbf{0}$ and $\mathbf{v} = \mathbf{0}$. Thus $\ker T = \{\mathbf{0}\}$, so T is injective, hence bijective by Corollary 3.3.2 (e). This is Corollary 10.6.6 (b) again, seen from the quadratic form.

Operators with the property in (a) are called **positive**, and they are the subject of Chapter 12; part (b) is the first half of the characterization proved there.

Exercise C2: Sums and products.

Let $S, T \in \mathcal{L}(V)$ be self-adjoint.

(a) Prove that $S+T$ and cT are self-adjoint for every **real** scalar c, and show by example that cT need not be self-adjoint for $c \in \mathbb{C}$.

(b) Prove that ST is self-adjoint if and only if $ST = TS$.

(c) Give self-adjoint $S, T \in \mathcal{L}(\mathbb{C}^2)$ with ST not self-adjoint.

Solution.
