and dividing by $\|\mathbf{E}\| > 0$ gives the claim.

(b) Suppose μ is an eigenvalue of $\mathbf{A}+\mathbf{E}$ with $|\mu-\lambda| = r$. Then $\|(\mathbf{A}-\mu\mathbf{I})^{-1}\| \leq M$ by hypothesis, and in particular $\mathbf{A}-\mu\mathbf{I}$ is invertible, so $\mu \notin \operatorname{spec}(\mathbf{A})$ and part (a) applies: $M \geq 1/\|\mathbf{E}\|$, that is $\|\mathbf{E}\| \geq 1/M$. Contrapositively, $\|\mathbf{E}\| < 1/M$ leaves no eigenvalue of $\mathbf{A}+\mathbf{E}$ on the circle.

Exercise C2: Density of the invertible matrices, and AB versus BA.

(a) Prove that for every $\mathbf{A} \in M_n(\mathbb{C})$ and every $\varepsilon > 0$ there is an **invertible** $\mathbf{A}'$ with $\|\mathbf{A}-\mathbf{A}'\| < \varepsilon$, in any norm. *Hint: consider* $\mathbf{A}-t\mathbf{I}$.

(b) Prove a version of Corollary 15.7.6 with "invertible" in place of "diagonalizable".

(c) Hence give a second proof that $p_{\mathbf{AB}} = p_{\mathbf{BA}}$ for all $\mathbf{A},\mathbf{B} \in M_n(\mathbb{C})$, a statement first proved in Theorem 8.10.4 (b).

Solution.

(a) The matrix $\mathbf{A}-t\mathbf{I}$ is singular exactly when $t \in \operatorname{spec}(\mathbf{A})$ (Theorem 8.2.1), and $\operatorname{spec}(\mathbf{A})$ has at most n elements. Let N_∞ and C be as in the proof of Corollary 15.7.5, so $\|\mathbf{M}\| \leq C\,N_\infty(\mathbf{M})$. Choose $t \neq 0$ with $|t| < \varepsilon/C$ and $t \notin \operatorname{spec}(\mathbf{A})$, possible because the disc of radius ε/C is infinite and only finitely many of its points are forbidden. Then $\mathbf{A}' = \mathbf{A}-t\mathbf{I}$ is invertible and $N_\infty(\mathbf{A}-\mathbf{A}') = |t|$, so $\|\mathbf{A}-\mathbf{A}'\| < \varepsilon$.

(b) Verbatim the proof of Corollary 15.7.6, with the sequence of diagonalizable matrices replaced by the sequence of invertible matrices supplied by (a) with $\varepsilon = 1/k$.

(c) Fix $\mathbf{B}$ and set $\Phi(\mathbf{A}) = \big(c_0(\mathbf{AB})-c_0(\mathbf{BA}),\dots,c_{n-1}(\mathbf{AB})-c_{n-1}(\mathbf{BA})\big)$, a row of n entries. Each entry of $\mathbf{AB}$ and of $\mathbf{BA}$ is a polynomial in the entries of $\mathbf{A}$, and each c_j is a polynomial in the entries of its argument, so Φ satisfies the hypothesis of (b). For invertible $\mathbf{A}$ we have $\mathbf{BA} = \mathbf{A}^{-1}(\mathbf{AB})\mathbf{A}$, so $\mathbf{AB}$ and $\mathbf{BA}$ are similar and $p_{\mathbf{AB}} = p_{\mathbf{BA}}$ by Theorem 10.3; that is exactly $\Phi(\mathbf{A}) = 0$, and it is Exercise (B3: **AB** and **BA**) (a). By (b), $\Phi(\mathbf{A}) = 0$ for every $\mathbf{A}$, and two monic polynomials of degree n with the same lower coefficients are equal.

Exercise C3: Distinct eigenvalues is an open condition.

Let $\mathbf{A} \in M_n(\mathbb{C})$ have n **distinct** eigenvalues $\lambda_1, \dots, \lambda_n$, and let $\|\cdot\|$ be a norm on $M_n(\mathbb{C})$.

(a) Prove that there is $\delta > 0$ such that every $\mathbf{B}$ with $\|\mathbf{B} - \mathbf{A}\| < \delta$ also has n distinct eigenvalues, and is therefore diagonalizable.

(b) Deduce that the set of matrices in $M_n(\mathbb{C})$ with a repeated eigenvalue contains no ball, that is, that its complement is dense.

(c) Is the set of diagonalizable matrices open? Justify your answer.

Solution.

(a) Put $2\varepsilon = \min_{i \neq j} |\lambda_i - \lambda_j|$, which is positive because the λ_i are distinct and there are finitely many pairs. Let δ be the number that Corollary 15.7.4 supplies for this ε. If $\|\mathbf{B} - \mathbf{A}\| < \delta$, number the eigenvalues of $\mathbf{B}$ so that $|\mu_i - \lambda_i| < \varepsilon$ for every i. For $i \neq j$, Theorem 0.6.4 gives

$$|\mu_i - \mu_j| \geq |\lambda_i - \lambda_j| - |\mu_i - \lambda_i| - |\mu_j - \lambda_j| > 2\varepsilon - \varepsilon - \varepsilon = 0,$$

so the μ_i are pairwise distinct. There are n of them, so $\mathbf{B}$ is diagonalizable by Corollary 8.4.2.

(b) Let $\mathbf{A}$ be arbitrary and $\varepsilon > 0$. By Exercise (C3: Distinct eigenvalues are dense, but not over the reals) (a) there is $\mathbf{A}'$ with n distinct eigenvalues and $|a_{ij} - a'_{ij}| < \varepsilon/C$ for all i, j, with C as in the proof of Corollary 15.7.5; hence $\|\mathbf{A} - \mathbf{A}'\| < \varepsilon$. So every ball meets the set of matrices with n distinct eigenvalues, and no ball is contained in its complement.

(c) No. The zero matrix is diagonalizable, and in $M_2(\mathbb{C})$ every ball around it contains $\varepsilon \mathbf{J}_2(0)$, whose only eigenvalue is 0, with eigenspace of dimension 1 and algebraic multiplicity 2; so it is not diagonalizable by Theorem 8.4.1 (e). Dense (Corollary 15.7.5) and open are independent properties, and the diagonalizable matrices are the first without being the second.

15.8 How Wrong Can the Answer Be

Chapter 2 solved $\mathbf{Ax} = \mathbf{b}$ and Chapter 10 solved it when it had no solution. Neither chapter could ask the question a user of either method asks first: the vector $\mathbf{b}$ is a measurement, so it is wrong in the last few digits, and the answer $\mathbf{x}$ is then wrong too — by how much? The question needs a way to compare the size of an error with the size of the thing it corrupts, and that is what the last seven sections have built.

The answer turns out to be one number attached to $\mathbf{A}$, independent of $\mathbf{b}$, and it is the last object this chapter defines. It also carries a warning, and the warning is more useful than the number.

Throughout, matrices are complex, as in Sections 4 to 7, and $\|\cdot\|$ is a norm on $\mathbb{C}^n$ together with the operator norm it induces on $M_n(\mathbb{C})$ (Definition 15.3.2) — the standing convention of Section 5, whose results are used here throughout. A real matrix is read inside $M_n(\mathbb{C})$, which changes none of the three norms we actually compute with, since Theorem 15.3.3 gives the same

three formulas over either field.

15.8.1 A recurring product

Let $\mathbf{A} \in M_n(\mathbb{C})$ be invertible, let $\mathbf{b} \neq \mathbf{0}$, and let $\mathbf{x}$ solve $\mathbf{Ax} = \mathbf{b}$. Suppose the data arrives as $\mathbf{b} + \Delta\mathbf{b}$ instead, so the computed answer solves $\mathbf{A}\widetilde{\mathbf{x}} = \mathbf{b} + \Delta\mathbf{b}$. Subtracting the two equations, $\mathbf{A}(\widetilde{\mathbf{x}} - \mathbf{x}) = \Delta\mathbf{b}$, so

$$\widetilde{\mathbf{x}} - \mathbf{x} = \mathbf{A}^{-1}\Delta\mathbf{b}, \qquad \|\widetilde{\mathbf{x}} - \mathbf{x}\| \leq \|\mathbf{A}^{-1}\|\,\|\Delta\mathbf{b}\|$$

by Theorem 15.3.2 (a). That is an *absolute* bound, and absolute bounds are the wrong currency: whether an error of 10^{-3} is a catastrophe depends on whether the answer is of size 1 or of size 10^6. Divide by $\|\mathbf{x}\|$, and use $\|\mathbf{b}\| = \|\mathbf{Ax}\| \leq \|\mathbf{A}\|\|\mathbf{x}\|$, that is $1/\|\mathbf{x}\| \leq \|\mathbf{A}\|/\|\mathbf{b}\|$:

$$\frac{\|\widetilde{\mathbf{x}} - \mathbf{x}\|}{\|\mathbf{x}\|} \;\leq\; \|\mathbf{A}^{-1}\|\,\|\Delta\mathbf{b}\|\,\frac{\|\mathbf{A}\|}{\|\mathbf{b}\|} \;=\; \|\mathbf{A}\|\|\mathbf{A}^{-1}\|\,\frac{\|\Delta\mathbf{b}\|}{\|\mathbf{b}\|}.$$

The relative error in the answer is at most the relative error in the data, multiplied by $\|\mathbf{A}\|\|\mathbf{A}^{-1}\|$. That product depends only on $\mathbf{A}$. It will reappear in every estimate in this section, so we name it.

The condition number is the worst factor by which $\mathbf{A}$ *can magnify a relative error.*

Definition 15.8.1 — Condition Number

Let $\|\cdot\|$ be a norm on $\mathbb{C}^n$, and write $\|\cdot\|$ also for the operator norm it induces on $M_n(\mathbb{C})$. For $\mathbf{A} \in M_n(\mathbb{C})$, the **condition number** of $\mathbf{A}$ **with respect to that norm** is

$$\kappa(\mathbf{A}) := \begin{cases} \|\mathbf{A}\|\,\|\mathbf{A}^{-1}\| & \text{if } \mathbf{A} \text{ is invertible,} \\ \infty & \text{if } \mathbf{A} \text{ is singular.} \end{cases}$$

We write $\kappa_1, \kappa_2, \kappa_\infty$ for the condition numbers with respect to $\|\cdot\|_1$, $\|\cdot\|_2$, $\|\cdot\|_\infty$; κ_2 is also called the **spectral condition number**. For a rectangular $\mathbf{A} \in M_{m\times n}(\mathbb{C})$ with $m \geq n$ and $\operatorname{rank}\mathbf{A} = n$, we define

$$\kappa_2(\mathbf{A}) := \frac{\sigma_1(\mathbf{A})}{\sigma_n(\mathbf{A})},$$

the ratio of the largest to the smallest singular value (Definition 12.8.1).

Clause by clause. The number is attached to **A and to a norm**: $\kappa_1(\mathbf{A})$, $\kappa_2(\mathbf{A})$ and $\kappa_\infty(\mathbf{A})$ are three different numbers, and a statement like "$\kappa(\mathbf{A}) = 400$" is incomplete until the norm is named. They cannot disagree wildly — Theorem 15.2.2 traps them within dimension-dependent factors of each other, and Exercise (C1: Changing the norm changes κ, but not much) makes that precise — so the *order of magnitude* of κ, which is all anyone uses, does not depend on the choice. The value ∞ for a singular matrix is a convention, and the right one: a singular $\mathbf{A}$ either makes $\mathbf{Ax} = \mathbf{b}$ unsolvable or makes its solution set a whole coset $\mathbf{x} + \operatorname{nul}(\mathbf{A})$ with $\operatorname{nul}(\mathbf{A}) \neq \{\mathbf{0}\}$ (Theorem 2.1.3), so no finite bound on the error can hold. Finally, the square case and the rectangular case agree where they overlap: Proposition 15.8.2 (d) shows $\kappa_2(\mathbf{A}) = \sigma_1/\sigma_n$ for an invertible square $\mathbf{A}$ as well.

Before the examples, a small lemma that says what κ is measuring. It is the one geometric picture in this section, and it is worth carrying.

Lemma 15.8.1 — The Inverse Measures the Smallest Stretch

Let $\mathbf{A} \in M_n(\mathbb{C})$ be invertible and let $\|\cdot\|$ be a norm on $\mathbb{C}^n$. Then

$$\|\mathbf{A}^{-1}\| = \frac{1}{\min\{\|\mathbf{Ax}\| : \|\mathbf{x}\| = 1\}}, \qquad \kappa(\mathbf{A}) = \frac{\max\{\|\mathbf{Ax}\| : \|\mathbf{x}\| = 1\}}{\min\{\|\mathbf{Ax}\| : \|\mathbf{x}\| = 1\}}.$$

Idea. Both maxima and the minimum exist by compactness, which is Lemma 15.3.1 and the same argument with a minimum. After that it is one substitution: as $\mathbf{x}$ runs over the non-zero vectors so does $\mathbf{y} = \mathbf{Ax}$, and the ratio $\|\mathbf{A}^{-1}\mathbf{y}\|/\|\mathbf{y}\|$ is the reciprocal of $\|\mathbf{Ax}\|/\|\mathbf{x}\|$.

Proof. The function $\mathbf{x} \mapsto \|\mathbf{Ax}\|$ is continuous on the unit sphere S, which is compact, so it attains a maximum and a minimum there (Lemma 15.3.1 for the maximum; the same proof, or the extreme value theorem (A4) applied to the same continuous function, for the minimum). Write $m = \min_{\mathbf{x}\in S}\|\mathbf{Ax}\|$. Since $\mathbf{A}$ is invertible, $\mathbf{Ax} \neq \mathbf{0}$ for $\mathbf{x} \in S$, so $m > 0$.

By Definition 15.3.2 and homogeneity, $\|\mathbf{A}^{-1}\| = \max\{\|\mathbf{A}^{-1}\mathbf{y}\|/\|\mathbf{y}\| : \mathbf{y} \neq \mathbf{0}\}$. The map $\mathbf{y} \mapsto \mathbf{A}^{-1}\mathbf{y}$ is a bijection of $\mathbb{C}^n \setminus \{\mathbf{0}\}$ onto itself, so substituting $\mathbf{y} = \mathbf{Ax}$ with $\mathbf{x} \neq \mathbf{0}$,

$$\|\mathbf{A}^{-1}\| = \max_{\mathbf{x}\neq\mathbf{0}} \frac{\|\mathbf{x}\|}{\|\mathbf{Ax}\|} = \frac{1}{\min\limits_{\mathbf{x}\neq\mathbf{0}} \dfrac{\|\mathbf{Ax}\|}{\|\mathbf{x}\|}} = \frac{1}{m},$$

the last step by homogeneity again, which lets the minimum over $\mathbf{x} \neq \mathbf{0}$ be taken over S. Multiplying by $\|\mathbf{A}\| = \max_{\mathbf{x}\in S}\|\mathbf{Ax}\|$ gives the second formula. This proves the lemma.

■

So $\kappa(\mathbf{A})$ is the **distortion** of $\mathbf{A}$: feed $\mathbf{A}$ the unit sphere and it comes out as a lopsided surface, and κ is the ratio of its longest radius to its shortest. A matrix with $\kappa = 1$ carries the sphere to a sphere. A matrix with $\kappa = 10^6$ flattens it into something a million times longer than it is wide, and a direction of $\mathbf{b}$ that lands along the short axis has its errors magnified by a million on the way back.

Some values, simplest first.

- **The identity, and any unitary matrix.** $\|\mathbf{I}\| = 1 = \|\mathbf{I}^{-1}\|$, so $\kappa(\mathbf{I}) = 1$ in every norm. For unitary $\mathbf{U}$, $\|\mathbf{Ux}\|_2 = \|\mathbf{x}\|_2$ for every $\mathbf{x}$ (Theorem 10.7.3), so every stretch is 1 and $\kappa_2(\mathbf{U}) = 1$ by Lemma 15.8.1. These are the best-conditioned matrices there are.
- **A diagonal matrix.** For $\mathbf{D} = \operatorname{diag}(d_1, \dots, d_n)$ with all $d_i \neq 0$, $\|\mathbf{D}\|_2 = \max_i |d_i|$ and $\|\mathbf{D}^{-1}\|_2 = 1/\min_i |d_i|$, so $\kappa_2(\mathbf{D})$ is the ratio of the largest to the smallest modulus. Thus $\kappa_2(\operatorname{diag}(1, 10^{-6})) = 10^6$.
- **A small matrix that is perfectly conditioned.** $\mathbf{A} = 10^{-6}\mathbf{I}$ has $\|\mathbf{A}\|_2 = 10^{-6}$, a tiny norm, and $\kappa_2(\mathbf{A}) = 1$. Being small and being ill-conditioned are unrelated.
- **A singular matrix**, the degenerate case: $\kappa = \infty$ by convention, consistent with Lemma 15.8.1, where the minimum stretch is 0.

Example. (Three condition numbers of one matrix)

Compute $\kappa_\infty(\mathbf{A})$ and $\kappa_2(\mathbf{A})$ for $\mathbf{A} = \begin{pmatrix} 2 & 1 \\ 1 & 1 \end{pmatrix}$.

Solution. $\det \mathbf{A} = 1$, so $\mathbf{A}^{-1} = \left(\begin{smallmatrix} 1 & -1 \\ -1 & 2 \end{smallmatrix}\right)$. The largest absolute row sums are 3 for $\mathbf{A}$ and 3 for $\mathbf{A}^{-1}$, so by Theorem 15.3.3 (b), $\kappa_\infty(\mathbf{A}) = 3 \cdot 3 = 9$.

For κ_2: $\mathbf{A}$ is real symmetric with $\operatorname{tr} \mathbf{A} = 3$ and $\det \mathbf{A} = 1$, so its eigenvalues are $(3 \pm \sqrt{5})/2$, both positive, and the singular values of a symmetric matrix with positive eigenvalues are those eigenvalues (its $\mathbf{A}^*\mathbf{A} = \mathbf{A}^2$ has eigenvalues their squares). Hence

$$\kappa_2(\mathbf{A}) = \frac{3 + \sqrt{5}}{3 - \sqrt{5}} = \frac{(3 + \sqrt{5})^2}{4} = \frac{7 + 3\sqrt{5}}{2} \approx 6.854.$$

Two different norms, two different numbers, the same order of magnitude — which is the general picture.

Warning. **A large κ is not a large determinant defect, and a small determinant is not ill-conditioning.** The matrix $10^{-6}\mathbf{I}_{10}$ has determinant 10^{-60} and $\kappa_2 = 1$; the matrix $\operatorname{diag}(10^6, 10^{-6})$ has determinant 1 and $\kappa_2 = 10^{12}$. The determinant scales with c^n under $\mathbf{A} \mapsto c\mathbf{A}$ while κ does not move at all (Proposition 15.8.2 (b)), so no threshold on $|\det \mathbf{A}|$ can detect ill-conditioning. This is the most common wrong test, and it fails in both directions.

The basic properties are all one line each, and the third is the reason κ behaves well under the factorizations of Chapters 10 and 12.

Proposition 15.8.2 — Properties of the Condition Number

Let $\mathbf{A}, \mathbf{B} \in M_n(\mathbb{C})$ be invertible and let $c \in \mathbb{C} \setminus \{0\}$. With respect to any operator norm:

(a) $\kappa(\mathbf{A}) \geq 1$;
(b) $\kappa(c\mathbf{A}) = \kappa(\mathbf{A})$;
(c) $\kappa(\mathbf{AB}) \leq \kappa(\mathbf{A})\kappa(\mathbf{B})$;
(d) $\kappa_2(\mathbf{A}) = \sigma_1(\mathbf{A})/\sigma_n(\mathbf{A})$, and $\kappa_2(\mathbf{UAV}) = \kappa_2(\mathbf{A})$ for all unitary $\mathbf{U}, \mathbf{V}$.

Proof.

(a) $1 = \|\mathbf{I}\| = \|\mathbf{A}\mathbf{A}^{-1}\| \leq \|\mathbf{A}\|\|\mathbf{A}^{-1}\| = \kappa(\mathbf{A})$, using Theorem 15.3.2 (c) and (d).

(b) $(c\mathbf{A})^{-1} = c^{-1}\mathbf{A}^{-1}$, so by homogeneity $\|c\mathbf{A}\|\|(c\mathbf{A})^{-1}\| = |c|\,|c|^{-1}\|\mathbf{A}\|\|\mathbf{A}^{-1}\|$.

(c) $(\mathbf{AB})^{-1} = \mathbf{B}^{-1}\mathbf{A}^{-1}$, so submultiplicativity (Theorem 15.3.2 (d)) gives $\|\mathbf{AB}\|\|\mathbf{B}^{-1}\mathbf{A}^{-1}\| \leq \|\mathbf{A}\|\|\mathbf{B}\|\|\mathbf{B}^{-1}\|\|\mathbf{A}^{-1}\|$.

(d) By Theorem 15.3.3 (c), $\|\mathbf{A}\|_2 = \sigma_1(\mathbf{A})$. By Lemma 15.8.1, $\|\mathbf{A}^{-1}\|_2 = 1/m$ with $m = \min\{\|\mathbf{Ax}\|_2 : \|\mathbf{x}\|_2 = 1\}$, so it remains to see $m = \sigma_n(\mathbf{A})$. Write $\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^*$ (Theorem 12.8.1) and $\mathbf{y} = \mathbf{V}^*\mathbf{x}$; unitary matrices preserve $\|\cdot\|_2$ (Theorem 10.7.3), so $\|\mathbf{x}\|_2 = \|\mathbf{y}\|_2$ and $\|\mathbf{Ax}\|_2 = \|\mathbf{\Sigma y}\|_2$. Then

$$\|\mathbf{\Sigma y}\|_2^2 = \sum_{i=1}^{n} \sigma_i^2 |y_i|^2 \geq \sigma_n^2 \sum_{i=1}^{n} |y_i|^2 = \sigma_n^2$$

for $\|\mathbf{y}\|_2 = 1$, with equality at $\mathbf{y} = \mathbf{e}_n$, that is at $\mathbf{x} = \mathbf{v}_n$, the last column of $\mathbf{V}$. So $m = \sigma_n$. For the last claim, if $\mathbf{A} = \mathbf{U}_1\mathbf{\Sigma}\mathbf{V}_1^*$ then $\mathbf{UAV} = (\mathbf{UU}_1)\mathbf{\Sigma}(\mathbf{V}^*\mathbf{V}_1)^*$, and a product of unitary matrices is unitary, so this is a singular value decomposition of $\mathbf{UAV}$ with the same $\mathbf{\Sigma}$: unitary factors do not change the singular values. This proves the proposition.

■

Part (d) is the reason κ_2 is the condition number of choice in theory: it is invariant under the unitary changes of coordinates that Chapters 10 to 12 use throughout, so it is a property of the linear map and not of the basis it is written in.

15.8.2 What the condition number predicts

The computation that opened the section is now a theorem, together with the version where $\mathbf{A}$ itself, and not only $\mathbf{b}$, carries the error. Both halves matter in practice: the entries of $\mathbf{A}$ are measurements too. Section 5 already proved the two perturbations together, in Theorem 15.5.3, and its constant $\|\mathbf{A}\|\|\mathbf{A}^{-1}\|$ is the product we have just named; what is added here is that the first half is sharp on its own, and that it needs no smallness hypothesis at all.

Theorem 15.8.3 — Relative Error Under Perturbation of the Data

Let $\mathbf{A} \in M_n(\mathbb{C})$ be invertible, let $\mathbf{b} \neq \mathbf{0}$, and let $\mathbf{Ax} = \mathbf{b}$.

(a) **(Perturbing b.)** If $\mathbf{A}\widetilde{\mathbf{x}} = \mathbf{b} + \Delta\mathbf{b}$, then

$$\frac{\|\widetilde{\mathbf{x}} - \mathbf{x}\|}{\|\mathbf{x}\|} \leq \kappa(\mathbf{A}) \frac{\|\Delta\mathbf{b}\|}{\|\mathbf{b}\|},$$

and there are $\mathbf{b}$ and $\Delta\mathbf{b}$ for which equality holds.

(b) **(Perturbing A.)** Let $\mathbf{E} \in M_n(\mathbb{C})$ with $r := \kappa(\mathbf{A})\|\mathbf{E}\|/\|\mathbf{A}\| < 1$. Then $\mathbf{A} + \mathbf{E}$ is invertible; and if $(\mathbf{A} + \mathbf{E})\widetilde{\mathbf{x}} = \mathbf{b}$, then

$$\frac{\|\widetilde{\mathbf{x}} - \mathbf{x}\|}{\|\widetilde{\mathbf{x}}\|} \leq \kappa(\mathbf{A}) \frac{\|\mathbf{E}\|}{\|\mathbf{A}\|}, \qquad \frac{\|\widetilde{\mathbf{x}} - \mathbf{x}\|}{\|\mathbf{x}\|} \leq \frac{r}{1 - r}.$$

Idea. For (a), the displayed computation at the head of the section, plus a choice of the two vectors that makes both inequalities in it equalities — and both are attained, because Lemma 15.3.1 says an operator norm is a maximum and not a supremum. For (b), factor $\mathbf{A} + \mathbf{E} = \mathbf{A}(\mathbf{I} + \mathbf{A}^{-1}\mathbf{E})$ so that Theorem 15.5.1 decides invertibility, then subtract the two equations. Subtracting gives $\widetilde{\mathbf{x}} - \mathbf{x}$ in terms of $\widetilde{\mathbf{x}}$, which is why the clean bound is relative to $\widetilde{\mathbf{x}}$; subadditivity of the norm converts it to a bound relative to $\mathbf{x}$ at the cost of the factor $1/(1 - r)$, and that factor is where "to first order" hides.

Proof. (a). Subtracting $\mathbf{Ax} = \mathbf{b}$ from $\mathbf{A}\widetilde{\mathbf{x}} = \mathbf{b} + \Delta\mathbf{b}$ gives $\mathbf{A}(\widetilde{\mathbf{x}} - \mathbf{x}) = \Delta\mathbf{b}$, so $\widetilde{\mathbf{x}} - \mathbf{x} = \mathbf{A}^{-1}\Delta\mathbf{b}$ and $\|\widetilde{\mathbf{x}} - \mathbf{x}\| \leq \|\mathbf{A}^{-1}\|\|\Delta\mathbf{b}\|$ by Theorem 15.3.2 (a). Also $\|\mathbf{b}\| = \|\mathbf{Ax}\| \leq \|\mathbf{A}\|\|\mathbf{x}\|$,

and $\mathbf{x} \neq \mathbf{0}$ because $\mathbf{b} \neq \mathbf{0}$, so $1/\|\mathbf{x}\| \leq \|\mathbf{A}\|/\|\mathbf{b}\|$. Multiplying the two estimates,

$$\frac{\|\widetilde{\mathbf{x}} - \mathbf{x}\|}{\|\mathbf{x}\|} \leq \|\mathbf{A}^{-1}\|\|\Delta\mathbf{b}\| \cdot \frac{\|\mathbf{A}\|}{\|\mathbf{b}\|} = \kappa(\mathbf{A})\frac{\|\Delta\mathbf{b}\|}{\|\mathbf{b}\|}.$$

For equality, use Lemma 15.3.1 twice. Choose a unit vector $\mathbf{x}$ with $\|\mathbf{A}\mathbf{x}\| = \|\mathbf{A}\|$ and put $\mathbf{b} = \mathbf{A}\mathbf{x}$, so that $\|\mathbf{b}\| = \|\mathbf{A}\|\|\mathbf{x}\|$ and the second estimate is an equality. Choose a unit vector $\mathbf{y}$ with $\|\mathbf{A}^{-1}\mathbf{y}\| = \|\mathbf{A}^{-1}\|$ and put $\Delta\mathbf{b} = \mathbf{y}$, so that the first estimate is an equality. Then

$$\frac{\|\widetilde{\mathbf{x}} - \mathbf{x}\|}{\|\mathbf{x}\|} \Big/ \frac{\|\Delta\mathbf{b}\|}{\|\mathbf{b}\|} = \frac{\|\mathbf{A}^{-1}\|}{1} \cdot \frac{\|\mathbf{A}\|}{1} = \kappa(\mathbf{A}).$$

(b). Write $\mathbf{A} + \mathbf{E} = \mathbf{A}(\mathbf{I} + \mathbf{A}^{-1}\mathbf{E})$. By Theorem 15.3.2 (d),

$$\|\mathbf{A}^{-1}\mathbf{E}\| \leq \|\mathbf{A}^{-1}\|\|\mathbf{E}\| = \kappa(\mathbf{A})\frac{\|\mathbf{E}\|}{\|\mathbf{A}\|} = r < 1,$$

so $\mathbf{I} - (-\mathbf{A}^{-1}\mathbf{E})$ is invertible by Theorem 15.5.1, and $\mathbf{A}+\mathbf{E}$ is a product of two invertible matrices, hence invertible. (This is the openness of $\mathrm{GL}_n(F)$ recorded in Corollary 15.5.2, with the radius made explicit.)

Since $b \neq \mathbf{0}$ we have $\widetilde{\mathbf{x}} = (\mathbf{A} + \mathbf{E})^{-1}\mathbf{b} \neq \mathbf{0}$. Subtracting $\mathbf{A}\mathbf{x} = \mathbf{b}$ from $(\mathbf{A} + \mathbf{E})\widetilde{\mathbf{x}} = \mathbf{b}$ gives $\mathbf{A}\widetilde{\mathbf{x}} - \mathbf{A}\mathbf{x} = -\mathbf{E}\widetilde{\mathbf{x}}$, hence

$$\widetilde{\mathbf{x}} - \mathbf{x} = -\mathbf{A}^{-1}\mathbf{E}\widetilde{\mathbf{x}}, \qquad \|\widetilde{\mathbf{x}} - \mathbf{x}\| \leq \|\mathbf{A}^{-1}\|\|\mathbf{E}\|\,\|\widetilde{\mathbf{x}}\| = r\,\|\widetilde{\mathbf{x}}\|,$$

which is the first bound. For the second, $\|\widetilde{\mathbf{x}}\| \leq \|\mathbf{x}\| + \|\widetilde{\mathbf{x}} - \mathbf{x}\|$ since $\|\cdot\|$ is subadditive (Definition 15.1.1), so $\|\widetilde{\mathbf{x}} - \mathbf{x}\| \leq r\|\mathbf{x}\| + r\|\widetilde{\mathbf{x}} - \mathbf{x}\|$; as $r < 1$ we may divide by $1 - r > 0$ to get $\|\widetilde{\mathbf{x}} - \mathbf{x}\| \leq \frac{r}{1-r}\|\mathbf{x}\|$. This proves the theorem.

■

The two bounds in (b) say the same thing differently. The first is exact and needs nothing but invertibility, but it measures the error against the *computed* answer. The second measures it against the true answer, at the cost of the factor $1/(1 - r)$ — which is $1 + r + r^2 + \cdots$, so for a small r it is 1 to first order and the two bounds agree. That is all "to first order in the perturbation of $\mathbf{A}$" ever means here, and it is now a stated inequality rather than a gesture. Adding the two halves, with the factor $1/(1-r)$ covering both, recovers Theorem 15.5.3 exactly.

Quick check. Where in the proof of (a) is the hypothesis $\mathbf{b} \neq \mathbf{0}$ used, and what goes wrong without it?

Solution. It is used to know $\mathbf{x} \neq \mathbf{0}$, so that $\|\mathbf{x}\|$ may be divided by, and to know $\|\mathbf{b}\| \neq 0$, so that the relative perturbation $\|\Delta\mathbf{b}\|/\|\mathbf{b}\|$ means anything. With $\mathbf{b} = \mathbf{0}$ the true solution is $\mathbf{x} = \mathbf{0}$ and *every* non-zero $\Delta\mathbf{b}$ produces an infinite relative error. Relative error is only defined against a non-zero reference.

Now a case where the bound of (a) is not merely an inequality. The point of computing the example exactly is to see that κ is not a pessimistic overestimate manufactured by the inequalities used to reach it: it is achieved.

Example. (A system where the bound is attained)

Let

$$\mathbf{A} = \begin{pmatrix} 1 & 1 \\ 1 & 1.01 \end{pmatrix}, \qquad \mathbf{b} = \begin{pmatrix} 2 \\ 2.01 \end{pmatrix},$$

whose solution is $\mathbf{x} = (1, 1)$. Compute $\kappa_\infty(\mathbf{A})$; then perturb $\mathbf{b}$ to $\mathbf{b} + \Delta\mathbf{b}$ with $\Delta\mathbf{b} = (0.01, -0.01)$, solve again, and compare the two relative errors.

Solution. Work with exact fractions: $1.01 = \frac{101}{100}$ and $\det \mathbf{A} = \frac{101}{100} - 1 = \frac{1}{100}$, so

$$\mathbf{A}^{-1} = 100 \begin{pmatrix} \frac{101}{100} & -1 \\ -1 & 1 \end{pmatrix} = \begin{pmatrix} 101 & -100 \\ -100 & 100 \end{pmatrix}.$$

The largest absolute row sums are $\frac{201}{100}$ for $\mathbf{A}$ and 201 for $\mathbf{A}^{-1}$, so by Theorem 15.3.3 (b),

$$\kappa_\infty(\mathbf{A}) = \tfrac{201}{100} \cdot 201 = \tfrac{40401}{100} = 404.01.$$

Check that $\mathbf{A}\mathbf{x} = \mathbf{b}$: the two rows give $1 + 1 = 2$ and $1 + \frac{101}{100} = \frac{201}{100}$. Now

$$\widetilde{\mathbf{x}} - \mathbf{x} = \mathbf{A}^{-1}\Delta\mathbf{b} = \tfrac{1}{100} \begin{pmatrix} 101 + 100 \\ -100 - 100 \end{pmatrix} = \begin{pmatrix} 2.01 \\ -2 \end{pmatrix},$$

so $\widetilde{\mathbf{x}} = (3.01, -1)$. Verify directly: $3.01 - 1 = 2.01$ and $3.01 - 1.01 = 2$, which is $\mathbf{b} + \Delta\mathbf{b} = (2.01, 2)$.

The two relative errors, in $\|\cdot\|_\infty$:

$$\frac{\|\Delta\mathbf{b}\|_\infty}{\|\mathbf{b}\|_\infty} = \frac{1/100}{201/100} = \frac{1}{201} \approx 0.50\%,$$
$$\frac{\|\widetilde{\mathbf{x}} - \mathbf{x}\|_\infty}{\|\mathbf{x}\|_\infty} = \frac{201/100}{1} = \frac{201}{100} = 201\%.$$

Their ratio is $\frac{201}{100} \cdot 201 = 404.01$, which is exactly $\kappa_\infty(\mathbf{A})$. A perturbation of half a percent in the data has turned the answer $(1, 1)$ into $(3.01, -1)$, and the bound of Theorem 15.8.3 (a) is attained, not approached.

Geometrically the example is Lemma 15.8.1 at work: the two rows of $\mathbf{A}$ are nearly parallel, so the two lines whose intersection is $\mathbf{x}$ cross at a very small angle, and moving either line slightly slides the crossing point a long way. Ill-conditioning is that picture, in any dimension.

Warning. **The condition number bounds the error; it does not produce it.** Theorem 15.8.3 is a worst case over all perturbations $\Delta\mathbf{b}$ of a given size. A particular $\Delta\mathbf{b}$ may do far less damage: in the example above, $\Delta\mathbf{b} = (0.01, 0.01)$ gives $\widetilde{\mathbf{x}} - \mathbf{x} = \mathbf{A}^{-1}\Delta\mathbf{b} = (0.01, 0)$, a relative error of 1% against a relative perturbation of 0.5% — a magnification of 2, not 404. A large κ says that *some* direction is dangerous, not that yours is.

15.8.3 Why the normal equations are worse

Chapter 10 §04 solved the least-squares problem through the normal equations $\mathbf{A}^*\mathbf{A}\mathbf{x} = \mathbf{A}^*\mathbf{b}$ (Theorem 10.4.2), and Chapter 10 §08 then recommended against actually forming that system. Its words were: "The deeper reason to prefer it is not the operation count: forming $\mathbf{A}^*\mathbf{A}$ squares the sensitivity of the problem to rounding, while (†) never forms that product at all. Chapter 23 makes 'sensitivity' precise and proves the comparison; here we record only the practice." The word "sensitivity" now has a meaning, and the word "squares" is now a theorem.

Theorem 15.8.4 — The Normal Equations Square the Condition Number

Let $m \geq n \geq 1$ and let $\mathbf{A} \in M_{m\times n}(\mathbb{C})$ have rank n. Then $\mathbf{A}^*\mathbf{A} \in M_n(\mathbb{C})$ is invertible, and

$$\kappa_2(\mathbf{A}^*\mathbf{A}) = \kappa_2(\mathbf{A})^2.$$

Idea. An SVD of $\mathbf{A}$ is also, after one multiplication, an eigenvalue decomposition of $\mathbf{A}^*\mathbf{A}$: the singular values get squared and nothing else happens. Both condition numbers are then ratios of the same list of numbers, one list being the squares of the other.

Proof. Write $\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^*$ with $\mathbf{U} \in M_m(\mathbb{C})$, $\mathbf{V} \in M_n(\mathbb{C})$ unitary and $\mathbf{\Sigma} \in M_{m\times n}(\mathbb{R})$ carrying $\sigma_1 \geq \cdots \geq \sigma_n \geq 0$ (Theorem 12.8.1). Since $\operatorname{rank}\mathbf{A} = n$, exactly n singular values are non-zero (Theorem 12.8.1), so $\sigma_n > 0$. Using $\mathbf{U}^*\mathbf{U} = \mathbf{I}_m$,

$$\mathbf{A}^*\mathbf{A} = \mathbf{V}\mathbf{\Sigma}^*\mathbf{U}^*\mathbf{U}\mathbf{\Sigma}\mathbf{V}^* = \mathbf{V}(\mathbf{\Sigma}^*\mathbf{\Sigma})\mathbf{V}^*, \qquad \mathbf{\Sigma}^*\mathbf{\Sigma} = \operatorname{diag}(\sigma_1^2, \ldots, \sigma_n^2).$$

So $\mathbf{A}^*\mathbf{A}$ is unitarily similar to a diagonal matrix with the positive entries σ_i^2; it is therefore invertible, Hermitian and positive definite, with eigenvalues $\sigma_1^2 \geq \cdots \geq \sigma_n^2 > 0$.

The singular values of $\mathbf{A}^*\mathbf{A}$ are those same numbers. Indeed the displayed identity *is* a singular value decomposition of $\mathbf{A}^*\mathbf{A}$, with both unitary factors equal to $\mathbf{V}$ and the diagonal entries already in decreasing order; alternatively, $(\mathbf{A}^*\mathbf{A})^*(\mathbf{A}^*\mathbf{A}) = \mathbf{V}\operatorname{diag}(\sigma_i^4)\mathbf{V}^*$ has eigenvalues σ_i^4, whose non-negative square roots are the σ_i^2 (Definition 12.8.1). Hence by Definition 15.8.1 and Proposition 15.8.2 (d),

$$\kappa_2(\mathbf{A}^*\mathbf{A}) = \frac{\sigma_1^2}{\sigma_n^2} = \left(\frac{\sigma_1}{\sigma_n}\right)^2 = \kappa_2(\mathbf{A})^2.$$

This proves the theorem. ∎

Example. (Squaring, on a 3×2 example)

Let $\mathbf{A} = \begin{pmatrix} 1 & 1 \\ 0.1 & 0 \\ 0 & 0.1 \end{pmatrix}$. Compute $\kappa_2(\mathbf{A})$ and $\kappa_2(\mathbf{A}^\top\mathbf{A})$.

Solution. $\mathbf{A}^\top\mathbf{A} = \left(\begin{smallmatrix} 1.01 & 1 \\ 1 & 1.01 \end{smallmatrix}\right)$. It sends $(1,1)$ to $2.01\,(1,1)$ and $(1,-1)$ to $0.01\,(1,-1)$, so

its eigenvalues are $\frac{201}{100}$ and $\frac{1}{100}$. Hence $\sigma_1(\mathbf{A}) = \sqrt{201}/10$ and $\sigma_2(\mathbf{A}) = 1/10$, so

$$\kappa_2(\mathbf{A}) = \sqrt{201} \approx 14.18, \qquad \kappa_2(\mathbf{A}^\top\mathbf{A}) = \frac{201/100}{1/100} = 201 = \left(\sqrt{201}\right)^2.$$

A matrix whose conditioning is unremarkable becomes, on forming $\mathbf{A}^\top\mathbf{A}$, a matrix whose conditioning is fourteen times worse.

What is proved here, and what is not. Theorem 15.8.4 is a statement about matrices: the matrix one *forms* when one writes down the normal equations has the square of the condition number of the matrix one started with. Combined with Theorem 15.8.3, it says that the linear system $\mathbf{A}^*\mathbf{A}\mathbf{x} = \mathbf{A}^*\mathbf{b}$, considered as a problem in its own data, is more sensitive than $\mathbf{A}$ itself by a factor $\kappa_2(\mathbf{A})$ — and the **QR** route $\mathbf{R}\mathbf{x} = \mathbf{Q}^*\mathbf{b}$ of Chapter 10 §08 never forms $\mathbf{A}^*\mathbf{A}$, so it never incurs that factor. Indeed the triangular matrix it does solve with is no worse conditioned than $\mathbf{A}$: from $\mathbf{A} = \mathbf{Q}\mathbf{R}$ with $\mathbf{Q}^*\mathbf{Q} = \mathbf{I}_n$ (Theorem 10.8.1) we get $\mathbf{A}^*\mathbf{A} = \mathbf{R}^*\mathbf{Q}^*\mathbf{Q}\mathbf{R} = \mathbf{R}^*\mathbf{R}$, so $\mathbf{A}$ and $\mathbf{R}$ have the same singular values (Definition 12.8.1) and $\kappa_2(\mathbf{R}) = \kappa_2(\mathbf{A})$ exactly.

Three things are *not* proved here, and all three belong to Chapter 23.

- **The conditioning of the least-squares problem itself** is not $\kappa_2(\mathbf{A})$. The map $\mathbf{b} \mapsto \mathbf{x}^+$ from data to least-squares solution has a sensitivity that depends on $\kappa_2(\mathbf{A})$, on the residual $\|\mathbf{A}\mathbf{x}^+ - \mathbf{b}\|$ and on the angle between $\mathbf{b}$ and $\operatorname{col}(\mathbf{A})$; when the residual is large, a term in $\kappa_2(\mathbf{A})^2$ appears even for the QR route. The bound above is about the *linear systems being solved*, not about the underlying fitting problem.
- **Nothing here is about arithmetic.** A condition number describes a problem, and an error bound of the form "relative error $\leq \kappa\cdot$ (relative perturbation)" only becomes a statement about a computation once one knows how large a perturbation the computation itself introduces. That requires a model of floating-point arithmetic and a backward error analysis, neither of which exists in this book yet.
- **Hence the comparison of the two algorithms** — that a stable implementation of the QR route loses about $\log_{10}\kappa_2(\mathbf{A})$ decimal digits while forming and solving the normal equations loses about $2\log_{10}\kappa_2(\mathbf{A})$ — is still Chapter 23's to prove. What this section supplies is the number that appears in both statements, and the reason a square appears in one of them.

15.8.4 Conditioning is a property of the problem

This is the last warning of the chapter, and it is the one readers most often need.

Warning. **Conditioning belongs to the problem; stability belongs to the algorithm.** $\kappa(\mathbf{A})$ is computed from $\mathbf{A}$ alone. It knows nothing about how anyone intends to solve $\mathbf{A}\mathbf{x} = \mathbf{b}$, and it does not change if the method changes. Two consequences, both regularly got wrong:

- **A large $\kappa(\mathbf{A})$ does not mean a computed answer is wrong.** It means that the answer is not determined to high relative accuracy by data of limited accuracy — a statement about the information available, not about the arithmetic performed. If the data are exact and the arithmetic is exact, the answer is exact however large κ is. And even in inexact arithmetic, a good algorithm returns the exact answer to a problem whose data differ from yours by a rounding error, which is the most anyone can ask of it.

- **A small $\kappa(\mathbf{A})$ does not make an algorithm trustworthy.** An unstable method can wreck a perfectly conditioned problem all by itself, by introducing errors far larger than the data warrant; Exercise (C3: A well-conditioned problem and a bad method) gives an elementary example in which κ_∞ is below 5 and a computed coordinate comes out as 0 instead of 1.

Chapter 23 draws the distinction properly, defines backward stability, and proves which of the algorithms in this book have it. Until then, read κ as an upper bound on what any method can promise, and never as a verdict on a particular answer.

15.8.5 What this chapter has settled

Nine chapters wrote promissory notes that only a norm could pay. Here is the ledger, with the section that closed each entry.

- **Chapter 10 §01** said that not every norm comes from an inner product and that the parallelogram law is the test. Section 1 proved it, in Theorem 15.1.3, building on the $\mathbb{R}^2$ case of Exercise (C1: The parallelogram law characterizes inner-product norms).
- **Chapter 9 §10** promised that this chapter would prove $\rho(\mathbf{A}) \le \|\mathbf{A}\|$ for the norm induced by any vector norm, and would recover $\rho(\mathbf{A})$ as a limit built from the norms of the powers. Section 4 did both: Theorem 15.4.1 and Gelfand's formula Theorem 15.4.4. The same section also gave ρ the labeled definition Definition 15.4.1 that Chapter 9 used only in prose, and Corollary 15.4.5 restored Chapter 9's convergence criterion with a rate attached. And Chapter 9's entrywise convergence turned out to be *the* convergence, by Corollary 15.2.4.
- **Chapter 12 §08 and §12** asked, twice, for a name for $\max\{\|\mathbf{Ax}\| : \|\mathbf{x}\| = 1\}$. Section 3 supplied it — Definition 15.3.2 — and separated the name from the computation $\|\mathbf{A}\|_2 = \sigma_1(\mathbf{A})$, which is Theorem 15.3.3 (c); Example (The oblique projection, finally measured) measured Chapter 12 §12's oblique projection. The spectral norm that Chapter 12 §10 needed in order even to *state* the second half of its approximation theorem now exists; the theorem itself waits for Chapter 16, which proves it from the min–max description of the singular values. The version covering every unitarily invariant norm at once is Chapter 20's.
- **Chapter 9 §09** promised a return to $e^{\mathbf{A}}$ with norms available, giving quantitative bounds in place of exact formulas. Section 6 gave them, in Theorem 15.6.1, and its Theorem 15.6.3 is the statement Chapter 11 §10 pointed at when it said that the consequence of stability for $\dot{\mathbf{x}} = \mathbf{Ax}$ belonged to Chapter 15.
- **Chapter 11 §01** said that this chapter, "where matrices acquire norms and limits can be spoken of properly, runs arguments of exactly this shape". Section 7 ran one: Corollary 15.7.5 and Corollary 15.7.6 turn "prove it for diagonalizable matrices, then take a limit" into three lines, and Example (Cayley–Hamilton, by a limit) is the demonstration.
- **Chapter 10 §08** deferred its reason for preferring **QR** to the normal equations. Theorem 15.8.4 supplies the matrix half of it; the arithmetic half is Chapter 23's, as listed above.

What the chapter has *not* done is equally worth recording. It has not bounded how far an individual eigenvalue moves under a perturbation — Example (A Jordan block's eigenvalues move like $\varepsilon^{1/k}$) shows there is no bound of the obvious kind, and the bounds that do exist, Weyl's and Bauer–Fike's, are Chapters 16 and 19. It has not said which norms are invariant under unitary multiplication, which is Chapter 20. And it has not touched arithmetic. The condition number is the bridge to that last subject: it is the exact point at which linear algebra

stops and numerical analysis begins.

15.8.6 Exercises

15.8.6.1 A. Check your understanding

Exercise A1.

(a) Define $\kappa(\mathbf{A})$, naming what it depends on besides $\mathbf{A}$.

(b) Explain why $\kappa(\mathbf{A}) \geq 1$ for every invertible $\mathbf{A}$.

(c) Decide whether each statement is correct, and justify: (i) "if $\kappa(\mathbf{A}) = 10^8$ then any computed solution of $\mathbf{Ax} = \mathbf{b}$ has at most a few correct digits"; (ii) "if $\kappa(\mathbf{A})$ is small then any method of solving $\mathbf{Ax} = \mathbf{b}$ is reliable".

(d) State what $\kappa_2(\mathbf{A}^*\mathbf{A})$ is in terms of $\kappa_2(\mathbf{A})$, and say what that has to do with the $\mathbf{QR}$ factorization.

Solution.

(a) See Definition 15.8.1: $\kappa(\mathbf{A}) = \|\mathbf{A}\|\|\mathbf{A}^{-1}\|$, with $\kappa(\mathbf{A}) = \infty$ for singular $\mathbf{A}$. Besides $\mathbf{A}$ it depends on the **choice of vector norm**, through the operator norm it induces; κ_1, κ_2 and κ_∞ are three different numbers.

(b) $1 = \|\mathbf{I}\| = \|\mathbf{A}\mathbf{A}^{-1}\| \leq \|\mathbf{A}\|\|\mathbf{A}^{-1}\|$, by Theorem 15.3.2 (c) and (d). See Proposition 15.8.2 (a).

(c) (i) Incorrect. κ bounds the effect of a perturbation of the data; with exact data and exact arithmetic the answer is exact. It says that the answer *cannot be determined* to high relative accuracy from inaccurate data, which is a statement about the problem, not a verdict on a computed answer. (ii) Incorrect. Conditioning is a property of the problem and stability a property of the algorithm; a small κ leaves an unstable method free to introduce errors of its own.

(d) $\kappa_2(\mathbf{A}^*\mathbf{A}) = \kappa_2(\mathbf{A})^2$ for $\mathbf{A}$ of full column rank (Theorem 15.8.4). The normal equations form $\mathbf{A}^*\mathbf{A}$ and so solve a system with the squared condition number, while the route $\mathbf{Rx} = \mathbf{Q}^*\mathbf{b}$ of Chapter 10 §08 never forms that product and keeps $\kappa_2(\mathbf{R}) = \kappa_2(\mathbf{A})$.

15.8.6.2 B. Practice

Exercise B1: Three condition numbers.

For $\mathbf{A} = \begin{pmatrix} 3 & 0 \\ 0 & -\frac{1}{2} \end{pmatrix}$ and $\mathbf{B} = \begin{pmatrix} 1 & 2 \\ 0 & 1 \end{pmatrix}$, compute κ_∞ and κ_2 of each. *Hint:* $\mathbf{B}^*\mathbf{B}$ *has trace* 6 *and determinant* 1.

Solution. $\mathbf{A}^{-1} = \operatorname{diag}(\frac{1}{3}, -2)$. Largest absolute row sums: 3 for $\mathbf{A}$, 2 for $\mathbf{A}^{-1}$, so $\kappa_\infty(\mathbf{A}) = 6$ by Theorem 15.3.3 (b). For κ_2: $\mathbf{A}^*\mathbf{A} = \operatorname{diag}(9, \frac{1}{4})$, so $\sigma_1 = 3$, $\sigma_2 = \frac{1}{2}$ and $\kappa_2(\mathbf{A}) = 6$ by Proposition 15.8.2 (d). The two agree here because $\mathbf{A}$ is diagonal.

$\mathbf{B}^{-1} = \left(\begin{smallmatrix} 1 & -2 \\ 0 & 1 \end{smallmatrix}\right)$, and both have largest absolute row sum 3, so $\kappa_\infty(\mathbf{B}) = 9$. For κ_2:

$\mathbf{B}^*\mathbf{B} = \left(\begin{smallmatrix} \frac{1}{2} & \frac{2}{5} \end{smallmatrix}\right)$ has trace 6 and determinant 1, so its eigenvalues are $3 \pm 2\sqrt{2}$, giving

$$\kappa_2(\mathbf{B}) = \sqrt{\frac{3+2\sqrt{2}}{3-2\sqrt{2}}} = 3 + 2\sqrt{2} \approx 5.828,$$

using $(3-2\sqrt{2})(3+2\sqrt{2}) = 1$, so that the ratio is $(3+2\sqrt{2})^2$.

Exercise B2: A perturbation, measured against the bound.

Let $\mathbf{A} = \begin{pmatrix} 1 & 1 \\ 1 & 1.01 \end{pmatrix}$ and $\mathbf{b} = (2, 2.01)$ as in Example (A system where the bound is attained), and take $\Delta\mathbf{b} = (0, 0.01)$.

(a) Solve $\mathbf{A}\widetilde{\mathbf{x}} = \mathbf{b} + \Delta\mathbf{b}$ exactly.

(b) Compute both relative errors in $\|\cdot\|_\infty$ and the factor between them, and compare with $\kappa_\infty(\mathbf{A}) = 404.01$.

Solution.

(a) With $\mathbf{A}^{-1} = \left(\begin{smallmatrix} 101 & -100 \\ -100 & 100 \end{smallmatrix}\right)$ from Example (A system where the bound is attained) and $\Delta\mathbf{b} = (0, \frac{1}{100})$,

$$\widetilde{\mathbf{x}} - \mathbf{x} = \mathbf{A}^{-1}\Delta\mathbf{b} = \begin{pmatrix} -1 \\ 1 \end{pmatrix}, \qquad \widetilde{\mathbf{x}} = \begin{pmatrix} 0 \\ 2 \end{pmatrix}.$$

Check: $0 + 2 = 2$ and $0 + 2 \cdot \frac{101}{100} = \frac{202}{100} = 2.02 = \mathbf{b} + \Delta\mathbf{b}$ in the second coordinate.

(b) $\|\Delta\mathbf{b}\|_\infty / \|\mathbf{b}\|_\infty = \frac{1/100}{201/100} = \frac{1}{201}$, and $\|\widetilde{\mathbf{x}} - \mathbf{x}\|_\infty / \|\mathbf{x}\|_\infty = 1$. The factor is 201, which is below $\kappa_\infty(\mathbf{A}) = 404.01$ by a factor of about 2. The bound holds, as Theorem 15.8.3 (a) requires, and is not attained: this $\Delta\mathbf{b}$ is not the worst direction, which Example (A system where the bound is attained) found.

Exercise B3: Squaring, again.

Let $\mathbf{A} = \begin{pmatrix} 1 & 0 \\ 0 & \frac{1}{2} \\ 0 & 0 \end{pmatrix}$.

(a) Compute the singular values of $\mathbf{A}$ and $\kappa_2(\mathbf{A})$.

(b) Compute $\mathbf{A}^\top\mathbf{A}$ and $\kappa_2(\mathbf{A}^\top\mathbf{A})$ directly, and confirm Theorem 15.8.4.

(c) Does κ_∞ also square? Compute $\kappa_\infty(\mathbf{A}^\top\mathbf{A})$ and compare with κ_∞ of the square matrix $\left(\begin{smallmatrix} 1 & 0 \\ 0 & \frac{1}{2} \end{smallmatrix}\right)$.

Solution.

(a) $\mathbf{A}^\top\mathbf{A} = \operatorname{diag}(1, \frac{1}{4})$, whose eigenvalues are 1 and $\frac{1}{4}$; so $\sigma_1(\mathbf{A}) = 1$, $\sigma_2(\mathbf{A}) = \frac{1}{2}$ and $\kappa_2(\mathbf{A}) = 2$.

(b) $\mathbf{A}^\top\mathbf{A} = \operatorname{diag}(1, \frac{1}{4})$ is diagonal with positive entries, so its singular values are 1 and $\frac{1}{4}$ and $\kappa_2(\mathbf{A}^\top\mathbf{A}) = 4 = 2^2 = \kappa_2(\mathbf{A})^2$, as Theorem 15.8.4 says.

(c) For a diagonal matrix every κ_p is the ratio of the largest to the smallest modulus on the diagonal, so $\kappa_\infty(\mathbf{A}^\top\mathbf{A}) = 4$ while $\kappa_\infty(\mathrm{diag}(1, \tfrac{1}{2})) = 2$; here the squaring happens in κ_∞ too. It does not in general: Theorem 15.8.4 is stated for κ_2, and the proof uses singular values, which only $\|\cdot\|_2$ sees. Exercise (C1: Changing the norm changes κ, but not much) bounds how far the other condition numbers can stray.

15.8.6.3 C. Going deeper

Exercise C1: Changing the norm changes κ, but not much.

Let $\|\cdot\|_a$ and $\|\cdot\|_b$ be norms on $\mathbb{C}^n$ with $c\|\mathbf{v}\|_b \le \|\mathbf{v}\|_a \le C\|\mathbf{v}\|_b$ for all $\mathbf{v}$, as supplied by Theorem 15.2.2, and write κ_a, κ_b for the corresponding condition numbers.

(a) Prove that $\|\mathbf{A}\|_a \le (C/c)\|\mathbf{A}\|_b$ for every $\mathbf{A} \in M_n(\mathbb{C})$.

(b) Deduce that $\kappa_a(\mathbf{A}) \le (C/c)^2\kappa_b(\mathbf{A})$ and $\kappa_b(\mathbf{A}) \le (C/c)^2\kappa_a(\mathbf{A})$ for every invertible $\mathbf{A}$.

(c) Using $\|\mathbf{v}\|_\infty \le \|\mathbf{v}\|_2 \le \sqrt{n}\,\|\mathbf{v}\|_\infty$, bound κ_2 in terms of κ_∞ for $n = 2$, and check the bound on the matrix $\mathbf{B} = \left(\begin{smallmatrix} 1 & 2 \\ 0 & 1 \end{smallmatrix}\right)$ of Exercise (B1: Three condition numbers).

Solution.

(a) Let $\mathbf{x} \neq \mathbf{0}$. Then
$$\frac{\|\mathbf{A}\mathbf{x}\|_a}{\|\mathbf{x}\|_a} \le \frac{C\|\mathbf{A}\mathbf{x}\|_b}{c\|\mathbf{x}\|_b} \le \frac{C}{c}\,\|\mathbf{A}\|_b,$$
using the two inequalities and Theorem 15.3.2 (a) for $\|\cdot\|_b$. Taking the maximum over $\mathbf{x} \neq \mathbf{0}$, which is $\|\mathbf{A}\|_a$ by Definition 15.3.2 and homogeneity, gives the claim.

(b) Apply (a) to $\mathbf{A}$ and to $\mathbf{A}^{-1}$ and multiply: $\kappa_a(\mathbf{A}) = \|\mathbf{A}\|_a\|\mathbf{A}^{-1}\|_a \le (C/c)^2\|\mathbf{A}\|_b\|\mathbf{A}^{-1}\|_b = (C/c)^2\kappa_b(\mathbf{A})$. The reverse follows by symmetry, since the hypothesis also reads $C^{-1}\|\mathbf{v}\|_a \le \|\mathbf{v}\|_b \le c^{-1}\|\mathbf{v}\|_a$, whose ratio of constants is again C/c.

(c) With $\|\cdot\|_a = \|\cdot\|_2$ and $\|\cdot\|_b = \|\cdot\|_\infty$, we have $c = 1$ and $C = \sqrt{n} = \sqrt{2}$, so $\kappa_2(\mathbf{A}) \le 2\kappa_\infty(\mathbf{A})$ and $\kappa_\infty(\mathbf{A}) \le 2\kappa_2(\mathbf{A})$. For $\mathbf{A} = \left(\begin{smallmatrix} 1 & 2 \\ 0 & 1 \end{smallmatrix}\right)$: $\kappa_2 = 3 + 2\sqrt{2} \approx 5.83$ and $\kappa_\infty = 9$, and indeed $5.83 \le 18$ and $9 \le 11.66$. Both bounds hold, with room to spare; the point is only that no choice of norm can turn a well-conditioned matrix into an ill-conditioned one.

Exercise C2: The condition number is the reciprocal distance to singularity.

Let $\mathbf{A} \in M_n(\mathbb{C})$ be invertible.

(a) Prove that every singular $\mathbf{B} \in M_n(\mathbb{C})$ satisfies
$$\frac{\|\mathbf{A} - \mathbf{B}\|}{\|\mathbf{A}\|} \ge \frac{1}{\kappa(\mathbf{A})}.$$

(b) For the 2-norm, prove that equality is achieved: exhibit a singular $\mathbf{B}$ with $\|\mathbf{A} - \mathbf{B}\|_2 = \sigma_n(\mathbf{A})$. *Hint: use a singular value decomposition and delete one term.*

(c) Hence interpret $1/\kappa_2(\mathbf{A})$ in one sentence, and say what it gives for the matrix of

Example (A system where the bound is attained).

Solution.

(a) Put $\mathbf{E} = \mathbf{B} - \mathbf{A}$, so $\mathbf{A} + \mathbf{E} = \mathbf{B}$ is singular. If $\|\mathbf{A}^{-1}\mathbf{E}\| < 1$ then $\mathbf{A} + \mathbf{E} = \mathbf{A}(\mathbf{I} + \mathbf{A}^{-1}\mathbf{E})$ would be invertible, by Theorem 15.5.1 and the fact that a product of invertible matrices is invertible; so $\|\mathbf{A}^{-1}\mathbf{E}\| \geq 1$. By Theorem 15.3.2 (d), $1 \leq \|\mathbf{A}^{-1}\|\|\mathbf{E}\|$, that is $\|\mathbf{E}\| \geq 1/\|\mathbf{A}^{-1}\|$. Dividing by $\|\mathbf{A}\|$,

$$\frac{\|\mathbf{A} - \mathbf{B}\|}{\|\mathbf{A}\|} = \frac{\|\mathbf{E}\|}{\|\mathbf{A}\|} \geq \frac{1}{\|\mathbf{A}\|\,\|\mathbf{A}^{-1}\|} = \frac{1}{\kappa(\mathbf{A})}.$$

(b) Let $\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^*$ (Theorem 12.8.1) with $\mathbf{\Sigma} = \operatorname{diag}(\sigma_1, \dots, \sigma_n)$, and put

$$\mathbf{B} = \mathbf{U}\,\operatorname{diag}(\sigma_1, \dots, \sigma_{n-1}, 0)\,\mathbf{V}^*.$$

Then $\mathbf{B}$ is singular, since $\operatorname{diag}(\sigma_1, \dots, \sigma_{n-1}, 0)$ is and $\mathbf{U}, \mathbf{V}$ are invertible; and $\mathbf{A} - \mathbf{B} = \mathbf{U}\,\operatorname{diag}(0, \dots, 0, \sigma_n)\,\mathbf{V}^*$, whose singular values are those of $\operatorname{diag}(0, \dots, 0, \sigma_n)$ — for any $\mathbf{M}$, $(\mathbf{U}\mathbf{M}\mathbf{V}^*)^*(\mathbf{U}\mathbf{M}\mathbf{V}^*) = \mathbf{V}\mathbf{M}^*\mathbf{M}\mathbf{V}^*$ is similar to $\mathbf{M}^*\mathbf{M}$, so unitary factors leave the singular values alone, invertible or not — the largest of them being σ_n; so $\|\mathbf{A} - \mathbf{B}\|_2 = \sigma_n$ by Theorem 15.3.3 (c). Since $\|\mathbf{A}\|_2 = \sigma_1$, the ratio is $\sigma_n/\sigma_1 = 1/\kappa_2(\mathbf{A})$, matching (a) with equality.

(c) $1/\kappa_2(\mathbf{A})$ is the relative distance, in the 2-norm, from $\mathbf{A}$ to the nearest singular matrix. For $\mathbf{A} = \left(\begin{smallmatrix} 1 & 1 \\ 1 & 1.01 \end{smallmatrix}\right)$, whose κ_2 is the ratio of the eigenvalues $(201 \pm \sqrt{40001})/200$ of the symmetric $\mathbf{A}$, one gets $\kappa_2(\mathbf{A}) \approx 402.0$, so a relative perturbation of about 0.25% suffices to make $\mathbf{A}$ singular. Ill-conditioned means *nearly singular*, in exactly this quantitative sense.

Exercise C3: A well-conditioned problem and a bad method.

Consider the two-by-two system

$$\begin{aligned} 10^{-15}x_1 + x_2 &= 1, \\ x_1 + x_2 &= 2, \end{aligned}$$

with coefficient matrix $\mathbf{A} = \left(\begin{smallmatrix} 10^{-15} & 1 \\ 1 & 1 \end{smallmatrix}\right)$.

(a) Show that $\kappa_\infty(\mathbf{A}) < 5$, so that the problem is well conditioned.

(b) Solve the system exactly.

(c) Eliminate x_1 using the **first** equation as the pivot row, rounding every intermediate quantity to 12 significant decimal digits, and compare the result with (b). Then do the same after exchanging the two equations, and say what the exchange achieved.

(d) What does this show about the relationship between $\kappa(\mathbf{A})$ and the accuracy of a computed answer?

Solution.

(a) Write $\varepsilon = 10^{-15}$. Then $\det \mathbf{A} = \varepsilon - 1 \neq 0$ and

$$\mathbf{A}^{-1} = \frac{1}{\varepsilon - 1}\begin{pmatrix} 1 & -1 \\ -1 & \varepsilon \end{pmatrix}.$$

The largest absolute row sum of $\mathbf{A}$ is 2, and that of $\mathbf{A}^{-1}$ is $2/(1-\varepsilon)$, so by Theorem 15.3.3 (b),

$$\kappa_\infty(\mathbf{A}) = \frac{4}{1-\varepsilon} < 5.$$

(b) Subtracting the first equation from the second gives $(1-\varepsilon)x_1 = 1$, so

$$x_1 = \frac{1}{1-\varepsilon} = 1 + 10^{-15} + \dots, \qquad x_2 = 1 - \varepsilon x_1 = \frac{1-2\varepsilon}{1-\varepsilon} = 1 - 10^{-15} + \dots.$$

Both coordinates are 1 to fourteen decimal places.

(c) *Without the exchange.* The multiplier is $1/\varepsilon = 10^{15}$, and the second equation becomes

$$(1 - 10^{15})x_2 = 2 - 10^{15}.$$

Both sides need fifteen significant digits to be recorded exactly, so at twelve digits both round to $-1.00000000000\times10^{15}$, and the computed x_2 is exactly 1 — accurate, as it happens. Back-substitution into the first equation then gives

$$x_1 = \frac{1 - x_2}{\varepsilon} = \frac{0}{10^{-15}} = 0,$$

against a true value of $1 + 10^{-15}$: every digit is wrong. The damage was done by subtracting two numbers that agree in all twelve retained digits, so that the difference retains none of them.

With the exchange. Pivoting on $x_1 + x_2 = 2$, the multiplier is $\varepsilon = 10^{-15}$ and the second equation becomes $(1-\varepsilon)x_2 = 1 - 2\varepsilon$. At twelve digits both coefficients round to 1.00000000000, giving $x_2 = 1.00000000000$, and back-substitution gives $x_1 = 2 - x_2 = 1.00000000000$. Both agree with (b) to all twelve digits. The exchange achieved one thing: it made the multiplier at most 1 in modulus, so nothing in the elimination was amplified, and no large quantity was ever created to be subtracted from a comparable one. This is why every practical elimination scheme chooses the largest available pivot.

(d) The conditioning of the problem is excellent, $\kappa_\infty(\mathbf{A}) < 5$, and it is the same for both computations, since it does not mention a method. Yet one method returns $(0, 1)$ and the other returns the right answer. Conditioning bounds what *any* method can promise; whether a given method keeps that promise is stability, and it is Chapter 23's subject.

Chapter 16

Variational Principles and Interlacing

Since Chapter 12 the book has written $\lambda_1(\mathbf{A}) \geq \cdots \geq \lambda_n(\mathbf{A})$ for the eigenvalues of a Hermitian matrix without ever saying what the middle ones *are*. The two at the ends have an answer. Chapter 10 observed that $\langle T\mathbf{v}, \mathbf{v}\rangle$ is real for a self-adjoint operator, and Chapter 12 §05 turned that into Lemma 12.5.2: on the unit sphere, $\langle \mathbf{Ax}, \mathbf{x}\rangle$ runs from $\lambda_n(\mathbf{A})$ up to $\lambda_1(\mathbf{A})$, and both ends are attained at eigenvectors. Everything between the ends was left blank, twice and deliberately. Chapter 12 §05 said it in one sentence: the intermediate eigenvalues "have no description as a plain maximum over the whole unit sphere". Chapter 12 §12 said where the blank would be filled: "Chapter 16 characterizes the eigenvalues of a Hermitian matrix as maxima and minima of $\langle \mathbf{Ax}, \mathbf{x}\rangle$ — at which point the test becomes the theory."

This is that chapter, and the device that fills the blank is a **min–max**. One maximum over the unit sphere is not enough information to see λ_2; a maximum over a *subspace*, followed by a minimum over all subspaces of the right dimension, is exactly enough. That is the Courant–Fischer theorem, and its proof is one dimension count repeated: two subspaces of F^n whose dimensions add to more than n must share a non-zero vector. Once every eigenvalue is a maximum and a minimum of a quantity that does not mention an eigenvector, eigenvalues of *different* matrices become comparable, and the rest of the chapter is the harvest. How far the eigenvalues move when the matrix moves (Weyl). How they move when a row and its column are deleted, or a rank-one matrix is added (Cauchy interlacing, and the secular equation). What sums of the largest eigenvalues optimize (Poincaré, Ky Fan), and what arbitrary index sets do (Wielandt, Lidskii). What the diagonal of a Hermitian matrix can be, given its spectrum (Schur). The same theory for singular values, which finally proves the approximation theorem Chapter 12 §10 could only state. Inertia, re-proved without a basis and then made additive across a Schur complement. And a first look at which scalar functions respect the Loewner order.

Every matrix whose eigenvalues are indexed in this chapter is Hermitian, and the field is $\mathbb{R}$ or $\mathbb{C}$. This is not a convenience. The index i in $\lambda_i(\mathbf{A})$ presupposes that the eigenvalues are real and can be sorted, which is Theorem 11.2.1, and every eigenvalue inequality below is false without it — §04 exhibits a non-Hermitian matrix with a 1×1 principal submatrix lying outside the convex hull of the whole matrix's spectrum. Each section states the hypothesis once and keeps it.

Eigenvalues are indexed decreasingly, $\lambda_1(\mathbf{A}) \geq \lambda_2(\mathbf{A}) \geq \cdots \geq \lambda_n(\mathbf{A})$, repeated according

to multiplicity, as Chapter 12 §05 fixed it. Many sources index the min–max theorem the other way, and the two statements differ by $i \leftrightarrow n+1-i$; §02 gives the increasing form once, as a remark, so that a reader who meets it elsewhere is not lost.

16.0.1 The analysis this chapter imports

None that is new. Chapter 15 named everything it borrowed from analysis in a numbered list (A1)–(A6) in its introduction, and this chapter uses that list and nothing else, citing an item by the same name at the point of use — "by the extreme value theorem, fact (A4) of Chapter 15's introduction". Compactness of the unit sphere (A3) and the extreme value theorem (A4) are the two that a reader will expect to see, since a min–max is an optimization and optimizations need their extrema to exist.

It is worth saying in advance that the expectation is not always met. In §§01–02, where the maxima and minima are first written down, **no analytic fact is invoked**: the spectral theorem is already available, and it hands over a maximizer explicitly, so the extreme value theorem is never called on to prove that one exists. That is not the same as saying no analysis lies underneath. The spectral theorem rests on the fundamental theorem of algebra, and Chapter 5 §05 proves that with the extreme value theorem on a closed disc; the analysis was paid for there, once, and is not paid again here. Chapter 11 §02 avoided that theorem on purpose and said so; §§01–02 below return to the remark and settle the account. Where a later section does need an item of the list, it names it. Nothing is added to the list.

16.0.2 What you need

- **Chapter 1 §07** — the dimension formula $\dim(U+W) = \dim U + \dim W - \dim(U \cap W)$, Theorem 1.7.3. It is the engine of every min–max proof in the chapter, and §02 packages it as a lemma.
- **Chapter 6 and Chapter 7** — principal submatrices (Definition 6.7.1) and Schur complements: Definition 7.3.1, Theorem 7.3.2, Theorem 7.3.1, Corollary 7.3.6. §§04, 05 and 10 lean on them.
- **Chapter 8** — the trace and determinant as sum and product of the eigenvalues, Theorem 8.3.3.
- **Chapter 10** — inner products, orthonormal bases and the adjoint: Definition 10.1.1, Definition 10.1.3, Theorem 10.1.5, Theorem 10.2.1, Definition 10.3.1, Theorem 10.3.2, Corollary 10.2.3, Definition 10.6.2, Theorem 10.6.3, Proposition 10.6.7.
- **Chapter 11** — the spectral theorems, in both the operator and the matrix form: Theorem 11.2.1, Theorem 11.4.2, Corollary 11.4.3, Theorem 11.5.1, Corollary 11.5.2, Corollary 11.5.4, and the functional calculus Definition 11.8.2, Theorem 11.8.3.
- **Chapter 12** — positivity, the Loewner order and the singular value decomposition: Definition 12.1.1, Theorem 12.1.4, Theorem 12.1.5, Theorem 12.2.1, Definition 12.5.1, Proposition 12.5.1, Lemma 12.5.2, Theorem 12.5.3, Proposition 12.5.4, Definition 12.8.1, Theorem 12.8.1, Theorem 12.8.3, Definition 12.10.1, Lemma 12.10.2, Theorem 12.10.3; from §04 the generalized eigenvalues (Definition 12.4.1, Theorem 12.4.2), and from §06 Hadamard's inequality and the block criterion (Theorem 12.6.4, Theorem 12.6.1), each of which gets a second proof here.
- **Chapter 13 §§02, 05** — congruence (Definition 13.2.1), inertia and signature: Theorem 13.5.1, Definition 13.5.1, Theorem 13.5.3.
- **Chapter 15** — the way a matrix is measured, and the questions left open: Defini-

tion 15.3.2, Theorem 15.3.2, and Theorem 15.3.3, whose part (c) is the formula $\|\mathbf{A}\|_2 = \sigma_1(\mathbf{A})$; then Definition 15.4.1, Theorem 15.4.1, Definition 15.8.1, and the imported-analysis list of the Chapter 15 introduction.

16.0.3 Roadmap

- **The Rayleigh quotient.** $R_{\mathbf{A}}(\mathbf{x}) = \langle \mathbf{Ax}, \mathbf{x}\rangle / \langle \mathbf{x}, \mathbf{x}\rangle$ promoted from a test to an object: its range is exactly $[\lambda_n, \lambda_1]$, its critical points on the unit sphere are exactly the unit eigenvectors, and the first description of λ_k — maximize after deflating by the top eigenvectors — is correct but circular.
- **The min–max theorem.** Courant–Fischer: λ_k is a minimum over subspaces of a maximum over vectors, and equally a maximum over subspaces of a minimum. No eigenvector is named, so two matrices can now be compared eigenvalue by eigenvalue.
- **How far eigenvalues move.** Weyl's inequalities, and the Lipschitz bound $|\lambda_i(\mathbf{A}+\mathbf{E}) - \lambda_i(\mathbf{A})| \le \|\mathbf{E}\|_2$ that Chapter 15 §07 promised.
- **Deleting a row and a column.** Cauchy interlacing: the spectrum of a principal submatrix is caught between consecutive eigenvalues of the whole matrix. When the interlacing is strict, which settles a promise of Chapter 10: the zeros of consecutive orthogonal polynomials interlace strictly. And why none of it survives without symmetry.
- **Adding a rank-one matrix.** Interlacing again, the secular equation that locates the new eigenvalues between the old, and the shifts that add up to $\tau\|\mathbf{v}\|^2$.
- **Subspaces and sums.** Poincaré's separation theorem, and Ky Fan's: the sum of the k largest eigenvalues is a maximum of a trace over orthonormal k-frames, hence a convex function of the matrix. Chapter 12's capture bound turns out to be one case of it.
- **Arbitrary index sets.** The Wielandt min–max over a flag of subspaces, and Lidskii's inequality. It contains Ky Fan's subadditivity and the Weyl inequalities with one index at an end — but not all of Weyl's, which is worth seeing.
- **The diagonal and the spectrum.** Majorization; Schur's theorem and Horn's converse, which together say that the diagonals of the Hermitian matrices with a given spectrum are exactly the vectors that spectrum majorizes.
- **The same theory for singular values.** The min–max for σ_k, perturbation with no hypothesis on the perturbation at all, the spectral-norm form of Eckart–Young, interlacing when a row or column is deleted, and the distance from an invertible matrix to the nearest singular one — which is what Chapter 15's condition number was measuring all along.
- **Inertia, again and additively.** A second proof of Sylvester's law with no basis in it, now over $\mathbb{C}$ as well; how far a rank-r perturbation can move the inertia; and Haynsworth's additivity across a Schur complement.
- **Which functions respect the order.** Operator monotone and operator convex functions, why the square root behaves and the square does not, and a statement of the classification that Chapter 20 proves.

16.0.4 Named moves

- **Count dimensions to force an intersection.** Two subspaces of an n-dimensional space whose dimensions add to more than n meet in a non-zero vector. This one line proves Courant–Fischer and Weyl directly, and Cauchy interlacing and Poincaré through Courant–Fischer. It is the chapter's single technique, and everything else is bookkeeping around it.
- **Prove a min–max by two inequalities of different characters.** One direction ex-

hibits a **witness** subspace — usually a span of eigenvectors — and computes on it. The other takes an **arbitrary** subspace and intersects it with a span of eigenvectors from the other end. Neither half resembles the other, and recognizing which half is which is most of the work in reading any proof below.

- **Apply the result to $-\mathbf{A}$.** The two halves of Courant–Fischer, the two families of Weyl inequalities and the top- and bottom-k trace theorems are each other's images under $\mathbf{A} \mapsto -\mathbf{A}$, which reverses the order and sends λ_i to $-\lambda_{n+1-i}$. Deriving the second statement this way is a genuine argument, not a wave of the hand, and it is written out each time.
- **Compress, then interlace.** Restricting the quadratic form to a subspace produces a smaller Hermitian matrix whose eigenvalues are trapped by the original's. Deleting rows and columns, adding a rank-one matrix and cutting a singular value decomposition short are all this move.
- **Perturb and compare, eigenvalue by eigenvalue.** Chapter 15's move, now applied one index at a time rather than to the spectrum as a whole.
- **Reduce singular values to eigenvalues.** Either through $\mathbf{A}^*\mathbf{A}$, which is shortest, or through the Hermitian dilation, which is symmetric in $\mathbf{A}$ and $\mathbf{A}^*$. Both appear, and each section says which it uses and why.
- **Majorize.** When the right comparison is between *sums* of the largest entries rather than individual ones, compare the partial sums of the decreasing rearrangements. The diagonal of a Hermitian matrix against its spectrum (§08), and the Ky Fan and Lidskii sums (§§06–07), are all of this type.

16.1 The Rayleigh Quotient

Chapter 12 used the number $\langle \mathbf{Ax}, \mathbf{x} \rangle$ as a *test*: positive for every non-zero $\mathbf{x}$ means positive definite, non-negative means positive semidefinite, and that was the end of it. Chapter 12 §05 then noticed that the test carries more information than the verdict — normalized, it ranges over the interval between the smallest and largest eigenvalues — and stopped there. This section makes the normalized quantity an object with a name, finds its range exactly, finds the vectors where it is flat, and extracts a first description of every eigenvalue as a maximum. The description is correct and unsatisfying, and saying precisely why is the business of §02.

Throughout, F is $\mathbb{R}$ or $\mathbb{C}$, every matrix is Hermitian, and its eigenvalues are indexed decreasingly, $\lambda_1(\mathbf{A}) \geq \cdots \geq \lambda_n(\mathbf{A})$, repeated according to multiplicity. The indexing presupposes that the eigenvalues are real, which is Theorem 11.2.1. Inner products are the standard ones of F^n, linear in the first slot.

16.1.1 From a test to an object

Look at what Lemma 12.5.2 actually says. For a unit vector $\mathbf{x}$, the number $\langle \mathbf{Ax}, \mathbf{x} \rangle$ lies between $\lambda_n(\mathbf{A})$ and $\lambda_1(\mathbf{A})$, and it reaches both ends. The restriction to unit vectors is a nuisance: doubling $\mathbf{x}$ quadruples $\langle \mathbf{Ax}, \mathbf{x} \rangle$, so for $\mathbf{A} \neq 0$ the raw quantity has no bounded range at all and every statement about it must carry the clause "for $\|\mathbf{x}\| = 1$" along. Dividing by $\|\mathbf{x}\|^2$ removes the nuisance permanently, and the resulting expression occurs often enough in what follows to deserve a name of its own.

The Rayleigh quotient measures how much a Hermitian matrix stretches a vector along its own direction, on a scale where the vector's length has been divided out.

Definition 16.1.1 — Rayleigh Quotient

Let F be $\mathbb{R}$ or $\mathbb{C}$ and let $\mathbf{A} \in M_n(F)$ be **Hermitian**. The **Rayleigh quotient** of $\mathbf{A}$ is the function

$$R_{\mathbf{A}}(\mathbf{x}) := \frac{\langle \mathbf{A}\mathbf{x}, \mathbf{x}\rangle}{\langle \mathbf{x}, \mathbf{x}\rangle},$$

defined at **every** $\mathbf{x} \in F^n$ with $\mathbf{x} \neq \mathbf{0}$, and at no other vector.

For a self-adjoint operator T on a finite-dimensional inner product space V over F, the same formula $R_T(\mathbf{v}) = \langle T\mathbf{v}, \mathbf{v}\rangle / \langle \mathbf{v}, \mathbf{v}\rangle$, for $\mathbf{v} \neq \mathbf{0}$, defines the Rayleigh quotient of T.

Clause by clause. The word **Hermitian** is what makes the values real, and so what makes it sensible to ask for a maximum: by Proposition 10.6.7 (a), $\langle \mathbf{A}\mathbf{x}, \mathbf{x}\rangle \in \mathbb{R}$ for every $\mathbf{x}$, even over $\mathbb{C}$. The condition $\mathbf{x} \neq \mathbf{0}$ is what makes the fraction mean anything: $\langle \mathbf{x}, \mathbf{x}\rangle = \|\mathbf{x}\|^2 > 0$ exactly for $\mathbf{x} \neq \mathbf{0}$, by positive definiteness of the inner product (Definition 10.1.1), and there is no value to assign at $\mathbf{0}$ — the numerator vanishes there too, and the quotient $0/0$ would have to be given a value by hand, which no theorem below would thank us for. So $R_{\mathbf{A}}$ is a real-valued function on $F^n \setminus \{\mathbf{0}\}$.

Well-definedness has a second half, and it is the useful one. For a scalar $c \neq 0$,

$$\langle \mathbf{A}(c\mathbf{x}), c\mathbf{x}\rangle = c\,\overline{c}\,\langle \mathbf{A}\mathbf{x}, \mathbf{x}\rangle = |c|^2 \langle \mathbf{A}\mathbf{x}, \mathbf{x}\rangle,$$
$$\langle c\mathbf{x}, c\mathbf{x}\rangle = |c|^2 \langle \mathbf{x}, \mathbf{x}\rangle,$$

so the factor $|c|^2$ cancels and

$$R_{\mathbf{A}}(c\mathbf{x}) = R_{\mathbf{A}}(\mathbf{x}) \qquad \text{for every } c \neq 0.$$

The Rayleigh quotient is therefore constant on each line through the origin with the origin removed. It is really a function on the set of lines, and the cheapest way to evaluate it is to normalize: for a **unit** vector $\mathbf{x}$,

$$R_{\mathbf{A}}(\mathbf{x}) = \langle \mathbf{A}\mathbf{x}, \mathbf{x}\rangle.$$

Every statement below may be read either way — over all non-zero vectors, or over the unit sphere — and we shall move between the two without comment.

Example. (A diagonal matrix, and the whole chapter in miniature)

Let $\mathbf{A} = \operatorname{diag}(d_1, \dots, d_n)$ with real d_i. Compute $R_{\mathbf{A}}$.

Solution. For $\mathbf{x} = (x_1, \dots, x_n) \neq \mathbf{0}$ we have $\mathbf{A}\mathbf{x} = (d_1 x_1, \dots, d_n x_n)$, so

$$R_{\mathbf{A}}(\mathbf{x}) = \frac{\sum_i d_i |x_i|^2}{\sum_i |x_i|^2} = \sum_i w_i d_i, \qquad w_i = \frac{|x_i|^2}{\|\mathbf{x}\|^2}.$$

The weights w_i are non-negative and sum to 1. So $R_{\mathbf{A}}(\mathbf{x})$ is a **weighted average of the diagonal entries**, and $\mathbf{x}$ is nothing but the recipe for the weights.

That one line is the entire chapter in miniature, and it is worth pausing on. A weighted average of $d_1, \dots, d_n$ can be any number between the smallest and the largest, and nothing else; it equals the largest only when all the weight sits on the largest entries; and to force it down to the second largest one must **forbid** the weight from sitting on the first. Every theorem in this chapter is

one of those three sentences, stated for a general Hermitian matrix, where the diagonal entries are replaced by the eigenvalues and the coordinates x_i by the coefficients of $\mathbf{x}$ in an orthonormal eigenbasis. The spectral theorem is what turns the general case into this one.

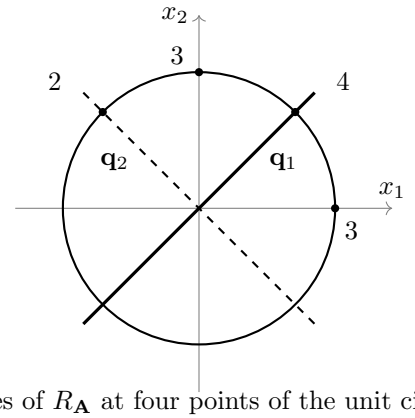
Example. (A symmetric matrix on the unit circle)

Let $\mathbf{A} = \begin{pmatrix} 3 & 1 \\ 1 & 3 \end{pmatrix} \in M_2(\mathbb{R})$. Describe $R_{\mathbf{A}}$ on the unit circle, and find its largest and smallest values.

Solution. The eigenvalues are 4 and 2, with orthogonal eigenvectors $\mathbf{q}_1 = \frac{1}{\sqrt{2}}(1,1)$ and $\mathbf{q}_2 = \frac{1}{\sqrt{2}}(1,-1)$: indeed $\mathbf{A}(1,1) = (4,4)$ and $\mathbf{A}(1,-1) = (2,-2)$. Writing a unit vector as $\mathbf{x} = (\cos\theta, \sin\theta)$,

$$R_{\mathbf{A}}(\mathbf{x}) = \langle \mathbf{A}\mathbf{x}, \mathbf{x} \rangle = 3\cos^2\theta + 2\cos\theta\sin\theta + 3\sin^2\theta = 3 + \sin 2\theta.$$

So the values run over $[2,4]$; the maximum 4 occurs at $\theta = \pi/4$ and $\theta = 5\pi/4$, that is along the line through $\mathbf{q}_1$, and the minimum 2 at $\theta = 3\pi/4$ and $7\pi/4$, along the line through $\mathbf{q}_2$. At $\theta = 0$ and $\theta = \pi/2$ the value is 3, the average of the two eigenvalues, which is also $a_{11} = a_{22}$.



The values of $R_{\mathbf{A}}$ at four points of the unit circle, for the symmetric matrix with diagonal entries 3 and off-diagonal entries 1. It is largest along the eigenline through $\mathbf{q}_1$, smallest along the one through $\mathbf{q}_2$, and takes every value in between

Example. (Two matrices whose quotient is forced)

Two further cases, at opposite extremes.

(a) **The identity.** $R_{\mathbf{I}}(\mathbf{x}) = \langle \mathbf{x}, \mathbf{x} \rangle / \langle \mathbf{x}, \mathbf{x} \rangle = 1$ for every $\mathbf{x} \neq \mathbf{0}$. The quotient is constant, and the constant is the only eigenvalue. More generally $R_{c\mathbf{I}} \equiv c$ for real c.

(b) **An orthogonal projection.** Let $\mathbf{P} \in M_n(F)$ be the matrix of the orthogonal projection onto a subspace U, so $\mathbf{P}^2 = \mathbf{P}$ and $\mathbf{P}^* = \mathbf{P}$ (Theorem 12.12.1). Then $\langle \mathbf{P}\mathbf{x}, \mathbf{x} \rangle = \langle \mathbf{P}^2\mathbf{x}, \mathbf{x} \rangle = \langle \mathbf{P}\mathbf{x}, \mathbf{P}\mathbf{x} \rangle = \|\mathbf{P}\mathbf{x}\|^2$, so

$$R_{\mathbf{P}}(\mathbf{x}) = \frac{\|\mathbf{P}\mathbf{x}\|^2}{\|\mathbf{x}\|^2} \in [0,1],$$

the fraction of $\mathbf{x}$ that survives the projection. Since $\|\mathbf{x}\|^2 = \|\mathbf{P}\mathbf{x}\|^2 + \|\mathbf{x} - \mathbf{P}\mathbf{x}\|^2$ by Theorem 10.1.3, it equals 1 exactly when $\mathbf{P}\mathbf{x} = \mathbf{x}$, that is on $U \setminus \{\mathbf{0}\}$, and 0 exactly when $\mathbf{P}\mathbf{x} = \mathbf{0}$, that is on $U^{\perp} \setminus \{\mathbf{0}\}$ — matching the eigenvalues 1 and 0 of $\mathbf{P}$.

Case (a) is the degenerate one, and it earns its place: when all the eigenvalues coincide the interval of values collapses to a point, every non-zero vector is an eigenvector, and every theorem below becomes an equality between two copies of the same number. A statement that fails to survive $\mathbf{A} = c\mathbf{I}$ has been stated wrongly.

Example. (Change one word: drop Hermitian)

Take $\mathbf{A} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} \in M_2(\mathbb{C})$, which is not Hermitian, and form $\langle \mathbf{A}\mathbf{x}, \mathbf{x} \rangle / \langle \mathbf{x}, \mathbf{x} \rangle$ anyway. At $\mathbf{x} = (1, i)$ the numerator is $\langle (i, 0), (1, i) \rangle = i \cdot \overline{1} = i$ and the denominator is 2, so the quotient is $i/2$, which is not real. The clause that fails is the word **Hermitian** in Definition 16.1.1, and it fails at the first step: Proposition 10.6.7 (a) is what made the numerator real, and its hypothesis is gone.

Over $\mathbb{R}$ the failure is quieter and worse. For $\mathbf{A} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} \in M_2(\mathbb{R})$ and real $\mathbf{x} = (x_1, x_2)$,

$$\langle \mathbf{A}\mathbf{x}, \mathbf{x} \rangle = -x_2 x_1 + x_1 x_2 = 0,$$

so the quotient is real, and identically 0. It is perfectly well behaved and tells us nothing: $\mathbf{A}$ has no real eigenvalue at all, and there is no interval $[\lambda_n, \lambda_1]$ for the quotient to describe.

Why this definition, then. Dropping "Hermitian" costs the reality of the values, hence any notion of largest; the real 2×2 example above shows that it also destroys the link with the spectrum even when the values happen to stay real. Dropping the denominator costs scale invariance, and with it the possibility of writing max without a side condition. Keeping the denominator but allowing $\mathbf{x} = \mathbf{0}$ costs nothing but sense.

Warning. **$R_{\mathbf{A}}(\mathbf{x})$ and $\langle \mathbf{A}\mathbf{x}, \mathbf{x} \rangle$ are the same number only for unit $\mathbf{x}$.** The bound $\langle \mathbf{A}\mathbf{x}, \mathbf{x} \rangle \leq \lambda_1(\mathbf{A})$ of Lemma 12.5.2 is stated for unit vectors and is false without that hypothesis: for $\mathbf{A} = \mathbf{I}_2$ and $\mathbf{x} = (10, 0)$ it would read $100 \leq 1$. The bound $R_{\mathbf{A}}(\mathbf{x}) \leq \lambda_1(\mathbf{A})$, by contrast, holds for every $\mathbf{x} \neq \mathbf{0}$. Whenever a maximum over "all $\mathbf{x}$" appears below, it is a maximum of the **quotient**; the un-normalized form of the same statement always carries $\|\mathbf{x}\| = 1$ with it.

16.1.2 What values it takes

Lemma 12.5.2 gives the two ends of the range. The following proposition adds that nothing in between is missing, which is a smaller statement than it looks and is worth proving explicitly rather than quoting a continuity argument.

Proposition 16.1.1 — The Range of the Rayleigh Quotient

Let $\mathbf{A} \in M_n(F)$ be Hermitian, $n \geq 1$. Then

$$\{R_{\mathbf{A}}(\mathbf{x}) : \mathbf{x} \in F^n,\ \mathbf{x} \neq \mathbf{0}\} = [\lambda_n(\mathbf{A}),\ \lambda_1(\mathbf{A})],$$

the whole closed interval. In particular

$$\lambda_1(\mathbf{A}) = \max_{\mathbf{x}\neq\mathbf{0}} R_{\mathbf{A}}(\mathbf{x}), \qquad \lambda_n(\mathbf{A}) = \min_{\mathbf{x}\neq\mathbf{0}} R_{\mathbf{A}}(\mathbf{x}),$$

and both are attained, at unit eigenvectors for $\lambda_1(\mathbf{A})$ and $\lambda_n(\mathbf{A})$.

Idea. Two inclusions of quite different weights. ($\subseteq$) is Lemma 12.5.2 with the normalization divided out, and costs one line. ($\supseteq$) asks for a vector realizing each intermediate value; the natural instinct is to move continuously along the sphere from a top eigenvector to a bottom one and quote the intermediate value theorem, but there is no need to import anything. Mixing a top eigenvector and a bottom eigenvector in the proportion $t : 1-t$ puts weight t on λ_1 and $1-t$ on λ_n, and the weighted average of Example (A diagonal matrix, and the whole chapter in miniature) sweeps the interval as t does.

Proof. By the spectral theorem for matrices — Corollary 11.4.3 over $\mathbb{C}$, Corollary 11.5.2 over $\mathbb{R}$ — there is an orthonormal basis $(\mathbf{q}_1, \dots, \mathbf{q}_n)$ of F^n with $\mathbf{A}\mathbf{q}_i = \lambda_i(\mathbf{A})\mathbf{q}_i$ for every i.

($\subseteq$) Let $\mathbf{x} \neq \mathbf{0}$ and put $\mathbf{u} = \mathbf{x}/\|\mathbf{x}\|$, a unit vector. By the scale invariance established above, $R_{\mathbf{A}}(\mathbf{x}) = R_{\mathbf{A}}(\mathbf{u}) = \langle \mathbf{A}\mathbf{u}, \mathbf{u}\rangle$, which lies in $[\lambda_n(\mathbf{A}), \lambda_1(\mathbf{A})]$ by Lemma 12.5.2.

($\supseteq$) Let $\mu \in [\lambda_n(\mathbf{A}), \lambda_1(\mathbf{A})]$. If $\lambda_1(\mathbf{A}) = \lambda_n(\mathbf{A})$ the interval is the single point $\mu = \lambda_1(\mathbf{A}) = R_{\mathbf{A}}(\mathbf{q}_1)$, and we are done. Otherwise put

$$t = \frac{\mu - \lambda_n(\mathbf{A})}{\lambda_1(\mathbf{A}) - \lambda_n(\mathbf{A})} \in [0, 1], \qquad \mathbf{x} = \sqrt{t}\,\mathbf{q}_1 + \sqrt{1-t}\,\mathbf{q}_n,$$

which is legitimate because the denominator is non-zero and both square roots are of non-negative reals. Note $n \geq 2$ here, since $\lambda_1 \neq \lambda_n$, so $\mathbf{q}_1$ and $\mathbf{q}_n$ are distinct members of an orthonormal list. By Theorem 10.2.1 (c),

$$\|\mathbf{x}\|^2 = t + (1-t) = 1,$$

so in particular $\mathbf{x} \neq \mathbf{0}$. Since $\mathbf{A}\mathbf{x} = \sqrt{t}\,\lambda_1(\mathbf{A})\mathbf{q}_1 + \sqrt{1-t}\,\lambda_n(\mathbf{A})\mathbf{q}_n$, Theorem 10.2.1 (b) gives

$$R_{\mathbf{A}}(\mathbf{x}) = \langle \mathbf{A}\mathbf{x}, \mathbf{x}\rangle = t\,\lambda_1(\mathbf{A}) + (1-t)\,\lambda_n(\mathbf{A}) = \mu,$$

the last equality by the choice of t. So every point of the interval is a value.

For the attainment, $R_{\mathbf{A}}(\mathbf{q}_1) = \lambda_1(\mathbf{A})$ and $R_{\mathbf{A}}(\mathbf{q}_n) = \lambda_n(\mathbf{A})$. This proves the proposition. ∎

So the range is an **interval**, not a finite set, even though $\mathbf{A}$ has at most n eigenvalues. That single fact is responsible for most of the confusion this chapter has to clear up, and the warning below spells out why.

Quick check. For $\mathbf{A} = \operatorname{diag}(6, 3, 0)$, write down two unit vectors with Rayleigh quotient 4, each having one zero coordinate, in different positions.

Solution. Mixing $\mathbf{e}_1$ and $\mathbf{e}_3$ as in the proof: $4 = 6t + 0(1-t)$ gives $t = 2/3$ and $\mathbf{x} = \big(\sqrt{2/3},\, 0,\, \sqrt{1/3}\big)$, for which $R_{\mathbf{A}}(\mathbf{x}) = 6 \cdot \frac{2}{3} + 0 \cdot \frac{1}{3} = 4$. Mixing $\mathbf{e}_1$ and $\mathbf{e}_2$ instead: $4 = 6t + 3(1-t)$ gives $t = 1/3$ and $\mathbf{y} = \big(\sqrt{1/3},\, \sqrt{2/3},\, 0\big)$, for which $R_{\mathbf{A}}(\mathbf{y}) = 6 \cdot \frac{1}{3} + 3 \cdot \frac{2}{3} = 4$. A value of $R_{\mathbf{A}}$ is realized by many vectors, and they need not resemble each other.

16.1.3 Where the quotient is flat

The maximum and the minimum are attained at eigenvectors. There is a converse, and it identifies the eigenvectors among all vectors by a condition that does not mention eigenvalues: they are the places where $R_{\mathbf{A}}$ does not move to first order. Everything needed is one algebraic identity, exact for every t, so no calculus enters.

Proposition 16.1.2 — Critical Points of the Rayleigh Quotient

Let $\mathbf{A} \in M_n(F)$ be Hermitian, let $\mathbf{x} \in F^n$ be a **unit** vector and put $\mu = R_{\mathbf{A}}(\mathbf{x}) = \langle \mathbf{A}\mathbf{x}, \mathbf{x} \rangle$. For every $\mathbf{v} \in F^n$ and every $t \in \mathbb{R}$ with $\mathbf{x} + t\mathbf{v} \neq \mathbf{0}$,

$$R_{\mathbf{A}}(\mathbf{x} + t\mathbf{v}) - \mu = \frac{2t\,\mathrm{Re}\langle \mathbf{A}\mathbf{x} - \mu\mathbf{x}, \mathbf{v} \rangle + t^2\big(\langle \mathbf{A}\mathbf{v}, \mathbf{v} \rangle - \mu\|\mathbf{v}\|^2\big)}{\|\mathbf{x} + t\mathbf{v}\|^2}. \tag{16.1.1}$$

Moreover:

(a) $\mathrm{Re}\langle \mathbf{A}\mathbf{x} - \mu\mathbf{x}, \mathbf{v} \rangle = 0$ for every $\mathbf{v} \in F^n$ **if and only if** $\mathbf{A}\mathbf{x} = \mu\mathbf{x}$; that is, if and only if $\mathbf{x}$ is an eigenvector of $\mathbf{A}$, necessarily for the eigenvalue μ.

(b) If $R_{\mathbf{A}}(\mathbf{x}) \geq R_{\mathbf{A}}(\mathbf{y})$ for every $\mathbf{y} \neq \mathbf{0}$, then the condition in (a) holds. The same is true if $R_{\mathbf{A}}(\mathbf{x}) \leq R_{\mathbf{A}}(\mathbf{y})$ for every $\mathbf{y} \neq \mathbf{0}$.

Idea. Expand the numerator and the denominator of $R_{\mathbf{A}}(\mathbf{x} + t\mathbf{v})$ in powers of t and subtract μ times the denominator from the numerator. The constant terms cancel by the definition of μ, and what is left is exactly Eq. 16.1.1. The coefficient of t is the object of interest: (a) says it vanishes in every direction precisely at eigenvectors, and (b) says that at a maximum it must vanish, since otherwise a small step in the right direction would increase the quotient — the t^2 term cannot interfere, because for small t it is smaller than the t term.

Proof. The identity. Expanding by sesquilinearity,

$$\begin{aligned} \langle \mathbf{A}(\mathbf{x} + t\mathbf{v}), \mathbf{x} + t\mathbf{v} \rangle &= \langle \mathbf{A}\mathbf{x}, \mathbf{x} \rangle + t\langle \mathbf{A}\mathbf{x}, \mathbf{v} \rangle + t\langle \mathbf{A}\mathbf{v}, \mathbf{x} \rangle + t^2\langle \mathbf{A}\mathbf{v}, \mathbf{v} \rangle \\ &= \mu + 2t\,\mathrm{Re}\langle \mathbf{A}\mathbf{x}, \mathbf{v} \rangle + t^2\langle \mathbf{A}\mathbf{v}, \mathbf{v} \rangle, \end{aligned}$$

where the second line used $\langle \mathbf{A}\mathbf{v}, \mathbf{x} \rangle = \langle \mathbf{v}, \mathbf{A}\mathbf{x} \rangle = \overline{\langle \mathbf{A}\mathbf{x}, \mathbf{v} \rangle}$, the first equality because $\mathbf{A}$ is Hermitian and the second by conjugate symmetry (Definition 10.1.1), together with $\langle \mathbf{A}\mathbf{x}, \mathbf{x} \rangle = \mu$ for the unit vector $\mathbf{x}$. The same computation with $\mathbf{A}$ replaced by $\mathbf{I}$, where the constant term is $\|\mathbf{x}\|^2 = 1$, gives

$$\|\mathbf{x} + t\mathbf{v}\|^2 = 1 + 2t\,\mathrm{Re}\langle \mathbf{x}, \mathbf{v} \rangle + t^2\|\mathbf{v}\|^2.$$

Since μ is real, $\mu\,\mathrm{Re}\langle \mathbf{x}, \mathbf{v}\rangle = \mathrm{Re}\langle \mu\mathbf{x}, \mathbf{v}\rangle$. Subtracting $\mu\|\mathbf{x}+t\mathbf{v}\|^2$ from the first display therefore leaves

$$2t\,\mathrm{Re}\langle \mathbf{A}\mathbf{x}-\mu\mathbf{x}, \mathbf{v}\rangle + t^2\big(\langle \mathbf{A}\mathbf{v}, \mathbf{v}\rangle - \mu\|\mathbf{v}\|^2\big),$$

and dividing by $\|\mathbf{x}+t\mathbf{v}\|^2 \neq 0$ gives Eq. 16.1.1.

(a) Put $\mathbf{w} = \mathbf{A}\mathbf{x} - \mu\mathbf{x}$. ($\Leftarrow$) If $\mathbf{A}\mathbf{x} = \mu\mathbf{x}$ then $\mathbf{w} = \mathbf{0}$ and every $\langle \mathbf{w}, \mathbf{v}\rangle$ vanishes. ($\Rightarrow$) Take $\mathbf{v} = \mathbf{w}$: the hypothesis gives $\mathrm{Re}\langle \mathbf{w}, \mathbf{w}\rangle = \|\mathbf{w}\|^2 = 0$, so $\mathbf{w} = \mathbf{0}$ by positive definiteness, that is $\mathbf{A}\mathbf{x} = \mu\mathbf{x}$. Since $\mathbf{x} \neq \mathbf{0}$, this exhibits $\mathbf{x}$ as an eigenvector for the eigenvalue μ.

(b) Suppose $\mathbf{x}$ maximizes $R_{\mathbf{A}}$ and, for a contradiction, that $c \coloneqq 2\,\mathrm{Re}\langle \mathbf{A}\mathbf{x}-\mu\mathbf{x}, \mathbf{v}\rangle \neq 0$ for some $\mathbf{v}$; then $\mathbf{v} \neq \mathbf{0}$. Put $d = \langle \mathbf{A}\mathbf{v}, \mathbf{v}\rangle - \mu\|\mathbf{v}\|^2$, and let t be any real number with

$$0 < |t| < \frac{1}{2\|\mathbf{v}\|}, \qquad |t|\,|d| < \tfrac{1}{2}|c|, \qquad t \text{ of the same sign as } c,$$

which is possible because the two upper bounds are positive. The first bound gives $\|\mathbf{x}+t\mathbf{v}\| \geq \|\mathbf{x}\| - |t|\|\mathbf{v}\| > 1 - \tfrac{1}{2} > 0$, by the triangle inequality (Corollary 10.1.6), so $\mathbf{x}+t\mathbf{v} \neq \mathbf{0}$ and the identity applies. The second gives $|td| < |c|/2$, so $c + td$ has the same sign as c, and hence $t(c+td) > 0$. By Eq. 16.1.1,

$$R_{\mathbf{A}}(\mathbf{x}+t\mathbf{v}) - \mu = \frac{t\,(c+td)}{\|\mathbf{x}+t\mathbf{v}\|^2} > 0,$$

contradicting the maximality of $R_{\mathbf{A}}(\mathbf{x})$. So $c = 0$ for every $\mathbf{v}$. For a minimizer, apply what has just been proved to $-\mathbf{A}$, whose Rayleigh quotient is $-R_{\mathbf{A}}$, so that a minimizer of $R_{\mathbf{A}}$ is a maximizer of $R_{-\mathbf{A}}$; the condition in (a) for $-\mathbf{A}$ and $-\mu$ is the same condition. This proves the proposition.

■

Call a unit vector $\mathbf{x}$ a **critical point** of $R_{\mathbf{A}}$ when the condition in (a) holds, that is, when the coefficient of t in Eq. 16.1.1 vanishes in every direction $\mathbf{v}$ — when $R_{\mathbf{A}}$ moves away from $R_{\mathbf{A}}(\mathbf{x})$ only at second order. Parts (a) and (b) then say: *the critical points of $R_{\mathbf{A}}$ on the unit sphere are exactly the unit eigenvectors of $\mathbf{A}$, the critical values are exactly the eigenvalues, and every maximizer and every minimizer is among them.* That the eigenvalues are all realized as critical values is a direct computation: $R_{\mathbf{A}}(\mathbf{q}_i) = \langle \lambda_i\mathbf{q}_i, \mathbf{q}_i\rangle = \lambda_i$, and each $\mathbf{q}_i$ is a unit eigenvector, hence a critical point by (b).

Remark. A reader who knows calculus will recognize Eq. 16.1.1 as saying that the directional derivative of $R_{\mathbf{A}}$ at a unit vector $\mathbf{x}$ in the direction $\mathbf{v}$ is $2\,\mathrm{Re}\langle \mathbf{A}\mathbf{x}-\mu\mathbf{x}, \mathbf{v}\rangle$, so that "critical point" has its usual meaning of a vanishing gradient. Nothing above uses derivatives: the identity Eq. 16.1.1 is exact for every t, not an approximation, and the argument in (b) compares two explicit numbers. This matters for the accounting in the next remark.

Remark. **The promise from Chapter 11 §02, and what it cost.** Chapter 11 §02 proved that a real self-adjoint operator has an eigenvalue by an algebraic route, and then described the alternative it was declining: "the function $\mathbf{v} \mapsto \langle T\mathbf{v}, \mathbf{v}\rangle$ is real-valued and continuous on the unit sphere of V, which is closed and bounded, so it attains a maximum, and a vector where it does so turns out to be an eigenvector for the largest eigenvalue. That argument is shorter to state but it is analysis, not algebra, and it needs the extreme value theorem; we keep to the algebraic route so that nothing in

this chapter depends on it. The maximization picture returns in Chapter 16, where the Rayleigh quotient and the Courant–Fischer theorem describe every eigenvalue of a self-adjoint operator by optimization."

The picture has now returned, and the account can be settled exactly. The clause "a vector where it does so turns out to be an eigenvector" is Proposition 16.1.2 (b) and (a), and that the eigenvalue is the *largest* one is Proposition 16.1.1; neither invokes an analytic fact. What Chapter 11 would have had to import is only the *existence* of the maximizer, which is the extreme value theorem — fact (A4) of Chapter 15's introduction — applied to a continuous function on the unit sphere, compact by fact (A3). This chapter does not import it, because it does not have to: the spectral theorem is available here and it hands over the maximizer by name, namely $\mathbf{q}_1$, in Proposition 16.1.1. So the optimization description of eigenvalues in this chapter is a **consequence** of the spectral theorem, not an independent proof of it. One honest qualification: the spectral theorem itself rests on the fundamental theorem of algebra, which Chapter 5 §05 proved with the extreme value theorem on a disc. So the analysis is not absent from the foundations — it was spent once, there, and nothing here spends it again. Section 2 completes the promise for the intermediate eigenvalues, on the same terms.

16.1.4 Why the second eigenvalue is not a second maximum

Warning. $\lambda_2(\mathbf{A})$ **is not "the second largest value of $R_{\mathbf{A}}$", and there is no sense in which it could be.** Take $\mathbf{A} = \operatorname{diag}(3, 1, -1)$, so $\lambda_1 = 3$, $\lambda_2 = 1$, $\lambda_3 = -1$. By Proposition 16.1.1 the set of values of $R_{\mathbf{A}}$ is the whole interval $[-1, 3]$. Three things go wrong at once.

- **There is no second largest value.** The values below 3 form the interval $[-1, 3)$, which has no largest element. So the phrase does not describe a number.
- **The value λ_2 is attained, but so is every other value, and not only at eigenvectors.** At $\mathbf{x} = \frac{1}{\sqrt{2}}(1, 0, 1)$ the quotient is $\frac{1}{2}(3) + \frac{1}{2}(-1) = 1 = \lambda_2(\mathbf{A})$, and $\mathbf{x}$ is not an eigenvector of $\mathbf{A}$: it mixes the eigenvectors $\mathbf{e}_1$ and $\mathbf{e}_3$ of the first and the *third* eigenvalues, and λ_2 plays no part in it.
- **Removing a direction does not help by itself.** At $\mathbf{y} = \frac{1}{\sqrt{2}}(1, 1, 0)$, which is orthogonal to the eigenvector $\mathbf{e}_3$ of λ_3, the quotient is $\frac{1}{2}(3) + \frac{1}{2}(1) = 2$, strictly between λ_1 and λ_2. Constraining $\mathbf{x}$ to a subspace changes the answer, and which subspace is everything.

Whatever describes λ_2 must be a maximum over something smaller than the sphere.

The last bullet says what to try. Cutting the sphere down by orthogonality to the top eigenvector does work, and the proof is Example (A diagonal matrix, and the whole chapter in miniature) again, with the top entry removed from the average.

Proposition 16.1.3 — Eigenvalues by Deflation

Let $\mathbf{A} \in M_n(F)$ be Hermitian and let $(\mathbf{q}_1, \dots, \mathbf{q}_n)$ be an orthonormal basis of F^n with

$\mathbf{A}\mathbf{q}_i = \lambda_i(\mathbf{A})\mathbf{q}_i$ for every i. Then for every k with $1 \le k \le n$,

$$\lambda_k(\mathbf{A}) = \max\{R_{\mathbf{A}}(\mathbf{x}) : \mathbf{x} \neq \mathbf{0},\ \mathbf{x} \perp \mathbf{q}_1, \dots, \mathbf{q}_{k-1}\},$$

the maximum being attained at $\mathbf{x} = \mathbf{q}_k$. For $k = 1$ the list of constraints is empty and the statement is Proposition 16.1.1.

Idea. The constraints do one thing: they delete the first $k-1$ coordinates in the eigenbasis. What is left is the weighted average of Example (A diagonal matrix, and the whole chapter in miniature) over the remaining eigenvalues $\lambda_k \ge \cdots \ge \lambda_n$, whose largest member is λ_k.

Proof. Let $W = \{\mathbf{x} \in F^n : \langle \mathbf{x}, \mathbf{q}_i \rangle = 0 \text{ for } 1 \le i \le k-1\}$. By Theorem 10.2.1 (a) every $\mathbf{x} \in F^n$ satisfies $\mathbf{x} = \sum_{i=1}^{n} \langle \mathbf{x}, \mathbf{q}_i \rangle \mathbf{q}_i$, so $\mathbf{x} \in W$ exactly when $\mathbf{x} \in \operatorname{span}(\mathbf{q}_k, \dots, \mathbf{q}_n)$.

Let $\mathbf{x} \in W$ with $\mathbf{x} \neq \mathbf{0}$, and write $c_i = \langle \mathbf{x}, \mathbf{q}_i \rangle$, so that $\mathbf{x} = \sum_{i \ge k} c_i \mathbf{q}_i$. Then $\mathbf{A}\mathbf{x} = \sum_{i \ge k} \lambda_i(\mathbf{A}) c_i \mathbf{q}_i$, and Theorem 10.2.1 (b), (c) give

$$\langle \mathbf{A}\mathbf{x}, \mathbf{x} \rangle = \sum_{i \ge k} \lambda_i(\mathbf{A}) |c_i|^2, \qquad \|\mathbf{x}\|^2 = \sum_{i \ge k} |c_i|^2 > 0.$$

Hence $R_{\mathbf{A}}(\mathbf{x})$ is a weighted average of $\lambda_k(\mathbf{A}), \dots, \lambda_n(\mathbf{A})$ with non-negative weights $|c_i|^2 / \|\mathbf{x}\|^2$ summing to 1. The largest of those eigenvalues is $\lambda_k(\mathbf{A})$, because the list is indexed decreasingly, so $R_{\mathbf{A}}(\mathbf{x}) \le \lambda_k(\mathbf{A})$.

Finally $\mathbf{q}_k \in W$, since the $\mathbf{q}_i$ are orthonormal, and $R_{\mathbf{A}}(\mathbf{q}_k) = \langle \lambda_k(\mathbf{A})\mathbf{q}_k, \mathbf{q}_k \rangle = \lambda_k(\mathbf{A})$. So the bound is attained and the supremum is a maximum. This proves the proposition.

■

Quick check. In Proposition 16.1.3, does the value of the maximum depend on which orthonormal eigenbasis $(\mathbf{q}_1, \dots, \mathbf{q}_n)$ is chosen? Does the *maximizing vector*?

Solution. The value does not: it is $\lambda_k(\mathbf{A})$, a number attached to $\mathbf{A}$ alone. The maximizing vector generally does, and so does the constraint set W. For $\mathbf{A} = \operatorname{diag}(1, 1, 0)$ and $k = 2$, one admissible eigenbasis is $(\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3)$, giving $W = \operatorname{span}(\mathbf{e}_2, \mathbf{e}_3)$ and maximizer $\mathbf{e}_2$; another is $\left(\frac{1}{\sqrt{2}}(1,1,0), \frac{1}{\sqrt{2}}(1,-1,0), \mathbf{e}_3\right)$, giving a different W and the maximizer $\frac{1}{\sqrt{2}}(1,-1,0)$. Both maxima equal $\lambda_2(\mathbf{A}) = 1$.

16.1.5 What is still wrong

Proposition 16.1.3 is a complete answer to the question "what is $\lambda_k(\mathbf{A})$, as an optimization?" and it is nearly useless. The reason is visible in its statement: the constraint set is built from $\mathbf{q}_1, \dots, \mathbf{q}_{k-1}$, which are eigenvectors of $\mathbf{A}$. To use the formula one must already know the eigenvectors, and to know the eigenvectors one must already have solved the problem the formula claims to describe. It is a description of $\lambda_k(\mathbf{A})$ in terms of $\mathbf{A}$'s own answer.

The cost is not merely aesthetic. The whole point of turning an eigenvalue into an optimization is to compare the eigenvalues of **different** matrices: to say that $\mathbf{A} \succeq \mathbf{B}$ forces $\lambda_i(\mathbf{A}) \ge \lambda_i(\mathbf{B})$, or that perturbing $\mathbf{A}$ moves λ_i only a little. A comparison needs the two optimizations to run over

the *same* set. Deflation gives $\lambda_i(\mathbf{A})$ as a maximum over the orthogonal complement of $\mathbf{A}$'s top eigenvectors, and $\lambda_i(\mathbf{B})$ as a maximum over the orthogonal complement of $\mathbf{B}$'s top eigenvectors, and those two subspaces have nothing to do with each other. Nothing can be concluded.

Chapter 12 §12 promised that "Chapter 16 characterizes the eigenvalues of a Hermitian matrix as maxima and minima of $\langle \mathbf{Ax}, \mathbf{x}\rangle$ — at which point the test becomes the theory". Proposition 16.1.1 and Proposition 16.1.3 are the first installment of that, and they show that the promise can be kept. The test has already become a statement about a single number: $\mathbf{A} \succ 0$ exactly when $\lambda_n(\mathbf{A}) = \min_{\mathbf{x}\neq\mathbf{0}} R_{\mathbf{A}}(\mathbf{x})$ is positive, and $\mathbf{A} \succeq 0$ exactly when it is non-negative, which is the eigenvalue criterion of Theorem 12.1.5 and Theorem 12.1.4 read through Proposition 16.1.1. The rest of it is the removal of the eigenvectors from the statement, which §02 achieves by a device that looks extravagant and is exactly right: keep the maximum over a subspace, but let the subspace vary over **all** subspaces of the appropriate dimension, and take the minimum of what comes out.

16.1.6 Exercises

16.1.6.1 A. Check your understanding

Exercise A1.

(a) State Definition 16.1.1, naming both hypotheses, and say what each one is for.

(b) Prove that $R_{\mathbf{A}}(c\mathbf{x}) = R_{\mathbf{A}}(\mathbf{x})$ for every scalar $c \neq 0$, and explain why this makes $R_{\mathbf{A}}$ a function on lines.

(c) Determine whether the following is correct, and justify your answer: if $\mathbf{A} \in M_3(\mathbb{R})$ is symmetric with three distinct eigenvalues, then $R_{\mathbf{A}}$ takes exactly three values.

(d) State Proposition 16.1.3, and say in one sentence why it is not a satisfactory description of $\lambda_k(\mathbf{A})$.

(e) Give a Hermitian $\mathbf{A}$ and a vector $\mathbf{x}$ that is **not** an eigenvector of $\mathbf{A}$ but has $R_{\mathbf{A}}(\mathbf{x})$ equal to an eigenvalue of $\mathbf{A}$.

Solution.

(a) Let F be $\mathbb{R}$ or $\mathbb{C}$ and $\mathbf{A} \in M_n(F)$ Hermitian. For $\mathbf{x} \neq \mathbf{0}$, the Rayleigh quotient is $R_{\mathbf{A}}(\mathbf{x}) = \langle \mathbf{Ax}, \mathbf{x}\rangle / \langle \mathbf{x}, \mathbf{x}\rangle$. Hermitian makes the numerator real (Proposition 10.6.7 (a)) and ties the values to the spectrum; $\mathbf{x} \neq \mathbf{0}$ makes the denominator non-zero (Definition 10.1.1).

(b) $\langle \mathbf{A}(c\mathbf{x}), c\mathbf{x}\rangle = c\overline{c}\langle \mathbf{Ax}, \mathbf{x}\rangle = |c|^2\langle \mathbf{Ax}, \mathbf{x}\rangle$ and likewise $\langle c\mathbf{x}, c\mathbf{x}\rangle = |c|^2\langle \mathbf{x}, \mathbf{x}\rangle$; the factor $|c|^2 \neq 0$ cancels. So $R_{\mathbf{A}}$ is constant on $\{c\mathbf{x} : c \neq 0\}$, the punctured line through $\mathbf{x}$, and its value depends only on which line $\mathbf{x}$ lies on.

(c) Incorrect. By Proposition 16.1.1 the set of values is the whole of the interval $[\lambda_3(\mathbf{A}), \lambda_1(\mathbf{A})]$, which is infinite whenever $\lambda_1(\mathbf{A}) \neq \lambda_3(\mathbf{A})$, and distinct eigenvalues guarantee that.

(d) With $(\mathbf{q}_1, \dots, \mathbf{q}_n)$ an orthonormal eigenbasis ordered so that $\mathbf{Aq}_i = \lambda_i(\mathbf{A})\mathbf{q}_i$, $\lambda_k(\mathbf{A})$ is the maximum of $R_{\mathbf{A}}$ over the non-zero vectors orthogonal to $\mathbf{q}_1, \dots, \mathbf{q}_{k-1}$. It is unsatisfactory because the constraint set is built from eigenvectors of $\mathbf{A}$, so the formula presupposes the answer and cannot compare two different matrices.

(e) $\mathbf{A} = \operatorname{diag}(3, 1, -1)$ and $\mathbf{x} = (1, 0, 1)$: $R_{\mathbf{A}}(\mathbf{x}) = (3 - 1)/2 = 1 = \lambda_2(\mathbf{A})$, while

$\mathbf{Ax} = (3, 0, -1)$ is not a multiple of $\mathbf{x}$. (Any mixture of a top and a bottom eigenvector in the right proportion does the same job.)

16.1.6.2 B. Practice

Exercise B1: Locating four values.

Let

$$\mathbf{A} = \begin{pmatrix} 2 & 2 & 0 \\ 2 & 3 & 2 \\ 0 & 2 & 4 \end{pmatrix} \in M_3(\mathbb{R}).$$

Its eigenvalues are $6, 3, 0$, with eigenvectors $(1, 2, 2)$, $(2, 1, -2)$ and $(2, -2, 1)$ respectively; you may take this as given. Compute $R_{\mathbf{A}}(\mathbf{x})$ for $\mathbf{x} = \mathbf{e}_1$, $\mathbf{x} = (1, 1, 1)$, $\mathbf{x} = (1, 1, 0)$ and $\mathbf{x} = (1, 0, -1)$, and check each value against Proposition 16.1.1. Hence exhibit a non-eigenvector at which $R_{\mathbf{A}}$ equals an eigenvalue.

Solution. The three given vectors are pairwise orthogonal, each of norm 3, so $\mathbf{q}_1 = \frac{1}{3}(1, 2, 2)$, $\mathbf{q}_2 = \frac{1}{3}(2, 1, -2)$, $\mathbf{q}_3 = \frac{1}{3}(2, -2, 1)$ is an orthonormal eigenbasis with $\lambda_1 = 6$, $\lambda_2 = 3$, $\lambda_3 = 0$. By Proposition 16.1.1 every value must lie in $[0, 6]$.

For $\mathbf{x} = \mathbf{e}_1$: $\mathbf{Ae}_1 = (2, 2, 0)$, so $\langle \mathbf{Ax}, \mathbf{x} \rangle = 2$ and $\|\mathbf{x}\|^2 = 1$, giving $R_{\mathbf{A}}(\mathbf{e}_1) = 2$. (This is the diagonal entry a_{11}, as it must be for a standard basis vector.)

For $\mathbf{x} = (1, 1, 1)$: $\mathbf{Ax} = (4, 7, 6)$ and $\langle \mathbf{Ax}, \mathbf{x} \rangle = 4 + 7 + 6 = 17$, while $\|\mathbf{x}\|^2 = 3$; so $R_{\mathbf{A}}(\mathbf{x}) = 17/3 \approx 5.67$.

For $\mathbf{x} = (1, 1, 0)$: $\mathbf{Ax} = (4, 5, 2)$ and $\langle \mathbf{Ax}, \mathbf{x} \rangle = 9$, $\|\mathbf{x}\|^2 = 2$; so $R_{\mathbf{A}}(\mathbf{x}) = 9/2$.

For $\mathbf{x} = (1, 0, -1)$: $\mathbf{Ax} = (2, 0, -4)$ and $\langle \mathbf{Ax}, \mathbf{x} \rangle = 2 + 4 = 6$, $\|\mathbf{x}\|^2 = 2$; so $R_{\mathbf{A}}(\mathbf{x}) = 3$.

All four values lie in $[0, 6]$. The last one equals $\lambda_2(\mathbf{A}) = 3$, yet $\mathbf{A}(1, 0, -1) = (2, 0, -4)$ is not a multiple of $(1, 0, -1)$, so $(1, 0, -1)$ is not an eigenvector. This is the trap of the warning above, in a concrete matrix.

Exercise B2: A prescribed value.

With $\mathbf{A}$ and the orthonormal eigenbasis of Exercise (B1: Locating four values), use the construction in the proof of Proposition 16.1.1 to produce a unit vector $\mathbf{x}$ with $R_{\mathbf{A}}(\mathbf{x}) = 2$. Then find, by mixing $\mathbf{q}_1$ and $\mathbf{q}_2$ in equal proportion, a vector with integer entries whose Rayleigh quotient is $9/2$.

Solution. For the first, $\mu = 2$ with $\lambda_1 = 6$ and $\lambda_3 = 0$ gives $t = (2 - 0)/(6 - 0) = 1/3$, so

$$\mathbf{x} = \sqrt{\tfrac{1}{3}}\,\mathbf{q}_1 + \sqrt{\tfrac{2}{3}}\,\mathbf{q}_3,$$

a unit vector with $R_{\mathbf{A}}(\mathbf{x}) = \frac{1}{3} \cdot 6 + \frac{2}{3} \cdot 0 = 2$.

For the second, $\mathbf{y} = \mathbf{q}_1 + \mathbf{q}_2 = \frac{1}{3}\big((1, 2, 2) + (2, 1, -2)\big) = (1, 1, 0)$, whose Rayleigh quotient is the average $\frac{1}{2}(6) + \frac{1}{2}(3) = 9/2$ — matching the direct computation in Exercise (B1: Locating four values). Equal proportions of two orthonormal eigenvectors give the plain average of their eigenvalues.

Exercise B3: The quotient of a projection.

Let $U = \operatorname{span}\{(1,1,0),(0,0,1)\} \subseteq \mathbb{R}^3$ and let $\mathbf{P}$ be the matrix of the orthogonal projection onto U.

(a) Compute $\mathbf{P}$, and list the eigenvalues of $\mathbf{P}$ with multiplicity.

(b) Compute $R_{\mathbf{P}}(\mathbf{x})$ for $\mathbf{x} = \mathbf{e}_1$, $\mathbf{x} = (1,-1,0)$ and $\mathbf{x} = (1,-1,1)$, and check each against Proposition 16.1.1.

Solution.

(a) The two spanning vectors are orthogonal, of norms $\sqrt{2}$ and 1, so $\mathbf{u}_1 = \frac{1}{\sqrt{2}}(1,1,0)$ and $\mathbf{u}_2 = (0,0,1)$ form an orthonormal basis of U and $\mathbf{P} = \mathbf{u}_1\mathbf{u}_1^{\top} + \mathbf{u}_2\mathbf{u}_2^{\top}$, that is

$$\mathbf{P} = \begin{pmatrix} 1/2 & 1/2 & 0 \\ 1/2 & 1/2 & 0 \\ 0 & 0 & 1 \end{pmatrix}.$$

Its eigenvalues are 1 with multiplicity 2 (on U) and 0 with multiplicity 1 (on $U^{\perp} = \operatorname{span}\{(1,-1,0)\}$), so $\lambda_1 = \lambda_2 = 1$ and $\lambda_3 = 0$.

(b) By Example (Two matrices whose quotient is forced) (b), $R_{\mathbf{P}}(\mathbf{x}) = \|\mathbf{P}\mathbf{x}\|^2/\|\mathbf{x}\|^2$. For $\mathbf{x} = \mathbf{e}_1$: $\mathbf{P}\mathbf{e}_1 = (\tfrac12,\tfrac12,0)$, so $\|\mathbf{P}\mathbf{x}\|^2 = \tfrac12$ and $R_{\mathbf{P}}(\mathbf{e}_1) = \tfrac12$. For $\mathbf{x} = (1,-1,0)$: $\mathbf{P}\mathbf{x} = \mathbf{0}$, so $R_{\mathbf{P}}(\mathbf{x}) = 0$. For $\mathbf{x} = (1,-1,1)$: $\mathbf{P}\mathbf{x} = (0,0,1)$, so $\|\mathbf{P}\mathbf{x}\|^2 = 1$ and $\|\mathbf{x}\|^2 = 3$, giving $R_{\mathbf{P}}(\mathbf{x}) = 1/3$. All three lie in $[\lambda_3, \lambda_1] = [0,1]$, and the middle one attains the lower end, as it must, being a non-zero vector of $U^{\perp}$.

16.1.6.3 C. Going deeper

Exercise C1: Why the quotient estimates eigenvalues so well.

Let $\mathbf{A} \in M_n(F)$ be Hermitian with orthonormal eigenbasis $(\mathbf{q}_1,\dots,\mathbf{q}_n)$, $\mathbf{A}\mathbf{q}_i = \lambda_i(\mathbf{A})\mathbf{q}_i$.

(a) Prove that for every unit vector $\mathbf{x}$,

$$\lambda_1(\mathbf{A}) - R_{\mathbf{A}}(\mathbf{x}) \;\le\; \big(\lambda_1(\mathbf{A}) - \lambda_n(\mathbf{A})\big)\,\|\mathbf{x} - \mathbf{q}_1\|^2.$$

(b) Deduce that if $\|\mathbf{x} - \mathbf{q}_1\| \le \varepsilon$ then $R_{\mathbf{A}}(\mathbf{x})$ approximates $\lambda_1(\mathbf{A})$ with error at most $(\lambda_1 - \lambda_n)\varepsilon^2$: an error in the eigen*vector* of size ε costs only ε^2 in the eigen*value*.

(c) Show that the exponent 2 cannot be improved, by computing both sides for $\mathbf{A} = \operatorname{diag}(1,0)$ and $\mathbf{x} = (\cos\varepsilon, \sin\varepsilon)$.

Hint for (a): expand $\mathbf{x}$ in the eigenbasis and compare the two sums term by term.

Solution.

(a) Write $c_i = \langle \mathbf{x}, \mathbf{q}_i\rangle$, so $\sum_i |c_i|^2 = 1$ by Theorem 10.2.1 (c). As in Proposition 16.1.3, $R_{\mathbf{A}}(\mathbf{x}) = \sum_i \lambda_i(\mathbf{A})|c_i|^2$, so

$$\lambda_1(\mathbf{A}) - R_{\mathbf{A}}(\mathbf{x}) = \sum_{i=1}^{n} \big(\lambda_1(\mathbf{A}) - \lambda_i(\mathbf{A})\big)|c_i|^2 \le \big(\lambda_1(\mathbf{A}) - \lambda_n(\mathbf{A})\big) \sum_{i\ge 2} |c_i|^2,$$

where the $i = 1$ term was dropped because it is 0 and each remaining factor $\lambda_1 - \lambda_i$ was enlarged to $\lambda_1 - \lambda_n$, legitimate since $|c_i|^2 \geq 0$ and the eigenvalues decrease. On the other side, again by Theorem 10.2.1 (c),

$$\|\mathbf{x} - \mathbf{q}_1\|^2 = |c_1 - 1|^2 + \sum_{i \geq 2} |c_i|^2 \;\geq\; \sum_{i \geq 2} |c_i|^2.$$

Combining the two displays gives the inequality.

(b) Immediate from (a), since the right-hand side is increasing in $\|\mathbf{x} - \mathbf{q}_1\|$.

(c) Here $\lambda_1 = 1$, $\lambda_2 = 0$ and $\mathbf{q}_1 = \mathbf{e}_1$. The vector $\mathbf{x} = (\cos\varepsilon, \sin\varepsilon)$ is a unit vector with

$$R_{\mathbf{A}}(\mathbf{x}) = \cos^2\varepsilon, \qquad \lambda_1 - R_{\mathbf{A}}(\mathbf{x}) = \sin^2\varepsilon,$$

while $\|\mathbf{x} - \mathbf{e}_1\|^2 = (\cos\varepsilon - 1)^2 + \sin^2\varepsilon = 2 - 2\cos\varepsilon$. The bound in (a) reads $\sin^2\varepsilon \leq 2 - 2\cos\varepsilon$, which is true, and the ratio of the two sides is

$$\frac{\sin^2\varepsilon}{2 - 2\cos\varepsilon} = \frac{(1 - \cos\varepsilon)(1 + \cos\varepsilon)}{2(1 - \cos\varepsilon)} = \frac{1 + \cos\varepsilon}{2},$$

which tends to 1 as $\varepsilon \to 0$. So the error really is of order ε^2, not smaller, and the constant in (a) is sharp in the limit. This second-order accuracy is why the Rayleigh quotient is the standard way to read an eigenvalue off an approximate eigenvector, and Chapter 23 builds an iteration on it.

Exercise C2: The equality case at the top.

Let $\mathbf{A} \in M_n(F)$ be Hermitian and let $E_{\lambda_1}(\mathbf{A}) = \ker(\mathbf{A} - \lambda_1(\mathbf{A})\mathbf{I})$ be the eigenspace of the largest eigenvalue.

(a) Prove that if $\mathbf{x} \neq \mathbf{0}$ and $R_{\mathbf{A}}(\mathbf{x}) = \lambda_1(\mathbf{A})$, then $\mathbf{x} \in E_{\lambda_1}(\mathbf{A})$.

(b) Deduce that $\{\mathbf{x} \neq \mathbf{0} : R_{\mathbf{A}}(\mathbf{x}) = \lambda_1(\mathbf{A})\} \cup \{\mathbf{0}\} = E_{\lambda_1}(\mathbf{A})$.

(c) Show that the corresponding statement for an intermediate eigenvalue is **false**, by naming a matrix, an index k with $1 < k < n$, and a vector.

Solution.

(a) We may assume $\|\mathbf{x}\| = 1$, by scale invariance and because $E_{\lambda_1}(\mathbf{A})$ is a subspace. Write $c_i = \langle \mathbf{x}, \mathbf{q}_i \rangle$ for an orthonormal eigenbasis as above, so $\sum_i |c_i|^2 = 1$ and $R_{\mathbf{A}}(\mathbf{x}) = \sum_i \lambda_i(\mathbf{A})|c_i|^2$. Then

$$0 = \lambda_1(\mathbf{A}) - R_{\mathbf{A}}(\mathbf{x}) = \sum_{i=1}^{n} \big(\lambda_1(\mathbf{A}) - \lambda_i(\mathbf{A})\big)|c_i|^2,$$

a sum of non-negative terms. Every term is therefore 0, so $c_i = 0$ whenever $\lambda_i(\mathbf{A}) < \lambda_1(\mathbf{A})$. Hence $\mathbf{x} = \sum_{i : \lambda_i = \lambda_1} c_i \mathbf{q}_i$, a combination of eigenvectors for $\lambda_1(\mathbf{A})$, so $\mathbf{x} \in E_{\lambda_1}(\mathbf{A})$.

(b) ($\subseteq$) is (a), together with $\mathbf{0} \in E_{\lambda_1}(\mathbf{A})$. ($\supseteq$) If $\mathbf{0} \neq \mathbf{x} \in E_{\lambda_1}(\mathbf{A})$ then $\mathbf{A}\mathbf{x} = \lambda_1(\mathbf{A})\mathbf{x}$, so $R_{\mathbf{A}}(\mathbf{x}) = \lambda_1(\mathbf{A})\langle \mathbf{x}, \mathbf{x} \rangle / \langle \mathbf{x}, \mathbf{x} \rangle = \lambda_1(\mathbf{A})$.

(c) Take $\mathbf{A} = \operatorname{diag}(3, 1, -1)$, $k = 2$ and $\mathbf{x} = (1, 0, 1)$. Then $R_{\mathbf{A}}(\mathbf{x}) = 1 = \lambda_2(\mathbf{A})$, but $\mathbf{A}\mathbf{x} = (3, 0, -1)$ is not a multiple of $\mathbf{x}$, so $\mathbf{x} \notin E_{\lambda_2}(\mathbf{A}) = \operatorname{span}\{\mathbf{e}_2\}$. The argument

in (a) breaks because the terms $(\lambda_2 - \lambda_i)|c_i|^2$ are no longer all of the same sign: the $i = 1$ term is negative and cancels against the $i = 3$ term instead of forcing both to vanish.

Exercise C3: What the quotient cannot see.

Let $\mathbf{M} \in M_n(F)$ be an arbitrary matrix, not assumed Hermitian, and put

$$\mathbf{A} = \tfrac{1}{2}(\mathbf{M} + \mathbf{M}^*), \qquad \mathbf{B} = \tfrac{1}{2}(\mathbf{M} - \mathbf{M}^*),$$

so that $\mathbf{M} = \mathbf{A} + \mathbf{B}$ with $\mathbf{A}^* = \mathbf{A}$ and $\mathbf{B}^* = -\mathbf{B}$.

(a) Prove that $\mathrm{Re}\langle \mathbf{M}\mathbf{x}, \mathbf{x}\rangle = \langle \mathbf{A}\mathbf{x}, \mathbf{x}\rangle$ for every $\mathbf{x} \in F^n$.

(b) Deduce that over $\mathbb{R}$, the function $\mathbf{x} \mapsto \langle \mathbf{M}\mathbf{x}, \mathbf{x}\rangle$ determines $\mathbf{A}$ and nothing whatever about $\mathbf{B}$. Give two distinct real 2×2 matrices with the same such function.

(c) Over $\mathbb{C}$, determine whether $\langle \mathbf{M}\mathbf{x}, \mathbf{x}\rangle = 0$ for all $\mathbf{x}$ forces $\mathbf{M} = 0$. Justify your answer.

Solution.

(a) By conjugate symmetry and the definition of the adjoint, $\langle \mathbf{M}^*\mathbf{x}, \mathbf{x}\rangle = \langle \mathbf{x}, \mathbf{M}\mathbf{x}\rangle = \overline{\langle \mathbf{M}\mathbf{x}, \mathbf{x}\rangle}$. Hence

$$\langle \mathbf{A}\mathbf{x}, \mathbf{x}\rangle = \tfrac{1}{2}\big(\langle \mathbf{M}\mathbf{x}, \mathbf{x}\rangle + \overline{\langle \mathbf{M}\mathbf{x}, \mathbf{x}\rangle}\big) = \mathrm{Re}\langle \mathbf{M}\mathbf{x}, \mathbf{x}\rangle.$$

(b) Over $\mathbb{R}$ every inner product value is real, so (a) reads $\langle \mathbf{M}\mathbf{x}, \mathbf{x}\rangle = \langle \mathbf{A}\mathbf{x}, \mathbf{x}\rangle$ for all $\mathbf{x}$: the function sees only $\mathbf{A}$. It determines $\mathbf{A}$ completely, since two symmetric matrices with the same quadratic form are equal (Theorem 11.2.5 applied to their difference). It sees nothing of $\mathbf{B}$: for

$$\mathbf{M}_1 = \begin{pmatrix} 0 & 0 \\ 0 & 0 \end{pmatrix}, \qquad \mathbf{M}_2 = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix},$$

both functions are identically 0, since $\langle \mathbf{M}_2\mathbf{x}, \mathbf{x}\rangle = -x_2x_1 + x_1x_2 = 0$, yet $\mathbf{M}_1 \neq \mathbf{M}_2$. This is Exercise (C3: What the real quadratic form does determine) in matrix language.

(c) Yes, over $\mathbb{C}$ it does force $\mathbf{M} = 0$. This is Theorem 11.2.6, and the reason the complex theory is the cleaner one: a complex quadratic form determines its matrix, so nothing is invisible. Concretely, (a) gives $\mathbf{A} = 0$, and applying the hypothesis to $i\mathbf{M}$ — or expanding $\langle \mathbf{M}(\mathbf{x} + \mathbf{y}), \mathbf{x} + \mathbf{y}\rangle$ and $\langle \mathbf{M}(\mathbf{x} + i\mathbf{y}), \mathbf{x} + i\mathbf{y}\rangle$ — kills $\mathbf{B}$ as well. The real 2×2 matrix $\mathbf{M}_2$ of (b) shows that the same statement over $\mathbb{R}$ is false, so this is genuinely a fact about the field.

16.2 The Min–Max Theorem

Section 1 ended with a description of $\lambda_k(\mathbf{A})$ that works and cannot be used: a maximum of the Rayleigh quotient over the orthogonal complement of $\mathbf{A}$'s own top eigenvectors. The defect is that the constraint set is built from the answer. This section repairs it by a move that

looks like an extravagance and is exactly the right one: keep the maximum over a subspace, stop insisting that the subspace be the right one, and let it range over **all** subspaces of the appropriate dimension. The minimum of what comes out is again $\lambda_k(\mathbf{A})$, and no eigenvector appears anywhere in the statement. That is the Courant–Fischer theorem, and everything in the rest of the chapter is a consequence of it.

Throughout, F is $\mathbb{R}$ or $\mathbb{C}$ and every matrix is Hermitian. The eigenvalues of a Hermitian $\mathbf{A} \in M_n(F)$ are real (Theorem 11.2.1) and are **indexed decreasingly**,

$$\lambda_1(\mathbf{A}) \;\geq\; \lambda_2(\mathbf{A}) \;\geq\; \dots \;\geq\; \lambda_n(\mathbf{A}),$$

each repeated according to multiplicity, so that the list has exactly n entries. This is the book's convention, fixed in Chapter 12 §05, and it is used without exception below. Many sources index the theorem of this section the other way round; the remark after the theorem gives that form, once.

16.2.1 Two subspaces that have to meet

One dimension count does all the work in this chapter, and it is worth a label of its own, because four later proofs cite it.

Two subspaces of an n-dimensional space cannot both be large and disjoint: if their dimensions add to more than n, they share a non-zero vector.

Lemma 16.2.1 — Large Subspaces Intersect

Let V be a vector space with $\dim V = n$ over any field, and let U and W be subspaces of V with

$$\dim U + \dim W > n.$$

Then $U \cap W \neq \{\mathbf{0}\}$. More precisely, $\dim(U \cap W) \geq \dim U + \dim W - n$.

Proof. By Theorem 1.7.3,

$$\dim(U + W) = \dim U + \dim W - \dim(U \cap W).$$

Both U and W are finite-dimensional, being subspaces of the n-dimensional V (Theorem 1.6.7); $U + W$ is a subspace of V (Theorem 1.7.1), so the same theorem gives $\dim(U + W) \leq n$, and rearranging gives

$$\dim(U \cap W) \;\geq\; \dim U + \dim W - n,$$

which is > 0 by hypothesis. A subspace of positive dimension contains a non-zero vector. This proves the lemma. ∎

Remark. The bound is sharp, and the hypothesis cannot be weakened to $\dim U + \dim W = n$: two distinct lines in $\mathbb{R}^2$ meet only at $\mathbf{0}$, and so do a line and a plane in $\mathbb{R}^3$ chosen in general position. What makes the count useful is that it needs nothing about the two subspaces beyond their dimensions — in every application below, one of them is a span of eigenvectors that we choose and the other is an arbitrary competitor we know

nothing about.

16.2.2 The quotient on a subspace

Before quantifying over subspaces, we must know that the inner maximum and minimum exist. They do, and for an algebraic reason: restricting the quadratic form to a subspace produces a smaller Hermitian matrix, to which Proposition 16.1.1 applies verbatim.

Lemma 16.2.2 — The Rayleigh Quotient on a Subspace

Let $\mathbf{A} \in M_n(F)$ be Hermitian and let $W \subseteq F^n$ be a subspace with $\dim W = m \geq 1$. Let $\mathbf{Q} \in M_{n\times m}(F)$ be a matrix whose columns form an orthonormal basis of W, and put $\mathbf{B} = \mathbf{Q}^*\mathbf{A}\mathbf{Q} \in M_m(F)$. Then $\mathbf{B}$ is Hermitian and

$$\{R_{\mathbf{A}}(\mathbf{x}) : \mathbf{0} \neq \mathbf{x} \in W\} = [\lambda_m(\mathbf{B}),\ \lambda_1(\mathbf{B})].$$

In particular $\max_{\mathbf{0}\neq\mathbf{x}\in W} R_{\mathbf{A}}(\mathbf{x})$ and $\min_{\mathbf{0}\neq\mathbf{x}\in W} R_{\mathbf{A}}(\mathbf{x})$ exist and are attained.

Idea. Coordinates on W. Writing a vector of W as $\mathbf{Q}\mathbf{c}$ turns $\langle \mathbf{A}\mathbf{x}, \mathbf{x}\rangle$ into $\langle \mathbf{B}\mathbf{c}, \mathbf{c}\rangle$ and, because the columns of $\mathbf{Q}$ are orthonormal, turns $\langle \mathbf{x}, \mathbf{x}\rangle$ into $\langle \mathbf{c}, \mathbf{c}\rangle$ with no distortion. So the Rayleigh quotient of $\mathbf{A}$ on W *is* the Rayleigh quotient of $\mathbf{B}$ on F^m, and Proposition 16.1.1 answers the question there.

Proof. Such a $\mathbf{Q}$ exists: W has an orthonormal basis by Theorem 10.2.2, and we take its members as columns. Orthonormality of the columns says exactly $\mathbf{Q}^*\mathbf{Q} = \mathbf{I}_m$. Then $\mathbf{B}^* = \mathbf{Q}^*\mathbf{A}^*\mathbf{Q} = \mathbf{Q}^*\mathbf{A}\mathbf{Q} = \mathbf{B}$, so $\mathbf{B}$ is Hermitian and Proposition 16.1.1 applies to it.

The map $\mathbf{c} \mapsto \mathbf{Q}\mathbf{c}$ sends F^m onto W, since the columns of $\mathbf{Q}$ span W, and it is injective, since $\mathbf{Q}\mathbf{c} = \mathbf{0}$ gives $\mathbf{c} = \mathbf{Q}^*\mathbf{Q}\mathbf{c} = \mathbf{0}$. So it is a bijection $F^m \to W$ carrying $\mathbf{0}$ to $\mathbf{0}$, hence a bijection from the non-zero vectors of F^m onto those of W. For $\mathbf{c} \neq \mathbf{0}$, writing the standard inner product as $\langle \mathbf{u}, \mathbf{v}\rangle = \mathbf{v}^*\mathbf{u}$,

$$\langle \mathbf{A}\mathbf{Q}\mathbf{c}, \mathbf{Q}\mathbf{c}\rangle = \mathbf{c}^*\mathbf{Q}^*\mathbf{A}\mathbf{Q}\mathbf{c} = \langle \mathbf{B}\mathbf{c}, \mathbf{c}\rangle,$$
$$\langle \mathbf{Q}\mathbf{c}, \mathbf{Q}\mathbf{c}\rangle = \mathbf{c}^*\mathbf{Q}^*\mathbf{Q}\mathbf{c} = \langle \mathbf{c}, \mathbf{c}\rangle,$$

so $R_{\mathbf{A}}(\mathbf{Q}\mathbf{c}) = R_{\mathbf{B}}(\mathbf{c})$. Therefore the two value sets $\{R_{\mathbf{A}}(\mathbf{x}) : \mathbf{0} \neq \mathbf{x} \in W\}$ and $\{R_{\mathbf{B}}(\mathbf{c}) : \mathbf{0} \neq \mathbf{c} \in F^m\}$ are equal, and the second is $[\lambda_m(\mathbf{B}), \lambda_1(\mathbf{B})]$ with both ends attained, by Proposition 16.1.1. This proves the lemma.

■

Remark. **Which analysis was invoked: none.** The existence of a maximum of a function over an infinite set is normally an analytic fact — the set of unit vectors of W is compact, by fact (A3) of Chapter 15's introduction, and $R_{\mathbf{A}}$ is continuous on it, so the extreme value theorem, fact (A4), applies. That route is available and correct. It is not needed. The spectral theorem, already proved in Chapter 11, produces the maximizing vector by name, and Lemma 16.2.2 inherits that. Nothing in this section, or in §01, uses an item of Chapter 15's imported-analysis list. The analysis has not vanished, only

moved: the spectral theorem rests on the fundamental theorem of algebra, whose proof in Chapter 5 §05 uses the extreme value theorem on a closed disc.

16.2.3 Every eigenvalue is a min–max

Theorem 16.2.3 — Courant–Fischer Min–Max Theorem

Let F be $\mathbb{R}$ or $\mathbb{C}$, let $\mathbf{A} \in M_n(F)$ be Hermitian and let $1 \le k \le n$. Then

$$\begin{aligned} \lambda_k(\mathbf{A}) &= \min_{\dim W = n-k+1} \ \max_{\mathbf{0} \neq \mathbf{x} \in W} R_{\mathbf{A}}(\mathbf{x}) \\ &= \max_{\dim W = k} \ \min_{\mathbf{0} \neq \mathbf{x} \in W} R_{\mathbf{A}}(\mathbf{x}), \end{aligned}$$

where in each line W runs over **all** subspaces of F^n of the stated dimension. All four extrema are attained.

Idea. Read the second line first, because it is the one with a slogan: *λ_k is the best value you can guarantee on a k-dimensional subspace.* On a k-dimensional subspace the quotient has a smallest value, which is what that subspace guarantees; the span of the top k eigenvectors guarantees λ_k, and no other k-dimensional subspace guarantees more.

The proof is three steps, and the first two have entirely different characters. **Step 1** exhibits a **witness** subspace and computes on it, giving one inequality. **Step 2** takes an **arbitrary** competitor subspace and shows it cannot beat the witness; the only thing known about a competitor is its dimension, so the only available tool is Lemma 16.2.1, which forces the competitor to meet a span of eigenvectors from the other end of the list. On that shared non-zero vector the quotient is pinned, and the inequality follows. **Step 3** obtains the second line from the first by applying it to $-\mathbf{A}$, which reverses the order of the eigenvalues and turns every maximum into a minimum.

Proof. By Corollary 11.4.3 over $\mathbb{C}$, or Corollary 11.5.2 over $\mathbb{R}$, fix an orthonormal basis $(\mathbf{q}_1, \dots, \mathbf{q}_n)$ of F^n with $\mathbf{A}\mathbf{q}_i = \lambda_i(\mathbf{A})\mathbf{q}_i$ for every i. Abbreviate $\lambda_i = \lambda_i(\mathbf{A})$ and put

$$U_j = \operatorname{span}(\mathbf{q}_1, \dots, \mathbf{q}_j), \qquad L_j = \operatorname{span}(\mathbf{q}_j, \dots, \mathbf{q}_n),$$

so that $\dim U_j = j$ and $\dim L_j = n - j + 1$, the lists being orthonormal and hence independent. By Lemma 16.2.2 the inner extrema below all exist.

> *Claim.* For every j: $R_{\mathbf{A}}(\mathbf{x}) \ge \lambda_j$ for all $\mathbf{0} \neq \mathbf{x} \in U_j$, and $R_{\mathbf{A}}(\mathbf{x}) \le \lambda_j$ for all $\mathbf{0} \neq \mathbf{x} \in L_j$. Both bounds are attained at $\mathbf{q}_j$.

Proof. Let $\mathbf{0} \neq \mathbf{x} \in U_j$ and write $c_i = \langle \mathbf{x}, \mathbf{q}_i \rangle$, so $\mathbf{x} = \sum_{i \leq j} c_i \mathbf{q}_i$ by Theorem 10.2.1 (a) and the definition of U_j. Then $\mathbf{A}\mathbf{x} = \sum_{i \leq j} \lambda_i c_i \mathbf{q}_i$, and Theorem 10.2.1 (b), (c) give

$$R_{\mathbf{A}}(\mathbf{x}) = \frac{\sum_{i \leq j} \lambda_i |c_i|^2}{\sum_{i \leq j} |c_i|^2},$$

a weighted average of $\lambda_1, \dots, \lambda_j$ with non-negative weights summing to 1. Since the list is indexed decreasingly, the smallest of those eigenvalues is λ_j, so the average is $\geq \lambda_j$. The statement for L_j is Proposition 16.1.3: L_j is precisely the set of vectors orthogonal to $\mathbf{q}_1, \dots, \mathbf{q}_{j-1}$, and the maximum of $R_{\mathbf{A}}$ there is λ_j. In both cases $R_{\mathbf{A}}(\mathbf{q}_j) = \lambda_j$.

■

Step 1. The witness for the first line. For each subspace W of dimension $n-k+1$ write $f(W) = \max_{\mathbf{0} \neq \mathbf{x} \in W} R_{\mathbf{A}}(\mathbf{x})$, which exists by Lemma 16.2.2. The outer minimum of f over all such W is not yet known to exist — there are infinitely many W — so we show that λ_k is a value of f and a lower bound for all its values; it is then the least value, which is what the minimum means. For the first half take $W = L_k$, of dimension $n-k+1$: by the claim, $f(L_k) = \lambda_k$.

Step 2. Every competitor is at least as large. Let $W \subseteq F^n$ be any subspace with $\dim W = n-k+1$. Then

$$\dim W + \dim U_k = (n-k+1) + k = n+1 > n,$$

so by Lemma 16.2.1 there is a vector $\mathbf{x} \neq \mathbf{0}$ lying in $W \cap U_k$. Being in U_k, it satisfies $R_{\mathbf{A}}(\mathbf{x}) \geq \lambda_k$ by the claim; being in W, it is one of the vectors the inner maximum ranges over. Therefore

$$\max_{\mathbf{0} \neq \mathbf{y} \in W} R_{\mathbf{A}}(\mathbf{y}) \;\geq\; R_{\mathbf{A}}(\mathbf{x}) \;\geq\; \lambda_k.$$

This holds for every competitor W, so $f(W) \geq \lambda_k$ for all of them. With Step 1, λ_k is a value of f and a lower bound for every value, so it is the least value: the minimum exists, equals λ_k, and is attained at $W = L_k$. This proves the first line.

Step 3. The second line, from the first applied to $-\mathbf{A}$. The matrix $-\mathbf{A}$ is Hermitian, its eigenvalues are the numbers $-\lambda_i$, and sorting those decreasingly reverses the list:

$$\lambda_j(-\mathbf{A}) = -\lambda_{n+1-j}(\mathbf{A}) \qquad (1 \leq j \leq n).$$

Also $R_{-\mathbf{A}}(\mathbf{x}) = -R_{\mathbf{A}}(\mathbf{x})$ for every $\mathbf{x} \neq \mathbf{0}$, directly from the definition. Since negation turns a maximum of a set of reals into the minimum of the negated set, and a minimum into a maximum,

$$\max_{\mathbf{0} \neq \mathbf{x} \in W} R_{-\mathbf{A}}(\mathbf{x}) = -\min_{\mathbf{0} \neq \mathbf{x} \in W} R_{\mathbf{A}}(\mathbf{x}),$$
$$\min_{\dim W = m} \big(-f(W)\big) = -\max_{\dim W = m} f(W)$$

for any real-valued f on subspaces, where each side exists exactly when the other does. Apply the first line, already proved, to $-\mathbf{A}$ with index j:

$$-\lambda_{n+1-j}(\mathbf{A}) = \lambda_j(-\mathbf{A}) = \min_{\dim W = n-j+1} \max_{\mathbf{0} \neq \mathbf{x} \in W} R_{-\mathbf{A}}(\mathbf{x})$$
$$= -\max_{\dim W = n-j+1} \min_{\mathbf{0} \neq \mathbf{x} \in W} R_{\mathbf{A}}(\mathbf{x}).$$

Now substitute $j = n + 1 - k$, so that $n - j + 1 = k$ and $n + 1 - j = k$. Multiplying by -1 gives

$$\lambda_k(\mathbf{A}) = \max_{\dim W = k} \min_{\mathbf{0} \neq \mathbf{x} \in W} R_{\mathbf{A}}(\mathbf{x}),$$

with the maximum attained, the attainment transported from Step 1 by the same negation; explicitly it occurs at $W = U_k$, which is the subspace L_{n+1-k} of the eigenbasis of $-\mathbf{A}$ taken in its own decreasing order. This proves the theorem.

■

The theorem removes the eigenvectors from the description of $\lambda_k(\mathbf{A})$. What is left mentions only $\mathbf{A}$, through $R_{\mathbf{A}}$, and the subspaces of F^n, which are the same for every matrix. Two Hermitian matrices of the same size can therefore be compared term by term, and that is the whole reason this chapter exists.

Remark. **The increasing-index form.** If the eigenvalues are listed *increasingly* as $\mu_1 \leq \mu_2 \leq \cdots \leq \mu_n$, then $\mu_j = \lambda_{n+1-j}(\mathbf{A})$, and substituting $k = n + 1 - j$ in Theorem 16.2.3 turns it into

$$\begin{aligned} \mu_j &= \min_{\dim W = j} \max_{\mathbf{0} \neq \mathbf{x} \in W} R_{\mathbf{A}}(\mathbf{x}) \\ &= \max_{\dim W = n-j+1} \min_{\mathbf{0} \neq \mathbf{x} \in W} R_{\mathbf{A}}(\mathbf{x}). \end{aligned}$$

The pairing of min max with max min is unchanged; only the dimensions move. Many books state the theorem this way, so a reader comparing sources should check which convention is in force before comparing formulas. This book uses the decreasing one everywhere, and this is the only place the other appears.

Warning. **Both the order of the two extrema and the dimension attached to each are load-bearing.** Neither

$$\max_{\dim W = n-k+1} \min_{\mathbf{0} \neq \mathbf{x} \in W} R_{\mathbf{A}}(\mathbf{x}) \qquad \text{nor} \qquad \min_{\dim W = k} \max_{\mathbf{0} \neq \mathbf{x} \in W} R_{\mathbf{A}}(\mathbf{x})$$

equals $\lambda_k(\mathbf{A})$. Each of them is, by Theorem 16.2.3 itself, equal to $\lambda_{n+1-k}(\mathbf{A})$: the first is the second line of the theorem at index $n - k + 1$, and the second is the first line at the index j with $n - j + 1 = k$, namely $j = n - k + 1$. So swapping either the order or the dimension returns the eigenvalue counted from the *other end* of the list.

For a witness take $\mathbf{A} = \operatorname{diag}(2, 0)$ and $k = 1$, so that $\lambda_1(\mathbf{A}) = 2$. The first false expression maximizes over the single subspace $W = F^2$ the minimum of $R_{\mathbf{A}}$, which is 0. The second minimizes over lines the maximum on the line, which is the value of $R_{\mathbf{A}}$ on that line, and the smallest such value is again 0. Both return $\lambda_2(\mathbf{A}) = 0$ instead of 2. The mistake is invisible when $n = 2k - 1$, since then $n + 1 - k = k$, and this is exactly why it survives in the wild.

Quick check. In the first line of Theorem 16.2.3, why is the dimension $n - k + 1$ rather than k? Check your reason against $k = 1$.

Solution. The competitor W must be forced to meet $U_k = \operatorname{span}(\mathbf{q}_1, \ldots, \mathbf{q}_k)$, which has dimension k; by Lemma 16.2.1 that needs $\dim W > n - k$, and $n - k + 1$ is the smallest such dimension. It must not be larger either: competitors of dimension $n - k + 2$ would be forced to meet U_{k-1} as well, and by the theorem itself the min–max over them is $\lambda_{k-1}(\mathbf{A})$, the wrong eigenvalue.

At $k = 1$ the dimension is $n - 1 + 1 = n$, so the only competitor is $W = F^n$, and the statement reads $\lambda_1(\mathbf{A}) = \max_{\mathbf{x}\neq\mathbf{0}} R_{\mathbf{A}}(\mathbf{x})$, which is Proposition 16.1.1. With the dimension $k = 1$ instead, we would be computing min over lines of the single value of $R_{\mathbf{A}}$ on the line, which is $\lambda_n(\mathbf{A})$ — the wrong end.

Example. (Both forms on one matrix)

Let

$$\mathbf{A} = \begin{pmatrix} 2 & 2 & 0 \\ 2 & 3 & 2 \\ 0 & 2 & 4 \end{pmatrix} \in M_3(\mathbb{R}),$$

whose eigenvalues are $6, 3, 0$, with orthonormal eigenvectors

$$\mathbf{q}_1 = \tfrac{1}{3}(1, 2, 2), \qquad \mathbf{q}_2 = \tfrac{1}{3}(2, 1, -2), \qquad \mathbf{q}_3 = \tfrac{1}{3}(2, -2, 1).$$

Verify both lines of Theorem 16.2.3 for $k = 2$ by computing the witness and two competitors in each case.

Solution. Throughout we use Lemma 16.2.2: for a subspace W with orthonormal basis the columns of $\mathbf{Q}$, the values of $R_{\mathbf{A}}$ on W fill the interval between the smallest and largest eigenvalues of the 2×2 matrix $\mathbf{B} = \mathbf{Q}^{\top}\mathbf{A}\mathbf{Q}$.

Max–min form, $\dim W = k = 2$. The witness is $U_2 = \operatorname{span}(\mathbf{q}_1, \mathbf{q}_2)$; since $\mathbf{q}_1, \mathbf{q}_2$ are eigenvectors, $\mathbf{B} = \operatorname{diag}(6, 3)$ and the minimum of $R_{\mathbf{A}}$ on U_2 is $3 = \lambda_2(\mathbf{A})$. Two competitors:

- $W = \operatorname{span}(\mathbf{e}_1, \mathbf{e}_2)$, where $\mathbf{B}$ is the top-left 2×2 block $\left(\begin{smallmatrix} 2 & 2 \\ 2 & 3 \end{smallmatrix}\right)$, with eigenvalues $\frac{1}{2}(5 \pm \sqrt{17})$. Its minimum is $\frac{1}{2}(5 - \sqrt{17}) \approx 0.438$, well below 3.
- $W = \operatorname{span}(\mathbf{e}_1, \mathbf{e}_3)$, where $\mathbf{B} = \operatorname{diag}(2, 4)$ because $a_{13} = 0$. Its minimum is 2, again below 3.

Min–max form, $\dim W = n - k + 1 = 2$ as well, since $n = 3$. The witness is $L_2 = \operatorname{span}(\mathbf{q}_2, \mathbf{q}_3)$, where $\mathbf{B} = \operatorname{diag}(3, 0)$ and the maximum is $3 = \lambda_2(\mathbf{A})$. The same two competitors now go the other way:

- on $\operatorname{span}(\mathbf{e}_1, \mathbf{e}_2)$ the maximum is $\frac{1}{2}(5 + \sqrt{17}) \approx 4.562 > 3$;
- on $\operatorname{span}(\mathbf{e}_1, \mathbf{e}_3)$ the maximum is $4 > 3$.

So each competitor overshoots in the min–max form and undershoots in the max–min form, and the two witnesses pin $\lambda_2(\mathbf{A}) = 3$ from both sides. Notice that the competitor $\operatorname{span}(\mathbf{e}_1, \mathbf{e}_2)$ is the coordinate plane obtained by deleting the third row and column, and its two eigenvalues $0.438\ldots$ and $4.562\ldots$ are caught between consecutive eigenvalues $0 \le 0.438 \le 3 \le 4.562 \le 6$ of $\mathbf{A}$. That is no accident; it is the interlacing theorem of §04.

16.2.4 The two debts this pays at once

Corollary 16.2.4 — The Loewner Order Compares Every Eigenvalue

Let $\mathbf{A}, \mathbf{B} \in M_n(F)$ be Hermitian with $\mathbf{A} \succeq \mathbf{B}$. Then

$$\lambda_i(\mathbf{A}) \;\geq\; \lambda_i(\mathbf{B}) \qquad \text{for every } i = 1, \dots, n.$$

Idea. $\mathbf{A} \succeq \mathbf{B}$ says the Rayleigh quotient of $\mathbf{A}$ sits above that of $\mathbf{B}$ at every vector. Courant–Fischer builds each λ_i out of the Rayleigh quotient by a minimum and then a maximum, and both operations preserve "everywhere above". So the domination passes straight through to every eigenvalue.

Proof. By Definition 12.5.1, $\mathbf{A} \succeq \mathbf{B}$ means $\mathbf{A} - \mathbf{B} \succeq 0$, so $\langle (\mathbf{A} - \mathbf{B})\mathbf{x}, \mathbf{x} \rangle \geq 0$ for every $\mathbf{x}$. Dividing by $\langle \mathbf{x}, \mathbf{x} \rangle > 0$ for $\mathbf{x} \neq \mathbf{0}$,

$$R_{\mathbf{A}}(\mathbf{x}) \;\geq\; R_{\mathbf{B}}(\mathbf{x}) \qquad \text{for every } \mathbf{x} \neq \mathbf{0}.$$

Fix i and let W be any subspace of F^n with $\dim W = i$. Let $\mathbf{x}_1 \in W \setminus \{\mathbf{0}\}$ attain $\min_{\mathbf{0} \neq \mathbf{x} \in W} R_{\mathbf{A}}(\mathbf{x})$, which exists by Lemma 16.2.2. Then

$$\min_{\mathbf{0} \neq \mathbf{x} \in W} R_{\mathbf{A}}(\mathbf{x}) = R_{\mathbf{A}}(\mathbf{x}_1) \;\geq\; R_{\mathbf{B}}(\mathbf{x}_1) \;\geq\; \min_{\mathbf{0} \neq \mathbf{x} \in W} R_{\mathbf{B}}(\mathbf{x}).$$

So the function $W \mapsto \min_{\mathbf{0} \neq \mathbf{x} \in W} R_{\mathbf{A}}(\mathbf{x})$ dominates the corresponding function for $\mathbf{B}$ at every W, and therefore so do their maxima over the subspaces of dimension i. By Theorem 16.2.3 applied to $\mathbf{A}$ and to $\mathbf{B}$, those maxima are $\lambda_i(\mathbf{A})$ and $\lambda_i(\mathbf{B})$. This proves the corollary.

■

Example. (Checking the corollary on a pair)

Let $\mathbf{A} = \left(\begin{smallmatrix} 4 & 1 \\ 1 & 3 \end{smallmatrix}\right)$ and $\mathbf{B} = \left(\begin{smallmatrix} 2 & 1 \\ 1 & 2 \end{smallmatrix}\right)$. Then $\mathbf{A} - \mathbf{B} = \operatorname{diag}(2, 1)$, which is positive semidefinite, so $\mathbf{A} \succeq \mathbf{B}$. The eigenvalues of $\mathbf{B}$ are 3 and 1, from trace 4 and determinant 3; those of $\mathbf{A}$ are $\frac{7 \pm \sqrt{5}}{2} \approx 4.618,\ 2.382$, from trace 7 and determinant 11. So $\lambda_1(\mathbf{A}) \approx 4.618 \geq 3 = \lambda_1(\mathbf{B})$ and $\lambda_2(\mathbf{A}) \approx 2.382 \geq 1 = \lambda_2(\mathbf{B})$, as the corollary demands. Note that the two gaps, $\frac{1+\sqrt{5}}{2} \approx 1.618$ and $\frac{5-\sqrt{5}}{2} \approx 1.382$, are different: the corollary orders the eigenvalues, and says nothing about moving them by the same amount.

This settles an account opened in Chapter 12 §05. Discussing Theorem 12.5.3 (b), which proved only $\lambda_1(\mathbf{A}) \geq \lambda_1(\mathbf{B})$ and $\lambda_n(\mathbf{A}) \geq \lambda_n(\mathbf{B})$, that section said: "The full statement is that $\lambda_i(\mathbf{A}) \geq \lambda_i(\mathbf{B})$ for **every** i, not only for $i = 1$ and $i = n$; but the intermediate eigenvalues have no description as a plain maximum over the whole unit sphere, and the min–max description that does the job is the Courant–Fischer theorem of Chapter 16." Corollary 16.2.4 is that full statement, and the diagnosis was exact: what was missing was not an extra trick but a description of λ_i that two different matrices could be measured against. The proof above is short, and all of its weight is carried by Theorem 16.2.3.

Corollary 16.2.5 — Courant–Fischer for a Self-Adjoint Operator

Let V be a finite-dimensional inner product space over $F = \mathbb{R}$ or $F = \mathbb{C}$, with $\dim V = n \geq 1$, and let $T \in \mathcal{L}(V)$ be self-adjoint, with eigenvalues $\lambda_1(T) \geq \cdots \geq \lambda_n(T)$ repeated according to multiplicity. Then for every k with $1 \leq k \leq n$,

$$\lambda_k(T) = \min_{\dim U = n-k+1} \max_{\mathbf{0} \neq \mathbf{v} \in U} \frac{\langle T\mathbf{v}, \mathbf{v} \rangle}{\langle \mathbf{v}, \mathbf{v} \rangle} = \max_{\dim U = k} \min_{\mathbf{0} \neq \mathbf{v} \in U} \frac{\langle T\mathbf{v}, \mathbf{v} \rangle}{\langle \mathbf{v}, \mathbf{v} \rangle},$$

where U runs over the subspaces of V of the stated dimension.

Idea. Transport the theorem along coordinates. An orthonormal basis of eigenvectors turns V into F^n without changing any inner product, turns T into a real diagonal matrix, and matches subspaces with subspaces of the same dimension. There is nothing to prove beyond checking that each of those three things is true.

Proof. By Proposition 10.6.7 (c) a self-adjoint operator is normal, so Theorem 11.4.2 over $\mathbb{C}$, and Theorem 11.5.1 over $\mathbb{R}$, give an orthonormal basis $\mathcal{E} = (\mathbf{e}_1, \dots, \mathbf{e}_n)$ of V consisting of eigenvectors of T; relabel it so that $T\mathbf{e}_i = \lambda_i(T)\mathbf{e}_i$ with the eigenvalues in decreasing order, which is possible because they are real by Theorem 11.2.1. In particular the eigenvalue list of T, repeated according to multiplicity, has exactly n entries.

Let $\Phi \colon V \to F^n$, $\Phi(\mathbf{v}) = [\mathbf{v}]_{\mathcal{E}}$, be the coordinate map, an isomorphism by Corollary 3.5.5. By Theorem 10.2.1 (b), $\langle \Phi\mathbf{u}, \Phi\mathbf{v} \rangle = \langle \mathbf{u}, \mathbf{v} \rangle$ for all $\mathbf{u}, \mathbf{v} \in V$, so Φ is an isometric isomorphism in the sense of Corollary 10.2.4. Put $\mathbf{A} = [T]_{\mathcal{E}}^{\mathcal{E}} = \operatorname{diag}(\lambda_1(T), \dots, \lambda_n(T))$, a real diagonal matrix, hence Hermitian, with $\lambda_i(\mathbf{A}) = \lambda_i(T)$ for every i. By Theorem 3.6.1, $\Phi(T\mathbf{v}) = \mathbf{A}\,\Phi(\mathbf{v})$.

Consequently, for $\mathbf{v} \neq \mathbf{0}$,

$$\frac{\langle T\mathbf{v}, \mathbf{v} \rangle}{\langle \mathbf{v}, \mathbf{v} \rangle} = \frac{\langle \mathbf{A}\Phi\mathbf{v}, \Phi\mathbf{v} \rangle}{\langle \Phi\mathbf{v}, \Phi\mathbf{v} \rangle} = R_{\mathbf{A}}(\Phi\mathbf{v}),$$

and $\Phi\mathbf{v} \neq \mathbf{0}$ because Φ is injective. Finally $U \mapsto \Phi(U)$ is a bijection from the subspaces of V to the subspaces of F^n preserving dimension, by Theorem 3.5.2, and it matches the non-zero vectors of U with those of $\Phi(U)$. So each of the two displayed expressions equals the corresponding expression for $\mathbf{A}$ in Theorem 16.2.3, which is $\lambda_k(\mathbf{A}) = \lambda_k(T)$. This proves the corollary. ∎

This is the statement Chapter 11 §02 promised when it wrote that "the maximization picture returns in Chapter 16, where the Rayleigh quotient and the Courant–Fischer theorem describe every eigenvalue of a self-adjoint operator by optimization". The picture has returned and the description is complete: every eigenvalue, not merely the extreme two, and stated for an operator on an abstract inner product space, which is the setting Chapter 11 worked in. The remark in §01 records what it cost — nothing. Chapter 11 declined the maximization route because it would have needed the extreme value theorem to know that a maximum exists; here the spectral theorem supplies the maximizing vectors explicitly, so the min–max description is a *consequence* of Chapter 11 rather than an alternative to it, and no analysis has been imported.

What has been bought is comparison. Two Hermitian matrices are now comparable eigenvalue by eigenvalue whenever their Rayleigh quotients are comparable vector by vector, and Corollary 16.2.4 is the first instance. Section 3 takes the same idea and applies it to $\mathbf{A}$ and $\mathbf{A}+\mathbf{E}$, where the quotients differ by at most $\|\mathbf{E}\|_2$, and gets the perturbation bound that Chapter 15 could not state.

16.2.5 Exercises

16.2.5.1 A. Check your understanding

Exercise A1.

(a) State both lines of Theorem 16.2.3, being careful about which dimension goes with which line.

(b) State Lemma 16.2.1, and say at which point of the proof of Theorem 16.2.3 it is used and what it is used on.

(c) Determine whether the following is correct, and justify your answer: $\lambda_k(\mathbf{A}) = \min_{\dim W = k} \max_{\mathbf{0}\neq\mathbf{x}\in W} R_{\mathbf{A}}(\mathbf{x})$.

(d) Write the first line of Theorem 16.2.3 in the increasing-index convention $\mu_1 \le \cdots \le \mu_n$.

(e) Explain in one or two sentences why Theorem 12.5.3 (b) could not be extended to intermediate eigenvalues by the argument Chapter 12 used, and what Theorem 16.2.3 supplies instead.

Solution.

(a) For Hermitian $\mathbf{A} \in M_n(F)$ and $1 \le k \le n$: $\lambda_k(\mathbf{A}) = \min \max$ over subspaces of dimension $n-k+1$ of the Rayleigh quotient, and $= \max \min$ over subspaces of dimension k. The large dimension goes with the minimum of maxima; the small one with the maximum of minima.

(b) If U, W are subspaces of an n-dimensional space with $\dim U + \dim W > n$, then $U \cap W \neq \{\mathbf{0}\}$. It is used in Step 2, applied to an arbitrary competitor W of dimension $n-k+1$ and the span U_k of the top k eigenvectors, whose dimensions add to $n+1$.

(c) Incorrect. By Theorem 16.2.3 itself, that expression is the first line evaluated at the index j with $n-j+1=k$, so it equals $\lambda_{n-k+1}(\mathbf{A})$. For $\mathbf{A}=\operatorname{diag}(2,0)$ and $k=1$ it returns 0, not $\lambda_1(\mathbf{A})=2$.

(d) $\mu_j = \min_{\dim W = j} \max_{\mathbf{0}\neq\mathbf{x}\in W} R_{\mathbf{A}}(\mathbf{x})$, obtained by setting $k = n+1-j$.

(e) Chapter 12's argument evaluated the quadratic form at a vector that is extremal for the *other* matrix, which works only when the extremal vector is characterized by a plain maximum over the whole sphere — true for λ_1 and λ_n and for no other index, since the range of $R_{\mathbf{A}}$ is an interval (Proposition 16.1.1). Theorem 16.2.3 supplies a description of every λ_i as an optimization over a family of subspaces that does not depend on the matrix, so the same subspace can be fed to both matrices; that is exactly what the proof of Corollary 16.2.4 does.

16.2.5.2 B. Practice

Exercise B1: Both forms on a diagonal matrix.

Let $\mathbf{A} = \operatorname{diag}(5, 2, -1) \in M_3(\mathbb{R})$ and $k = 2$.

(a) Give the witness subspace for the max–min form, compute the minimum of $R_{\mathbf{A}}$ on it, and check the value against Theorem 16.2.3.

(b) Do the same for the min–max form.

(c) Put $\mathbf{u} = \frac{1}{\sqrt{2}}(0, 1, 1)$. Compute the minimum of $R_{\mathbf{A}}$ over the non-zero vectors of $\operatorname{span}(\mathbf{e}_1, \mathbf{u})$, and over those of $\operatorname{span}(\mathbf{e}_2, \mathbf{e}_3)$, and verify that neither subspace beats the witness in (a).

Solution.

(a) The eigenvalues are $\lambda_1 = 5$, $\lambda_2 = 2$, $\lambda_3 = -1$ with eigenvectors $\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3$. The witness is $U_2 = \operatorname{span}(\mathbf{e}_1, \mathbf{e}_2)$, of dimension $k = 2$. There $\mathbf{B} = \operatorname{diag}(5, 2)$, so by Lemma 16.2.2 the values of $R_{\mathbf{A}}$ fill $[2, 5]$ and the minimum is $2 = \lambda_2(\mathbf{A})$.

(b) Here $n - k + 1 = 2$ as well, and the witness is $L_2 = \operatorname{span}(\mathbf{e}_2, \mathbf{e}_3)$, where $\mathbf{B} = \operatorname{diag}(2, -1)$; the values fill $[-1, 2]$ and the maximum is $2 = \lambda_2(\mathbf{A})$.

(c) For $W = \operatorname{span}(\mathbf{e}_1, \mathbf{u})$ the two spanning vectors are orthonormal, and

$$\mathbf{B} = \begin{pmatrix} 5 & 0 \\ 0 & \frac{1}{2}(2-1) \end{pmatrix} = \operatorname{diag}\left(5, \tfrac{1}{2}\right),$$

the off-diagonal entry vanishing because $\mathbf{A}\mathbf{e}_1 = 5\mathbf{e}_1$ is orthogonal to $(0, 1, 1)$. So the minimum is $\frac{1}{2} < 2$. For $W = \operatorname{span}(\mathbf{e}_2, \mathbf{e}_3)$ we get $\mathbf{B} = \operatorname{diag}(2, -1)$ and minimum $-1 < 2$. Neither competitor reaches $\lambda_2(\mathbf{A}) = 2$, as Theorem 16.2.3 requires.

Exercise B2: Shifting by a multiple of the identity.

Let $\mathbf{A} \in M_n(F)$ be Hermitian and let $c \in \mathbb{R}$. Prove that $\lambda_k(\mathbf{A} + c\mathbf{I}) = \lambda_k(\mathbf{A}) + c$ for every k, using the first line of Theorem 16.2.3 for both matrices.

Solution. The matrix $\mathbf{A} + c\mathbf{I}$ is Hermitian, since c is real. For every $\mathbf{x} \neq \mathbf{0}$,

$$R_{\mathbf{A}+c\mathbf{I}}(\mathbf{x}) = \frac{\langle \mathbf{A}\mathbf{x}, \mathbf{x} \rangle + c\langle \mathbf{x}, \mathbf{x} \rangle}{\langle \mathbf{x}, \mathbf{x} \rangle} = R_{\mathbf{A}}(\mathbf{x}) + c.$$

Adding a constant to a real-valued function adds it to every maximum and every minimum of that function over any non-empty set. So for each subspace W,

$$\max_{\mathbf{0} \neq \mathbf{x} \in W} R_{\mathbf{A}+c\mathbf{I}}(\mathbf{x}) = \left(\max_{\mathbf{0} \neq \mathbf{x} \in W} R_{\mathbf{A}}(\mathbf{x}) \right) + c,$$

and taking the minimum over all W of dimension $n - k + 1$ adds c again. By Theorem 16.2.3 applied to $\mathbf{A} + c\mathbf{I}$ on the left and to $\mathbf{A}$ on the right, $\lambda_k(\mathbf{A} + c\mathbf{I}) = \lambda_k(\mathbf{A}) + c$.

Exercise B3: Comparing two matrices.

Let

$$\mathbf{A} = \begin{pmatrix} 3 & 1 \\ 1 & 3 \end{pmatrix}, \qquad \mathbf{B} = \begin{pmatrix} 2 & 0 \\ 0 & 1 \end{pmatrix}.$$

Verify that $\mathbf{A} \succeq \mathbf{B}$, compute both eigenvalue lists, and check Corollary 16.2.4. Check whether $\lambda_1(\mathbf{A}) - \lambda_1(\mathbf{B}) \le \lambda_1(\mathbf{A} - \mathbf{B})$ holds for this pair. (Whether it holds for every pair is a question for Section 3.)

Solution. $\mathbf{A} - \mathbf{B} = \left(\begin{smallmatrix} 1 & 1 \\ 1 & 2 \end{smallmatrix}\right)$ is symmetric with leading principal minors $1 > 0$ and det $= 2 - 1 = 1 > 0$, so $\mathbf{A} - \mathbf{B} \succ 0$ by Theorem 12.1.5; in particular $\mathbf{A} \succeq \mathbf{B}$.

The eigenvalues: $\mathbf{A}$ has $p_{\mathbf{A}}(x) = (x-3)^2 - 1$, so $\lambda_1(\mathbf{A}) = 4$, $\lambda_2(\mathbf{A}) = 2$; and $\mathbf{B}$ is diagonal with $\lambda_1(\mathbf{B}) = 2$, $\lambda_2(\mathbf{B}) = 1$. Indeed $4 \ge 2$ and $2 \ge 1$, as Corollary 16.2.4 requires.

For the last question, $\mathbf{A}-\mathbf{B}$ has trace 3 and determinant 1, so its eigenvalues are $\frac{1}{2}(3 \pm \sqrt{5})$ and $\lambda_1(\mathbf{A} - \mathbf{B}) = \frac{1}{2}(3 + \sqrt{5}) \approx 2.618$. The inequality asks whether $4 - 2 \le 2.618$, which holds. (It is not an accident: it is the simplest of the perturbation inequalities of §03, which carry Weyl's name. Note that Corollary 16.2.4 alone gives no upper bound on the gap $\lambda_i(\mathbf{A}) - \lambda_i(\mathbf{B})$.)

16.2.5.3 C. Going deeper

Exercise C1: The definite generalized eigenvalue problem.

Let $\mathbf{A}, \mathbf{B} \in M_n(F)$ be Hermitian with $\mathbf{A} \succ 0$, and recall Definition 12.4.1: λ is a generalized eigenvalue of the pair $(\mathbf{A}, \mathbf{B})$ when $\mathbf{B}\mathbf{x} = \lambda \mathbf{A}\mathbf{x}$ for some $\mathbf{x} \neq \mathbf{0}$. Define the **generalized Rayleigh quotient**

$$R_{\mathbf{A},\mathbf{B}}(\mathbf{x}) = \frac{\langle \mathbf{B}\mathbf{x}, \mathbf{x} \rangle}{\langle \mathbf{A}\mathbf{x}, \mathbf{x} \rangle} \qquad (\mathbf{x} \neq \mathbf{0}).$$

(a) Prove that $R_{\mathbf{A},\mathbf{B}}$ is well defined and real-valued.

(b) Put $\mathbf{C} = \mathbf{A}^{-1/2}\mathbf{B}\mathbf{A}^{-1/2}$. Prove that $\mathbf{C}$ is Hermitian and that $\det(\mathbf{B} - \lambda\mathbf{A}) = \det(\mathbf{A}) \det(\mathbf{C} - \lambda\mathbf{I})$, so that the generalized eigenvalues of $(\mathbf{A}, \mathbf{B})$, with multiplicity, are exactly the eigenvalues of $\mathbf{C}$. Write them $d_1 \ge \cdots \ge d_n$.

(c) Prove that for every k,

$$d_k = \min_{\dim W = n-k+1} \; \max_{\mathbf{0} \neq \mathbf{x} \in W} R_{\mathbf{A},\mathbf{B}}(\mathbf{x}).$$

Hint for (c): the substitution $\mathbf{x} = \mathbf{A}^{-1/2}\mathbf{y}$.

Solution.

(a) By Theorem 12.2.1 and Theorem 12.1.5, $\mathbf{A} \succ 0$ has a positive definite square root $\mathbf{A}^{1/2}$, which is invertible; write $\mathbf{A}^{-1/2}$ for its inverse, again Hermitian and positive definite. For $\mathbf{x} \neq \mathbf{0}$, $\langle \mathbf{A}\mathbf{x}, \mathbf{x} \rangle > 0$ by definiteness, so the denominator is a nonzero real; the numerator is real by Proposition 10.6.7 (a). So the quotient is a well-defined real number.

(b) $\mathbf{C}^* = \mathbf{A}^{-1/2}\mathbf{B}^*\mathbf{A}^{-1/2} = \mathbf{C}$. Since $\mathbf{A}^{1/2}\mathbf{C}\mathbf{A}^{1/2} = \mathbf{B}$ and $\mathbf{A}^{1/2}\mathbf{A}^{1/2} = \mathbf{A}$,

$$\mathbf{B} - \lambda\mathbf{A} = \mathbf{A}^{1/2}(\mathbf{C} - \lambda\mathbf{I})\mathbf{A}^{1/2},$$

so taking determinants and using Theorem 6.5.4 gives

$$\det(\mathbf{B}-\lambda\mathbf{A}) = \det(\mathbf{A}^{1/2})^2\det(\mathbf{C}-\lambda\mathbf{I}) = \det(\mathbf{A})\det(\mathbf{C}-\lambda\mathbf{I}).$$

Since $\det\mathbf{A}\neq 0$, the two polynomials in λ have the same roots with the same multiplicities. By Theorem 12.4.2 (b) the generalized eigenvalues of $(\mathbf{A},\mathbf{B})$ are the roots of $\det(\mathbf{B}-\lambda\mathbf{A})$, so they are the eigenvalues of $\mathbf{C}$, all real because $\mathbf{C}$ is Hermitian.

(c) Put $\mathbf{S}=\mathbf{A}^{-1/2}$, which is Hermitian and invertible. For $\mathbf{y}\neq\mathbf{0}$ set $\mathbf{x}=\mathbf{S}\mathbf{y}\neq\mathbf{0}$. Then

$$\langle\mathbf{B}\mathbf{x},\mathbf{x}\rangle = \langle\mathbf{S}\mathbf{B}\mathbf{S}\mathbf{y},\mathbf{y}\rangle = \langle\mathbf{C}\mathbf{y},\mathbf{y}\rangle, \qquad \langle\mathbf{A}\mathbf{x},\mathbf{x}\rangle = \langle\mathbf{S}\mathbf{A}\mathbf{S}\mathbf{y},\mathbf{y}\rangle = \langle\mathbf{y},\mathbf{y}\rangle,$$

using $\mathbf{S}\mathbf{A}\mathbf{S}=\mathbf{A}^{-1/2}\mathbf{A}\mathbf{A}^{-1/2}=\mathbf{I}$. Hence $R_{\mathbf{A},\mathbf{B}}(\mathbf{S}\mathbf{y})=R_{\mathbf{C}}(\mathbf{y})$. The map $\mathbf{y}\mapsto\mathbf{S}\mathbf{y}$ is an isomorphism of F^n, so $W\mapsto\mathbf{S}^{-1}W$ is a bijection of the subspaces of dimension $n-k+1$ onto themselves, matching non-zero vectors with non-zero vectors. Therefore

$$\max_{\mathbf{0}\neq\mathbf{x}\in W} R_{\mathbf{A},\mathbf{B}}(\mathbf{x}) = \max_{\mathbf{0}\neq\mathbf{y}\in\mathbf{S}^{-1}W} R_{\mathbf{C}}(\mathbf{y}),$$

and minimizing both sides over all W of dimension $n-k+1$ gives, by Theorem 16.2.3 applied to $\mathbf{C}$, the value $\lambda_k(\mathbf{C})=d_k$.

Exercise C2: How much weaker the eigenvalue comparison is.

(a) Give Hermitian $\mathbf{A},\mathbf{B}\in M_2(\mathbb{R})$ with $\lambda_i(\mathbf{A})\geq\lambda_i(\mathbf{B})$ for $i=1,2$ but $\mathbf{A}\not\succeq\mathbf{B}$. So the converse of Corollary 16.2.4 is false.

(b) Prove that if $\mathbf{A}$ and $\mathbf{B}$ are Hermitian with $\lambda_i(\mathbf{A})\geq\lambda_i(\mathbf{B})$ for every i and $\operatorname{tr}\mathbf{A}=\operatorname{tr}\mathbf{B}$, then $\lambda_i(\mathbf{A})=\lambda_i(\mathbf{B})$ for every i.

(c) Prove that if $\mathbf{A}\succeq\mathbf{B}$ and $\operatorname{tr}\mathbf{A}=\operatorname{tr}\mathbf{B}$, then $\mathbf{A}=\mathbf{B}$.

Solution.

(a) Take $\mathbf{A}=\operatorname{diag}(2,0)$ and $\mathbf{B}=\operatorname{diag}(0,1)$. Then $\lambda_1(\mathbf{A})=2\geq 1=\lambda_1(\mathbf{B})$ and $\lambda_2(\mathbf{A})=0\geq 0=\lambda_2(\mathbf{B})$. But $\mathbf{A}-\mathbf{B}=\operatorname{diag}(2,-1)$ has the eigenvalue $-1<0$, so $\mathbf{A}-\mathbf{B}\not\succeq 0$ by Theorem 12.1.4 and $\mathbf{A}\not\succeq\mathbf{B}$. Ordering the two spectra says nothing about how the eigen*vectors* are placed relative to each other, and the Loewner order sees both.

(b) By Theorem 8.3.3 the trace is the sum of the eigenvalues with multiplicity, so

$$0=\operatorname{tr}\mathbf{A}-\operatorname{tr}\mathbf{B}=\sum_{i=1}^{n}\bigl(\lambda_i(\mathbf{A})-\lambda_i(\mathbf{B})\bigr).$$

Every summand is ≥ 0 by hypothesis, and a sum of non-negative reals is zero only if each is zero. Hence $\lambda_i(\mathbf{A})=\lambda_i(\mathbf{B})$ for every i.

(c) Put $\mathbf{C}=\mathbf{A}-\mathbf{B}$, Hermitian with $\mathbf{C}\succeq 0$, so every eigenvalue of $\mathbf{C}$ is ≥ 0 by Theorem 12.1.4. Also $\operatorname{tr}\mathbf{C}=\operatorname{tr}\mathbf{A}-\operatorname{tr}\mathbf{B}=0$, which by Theorem 8.3.3 is the sum of those eigenvalues; a sum of non-negative reals vanishing forces each to vanish, so every eigenvalue of $\mathbf{C}$ is 0. By Corollary 11.4.3 (or Corollary 11.5.2), $\mathbf{C}=\mathbf{U}\mathbf{D}\mathbf{U}^{*}$ with $\mathbf{D}$ the diagonal matrix of eigenvalues, which is $\mathbf{0}$; hence $\mathbf{C}=\mathbf{0}$ and $\mathbf{A}=\mathbf{B}$. (One may also finish with (b) and Corollary 16.2.4, which give the equality of the

two spectra but not yet of the matrices; the trace argument on $\mathbf{C}$ is what closes the gap.)

Exercise C3: Does enlarging the field change the answer?.

Let $\mathbf{A} \in M_n(\mathbb{R})$ be symmetric. It may be read as an element of $M_n(\mathbb{C})$, where it is Hermitian, and then Theorem 16.2.3 minimizes over a much larger collection of subspaces.

(a) Prove that the eigenvalue lists of $\mathbf{A}$ over $\mathbb{R}$ and over $\mathbb{C}$, with multiplicity, are the same.

(b) Deduce that for every k,

$$\min_{\substack{W \subseteq \mathbb{R}^n \\ \dim W = n-k+1}} \max_{\mathbf{0} \neq \mathbf{x} \in W} R_{\mathbf{A}}(\mathbf{x}) = \min_{\substack{W \subseteq \mathbb{C}^n \\ \dim W = n-k+1}} \max_{\mathbf{0} \neq \mathbf{x} \in W} R_{\mathbf{A}}(\mathbf{x}).$$

(c) Show that the second minimum really does range over strictly more subspaces, by exhibiting a one-dimensional subspace of $\mathbb{C}^2$ that contains no non-zero real vector.

Solution.

(a) By Corollary 11.5.2 there is an orthogonal $\mathbf{Q} \in M_n(\mathbb{R})$ and a real diagonal $\mathbf{D}$ with $\mathbf{A} = \mathbf{Q}\mathbf{D}\mathbf{Q}^{\top}$, and the diagonal of $\mathbf{D}$ is the eigenvalue list of $\mathbf{A}$ over $\mathbb{R}$ with multiplicity. Read over $\mathbb{C}$, the same $\mathbf{Q}$ is unitary, since $\mathbf{Q}^{*} = \overline{\mathbf{Q}}^{\top} = \mathbf{Q}^{\top} = \mathbf{Q}^{-1}$, and the same equation $\mathbf{A} = \mathbf{Q}\mathbf{D}\mathbf{Q}^{*}$ holds. So $\mathbf{A}$ is unitarily similar over $\mathbb{C}$ to the same $\mathbf{D}$, and its complex eigenvalue list with multiplicity is again the diagonal of $\mathbf{D}$.

(b) Apply Theorem 16.2.3 twice: once with $F = \mathbb{R}$, where the left-hand side equals $\lambda_k(\mathbf{A})$ computed over $\mathbb{R}$, and once with $F = \mathbb{C}$, where the right-hand side equals $\lambda_k(\mathbf{A})$ computed over $\mathbb{C}$. By (a) these are the same number.

(c) Take $W = \operatorname{span}_{\mathbb{C}}\{(1, i)\} \subseteq \mathbb{C}^2$. A non-zero element of W is $c(1, i) = (c, ci)$ with $c \neq 0$; for it to be real we would need $c \in \mathbb{R}$ and $ci \in \mathbb{R}$, and $c \neq 0$ makes the second impossible. So W is not the complex span of any real subspace.

The lesson is worth stating. Enlarging the field adds competitors to the minimization, which can only push the minimum **down**, and adds vectors to each inner maximization, which can only push those maxima **up**. The two effects cancel exactly, because both the witness subspace and the bound of Step 2 in the proof of Theorem 16.2.3 survive the enlargement unchanged: the witness is spanned by real eigenvectors, and the dimension count of Lemma 16.2.1 holds over any field.

16.3 How Far Eigenvalues Move

Chapter 15 §07 asked what happens to the eigenvalues of a matrix when the matrix is nudged, and came back with a discouraging answer: they move continuously, and nothing better. Example (A Jordan block's eigenvalues move like $\varepsilon^{1/k}$) exhibits a perturbation of size ε that moves every eigenvalue a distance $\varepsilon^{1/k}$, so no Lipschitz constant survives. That section also promised that the Hermitian case is different, and left the proof here.

The reason the Hermitian case is different is now available. Theorem 16.2.3 describes $\lambda_k(\mathbf{A})$ as an optimization over subspaces, and an optimization over subspaces reacts to a change in $\mathbf{A}$ the way any optimization reacts to a change in the objective: by at most the change in the objective. Turning that sentence into inequalities is the business of this section, and the inequalities are sharper than the sentence suggests, because the index may be shifted as well.

Throughout this section the field is $\mathbb{R}$ or $\mathbb{C}$, and every matrix whose eigenvalues are written down is Hermitian, that is, $\mathbf{A}^* = \mathbf{A}$ with $\mathbf{A} \in M_n(F)$ and $n \geq 1$. Its eigenvalues are real and are always indexed **decreasingly**, $\lambda_1(\mathbf{A}) \geq \lambda_2(\mathbf{A}) \geq \cdots \geq \lambda_n(\mathbf{A})$, as they have been since Chapter 12. Sums of Hermitian matrices are Hermitian, so $\mathbf{A} + \mathbf{B}$ is again a matrix this section may write λ_i of.

16.3.1 Two small facts about eigenvalue lists

One small fact is used in every proof below, and it is the reason the index bookkeeping works out. If a vector lies in the span of the *bottom* eigenvectors of $\mathbf{A}$, its Rayleigh quotient cannot exceed the largest eigenvalue in that span; if it lies in the span of the *top* ones, the quotient cannot fall below the smallest eigenvalue there.

Lemma 16.3.1 — The Quotient on a Span of Eigenvectors

Let $\mathbf{A} \in M_n(F)$ be Hermitian and let $(\mathbf{u}_1, \dots, \mathbf{u}_n)$ be an orthonormal basis of F^n with $\mathbf{A}\mathbf{u}_p = \lambda_p(\mathbf{A})\mathbf{u}_p$ for every p. Fix i with $1 \leq i \leq n$.

(a) If $\mathbf{x} \neq \mathbf{0}$ lies in $\operatorname{span}\{\mathbf{u}_i, \mathbf{u}_{i+1}, \dots, \mathbf{u}_n\}$, then $R_{\mathbf{A}}(\mathbf{x}) \leq \lambda_i(\mathbf{A})$.

(b) If $\mathbf{x} \neq \mathbf{0}$ lies in $\operatorname{span}\{\mathbf{u}_1, \mathbf{u}_2, \dots, \mathbf{u}_i\}$, then $R_{\mathbf{A}}(\mathbf{x}) \geq \lambda_i(\mathbf{A})$.

Proof. Such a basis exists by the spectral theorem: Corollary 11.4.3 over $\mathbb{C}$, where a Hermitian matrix is normal and its eigenvalues may be listed in any prescribed order, and Corollary 11.5.2 over $\mathbb{R}$, where Hermitian means symmetric.

(a) Write $\mathbf{x} = \sum_{p \geq i} c_p \mathbf{u}_p$, with the c_p not all zero. Since the $\mathbf{u}_p$ are orthonormal,

$$\langle \mathbf{A}\mathbf{x}, \mathbf{x} \rangle = \Big\langle \sum_{p \geq i} c_p \lambda_p(\mathbf{A}) \mathbf{u}_p,\ \sum_{q \geq i} c_q \mathbf{u}_q \Big\rangle = \sum_{p \geq i} \lambda_p(\mathbf{A}) |c_p|^2,$$
$$\|\mathbf{x}\|^2 = \sum_{p \geq i} |c_p|^2.$$

Every index in these sums satisfies $p \geq i$, so $\lambda_p(\mathbf{A}) \leq \lambda_i(\mathbf{A})$ by the decreasing indexing, and therefore $\langle \mathbf{A}\mathbf{x}, \mathbf{x} \rangle \leq \lambda_i(\mathbf{A}) \|\mathbf{x}\|^2$. Since $\mathbf{x} \neq \mathbf{0}$ we have $\|\mathbf{x}\|^2 > 0$ and may divide, which gives $R_{\mathbf{A}}(\mathbf{x}) \leq \lambda_i(\mathbf{A})$ by Definition 16.1.1.

(b) The same computation with $\mathbf{x} = \sum_{p \leq i} c_p \mathbf{u}_p$ gives $\langle \mathbf{A}\mathbf{x}, \mathbf{x} \rangle = \sum_{p \leq i} \lambda_p(\mathbf{A}) |c_p|^2$, and now every index satisfies $p \leq i$, so $\lambda_p(\mathbf{A}) \geq \lambda_i(\mathbf{A})$ and the inequality reverses. This proves the lemma. ∎

The two halves are the two ways of using an eigenvector span: (a) caps a quotient from above, (b) props it up from below. The proof of Weyl's inequalities needs only (a), applied to a single

vector for two different matrices at once; (b) is the form in which the same fact enters the witness half of a min–max argument.

A second small fact converts statements about the top of an eigenvalue list into statements about the bottom. Negating a matrix negates its eigenvalues, and negation reverses the order of real numbers.

Lemma 16.3.2 — Negation Reverses the List

Let $\mathbf{A} \in M_n(F)$ be Hermitian. Then $-\mathbf{A}$ is Hermitian and

$$\lambda_p(-\mathbf{A}) = -\lambda_{n+1-p}(\mathbf{A}) \qquad (1 \le p \le n).$$

Proof. $(-\mathbf{A})^* = -\mathbf{A}^* = -\mathbf{A}$, so $-\mathbf{A}$ is Hermitian. By the spectral theorem quoted in the proof of Lemma 16.3.1, $\mathbf{A} = \mathbf{U}\mathbf{D}\mathbf{U}^*$ with $\mathbf{D} = \operatorname{diag}(\lambda_1(\mathbf{A}), \dots, \lambda_n(\mathbf{A}))$ and $\mathbf{U}$ unitary, whence $-\mathbf{A} = \mathbf{U}(-\mathbf{D})\mathbf{U}^*$. So the eigenvalue list of $-\mathbf{A}$, with multiplicity, is $-\lambda_1(\mathbf{A}), \dots, -\lambda_n(\mathbf{A})$. Multiplying by -1 reverses the order of real numbers, so listing these decreasingly gives

$$-\lambda_n(\mathbf{A}) \;\ge\; -\lambda_{n-1}(\mathbf{A}) \;\ge\; \dots \;\ge\; -\lambda_1(\mathbf{A}),$$

whose p-th entry is $-\lambda_{n+1-p}(\mathbf{A})$. This proves the lemma. ∎

16.3.2 The two families of Weyl inequalities

Here is the question. Given the eigenvalues of $\mathbf{A}$ and the eigenvalues of $\mathbf{B}$, separately, what can be said about the eigenvalues of $\mathbf{A}+\mathbf{B}$? Nothing exact: $\operatorname{diag}(1,0)$ and $\operatorname{diag}(0,1)$ have the same eigenvalue list as $\operatorname{diag}(1,0)$ and $\operatorname{diag}(1,0)$, while the two sums $\mathbf{I}$ and $\operatorname{diag}(2,0)$ do not. But a great deal inexactly, and the shape of the answer is dictated by the index arithmetic.

Theorem 16.3.3 — Weyl's Inequalities

Let $\mathbf{A}, \mathbf{B} \in M_n(F)$ be Hermitian and let $1 \le i, j \le n$.

(a) If $i + j - 1 \le n$, then

$$\lambda_{i+j-1}(\mathbf{A}+\mathbf{B}) \;\le\; \lambda_i(\mathbf{A}) + \lambda_j(\mathbf{B}).$$

(b) If $i + j - n \ge 1$, then

$$\lambda_{i+j-n}(\mathbf{A}+\mathbf{B}) \;\ge\; \lambda_i(\mathbf{A}) + \lambda_j(\mathbf{B}).$$

Idea. For (a), read $\lambda_{i+j-1}(\mathbf{A}+\mathbf{B})$ through the **max–min** half of Theorem 16.2.3: it is the best guaranteed value of $R_{\mathbf{A}+\mathbf{B}}$ on a subspace of dimension $i+j-1$. So take an arbitrary such subspace W and find one bad vector inside it — a vector on which $R_{\mathbf{A}}$ is capped by $\lambda_i(\mathbf{A})$ and $R_{\mathbf{B}}$ is capped by $\lambda_j(\mathbf{B})$ simultaneously. The span of the bottom $n-i+1$ eigenvectors of $\mathbf{A}$ is a *subspace* on which $R_{\mathbf{A}}$ is capped by $\lambda_i(\mathbf{A})$, and the span

of the bottom $n-j+1$ eigenvectors of $\mathbf{B}$ is one on which $R_{\mathbf{B}}$ is capped by $\lambda_j(\mathbf{B})$. (The set of *all* vectors capped by $\lambda_i(\mathbf{A})$ is larger and is not a subspace; the spans are what the dimension count can use.) Three subspaces must meet, and the dimensions have been chosen so that they do — twice, by Lemma 16.2.1. Since $R_{\mathbf{A}+\mathbf{B}} = R_{\mathbf{A}} + R_{\mathbf{B}}$, that one vector finishes the argument.

Part (b) is not a new proof. Negating a Hermitian matrix reverses its eigenvalue list (Lemma 16.3.2), so (a) applied to $-\mathbf{A}$ and $-\mathbf{B}$ at the reflected indices $n+1-i$ and $n+1-j$ says exactly (b), once every index is translated back.

Proof. **(a)** Put $k = i+j-1$, so $1 \le k \le n$. By the spectral theorem choose an orthonormal basis $(\mathbf{u}_1, \dots, \mathbf{u}_n)$ of eigenvectors of $\mathbf{A}$ with $\mathbf{A}\mathbf{u}_p = \lambda_p(\mathbf{A})\mathbf{u}_p$, and an orthonormal basis $(\mathbf{v}_1, \dots, \mathbf{v}_n)$ of eigenvectors of $\mathbf{B}$ with $\mathbf{B}\mathbf{v}_q = \lambda_q(\mathbf{B})\mathbf{v}_q$. Set

$$U = \operatorname{span}\{\mathbf{u}_i, \dots, \mathbf{u}_n\}, \qquad V = \operatorname{span}\{\mathbf{v}_j, \dots, \mathbf{v}_n\},$$

so that $\dim U = n-i+1$ and $\dim V = n-j+1$, the two lists being independent as parts of a basis.

Let $W \le F^n$ be **any** subspace with $\dim W = k$. Then

$$\dim W + \dim U = (i+j-1) + (n-i+1) = n+j > n,$$

since $j \ge 1$, so $W \cap U \neq \{\mathbf{0}\}$ by Lemma 16.2.1. More than that is needed, namely how large $W \cap U$ is, and the dimension formula Theorem 1.7.3 supplies it:

$$\dim(W \cap U) = \dim W + \dim U - \dim(W + U) \;\ge\; (n+j) - n = j,$$

because $W + U$ is a subspace of F^n. Therefore

$$\dim(W \cap U) + \dim V \;\ge\; j + (n-j+1) = n+1 > n,$$

and a second application of Lemma 16.2.1, to the subspaces $W \cap U$ and V, produces a vector

$$\mathbf{x} \in W \cap U \cap V, \qquad \mathbf{x} \neq \mathbf{0}.$$

Now evaluate. Since $\mathbf{x} \in U$, part (a) of Lemma 16.3.1 gives $R_{\mathbf{A}}(\mathbf{x}) \le \lambda_i(\mathbf{A})$; since $\mathbf{x} \in V$, the same part applied to $\mathbf{B}$ gives $R_{\mathbf{B}}(\mathbf{x}) \le \lambda_j(\mathbf{B})$. The inner product is additive in its first slot, so $\langle(\mathbf{A}+\mathbf{B})\mathbf{x}, \mathbf{x}\rangle = \langle \mathbf{A}\mathbf{x}, \mathbf{x}\rangle + \langle \mathbf{B}\mathbf{x}, \mathbf{x}\rangle$ and hence $R_{\mathbf{A}+\mathbf{B}}(\mathbf{x}) = R_{\mathbf{A}}(\mathbf{x}) + R_{\mathbf{B}}(\mathbf{x})$. Since $\mathbf{x}$ is a non-zero vector of W,

$$\min_{\mathbf{0}\neq\mathbf{y}\in W} R_{\mathbf{A}+\mathbf{B}}(\mathbf{y}) \;\le\; R_{\mathbf{A}+\mathbf{B}}(\mathbf{x}) \;\le\; \lambda_i(\mathbf{A}) + \lambda_j(\mathbf{B}).$$

The subspace W of dimension k was arbitrary, so the maximum of the left-hand side over all such W obeys the same bound; and that maximum is $\lambda_k(\mathbf{A}+\mathbf{B})$ by the max–min half of Theorem 16.2.3. This proves (a).

(b) Suppose $i+j-n \ge 1$ and set

$$i' = n+1-i, \qquad j' = n+1-j,$$

both of which lie in $\{1, \dots, n\}$. Then

$$i' + j' - 1 = 2n+1-i-j \le n$$

precisely because $i+j-n \geq 1$, so part (a) applies to the Hermitian matrices $-\mathbf{A}$ and $-\mathbf{B}$ at the indices i', j':

$$\lambda_{i'+j'-1}(-\mathbf{A}-\mathbf{B}) \;\leq\; \lambda_{i'}(-\mathbf{A})+\lambda_{j'}(-\mathbf{B}).$$

Translate each term with Lemma 16.3.2. On the right, $\lambda_{i'}(-\mathbf{A}) = -\lambda_{n+1-i'}(\mathbf{A}) = -\lambda_i(\mathbf{A})$, and likewise $\lambda_{j'}(-\mathbf{B}) = -\lambda_j(\mathbf{B})$. On the left, $-\mathbf{A}-\mathbf{B} = -(\mathbf{A}+\mathbf{B})$ with $\mathbf{A}+\mathbf{B}$ Hermitian, and $i'+j'-1 = 2n+1-i-j$, so

$$\lambda_{i'+j'-1}\big(-(\mathbf{A}+\mathbf{B})\big) = -\lambda_{n+1-(2n+1-i-j)}(\mathbf{A}+\mathbf{B}) = -\lambda_{i+j-n}(\mathbf{A}+\mathbf{B}).$$

The displayed inequality therefore reads $-\lambda_{i+j-n}(\mathbf{A}+\mathbf{B}) \leq -\lambda_i(\mathbf{A})-\lambda_j(\mathbf{B})$. Multiplying by -1 reverses it and gives (b). This proves the theorem.

■

Two remarks on the bookkeeping, because it is the whole content. First, the index on the left is *not* i or j but $i+j-1$, so a fixed eigenvalue $\lambda_k(\mathbf{A}+\mathbf{B})$ receives k upper bounds from (a), one for each way of splitting $k = i+j-1$, and the best of them is their minimum. Second, (a) only ever bounds from above and (b) only from below. To trap one eigenvalue $\lambda_i(\mathbf{A}+\mathbf{B})$ from both sides with the index of $\mathbf{A}$ unchanged, take $j=1$ in (a) and $j=n$ in (b); that is the next corollary.

Quick check. Take $i=j=1$ in (a) and $i=j=n$ in (b). What do the two inequalities say, and which earlier result are they?

Solution. They say $\lambda_1(\mathbf{A}+\mathbf{B}) \leq \lambda_1(\mathbf{A})+\lambda_1(\mathbf{B})$ and $\lambda_n(\mathbf{A}+\mathbf{B}) \geq \lambda_n(\mathbf{A})+\lambda_n(\mathbf{B})$. For $i=j=n$ the index on the left of (b) is $n+n-n=n$, as required. These are the statements that the largest eigenvalue is subadditive and the smallest superadditive, which one can also read straight off Lemma 12.5.2: $\langle(\mathbf{A}+\mathbf{B})\mathbf{x},\mathbf{x}\rangle = \langle\mathbf{A}\mathbf{x},\mathbf{x}\rangle+\langle\mathbf{B}\mathbf{x},\mathbf{x}\rangle \leq \lambda_1(\mathbf{A})+\lambda_1(\mathbf{B})$ for every unit $\mathbf{x}$. Weyl's inequalities are what happens when this easy observation is run at every index instead of only at the two ends.

Warning. **The eigenvalues are not subadditive index by index.** It is tempting to read Weyl as $\lambda_i(\mathbf{A}+\mathbf{B}) \leq \lambda_i(\mathbf{A})+\lambda_i(\mathbf{B})$, and that statement is false. Take $\mathbf{A} = \operatorname{diag}(1,0)$ and $\mathbf{B} = \operatorname{diag}(0,1)$, so that $\lambda(\mathbf{A}) = \lambda(\mathbf{B}) = (1,0)$ and $\mathbf{A}+\mathbf{B} = \mathbf{I}_2$ with $\lambda(\mathbf{A}+\mathbf{B}) = (1,1)$. At $i=2$ the proposed inequality reads $1 \leq 0+0$. The reverse reading $\lambda_i(\mathbf{A}+\mathbf{B}) \geq \lambda_i(\mathbf{A})+\lambda_i(\mathbf{B})$ fails on the same pair at $i=1$, where it reads $1 \geq 2$. Only the shifted indices $i+j-1$ and $i+j-n$ are correct.

Here is the theorem in full on one pair of matrices, so that the index arithmetic can be seen doing its work.

Example. (Both families on one pair)

Let

$$\mathbf{A} = \begin{pmatrix} 1 & 1 & 2 \\ 1 & 1 & 2 \\ 2 & 2 & 0 \end{pmatrix}, \qquad \mathbf{B} = \begin{pmatrix} 3 & 2 & 0 \\ 2 & 3 & 0 \\ 0 & 0 & 0 \end{pmatrix}.$$

Find the eigenvalues of $\mathbf{A}$, $\mathbf{B}$ and $\mathbf{A}+\mathbf{B}$, and check every inequality of Theorem 16.3.3.

Solution. All three matrices are real symmetric. Their characteristic polynomials factor over $\mathbb{Z}$:

$$p_{\mathbf{A}}(x) = x(x-4)(x+2),$$
$$p_{\mathbf{B}}(x) = x(x-5)(x-1),$$
$$p_{\mathbf{A}+\mathbf{B}}(x) = (x-8)(x-1)(x+1),$$

so, in decreasing order,

$$\lambda(\mathbf{A}) = (4, 0, -2), \qquad \lambda(\mathbf{B}) = (5, 1, 0), \qquad \lambda(\mathbf{A}+\mathbf{B}) = (8, 1, -1).$$

For $\mathbf{A}$ one can see the list without computing: the rows $(1,1,2)$ and $(1,1,2)$ are equal, so $\operatorname{rank}\mathbf{A} = 2$ and 0 is an eigenvalue; $\operatorname{tr}\mathbf{A} = 2$ and $\operatorname{tr}(\mathbf{A}^2) = 20$ then force the other two to be 4 and -2.

With $n = 3$, family (a) applies when $i + j \le 4$ and family (b) when $i + j \ge 4$.

(i,j)	family (a): $\lambda_{i+j-1}(\mathbf{A}+\mathbf{B}) \le \lambda_i(\mathbf{A}) + \lambda_j(\mathbf{B})$
$(1,1)$	$8 \le 4 + 5 = 9$
$(1,2)$	$1 \le 4 + 1 = 5$
$(2,1)$	$1 \le 0 + 5 = 5$
$(1,3)$	$-1 \le 4 + 0 = 4$
$(2,2)$	$-1 \le 0 + 1 = 1$
$(3,1)$	$-1 \le -2 + 5 = 3$

(i,j)	family (b): $\lambda_{i+j-3}(\mathbf{A}+\mathbf{B}) \ge \lambda_i(\mathbf{A}) + \lambda_j(\mathbf{B})$
$(1,3)$	$8 \ge 4 + 0 = 4$
$(3,1)$	$8 \ge -2 + 5 = 3$
$(2,2)$	$8 \ge 0 + 1 = 1$
$(2,3)$	$1 \ge 0 + 0 = 0$
$(3,2)$	$1 \ge -2 + 1 = -1$
$(3,3)$	$-1 \ge -2 + 0 = -2$

Every inequality holds, and every one of them is strict. At $(1,1)$ one can see why. Equality there would mean a unit $\mathbf{x}$ with $R_{\mathbf{A}+\mathbf{B}}(\mathbf{x}) = \lambda_1(\mathbf{A}) + \lambda_1(\mathbf{B})$; since $R_{\mathbf{A}}(\mathbf{x}) \le \lambda_1(\mathbf{A})$ and $R_{\mathbf{B}}(\mathbf{x}) \le \lambda_1(\mathbf{B})$ by Lemma 16.3.1 (a) at $i = 1$, both would have to be equalities, and the computation in that proof shows that equality in $\sum_p \lambda_p |c_p|^2 \le \lambda_1 \sum_p |c_p|^2$ forces $c_p = 0$ at every p with $\lambda_p < \lambda_1$. So $\mathbf{x}$ would lie in the λ_1-eigenspace of $\mathbf{A}$ and in that of $\mathbf{B}$. Those are the lines through $(1,1,1)$ and through $(1,1,0)$ — as $\mathbf{A}(1,1,1) = 4(1,1,1)$ and $\mathbf{B}(1,1,0) = 5(1,1,0)$, and both eigenvalues are simple — and two distinct lines meet only at $\mathbf{0}$.

16.3.3 Perturbing one matrix

Setting $j = 1$ in family (a) and $j = n$ in family (b) leaves the index on the left equal to i. That is the case in which Weyl becomes a statement about *perturbation*: one matrix, moved.

Corollary 16.3.4 — Perturbation, Two-Sided

Let $\mathbf{A}, \mathbf{B} \in M_n(F)$ be Hermitian. Then for every i,

$$\lambda_i(\mathbf{A}) + \lambda_n(\mathbf{B}) \;\le\; \lambda_i(\mathbf{A}+\mathbf{B}) \;\le\; \lambda_i(\mathbf{A}) + \lambda_1(\mathbf{B}).$$

Proof. For the upper bound take $j = 1$ in Theorem 16.3.3 (a): the hypothesis $i+1-1 = i \le n$ holds, and the conclusion is $\lambda_i(\mathbf{A}+\mathbf{B}) \le \lambda_i(\mathbf{A}) + \lambda_1(\mathbf{B})$. For the lower bound take $j = n$ in Theorem 16.3.3 (b): the hypothesis $i+n-n = i \ge 1$ holds, and the conclusion is $\lambda_i(\mathbf{A}+\mathbf{B}) \ge \lambda_i(\mathbf{A}) + \lambda_n(\mathbf{B})$. This proves the corollary. ∎

In words: adding $\mathbf{B}$ shifts each eigenvalue of $\mathbf{A}$, in order, by an amount trapped between the smallest and the largest eigenvalue of $\mathbf{B}$. Taking $\mathbf{B} \succeq 0$, so that $\lambda_n(\mathbf{B}) \ge 0$ by Theorem 12.1.4 (b), the lower bound becomes $\lambda_i(\mathbf{A}+\mathbf{B}) \ge \lambda_i(\mathbf{A})$ — which is Corollary 16.2.4 again, now as a special case of Weyl's inequalities.

To turn Corollary 16.3.4 into a bound of the kind Chapter 15 wanted, the two numbers $\lambda_1(\mathbf{B})$ and $\lambda_n(\mathbf{B})$ must be replaced by one, and the right one is a norm.

Lemma 16.3.5 — The Spectral Norm of a Hermitian Matrix

Let $\mathbf{E} \in M_n(F)$ be Hermitian. Then

$$\|\mathbf{E}\|_2 = \max_{1 \le i \le n} |\lambda_i(\mathbf{E})| = \max\big(\lambda_1(\mathbf{E}),\; -\lambda_n(\mathbf{E})\big).$$

Proof. By the spectral theorem, $\mathbf{E} = \mathbf{U}\mathbf{D}\mathbf{U}^*$ with $\mathbf{U}$ unitary and $\mathbf{D} = \operatorname{diag}(\lambda_1(\mathbf{E}), \dots, \lambda_n(\mathbf{E}))$ real. Then

$$\mathbf{E}^*\mathbf{E} = \mathbf{E}^2 = \mathbf{U}\mathbf{D}^2\mathbf{U}^*,$$

so the eigenvalues of $\mathbf{E}^*\mathbf{E}$ are the numbers $\lambda_i(\mathbf{E})^2$, and the singular values of $\mathbf{E}$, which are their non-negative square roots listed decreasingly (Definition 12.8.1), are the numbers $|\lambda_i(\mathbf{E})|$ listed decreasingly. Hence $\sigma_1(\mathbf{E}) = \max_i |\lambda_i(\mathbf{E})|$, and $\|\mathbf{E}\|_2 = \sigma_1(\mathbf{E})$ by Theorem 15.3.3 (c).

For the second equality, $\lambda_n(\mathbf{E}) \le \lambda_i(\mathbf{E}) \le \lambda_1(\mathbf{E})$ for every i gives $|\lambda_i(\mathbf{E})| \le \max(|\lambda_1(\mathbf{E})|, |\lambda_n(\mathbf{E})|)$, so the maximum is attained at one end of the list. Now $\lambda_1(\mathbf{E}) \le |\lambda_1(\mathbf{E})|$ and $-\lambda_n(\mathbf{E}) \le |\lambda_n(\mathbf{E})|$, which gives one inequality between the two expressions. Conversely, $|\lambda_1(\mathbf{E})|$ is either $\lambda_1(\mathbf{E})$ or $-\lambda_1(\mathbf{E}) \le -\lambda_n(\mathbf{E})$, and $|\lambda_n(\mathbf{E})|$ is either $-\lambda_n(\mathbf{E})$ or $\lambda_n(\mathbf{E}) \le \lambda_1(\mathbf{E})$; in every case it is at most $\max(\lambda_1(\mathbf{E}), -\lambda_n(\mathbf{E}))$. This proves the lemma. ∎

Corollary 16.3.6 — Hermitian Eigenvalues Are 1-Lipschitz

Let $\mathbf{A}, \mathbf{E} \in M_n(F)$ be Hermitian. Then

$$|\lambda_i(\mathbf{A}+\mathbf{E}) - \lambda_i(\mathbf{A})| \;\le\; \|\mathbf{E}\|_2 \qquad \text{for every } i = 1, \dots, n.$$

Proof. By Corollary 16.3.4 applied with $\mathbf{B} = \mathbf{E}$,

$$\lambda_n(\mathbf{E}) \;\le\; \lambda_i(\mathbf{A}+\mathbf{E}) - \lambda_i(\mathbf{A}) \;\le\; \lambda_1(\mathbf{E}).$$

By Lemma 16.3.5, $\lambda_1(\mathbf{E}) \le \|\mathbf{E}\|_2$ and $-\lambda_n(\mathbf{E}) \le \|\mathbf{E}\|_2$, that is, $-\|\mathbf{E}\|_2 \le \lambda_n(\mathbf{E})$. So the difference lies in $[-\|\mathbf{E}\|_2, \|\mathbf{E}\|_2]$, which is the assertion. This proves the corollary. ∎

This is the sentence Chapter 15 §07 promised: **the eigenvalues of a Hermitian matrix move by at most $\|\mathbf{E}\|_2$ under a Hermitian perturbation.** It is worth being precise about what it adds to Corollary 15.7.4, the continuity statement of that section, because the gain is not continuity — that was already had — but a constant.

- Corollary 15.7.4 says: for each $\mathbf{A}$ and each $\varepsilon > 0$ there is a $\delta > 0$ such that every matrix within δ of $\mathbf{A}$ has eigenvalues that can be numbered to lie within ε of those of $\mathbf{A}$. The δ depends on $\mathbf{A}$, and Example (A Jordan block's eigenvalues move like $\varepsilon^{1/k}$) shows that it must.
- Corollary 16.3.6 says, for Hermitian $\mathbf{A}$ and Hermitian perturbations measured in $\|\cdot\|_2$: $\delta = \varepsilon$ works, for every $\mathbf{A}$ at once, and the numbering is simply the decreasing order. The movement is bounded by the perturbation itself, with **Lipschitz constant** 1.

The constant does not depend on the size n of the matrices, it does not depend on how ill-conditioned $\mathbf{A}$ is, and it does not depend on how close together the eigenvalues of $\mathbf{A}$ are — three quantities that every reader of Chapter 15 has learned to expect in an error bound. It also cannot be improved: $\mathbf{E} = t\mathbf{I}$ with $t \in \mathbb{R}$ gives $\lambda_i(\mathbf{A} + t\mathbf{I}) = \lambda_i(\mathbf{A}) + t$ for every i, while $\|t\mathbf{I}\|_2 = |t|$, so the inequality is an equality at every index. Finally, the eigenvalues are matched **by index**: the i-th of $\mathbf{A}+\mathbf{E}$ is compared with the i-th of $\mathbf{A}$, not with whichever eigenvalue of $\mathbf{A}$ happens to be nearest, and no search for a good numbering is needed.

Corollary 16.3.7 — The Hermitian Eigenvalue Problem Is Perfectly Conditioned in Absolute Terms

Let $\mathbf{A}, \mathbf{E} \in M_n(F)$ be Hermitian and write $\lambda(\mathbf{A}) = (\lambda_1(\mathbf{A}), \dots, \lambda_n(\mathbf{A}))$ for the decreasing eigenvalue list. Then

$$\|\lambda(\mathbf{A}+\mathbf{E}) - \lambda(\mathbf{A})\|_\infty \;\le\; \|\mathbf{E}\|_2,$$

and the constant 1 is the smallest one for which this holds.

Proof. The ∞-norm of a vector is the largest modulus of its entries, so the left-hand side is $\max_i |\lambda_i(\mathbf{A}+\mathbf{E}) - \lambda_i(\mathbf{A})|$, and the inequality is Corollary 16.3.6 read over all i at once. For the last clause, $\mathbf{E} = t\mathbf{I}$ with $t > 0$ makes both sides equal to t, so no constant below 1 can work. This proves the corollary. ∎

Chapter 15 §08 measured a linear system by $\kappa(\mathbf{A}) = \|\mathbf{A}\|\|\mathbf{A}^{-1}\|$ (Definition 15.8.1), the worst factor by which $\mathbf{A}$ magnifies a relative error in the data. The corollary above is the corresponding statement for a different problem — not "solve $\mathbf{Ax} = \mathbf{b}$" but "report the eigenvalues of $\mathbf{A}$" — and the factor there is 1, in absolute rather than relative terms. The difference between

absolute and relative matters here, and it is worth being exact. $\mathbf{A} = \operatorname{diag}(10^6, 10^{-6})$ is Hermitian with $\kappa_2(\mathbf{A}) = 10^{12}$, so solving with it is a delicate business, and yet its eigenvalues move by at most $\|\mathbf{E}\|_2$ under any Hermitian $\mathbf{E}$, exactly as those of every other Hermitian matrix do. **Ill-conditioning of the linear system says nothing about the *absolute* conditioning of the eigenvalues.** In *relative* terms the two numbers meet again. The Hermitian perturbation $\mathbf{E} = -10^{-6}\,\mathbf{e}_2\mathbf{e}_2^{\top}$ has relative size $\|\mathbf{E}\|_2/\|\mathbf{A}\|_2 = 10^{-12}$ and sends the eigenvalue 10^{-6} to 0, a relative change of 100%: an amplification of exactly $10^{12} = \kappa_2(\mathbf{A})$. In general, for an invertible Hermitian $\mathbf{A}$, Corollary 16.3.6 bounds the relative change of the eigenvalue of smallest modulus by $\|\mathbf{E}\|_2/\sigma_n(\mathbf{A})$, which is $\kappa_2(\mathbf{A})$ times the relative size of $\mathbf{E}$, and a rank-one $\mathbf{E}$ along its eigenvector attains it. So for Hermitian matrices, κ_2 *is* the relative condition number of the smallest eigenvalue.

The contrast that makes the corollary worth having is with Example (A Jordan block's eigenvalues move like $\varepsilon^{1/k}$). There $\mathbf{A} = \mathbf{J}_k(0)$ and $\mathbf{E} = \varepsilon\mathbf{E}_{k1}$, and the eigenvalues move a distance $\varepsilon^{1/k}$ while $\|\mathbf{E}\|_2 = \varepsilon$, an amplification of $\varepsilon^{-(k-1)/k}$ that is unbounded as $\varepsilon \to 0^+$. Neither matrix there is Hermitian, and Corollary 16.3.6 explains which hypothesis is doing the work: for $k = 2$ the perturbed matrix $\left(\begin{smallmatrix} 0 & 1 \\ \varepsilon & 0 \end{smallmatrix}\right)$ has the perfectly real eigenvalues $\pm\sqrt{\varepsilon}$, so the conclusion of Corollary 16.3.6 can be *stated* for it, and it is false — $\sqrt{\varepsilon} > \varepsilon$ for $0 < \varepsilon < 1$, by a factor of 1000 at $\varepsilon = 10^{-6}$.

Warning. **Both matrices must be Hermitian, and "small" is no substitute.** If $\mathbf{A}$ is not Hermitian, the corollary fails even when $\mathbf{E}$ is: take $\mathbf{A} = \mathbf{J}_2(0)$ and the Hermitian $\mathbf{E} = \varepsilon\left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$, with $\|\mathbf{E}\|_2 = \varepsilon$. Then $\mathbf{A}+\mathbf{E} = \left(\begin{smallmatrix} 0 & 1+\varepsilon \\ \varepsilon & 0 \end{smallmatrix}\right)$ has the real eigenvalues $\pm\sqrt{\varepsilon(1+\varepsilon)}$, which have moved from 0 by more than ε. If $\mathbf{E}$ is not Hermitian, the conclusion usually cannot even be stated: $\mathbf{A} = \mathbf{0}$ is Hermitian and $\mathbf{E} = \left(\begin{smallmatrix} 0 & -1 \\ 1 & 0 \end{smallmatrix}\right)$ has $\|\mathbf{E}\|_2 = 1$, but $\mathbf{A} + \mathbf{E}$ has eigenvalues $\pm i$, so there is no decreasing list $\lambda_i(\mathbf{A} + \mathbf{E})$ of real numbers to compare with anything. A bound for a diagonalizable $\mathbf{A}$ and an arbitrary $\mathbf{E}$ does exist — the theorem of Bauer and Fike, in Chapter 19 — and it carries an extra factor that measures how far the eigenvector basis of $\mathbf{A}$ is from orthonormal.

Example. (Locating eigenvalues without recomputing them)

Let

$$\mathbf{A} = \begin{pmatrix} 2 & 1 & 0 \\ 1 & 2 & 1 \\ 0 & 1 & 2 \end{pmatrix}, \qquad \mathbf{E} = \tfrac{1}{10}\big(\mathbf{E}_{13} + \mathbf{E}_{31}\big).$$

Use Corollary 16.3.6 to locate the eigenvalues of $\mathbf{A}+\mathbf{E}$, then compute them exactly and compare.

Solution. The unperturbed spectrum. Expanding along the first row, $p_{\mathbf{A}}(x) = (x - 2)\big((x-2)^2 - 2\big)$, so

$$\lambda(\mathbf{A}) = \big(2 + \sqrt{2},\ 2,\ 2 - \sqrt{2}\big) \approx (3.41421,\ 2,\ 0.58579).$$

The size of the perturbation. $\mathbf{E}$ is real symmetric with $\mathbf{E}^2 = \frac{1}{100}(\mathbf{E}_{11} + \mathbf{E}_{33})$, whose eigenvalues are $\frac{1}{100}, \frac{1}{100}, 0$; so the singular values of $\mathbf{E}$ are $\frac{1}{10}, \frac{1}{10}, 0$ and $\|\mathbf{E}\|_2 = \frac{1}{10}$ by Theorem 15.3.3 (c). (One can also read this off Lemma 16.3.5: the eigenvalues of $\mathbf{E}$ are $\frac{1}{10}, 0, -\frac{1}{10}$.)

The prediction. By Corollary 16.3.6 each eigenvalue of $\mathbf{A} + \mathbf{E}$ lies within $\frac{1}{10}$ of the

corresponding eigenvalue of $\mathbf{A}$:

$$\lambda_1 \in [3.31421,\ 3.51421], \qquad \lambda_2 \in [1.9,\ 2.1], \qquad \lambda_3 \in [0.48579,\ 0.68579].$$

In particular $\mathbf{A}+\mathbf{E}$ is positive definite, since $\lambda_3 > 0$, and its three eigenvalues are distinct, since the three intervals are disjoint.

The check. The characteristic polynomial of $\mathbf{A}+\mathbf{E}$ factors as

$$p_{\mathbf{A}+\mathbf{E}}(x) = \Big(x - \tfrac{19}{10}\Big)\Big(x^2 - \tfrac{41}{10}x + \tfrac{11}{5}\Big),$$

so

$$\begin{aligned}\lambda(\mathbf{A}+\mathbf{E}) &= \Big(\tfrac{41+3\sqrt{89}}{20},\ \tfrac{19}{10},\ \tfrac{41-3\sqrt{89}}{20}\Big)\\ &\approx (3.46510,\ 1.9,\ 0.63490).\end{aligned}$$

All three lie in the predicted intervals. The middle one lies at the very end of its interval: λ_2 has moved by exactly $\frac{1}{10} = \|\mathbf{E}\|_2$. That is not luck. The vector $(1,0,-1)$ is an eigenvector of $\mathbf{A}$ for 2 and of $\mathbf{E}$ for $-\frac{1}{10}$, hence an eigenvector of $\mathbf{A}+\mathbf{E}$ for $2-\frac{1}{10}$; a shared eigenvector is exactly what makes the bound tight.

16.3.4 Perturbations of small rank

The last corollary trades size for rank. A perturbation of rank r need not be small in norm at all, but it can only disturb r directions, and Weyl converts that into a shift of the index by r.

Corollary 16.3.8 — A Rank-r Perturbation Shifts the Index by r

Let $\mathbf{A},\mathbf{B} \in M_n(F)$ be Hermitian, let $r \geq 0$ be an integer, and suppose $\operatorname{rank}\mathbf{B} \leq r$. Then

$$\begin{aligned}\lambda_{i+r}(\mathbf{A}+\mathbf{B}) &\leq \lambda_i(\mathbf{A}) && (1 \leq i,\ i+r \leq n),\\ \lambda_i(\mathbf{A}) &\leq \lambda_{i-r}(\mathbf{A}+\mathbf{B}) && (i \leq n,\ i-r \geq 1).\end{aligned}$$

Idea. A Hermitian matrix of rank at most r has at most r non-zero eigenvalues, so once one walks $r+1$ places down its decreasing list one is certainly at a non-positive number, and once one stops r places short of the bottom one is certainly at a non-negative number. Feed those two facts into the two Weyl families at $j = r+1$ and $j = n-r$.

Proof. By the spectral theorem $\mathbf{B} = \mathbf{U}\mathbf{D}\mathbf{U}^*$ with $\mathbf{D} = \operatorname{diag}(\lambda_1(\mathbf{B}),\dots,\lambda_n(\mathbf{B}))$ and $\mathbf{U}$ unitary, so $\operatorname{rank}\mathbf{B} = \operatorname{rank}\mathbf{D}$ is the number of non-zero $\lambda_q(\mathbf{B})$, which is at most r by hypothesis.

Two facts about the list of $\mathbf{B}$. If $\lambda_{r+1}(\mathbf{B}) > 0$, then $\lambda_1(\mathbf{B}),\dots,\lambda_{r+1}(\mathbf{B})$ are all positive by the decreasing indexing, giving $r+1$ non-zero eigenvalues, a contradiction; hence

$$\lambda_{r+1}(\mathbf{B}) \leq 0 \qquad \text{whenever } r+1 \leq n.$$

If $\lambda_{n-r}(\mathbf{B}) < 0$, then $\lambda_{n-r}(\mathbf{B}),\dots,\lambda_n(\mathbf{B})$ are all negative, again $r+1$ non-zero eigenvalues and a contradiction; hence

$$\lambda_{n-r}(\mathbf{B}) \geq 0 \qquad \text{whenever } n-r \geq 1.$$

First inequality. Assume $i \geq 1$ and $i + r \leq n$; then $r + 1 \leq n$, so the index $j = r + 1$ is legitimate and $i + j - 1 = i + r \leq n$. By Theorem 16.3.3 (a) and the first fact,

$$\lambda_{i+r}(\mathbf{A} + \mathbf{B}) \leq \lambda_i(\mathbf{A}) + \lambda_{r+1}(\mathbf{B}) \leq \lambda_i(\mathbf{A}).$$

Second inequality. Assume $i \leq n$ and $i - r \geq 1$; then $n - r \geq n - i + 1 \geq 1$, so the index $j = n - r$ is legitimate, and $i + j - n = i - r \geq 1$. By Theorem 16.3.3 (b) and the second fact,

$$\lambda_{i-r}(\mathbf{A} + \mathbf{B}) \geq \lambda_i(\mathbf{A}) + \lambda_{n-r}(\mathbf{B}) \geq \lambda_i(\mathbf{A}).$$

This proves the corollary. ∎

Read together, the two inequalities say that the two eigenvalue lists interlace with a lag of r:

$$\lambda_{i+r}(\mathbf{A} + \mathbf{B}) \;\leq\; \lambda_i(\mathbf{A}) \;\leq\; \lambda_{i-r}(\mathbf{A} + \mathbf{B}),$$

whenever all three indices make sense. For $r = 0$ this collapses to $\lambda_i(\mathbf{A} + \mathbf{B}) = \lambda_i(\mathbf{A})$, correctly, since a Hermitian matrix of rank 0 is $\mathbf{0}$. For $r = 1$ it is the statement that adding a Hermitian rank-one matrix moves each eigenvalue by at most one place in the list. That case is the subject of Section 5, and Section 9 returns to low-rank perturbations when it finishes the approximation theorem that Chapter 12 §10 could only state in the Frobenius norm.

Remark. The bound is about the *index*, not the *value*. A rank-one $\mathbf{B}$ can be enormous: $\mathbf{B} = 10^6\, \mathbf{e}_1 \mathbf{e}_1^*$ has rank 1, and $\lambda_1(\mathbf{A} + \mathbf{B})$ lies within $\|\mathbf{A}\|_2$ of 10^6, by Corollary 16.3.6 with the roles of the two matrices exchanged. What Corollary 16.3.8 guarantees is that the others are trapped all the same: $\lambda_{k+1}(\mathbf{A}) \leq \lambda_k(\mathbf{A} + \mathbf{B}) \leq \lambda_{k-1}(\mathbf{A})$ for $2 \leq k \leq n - 1$, however large the one that escapes.

16.3.5 Exercises

16.3.5.1 A. Check your understanding

Exercise A1.

(a) State both families of Theorem 16.3.3, with their index conditions, and say why the condition $i + j - 1 \leq n$ cannot be dropped from the first.

(b) Determine whether the following is correct, and justify your answer: for Hermitian $\mathbf{A}, \mathbf{B}$, $\lambda_2(\mathbf{A} + \mathbf{B}) \leq \lambda_2(\mathbf{A}) + \lambda_2(\mathbf{B})$.

(c) Corollary 15.7.4 already said that eigenvalues move continuously. What does Corollary 16.3.6 add?

(d) Explain why Corollary 16.3.6 cannot be applied to $\mathbf{A} = \mathbf{J}_2(0)$ and $\mathbf{E} = \varepsilon \mathbf{E}_{21}$, and what goes wrong if one applies it anyway.

(e) If $\mathbf{B}$ is Hermitian of rank 3 and $\mathbf{A}$ is Hermitian of size 10, which eigenvalue of $\mathbf{A} + \mathbf{B}$ is guaranteed to be at most $\lambda_4(\mathbf{A})$?

Solution.

(a) See Theorem 16.3.3. Family (a) needs $i + j - 1 \leq n$ and family (b) needs $i + j - n \geq 1$.

Without the first condition the symbol $\lambda_{i+j-1}(\mathbf{A}+\mathbf{B})$ names nothing: a matrix of size n has only n eigenvalues, and there is no λ_{n+1}.

(b) Incorrect. With $\mathbf{A} = \operatorname{diag}(1,0)$ and $\mathbf{B} = \operatorname{diag}(0,1)$ it reads $\lambda_2(\mathbf{I}_2) = 1 \le 0+0$. The correct instance of Theorem 16.3.3 (a) at $i=j=2$ needs $i+j-1 = 3 \le n$, so it says nothing when $n=2$; when $n \ge 3$ it bounds λ_3, not λ_2.

(c) A constant. Corollary 15.7.4 gives, for each $\mathbf{A}$ and ε, some unspecified δ depending on $\mathbf{A}$; Corollary 16.3.6 gives $\delta = \varepsilon$ for every $\mathbf{A}$ simultaneously, that is, a Lipschitz constant of 1, independent of n, of the conditioning of $\mathbf{A}$ and of the gaps between its eigenvalues. It also matches the eigenvalues by index rather than as a multiset.

(d) Neither matrix is Hermitian, and the corollary's hypothesis is that both are. Applying it anyway predicts movement at most $\|\mathbf{E}\|_2 = \varepsilon$, whereas the eigenvalues are $\pm\sqrt{\varepsilon}$ and have moved a distance $\sqrt{\varepsilon}$, which exceeds ε for every $\varepsilon \in (0,1)$ — see Example (A Jordan block's eigenvalues move like $\varepsilon^{1/k}$).

(e) $\lambda_7(\mathbf{A}+\mathbf{B})$, and hence every later one, by Corollary 16.3.8 with $i=4$ and $r=3$.

16.3.5.2 B. Practice

Exercise B1: A small table.

Let $\mathbf{A} = \begin{pmatrix} 0 & 4 \\ 4 & 0 \end{pmatrix}$ and $\mathbf{B} = \begin{pmatrix} 3 & 0 \\ 0 & -3 \end{pmatrix}$. Compute the eigenvalues of $\mathbf{A}$, $\mathbf{B}$ and $\mathbf{A}+\mathbf{B}$, write out every inequality of Theorem 16.3.3 for this pair, and verify Corollary 16.3.6 with $\mathbf{E} = \mathbf{B}$.

Solution. $p_{\mathbf{A}}(x) = x^2 - 16$, so $\lambda(\mathbf{A}) = (4,-4)$; $\mathbf{B}$ is diagonal, so $\lambda(\mathbf{B}) = (3,-3)$; and $\mathbf{A}+\mathbf{B} = \left(\begin{smallmatrix} 3 & 4 \\ 4 & -3 \end{smallmatrix}\right)$ has $\operatorname{tr} = 0$ and $\det = -25$, so $p_{\mathbf{A}+\mathbf{B}}(x) = x^2 - 25$ and $\lambda(\mathbf{A}+\mathbf{B}) = (5,-5)$.

Family (a), for $i+j \le 3$:

$$\begin{aligned} (1,1):&\ 5 \le 4+3 = 7, \\ (1,2):&\ -5 \le 4-3 = 1, \\ (2,1):&\ -5 \le -4+3 = -1. \end{aligned}$$

Family (b), for $i+j \ge 3$:

$$\begin{aligned} (1,2):&\ 5 \ge 4-3 = 1, \\ (2,1):&\ 5 \ge -4+3 = -1, \\ (2,2):&\ -5 \ge -4-3 = -7. \end{aligned}$$

All six hold. For the last part, $\mathbf{B}$ is Hermitian with eigenvalues ± 3, so $\|\mathbf{B}\|_2 = 3$ by Lemma 16.3.5, and

$$\begin{aligned} |\lambda_1(\mathbf{A}+\mathbf{B}) - \lambda_1(\mathbf{A})| &= |5-4| = 1 \le 3, \\ |\lambda_2(\mathbf{A}+\mathbf{B}) - \lambda_2(\mathbf{A})| &= |-5+4| = 1 \le 3, \end{aligned}$$

as Corollary 16.3.6 requires.

Exercise B2: An interval for each eigenvalue.

Let $\mathbf{A} = \begin{pmatrix} 2 & 1 & 0 \\ 1 & 2 & 1 \\ 0 & 1 & 2 \end{pmatrix}$, whose eigenvalues are $2 \pm \sqrt{2}$ and 2, and let $\mathbf{E} = \frac{1}{100}\mathbf{J}$, where

$\mathbf{J} \in M_3(\mathbb{R})$ is the all-ones matrix.

(a) Compute $\|\mathbf{E}\|_2$ and give an interval containing each eigenvalue of $\mathbf{A}+\mathbf{E}$.

(b) Deduce that $\mathbf{A}+\mathbf{E}$ is positive definite.

Solution.

(a) $\mathbf{J}$ is real symmetric with $\mathbf{J}^2 = 3\mathbf{J}$, so its eigenvalues satisfy $\lambda^2 = 3\lambda$ and are 3 and 0; since $\operatorname{rank}\mathbf{J} = 1$ the list is $(3,0,0)$. Hence $\mathbf{E}$ has eigenvalues $(\frac{3}{100},0,0)$ and $\|\mathbf{E}\|_2 = \frac{3}{100}$ by Lemma 16.3.5. By Corollary 16.3.6,

$$\begin{aligned}\lambda_1(\mathbf{A}+\mathbf{E}) &\in [3.38421,\ 3.44421],\\ \lambda_2(\mathbf{A}+\mathbf{E}) &\in [1.97,\ 2.03],\\ \lambda_3(\mathbf{A}+\mathbf{E}) &\in [0.55579,\ 0.61579],\end{aligned}$$

the centers being $2+\sqrt{2} \approx 3.41421$, 2 and $2-\sqrt{2} \approx 0.58579$.

(b) Every interval lies strictly to the right of 0, so all three eigenvalues of the Hermitian matrix $\mathbf{A}+\mathbf{E}$ are positive and $\mathbf{A}+\mathbf{E} \succ 0$ by Theorem 12.1.5 (b). No characteristic polynomial was computed. (For the record, the exact eigenvalues are 2 and $\frac{403\pm\sqrt{81609}}{200}$, that is 2, 3.44336… and 0.58664…; the middle one is unmoved because $(1,0,-1)$ is an eigenvector of both $\mathbf{A}$ and $\mathbf{J}$.)

Exercise B3: What a low-rank update can do.

Let $\mathbf{A} \in M_5(\mathbb{C})$ be Hermitian with $\lambda(\mathbf{A}) = (5,4,3,2,1)$, and let $\mathbf{B} \in M_5(\mathbb{C})$ be Hermitian with $\operatorname{rank}\mathbf{B} \le 2$. Find the best bounds that Corollary 16.3.8 gives for $\lambda_3(\mathbf{A}+\mathbf{B})$, and give examples showing that each is attained.

Solution. Take $r = 2$. The first inequality reads $\lambda_{i+2}(\mathbf{A}+\mathbf{B}) \le \lambda_i(\mathbf{A})$, and it mentions $\lambda_3(\mathbf{A}+\mathbf{B})$ only at $i=1$, giving $\lambda_3(\mathbf{A}+\mathbf{B}) \le \lambda_1(\mathbf{A}) = 5$. The second reads $\lambda_i(\mathbf{A}) \le \lambda_{i-2}(\mathbf{A}+\mathbf{B})$, and it mentions $\lambda_3(\mathbf{A}+\mathbf{B})$ only at $i=5$, giving $\lambda_3(\mathbf{A}+\mathbf{B}) \ge \lambda_5(\mathbf{A}) = 1$. So the corollary gives exactly $\lambda_3(\mathbf{A}+\mathbf{B}) \in [1,5]$.

Both ends are attained. Write $\mathbf{A} = \mathbf{U}\operatorname{diag}(5,4,3,2,1)\mathbf{U}^*$ with $\mathbf{U}$ unitary (Corollary 11.4.3) and let $\mathbf{q}_1,\dots,\mathbf{q}_5$ be its columns, an orthonormal eigenbasis.

For the upper bound take $\mathbf{B} = 4(\mathbf{q}_4\mathbf{q}_4^* + \mathbf{q}_5\mathbf{q}_5^*)$, which is Hermitian of rank 2. It adds 4 to the fourth and fifth eigenvalues and leaves the rest alone, so $\mathbf{A}+\mathbf{B} = \mathbf{U}\operatorname{diag}(5,4,3,6,5)\mathbf{U}^*$, whose eigenvalue list sorted decreasingly is $(6,5,5,4,3)$. Hence $\lambda_3(\mathbf{A}+\mathbf{B}) = 5 = \lambda_1(\mathbf{A})$.

For the lower bound take $\mathbf{B} = -4(\mathbf{q}_1\mathbf{q}_1^* + \mathbf{q}_2\mathbf{q}_2^*)$, again Hermitian of rank 2. Then $\mathbf{A}+\mathbf{B} = \mathbf{U}\operatorname{diag}(1,0,3,2,1)\mathbf{U}^*$, sorted $(3,2,1,1,0)$, so $\lambda_3(\mathbf{A}+\mathbf{B}) = 1 = \lambda_5(\mathbf{A})$.

16.3.5.3 C. Going deeper

Exercise C1: The Loewner order through Weyl.

Let $\mathbf{A},\mathbf{B} \in M_n(F)$ be Hermitian.

(a) Prove that if $\mathbf{A} \succeq \mathbf{B}$ then $\lambda_i(\mathbf{A}) \geq \lambda_i(\mathbf{B})$ for every i, as a consequence of Corollary 16.3.4.

(b) Hence deduce that $|\lambda_i(\mathbf{A}) - \lambda_i(\mathbf{B})| \leq \|\mathbf{A} - \mathbf{B}\|_2$ for every i, without invoking Corollary 16.3.6.

Solution.

(a) Put $\mathbf{C} = \mathbf{A} - \mathbf{B}$, which is Hermitian, and $\mathbf{C} \succeq 0$ by hypothesis and Definition 12.5.1. By Theorem 12.1.4 (b) every eigenvalue of $\mathbf{C}$ is ≥ 0, in particular $\lambda_n(\mathbf{C}) \geq 0$. Applying Corollary 16.3.4 to $\mathbf{B}$ and $\mathbf{C}$,

$$\lambda_i(\mathbf{A}) = \lambda_i(\mathbf{B} + \mathbf{C}) \;\geq\; \lambda_i(\mathbf{B}) + \lambda_n(\mathbf{C}) \;\geq\; \lambda_i(\mathbf{B}).$$

This is Corollary 16.2.4.

(b) Put $\mathbf{C} = \mathbf{A} - \mathbf{B}$ again, now with no sign hypothesis, and let $t = \|\mathbf{C}\|_2$. By Lemma 16.3.5, $-t \leq \lambda_n(\mathbf{C})$ and $\lambda_1(\mathbf{C}) \leq t$, so $t\mathbf{I} - \mathbf{C} \succeq 0$ and $\mathbf{C} + t\mathbf{I} \succeq 0$ by Theorem 12.1.4 (b) applied to the Hermitian matrices $t\mathbf{I} - \mathbf{C}$ and $\mathbf{C} + t\mathbf{I}$, whose eigenvalues are $t - \lambda_q(\mathbf{C})$ and $\lambda_q(\mathbf{C}) + t$. Hence $\mathbf{B} + t\mathbf{I} \succeq \mathbf{A} \succeq \mathbf{B} - t\mathbf{I}$, and part (a) gives

$$\lambda_i(\mathbf{B}) + t = \lambda_i(\mathbf{B} + t\mathbf{I}) \;\geq\; \lambda_i(\mathbf{A}),$$
$$\lambda_i(\mathbf{A}) \geq \lambda_i(\mathbf{B} - t\mathbf{I}) = \lambda_i(\mathbf{B}) - t,$$

using $\lambda_i(\mathbf{M} + s\mathbf{I}) = \lambda_i(\mathbf{M}) + s$ for real s, which holds because $\mathbf{M}$ and $\mathbf{M} + s\mathbf{I}$ have the same eigenvectors with eigenvalues shifted by s, and shifting by a constant preserves the decreasing order. Rearranged, this is $|\lambda_i(\mathbf{A}) - \lambda_i(\mathbf{B})| \leq t$, as claimed.

Exercise C2: The largest eigenvalue is a convex function.

Let $\mathbf{A}, \mathbf{B} \in M_n(F)$ be Hermitian and let $t \in [0, 1]$.

(a) Prove that $\lambda_1(t\mathbf{A} + (1-t)\mathbf{B}) \leq t\lambda_1(\mathbf{A}) + (1-t)\lambda_1(\mathbf{B})$.

(b) Deduce that for every $c \in \mathbb{R}$ the set $\{\mathbf{M} \in M_n(F) : \mathbf{M}^* = \mathbf{M},\ \lambda_1(\mathbf{M}) \leq c\}$ is convex.

(c) Show that λ_2 is **not** convex in this sense, by producing two Hermitian 2×2 matrices and a value of t where the inequality fails.

Solution.

(a) For $s \geq 0$ and Hermitian $\mathbf{M}$ we have $\lambda_1(s\mathbf{M}) = s\lambda_1(\mathbf{M})$, since $s\mathbf{M} = \mathbf{U}(s\mathbf{D})\mathbf{U}^*$ and multiplying a decreasing list of reals by $s \geq 0$ keeps it decreasing. By Theorem 16.3.3 (a) at $i = j = 1$, applied to the Hermitian matrices $t\mathbf{A}$ and $(1-t)\mathbf{B}$,

$$\lambda_1\big(t\mathbf{A} + (1-t)\mathbf{B}\big) \leq \lambda_1(t\mathbf{A}) + \lambda_1\big((1-t)\mathbf{B}\big) = t\lambda_1(\mathbf{A}) + (1-t)\lambda_1(\mathbf{B}).$$

(b) Let $\mathbf{A}, \mathbf{B}$ lie in the set and let $t \in [0, 1]$. The matrix $t\mathbf{A} + (1-t)\mathbf{B}$ is Hermitian, and by (a) its largest eigenvalue is at most $tc + (1-t)c = c$. So the set contains the whole segment between any two of its points.

(c) Take $\mathbf{A} = \operatorname{diag}(1, 0)$, $\mathbf{B} = \operatorname{diag}(0, 1)$ and $t = \tfrac{1}{2}$. Then $\lambda_2(\mathbf{A}) = \lambda_2(\mathbf{B}) = 0$, while $t\mathbf{A} + (1-t)\mathbf{B} = \tfrac{1}{2}\mathbf{I}_2$ has $\lambda_2 = \tfrac{1}{2}$. So $\tfrac{1}{2} \leq \tfrac{1}{2} \cdot 0 + \tfrac{1}{2} \cdot 0 = 0$ is false. The reason is visible in Theorem 16.3.3: at $i = j = 2$ the index on the left is 3, not 2.

Exercise C3: Sharpness of the whole family.

Fix n and indices i, j with $i + j - 1 \le n$. Construct Hermitian $\mathbf{A}, \mathbf{B} \in M_n(\mathbb{R})$, both diagonal, for which

$$\lambda_{i+j-1}(\mathbf{A} + \mathbf{B}) = \lambda_i(\mathbf{A}) + \lambda_j(\mathbf{B}).$$

Hint: with diagonal matrices every quantity in sight is a sorting problem; arrange for the $(i + j - 1)$-st largest entry of the sum to sit in a coordinate where $\mathbf{A}$ contributes its i-th largest and $\mathbf{B}$ its j-th largest.

Solution. Let $k = i + j - 1$ and let $\mathbf{A} = \operatorname{diag}(a_1, \dots, a_n)$ and $\mathbf{B} = \operatorname{diag}(b_1, \dots, b_n)$ with

$$a_p = \begin{cases} 1 & p \le i - 1, \\ 0 & p \ge i, \end{cases} \qquad b_p = \begin{cases} 0 & p \le i - 1, \\ 1 & i \le p \le k, \\ 0 & p > k. \end{cases}$$

Both are diagonal with entries 0 and 1, hence Hermitian, and their diagonals are already their eigenvalue lists up to sorting. The matrix $\mathbf{A}$ has $i - 1$ entries equal to 1, so $\lambda_i(\mathbf{A}) = 0$. The matrix $\mathbf{B}$ has $k - i + 1 = j$ entries equal to 1, so $\lambda_j(\mathbf{B}) = 1$. The sum is $\mathbf{A} + \mathbf{B} = \operatorname{diag}(1, \dots, 1, 0, \dots, 0)$ with exactly k ones, since the ones of $\mathbf{A}$ occupy coordinates $1, \dots, i-1$ and those of $\mathbf{B}$ occupy $i, \dots, k$, and these two sets of coordinates do not overlap. Hence $\lambda_k(\mathbf{A} + \mathbf{B}) = 1 = \lambda_i(\mathbf{A}) + \lambda_j(\mathbf{B})$.

Every inequality of the first family is therefore attained, for every admissible pair (i, j), already by 0–1 diagonal matrices. Applying Lemma 16.3.2 to $-\mathbf{A}$ and $-\mathbf{B}$, as in the proof of Theorem 16.3.3 (b), turns this family of equalities into one showing that the second family is attained as well.

16.4 Deleting a Row and a Column

Take a Hermitian matrix, cross out the last row and the last column, and look at what is left. It is again Hermitian, one size smaller, and it has its own eigenvalues. Two lists of numbers are now in play, n of them and $n - 1$ of them, and they cannot be independent of each other: the smaller matrix is the larger one restricted to a hyperplane, and Theorem 16.2.3 describes every eigenvalue by what happens on subspaces. Restricting the supply of subspaces can only make the description worse in one direction and better in the other, and the exact bookkeeping is this section's subject.

The answer is as tight as it could be. The $n-1$ eigenvalues of the corner fall into the $n-1$ gaps of the eigenvalues of the whole, one to a gap. Nothing stronger holds: every interlacing pattern actually occurs (Exercise C2 proves the case $n = 2$).

Throughout this section the field is $\mathbb{R}$ or $\mathbb{C}$, and every matrix whose eigenvalues are written down is Hermitian, with eigenvalues real and indexed **decreasingly**. For an index set $I \subseteq \{1, \dots, n\}$ we write $\mathbf{A}_{I,I}$ for the **principal submatrix** of $\mathbf{A}$ on the rows and columns indexed by I, as in Definition 6.7.1. A principal submatrix of a Hermitian matrix is Hermitian, since $(\mathbf{A}_{I,I})^* = (\mathbf{A}^*)_{I,I} = \mathbf{A}_{I,I}$.

16.4.1 A matrix restricted to a coordinate hyperplane

Deleting row m and column m is not an arbitrary mutilation of $\mathbf{A}$. It is what $\mathbf{A}$ looks like to vectors whose m-th coordinate is zero, and that is the only observation the proof needs.

Lemma 16.4.1 — Deleting a Row and a Column Is Restricting to a Hyperplane

Let $\mathbf{A} \in M_n(F)$ be Hermitian with $n \geq 2$, fix m with $1 \leq m \leq n$, put $I = \{1, \dots, n\} \setminus \{m\}$ and $\mathbf{B} = \mathbf{A}_{I,I} \in M_{n-1}(F)$. Let

$$H = \{\mathbf{x} \in F^n : x_m = 0\},$$

and let $\varphi \colon H \to F^{n-1}$ delete the m-th coordinate. Then φ is a linear isomorphism, and for every $\mathbf{x} \in H$,

$$\langle \mathbf{A}\mathbf{x}, \mathbf{x} \rangle = \langle \mathbf{B}\varphi(\mathbf{x}), \varphi(\mathbf{x}) \rangle, \qquad \|\mathbf{x}\| = \|\varphi(\mathbf{x})\|.$$

In particular $R_{\mathbf{A}}(\mathbf{x}) = R_{\mathbf{B}}(\varphi(\mathbf{x}))$ for every $\mathbf{x} \in H$ with $\mathbf{x} \neq \mathbf{0}$.

Proof. The map φ is linear, being given by deleting a coordinate, and it is bijective from H to F^{n-1} because inserting 0 in position m inverts it. Write $I = \{i_1 < \cdots < i_{n-1}\}$, so that $\varphi(\mathbf{x})_r = x_{i_r}$ and $(\mathbf{B})_{rs} = a_{i_r i_s}$ by Definition 6.7.1.

Let $\mathbf{x} \in H$. Expanding the inner product of F^n, which is linear in the first slot and conjugate-linear in the second,

$$\langle \mathbf{A}\mathbf{x}, \mathbf{x} \rangle = \sum_{p=1}^{n} \sum_{q=1}^{n} a_{pq}\, x_q\, \overline{x_p}.$$

Every term with $p = m$ or $q = m$ vanishes, because $x_m = 0$. The remaining terms are indexed by $p, q \in I$, say $p = i_r$ and $q = i_s$, and there the summand is $a_{i_r i_s} \varphi(\mathbf{x})_s \overline{\varphi(\mathbf{x})_r} = (\mathbf{B})_{rs} \varphi(\mathbf{x})_s \overline{\varphi(\mathbf{x})_r}$. Summing over r, s gives $\langle \mathbf{B}\varphi(\mathbf{x}), \varphi(\mathbf{x}) \rangle$. The same deletion of a zero coordinate gives $\|\mathbf{x}\|^2 = \sum_{p \neq m} |x_p|^2 = \|\varphi(\mathbf{x})\|^2$. Dividing the first identity by the second, which is positive when $\mathbf{x} \neq \mathbf{0}$, gives the statement about the Rayleigh quotients (Definition 16.1.1). This proves the lemma.

■

Because φ is an isomorphism, it matches the k-dimensional subspaces of H with the k-dimensional subspaces of F^{n-1}, for every k. So a statement about $R_{\mathbf{B}}$ on subspaces of F^{n-1} *is* a statement about $R_{\mathbf{A}}$ on subspaces of H, and the only thing lost in passing from $\mathbf{A}$ to $\mathbf{B}$ is the subspaces of F^n that are not inside H.

16.4.2 Interlacing

Theorem 16.4.2 — Cauchy's Interlacing Theorem

Let $\mathbf{A} \in M_n(F)$ be Hermitian with $n \geq 2$, let $I \subseteq \{1, \ldots, n\}$ with $|I| = n-1$, and let $\mathbf{B} = \mathbf{A}_{I,I}$. Then

$$\lambda_k(\mathbf{A}) \;\geq\; \lambda_k(\mathbf{B}) \;\geq\; \lambda_{k+1}(\mathbf{A}) \qquad (1 \leq k \leq n-1),$$

that is,

$$\lambda_1(\mathbf{A}) \geq \lambda_1(\mathbf{B}) \geq \lambda_2(\mathbf{A}) \geq \lambda_2(\mathbf{B}) \geq \cdots \geq \lambda_{n-1}(\mathbf{B}) \geq \lambda_n(\mathbf{A}).$$

Idea. Both halves of Theorem 16.2.3 are used, one for each inequality, and each time the move is the same: a subspace of H is also a subspace of F^n.

① For $\lambda_k(\mathbf{B}) \leq \lambda_k(\mathbf{A})$ use the **max–min** form. The best k-dimensional subspace for $\mathbf{B}$ lives inside H; transplanted to F^n it is one competitor among more, so the maximum over all of them is at least as large.

② For $\lambda_{k+1}(\mathbf{A}) \leq \lambda_k(\mathbf{B})$ use the **min–max** form, and count dimensions. The best subspace for $\mathbf{B}$ there has dimension $(n-1)-k+1 = n-k$, and $n-k = n-(k+1)+1$ is exactly the dimension the min–max form for $\lambda_{k+1}(\mathbf{A})$ asks for. So the same subspace, viewed in F^n, is admissible for $\mathbf{A}$ at the index $k+1$.

The dimension count that makes min–max work at all is Lemma 16.2.1, and it has already been spent inside Theorem 16.2.3; nothing more is needed here than the coincidence of the two numbers in ②.

Proof. Let m be the index not in I, and let H and φ be as in Lemma 16.4.1, so that $R_{\mathbf{A}}(\mathbf{x}) = R_{\mathbf{B}}(\varphi(\mathbf{x}))$ for every non-zero $\mathbf{x} \in H$. Both $\mathbf{A}$ and $\mathbf{B}$ are Hermitian, so Theorem 16.2.3 applies to each, to $\mathbf{A}$ with n and to $\mathbf{B}$ with $n-1$ in the role of the size. Fix k with $1 \leq k \leq n-1$.

($\lambda_k(\mathbf{B}) \leq \lambda_k(\mathbf{A})$) By the max–min form of Theorem 16.2.3 for $\mathbf{B}$, there is a subspace $W' \leq F^{n-1}$ with $\dim W' = k$ and

$$\lambda_k(\mathbf{B}) = \min_{\mathbf{0} \neq \mathbf{y} \in W'} R_{\mathbf{B}}(\mathbf{y}).$$

Put $W = \varphi^{-1}(W') \leq H \leq F^n$. Since φ is an isomorphism, $\dim W = k$, and φ carries the non-zero vectors of W onto the non-zero vectors of W', so

$$\min_{\mathbf{0} \neq \mathbf{x} \in W} R_{\mathbf{A}}(\mathbf{x}) = \min_{\mathbf{0} \neq \mathbf{y} \in W'} R_{\mathbf{B}}(\mathbf{y}) = \lambda_k(\mathbf{B}).$$

Now W is one of the k-dimensional subspaces of F^n over which the max–min form for $\mathbf{A}$ takes its maximum, so $\lambda_k(\mathbf{A}) \geq \lambda_k(\mathbf{B})$.

($\lambda_{k+1}(\mathbf{A}) \leq \lambda_k(\mathbf{B})$) By the min–max form of Theorem 16.2.3 for $\mathbf{B}$, whose matrices have size $n-1$, there is a subspace $W' \leq F^{n-1}$ with $\dim W' = (n-1)-k+1 = n-k$ and

$$\lambda_k(\mathbf{B}) = \max_{\mathbf{0} \neq \mathbf{y} \in W'} R_{\mathbf{B}}(\mathbf{y}).$$

Put $W = \varphi^{-1}(W') \leq F^n$, of dimension $n-k$. Since $1 \leq k+1 \leq n$ and $n-(k+1)+1 = n-k = \dim W$, the subspace W is admissible in the min–max form for $\lambda_{k+1}(\mathbf{A})$, and that form takes the minimum over all such subspaces. Hence

$$\lambda_{k+1}(\mathbf{A}) \;\leq\; \max_{\mathbf{0} \neq \mathbf{x} \in W} R_{\mathbf{A}}(\mathbf{x}) = \max_{\mathbf{0} \neq \mathbf{y} \in W'} R_{\mathbf{B}}(\mathbf{y}) = \lambda_k(\mathbf{B}).$$

This proves the theorem.

■

The picture to keep is one of nesting. The interval $[\lambda_n(\mathbf{A}), \lambda_1(\mathbf{A})]$ contains the interval $[\lambda_{n-1}(\mathbf{B}), \lambda_1(\mathbf{B})]$, and inside it the two lists alternate, an eigenvalue of $\mathbf{B}$ between each consecutive pair of eigenvalues of $\mathbf{A}$. Deleting a row and a column can only shrink the spectrum inward, never spread it out.

Quick check. Both inequalities in Theorem 16.4.2 can be equalities. Give a matrix $\mathbf{A}$ for which $\lambda_1(\mathbf{A}) = \lambda_1(\mathbf{B})$, and one for which $\lambda_1(\mathbf{B}) = \lambda_2(\mathbf{A})$.

Solution. For the first, $\mathbf{A} = \mathbf{I}_2$ with $I = \{1\}$: then $\mathbf{B} = (1)$ and $\lambda_1(\mathbf{A}) = \lambda_1(\mathbf{B}) = 1$. For the second, $\mathbf{A} = \operatorname{diag}(1, 0)$ with $I = \{2\}$: then $\mathbf{B} = (0)$, and $\lambda_1(\mathbf{B}) = 0 = \lambda_2(\mathbf{A})$. Nothing in the theorem forces a gap; when a gap is forced is exactly the question settled later in this section.

Deleting one index at a time and iterating gives the general statement.

Corollary 16.4.3 — Deleting m Rows and the Same m Columns

Let $\mathbf{A} \in M_n(F)$ be Hermitian, let $0 \le m \le n-1$, let $I \subseteq \{1, \dots, n\}$ with $|I| = n - m$, and let $\mathbf{B} = \mathbf{A}_{I,I}$. Then

$$\lambda_i(\mathbf{A}) \;\ge\; \lambda_i(\mathbf{B}) \;\ge\; \lambda_{i+m}(\mathbf{A}) \qquad (1 \le i \le n-m).$$

Proof. Induction on m. For $m = 0$ we have $\mathbf{B} = \mathbf{A}$ and both inequalities are equalities.

Let $m \ge 1$ and suppose the statement holds for $m-1$, for every Hermitian matrix. Choose an index $j \notin I$ and put $I' = I \cup \{j\}$, so $|I'| = n - m + 1$, and $\mathbf{B}' = \mathbf{A}_{I',I'} \in M_{n-m+1}(F)$, which is Hermitian. Since $I \subseteq I'$, taking the principal submatrix on I of $\mathbf{B}'$ means keeping the rows and columns of $\mathbf{A}$ indexed by I, so $(\mathbf{B}')_{I,I} = \mathbf{B}$ after relabeling the indices of I inside I'; and $|I| = |I'| - 1$.

Fix i with $1 \le i \le n - m$. By the inductive hypothesis applied to $\mathbf{A}$ and $\mathbf{B}'$,

$$\lambda_i(\mathbf{A}) \;\ge\; \lambda_i(\mathbf{B}') \;\ge\; \lambda_{i+m-1}(\mathbf{A}),$$

which is available because $i \le n - m < n - m + 1$. By Theorem 16.4.2 applied to $\mathbf{B}'$ and its principal submatrix $\mathbf{B}$, which is one size smaller,

$$\lambda_k(\mathbf{B}') \;\ge\; \lambda_k(\mathbf{B}) \;\ge\; \lambda_{k+1}(\mathbf{B}') \qquad (1 \le k \le n-m).$$

Combining, $\lambda_i(\mathbf{B}) \le \lambda_i(\mathbf{B}') \le \lambda_i(\mathbf{A})$, which is the first inequality. For the second, take $k = i$ in the display above and then use the inductive hypothesis at the index $i + 1$, legitimate since $i + 1 \le n - m + 1$:

$$\lambda_i(\mathbf{B}) \;\ge\; \lambda_{i+1}(\mathbf{B}') \;\ge\; \lambda_{(i+1)+m-1}(\mathbf{A}) = \lambda_{i+m}(\mathbf{A}).$$

This proves the corollary.

■

The extreme case $m = n - 1$ is worth writing down, because it recovers a fact about diagonal entries that also follows from Chapter 12's description of the extreme eigenvalues.

Example. (The diagonal lies inside the spectrum)

Let $\mathbf{A} \in M_n(F)$ be Hermitian. Show that $\lambda_n(\mathbf{A}) \le a_{ii} \le \lambda_1(\mathbf{A})$ for every i.

Solution. Take $I = \{i\}$, so $m = n - 1$ and $\mathbf{B} = \mathbf{A}_{I,I} = (a_{ii})$, a 1×1 Hermitian matrix whose single eigenvalue is a_{ii} — real, as a diagonal entry of a Hermitian matrix must be. Corollary 16.4.3 at $i = 1$ gives

$$\lambda_1(\mathbf{A}) \;\ge\; \lambda_1(\mathbf{B}) = a_{ii} \;\ge\; \lambda_{1+(n-1)}(\mathbf{A}) = \lambda_n(\mathbf{A}).$$

The same conclusion follows from Lemma 12.5.2 applied to the unit vector $\mathbf{e}_i$, since $\langle \mathbf{A}\mathbf{e}_i, \mathbf{e}_i \rangle = a_{ii}$. What interlacing adds is the version for larger index sets: any k diagonal entries are the diagonal of a $k \times k$ principal submatrix, whose i-th eigenvalue is trapped between $\lambda_{i+n-k}(\mathbf{A})$ and $\lambda_i(\mathbf{A})$. How much more can be said about the diagonal of a Hermitian matrix, given its spectrum, is the subject of Section 8.

16.4.3 When is the interlacing strict?

Theorem 16.4.2 allows equalities, and the Quick check produced them. Deciding when they occur is the delicate part of the subject, and it is easiest to see when the deleted index is the last one, so that $\mathbf{A}$ is presented as $\mathbf{B}$ with a border added.

Theorem 16.4.4 — Bordering a Hermitian Matrix

Let $\mathbf{B} \in M_{n-1}(F)$ be Hermitian with $n \ge 2$, let $\mathbf{b} \in F^{n-1}$, let $c \in \mathbb{R}$, and let

$$\mathbf{A} = \begin{pmatrix} \mathbf{B} & \mathbf{b} \\ \mathbf{b}^* & c \end{pmatrix} \in M_n(F),$$

which is Hermitian and has $\mathbf{A}_{I,I} = \mathbf{B}$ for $I = \{1, \dots, n-1\}$. For an eigenvalue ν of $\mathbf{B}$, write P_ν for the orthogonal projection of F^{n-1} onto the eigenspace $E_\nu(\mathbf{B})$, and $m_\nu = \dim E_\nu(\mathbf{B})$.

(a) If $P_\nu \mathbf{b} \neq \mathbf{0}$, then ν is a root of $p_{\mathbf{A}}$ of multiplicity **exactly** $m_\nu - 1$; in particular, if $m_\nu = 1$ then ν is not an eigenvalue of $\mathbf{A}$.

(b) If $P_\nu \mathbf{b} = \mathbf{0}$, then ν is a root of $p_{\mathbf{A}}$ of multiplicity **at least** m_ν.

(c) The interlacing $\lambda_1(\mathbf{A}) \ge \lambda_1(\mathbf{B}) \ge \cdots \ge \lambda_{n-1}(\mathbf{B}) \ge \lambda_n(\mathbf{A})$ is strict at every one of its $2(n-1)$ inequalities if and only if $\mathbf{B}$ has $n - 1$ **distinct** eigenvalues **and** $P_\nu \mathbf{b} \neq \mathbf{0}$ for every eigenvalue ν of $\mathbf{B}$.

Idea. Write the characteristic polynomial of $\mathbf{A}$ down. With $\mathbf{B}$ diagonalized, a Schur complement turns $\det(x\mathbf{I} - \mathbf{A})$ into

$$\Big(\prod_k (x - \mu_k)\Big)\Big((x - c) - \sum_k \frac{|\tilde{b}_k|^2}{x - \mu_k}\Big),$$

and clearing the denominators leaves a polynomial identity in which each μ_k appears with one factor fewer than one might expect — provided $P_\nu \mathbf{b} \neq \mathbf{0}$, that is, provided the $|\tilde{b}_k|^2$ over the group belonging to that eigenvalue do not all vanish (for a repeated eigenvalue the individual $\tilde{b}_k$ depend on the choice of basis, but their sum does not). Part (c) then costs almost nothing: strict interlacing means the combined list of $2n-1$ numbers is strictly decreasing, hence has no repetitions at all, and (a) and (b) say exactly which repetitions are possible.

Proof. **Step 1: diagonalize the corner.** By the spectral theorem (Corollary 11.4.3 over $\mathbb{C}$, Corollary 11.5.2 over $\mathbb{R}$) write $\mathbf{B} = \mathbf{U}\mathbf{D}\mathbf{U}^*$ with $\mathbf{U} \in M_{n-1}(F)$ unitary and $\mathbf{D} = \operatorname{diag}(\mu_1, \dots, \mu_{n-1})$ carrying the eigenvalues of $\mathbf{B}$ in decreasing order, the columns $\mathbf{u}_1, \dots, \mathbf{u}_{n-1}$ of $\mathbf{U}$ being an orthonormal basis of eigenvectors. Let $\mathbf{V} = \left(\begin{smallmatrix} \mathbf{U} & \mathbf{0} \\ \mathbf{0}^* & 1 \end{smallmatrix}\right) \in M_n(F)$, which is unitary because $\mathbf{V}^*\mathbf{V} = \mathbf{I}_n$. Multiplying in blocks (Theorem 7.1.1) gives

$$\mathbf{V}^*\mathbf{A}\mathbf{V} = \begin{pmatrix} \mathbf{D} & \tilde{\mathbf{b}} \\ \tilde{\mathbf{b}}^* & c \end{pmatrix}, \qquad \tilde{\mathbf{b}} = \mathbf{U}^*\mathbf{b}.$$

Similar matrices have the same characteristic polynomial (Theorem 6.10.3), so we may compute with the right-hand side. Moreover $\tilde{b}_k = (\mathbf{U}^*\mathbf{b})_k = \langle \mathbf{b}, \mathbf{u}_k \rangle$, and the $\mathbf{u}_k$ with $\mu_k = \nu$ form an orthonormal basis of $E_\nu(\mathbf{B})$: they lie in it, and a vector $\mathbf{x} = \sum_k c_k \mathbf{u}_k$ with $\mathbf{B}\mathbf{x} = \nu\mathbf{x}$ has $(\mu_k - \nu)c_k = 0$ for every k, so $c_k = 0$ unless $\mu_k = \nu$. Hence exactly m_ν of the μ_k equal ν, and

$$P_\nu \mathbf{b} = \sum_{k:\mu_k=\nu} \langle \mathbf{b}, \mathbf{u}_k \rangle \, \mathbf{u}_k \quad \text{and} \quad \|P_\nu \mathbf{b}\|^2 = \sum_{k:\mu_k=\nu} |\tilde{b}_k|^2.$$

In particular $P_\nu \mathbf{b} = \mathbf{0}$ exactly when $\tilde{b}_k = 0$ for every k with $\mu_k = \nu$.

Step 2: the characteristic polynomial. We claim that, as polynomials in x,

$$\begin{aligned} p_{\mathbf{A}}(x) = (x - c) \prod_{k=1}^{n-1} (x - \mu_k) \\ - \sum_{k=1}^{n-1} |\tilde{b}_k|^2 \prod_{l \neq k} (x - \mu_l). \end{aligned} \tag{16.4.1}$$

Claim. Eq. 16.4.1 holds.

Proof. Fix a scalar x_0 that is not an eigenvalue of $\mathbf{B}$. Then $x_0\mathbf{I}_{n-1} - \mathbf{D}$ is invertible, being diagonal with non-zero diagonal entries, so Theorem 7.3.2 (a), applied to

$$\mathbf{M} = x_0\mathbf{I}_n - \mathbf{V}^*\mathbf{A}\mathbf{V} = \begin{pmatrix} x_0\mathbf{I}_{n-1} - \mathbf{D} & -\tilde{\mathbf{b}} \\ -\tilde{\mathbf{b}}^* & x_0 - c \end{pmatrix}$$

with the invertible block in the top left, gives $\det \mathbf{M} = \det(x_0\mathbf{I}-\mathbf{D})\cdot\det(\mathbf{M}/(x_0\mathbf{I}-\mathbf{D}))$, where the Schur complement is the 1×1 matrix

$$(x_0 - c) - (-\tilde{\mathbf{b}}^*)(x_0\mathbf{I} - \mathbf{D})^{-1}(-\tilde{\mathbf{b}}) = (x_0 - c) - \sum_k \frac{|\tilde{b}_k|^2}{x_0 - \mu_k}.$$

Multiplying out $\det(x_0\mathbf{I} - \mathbf{D}) = \prod_k (x_0 - \mu_k)$ against this scalar, and canceling one factor $(x_0 - \mu_k)$ in the k-th summand, gives exactly the right-hand side of Eq. 16.4.1 evaluated at x_0. So the two sides of Eq. 16.4.1, which are polynomials of degree n, agree at every scalar outside the finite set $\mathrm{spec}(\mathbf{B})$. Their difference is therefore a polynomial of degree at most n with infinitely many roots in F, and a non-zero polynomial of degree at most n has at most n roots (Corollary 5.1.4); so the difference is zero.

■

Step 3: multiplicities. Let $\nu_1 > \cdots > \nu_p$ be the distinct eigenvalues of $\mathbf{B}$, with multiplicities $m_1, \ldots, m_p$ summing to $n - 1$, and put $\beta_t = \|P_{\nu_t}\mathbf{b}\|^2$. Grouping equal μ_k in Eq. 16.4.1 — the product $\prod_{l\neq k}(x - \mu_l)$ is the same for all k in one group, and the coefficients $|\tilde{b}_k|^2$ add up to β_t by Step 1 — turns it into

$$p_{\mathbf{A}}(x) = (x - c)\prod_{t=1}^{p}(x - \nu_t)^{m_t} - \sum_{t=1}^{p} \beta_t\,(x - \nu_t)^{m_t - 1}\prod_{s\neq t}(x - \nu_s)^{m_s}.$$

Fix t. Every term on the right is divisible by $(x - \nu_t)^{m_t-1}$, so $p_{\mathbf{A}}(x) = (x - \nu_t)^{m_t-1}g(x)$ with

$$g(x) = (x - c)(x - \nu_t)\prod_{s\neq t}(x - \nu_s)^{m_s} - \beta_t\prod_{s\neq t}(x - \nu_s)^{m_s} - \sum_{u\neq t}\beta_u\,(x - \nu_t)(x - \nu_u)^{m_u-1}\prod_{s\neq u,t}(x - \nu_s)^{m_s}.$$

Evaluate at $x = \nu_t$. The first term vanishes because of its factor $(x - \nu_t)$, and so does every summand of the third, for the same reason. What is left is

$$g(\nu_t) = -\beta_t\prod_{s\neq t}(\nu_t - \nu_s)^{m_s},$$

and the product is non-zero because the ν_s are distinct. So $g(\nu_t) \neq 0$ exactly when $\beta_t \neq 0$, that is, exactly when $P_{\nu_t}\mathbf{b} \neq \mathbf{0}$. In that case ν_t is a root of $p_{\mathbf{A}}$ of multiplicity exactly $m_t - 1$, which proves (a); in the other case $(x - \nu_t)$ divides g, so the multiplicity is at least m_t, which proves (b).

Step 4: strictness. ($\Leftarrow$) Suppose $\mathbf{B}$ has $n-1$ distinct eigenvalues, so every $m_t = 1$, and $P_\nu \mathbf{b} \neq \mathbf{0}$ for each of them. By (a), no eigenvalue of $\mathbf{B}$ is an eigenvalue of $\mathbf{A}$. Theorem 16.4.2 gives $\lambda_k(\mathbf{A}) \geq \lambda_k(\mathbf{B}) \geq \lambda_{k+1}(\mathbf{A})$ for each k; since $\lambda_k(\mathbf{B})$ is an eigenvalue of $\mathbf{B}$ and $\lambda_k(\mathbf{A})$, $\lambda_{k+1}(\mathbf{A})$ are eigenvalues of $\mathbf{A}$, neither inequality can be an equality. So all $2(n-1)$ of them are strict.

($\Rightarrow$) Suppose all of them are strict, that is,

$$\lambda_1(\mathbf{A}) > \lambda_1(\mathbf{B}) > \lambda_2(\mathbf{A}) > \cdots > \lambda_{n-1}(\mathbf{B}) > \lambda_n(\mathbf{A}).$$

Reading two steps at a time gives $\lambda_k(\mathbf{B}) > \lambda_{k+1}(\mathbf{A}) > \lambda_{k+1}(\mathbf{B})$ for $1 \leq k \leq n-2$, so the eigenvalues of $\mathbf{B}$ are distinct. And the displayed chain is strictly decreasing, so its $2n-1$ entries are pairwise distinct; in particular no eigenvalue of $\mathbf{B}$ is an eigenvalue of $\mathbf{A}$. By (b), read as a contrapositive, $P_\nu \mathbf{b} \neq \mathbf{0}$ for every eigenvalue ν of $\mathbf{B}$. This proves the theorem.

■

Remark. Part (b) is deliberately one-sided. When $P_\nu \mathbf{b} = \mathbf{0}$ the multiplicity of ν in $p_\mathbf{A}$ may be m_ν or $m_\nu + 1$ — never more, since by Cauchy interlacing q equal eigenvalues ν of $\mathbf{A}$ squeeze $q-1$ eigenvalues of $\mathbf{B}$ to ν — and both occur: $\mathbf{B} = \operatorname{diag}(3,1)$, $\mathbf{b} = (0,1)$, $c = 0$ gives $p_\mathbf{A}(x) = (x-3)(x^2 - x - 1)$, where 3 keeps multiplicity $1 = m_3$; while $\mathbf{B} = (\mu)$, $\mathbf{b} = \mathbf{0}$, $c = \mu$ gives $\mathbf{A} = \mu \mathbf{I}_2$, where μ has multiplicity $2 = m_\mu + 1$. Deciding between the two needs the value of c as well, and Theorem 16.4.4 does not attempt it; what it does settle completely is the strictness question (c), which is what interlacing asks.

Warning. **Strictness needs both clauses, and a non-zero border is not enough.** It is tempting to say that the interlacing is strict as soon as $\mathbf{b} \neq \mathbf{0}$, or as soon as $\mathbf{b}$ meets every eigenspace of $\mathbf{B}$. The first is wrong even when the eigenvalues of $\mathbf{B}$ are distinct (Exercise B3(a)); the second fails exactly when $\mathbf{B}$ has a repeated eigenvalue. Take $\mathbf{B} = 2\mathbf{I}_2$, $\mathbf{b} = (1,1)$ and $c = 2$. Here $\mathbf{b}$ has a non-zero component in the one eigenspace $E_2(\mathbf{B}) = F^2$, and yet $\lambda_1(\mathbf{B}) = \lambda_2(\mathbf{B}) = 2$, so the middle of the interlacing chain reads $2 \geq \lambda_2(\mathbf{A}) \geq 2$ and $\lambda_2(\mathbf{A}) = 2$ with no freedom at all. A repeated eigenvalue of $\mathbf{B}$ is passed on to $\mathbf{A}$, by Theorem 16.4.4 (a) with $m_\nu = 2$.

To apply Theorem 16.4.4 when the deleted index is not the last one, permute. Let $I = \{i_1 < \cdots < i_{n-1}\} = \{1, \ldots, n\} \setminus \{m\}$, and let $\mathbf{P}$ be the matrix with columns $\mathbf{e}_{i_1}, \ldots, \mathbf{e}_{i_{n-1}}, \mathbf{e}_m$, a permutation matrix. Its columns are orthonormal, so $\mathbf{P}^\top \mathbf{P} = \mathbf{I}$ and $\mathbf{P}$ is unitary (Lemma 2.6.6 (b)); hence $\mathbf{P}^\top \mathbf{A} \mathbf{P}$ is Hermitian and similar to $\mathbf{A}$, with the same eigenvalues. Its (r,s) entry is $\mathbf{e}_{i_r}^\top \mathbf{A} \mathbf{e}_{i_s} = a_{i_r i_s}$ for $r, s \leq n-1$, so its leading $(n-1) \times (n-1)$ corner is $\mathbf{A}_{I,I}$, and its border is the column $(a_{i_1 m}, \ldots, a_{i_{n-1} m})$ with corner entry a_{mm}. So $\mathbf{P}^\top \mathbf{A} \mathbf{P}$ is a bordered matrix with corner $\mathbf{A}_{I,I}$, and Theorem 16.4.4 applies to it verbatim.

The strictness criterion pays a debt from Chapter 10. The solution of Exercise (C1: Interlacing roots) proved by hand that the roots of consecutive orthogonal polynomials interlace for degrees $1, 2, 3$, and then said: "The general case is not proved this way. The coefficients a_k and b_k assemble into a symmetric tridiagonal matrix whose characteristic polynomial is p_k, and the interlacing then follows from the interlacing theorem for the eigenvalues of a symmetric matrix and its leading submatrices, which is Chapter 16's business." Two things in that sentence were asserted, not proved: that the characteristic polynomial is p_k, and that the interlacing is **strict**, which is what "exactly one root strictly between" demands. Plain Theorem 16.4.2 gives only $\geq$.

Strictness needs Theorem 16.4.4 (c), and (c) needs one fact about tridiagonal matrices.

Lemma 16.4.5 — Eigenvectors of an Unreduced Tridiagonal Matrix

Let $\mathbf{T} \in M_k(\mathbb{R})$ be symmetric and tridiagonal, with every entry $t_{i,i+1} = t_{i+1,i}$ $(1 \le i \le k-1)$ **non-zero**. Then every eigenvector $\mathbf{u}$ of $\mathbf{T}$ has $u_k \neq 0$. Consequently every eigenspace of $\mathbf{T}$ has dimension 1, so $\mathbf{T}$ has k distinct eigenvalues.

Proof. Let $\mathbf{Tu} = \nu\mathbf{u}$ and suppose $u_k = 0$; we show $\mathbf{u} = \mathbf{0}$. If $k = 1$ this is immediate. Otherwise row k of $\mathbf{Tu} = \nu\mathbf{u}$ reads $t_{k,k-1}u_{k-1} + t_{kk}u_k = \nu u_k$, so $t_{k,k-1}u_{k-1} = 0$ and $u_{k-1} = 0$, since $t_{k,k-1} \neq 0$. Now suppose $u_i = u_{i+1} = 0$ for some $2 \le i \le k-1$. Row i reads $t_{i,i-1}u_{i-1} + t_{ii}u_i + t_{i,i+1}u_{i+1} = \nu u_i$, so $t_{i,i-1}u_{i-1} = 0$ and $u_{i-1} = 0$. Walking up from $i = k-1$ to $i = 2$ gives $u_{k-2} = \cdots = u_1 = 0$, so $\mathbf{u} = \mathbf{0}$, and $\mathbf{u}$ is not an eigenvector.

If some eigenspace $E_\nu(\mathbf{T})$ contained two independent vectors $\mathbf{u}, \mathbf{u}'$, then $u'_k\mathbf{u} - u_k\mathbf{u}'$ would be a non-zero vector of $E_\nu(\mathbf{T})$ — non-zero by independence, since $u_k \neq 0$ — with last coordinate 0, which we have just excluded. So each eigenspace is a line. Since $\mathbf{T}$ is real symmetric, its eigenspaces have dimensions adding up to k (Corollary 11.5.2), so there are k of them, that is, k distinct eigenvalues. This proves the lemma.

■

Corollary 16.4.6 — Zeros of Orthogonal Polynomials Interlace

Let (p_k) be the monic orthogonal polynomial sequence of an inner product on $\mathbb{R}[x]$ to which Theorem 10.10.3 applies, with coefficients a_k and $b_k > 0$; for the node inner product on $\mathbb{R}[x]_{\le n}$ read everything below for $k+1 \le n$. For $k \ge 1$ let $\mathbf{T}_k$ (the **Jacobi matrix** of the sequence) be the $k \times k$ real symmetric tridiagonal matrix with diagonal $a_0, a_1, \ldots, a_{k-1}$ and entries $\sqrt{b_1}, \ldots, \sqrt{b_{k-1}}$ just above and just below it.

(a) $p_{\mathbf{T}_k} = p_k$; so the roots of p_k are the eigenvalues of $\mathbf{T}_k$, and they are real and distinct.

(b) If $r_1 > \cdots > r_{k+1}$ are the roots of p_{k+1} and $s_1 > \cdots > s_k$ those of p_k, then

$$r_1 > s_1 > r_2 > s_2 > \cdots > s_k > r_{k+1}.$$

Idea. The polynomials p_k are the characteristic polynomials of a nested family of symmetric tridiagonal matrices, each the leading corner of the next. So their zeros are eigenvalues of a matrix and of its corner, and Cauchy interlacing applies at once — non-strictly. Strictness is the bordered-matrix criterion, and both of its clauses come from one fact about tridiagonal matrices with non-zero off-diagonal entries: an eigenvector can never end in a zero.

Proof.

(a) Put $D_k(x) = \det(x\mathbf{I}_k - \mathbf{T}_k)$ and $D_0 = 1$. For each real x_0, the matrix $x_0\mathbf{I}_k - \mathbf{T}_k$ is tridiagonal in the sense of Chapter 6, with diagonal entries $x_0 - a_{i-1}$ and off-diagonal entries $-\sqrt{b_i}$ in both positions $(i, i+1)$ and $(i+1, i)$, so Theorem 6.8.3

gives $D_1(x_0) = x_0 - a_0$ and

$$\begin{aligned} D_{k+1}(x_0) &= (x_0 - a_k)D_k(x_0) - (-\sqrt{b_k})^2 D_{k-1}(x_0) \\ &= (x_0 - a_k)D_k(x_0) - b_k D_{k-1}(x_0) \end{aligned}$$

for $k \geq 1$. Here $D_k(x_0) = \det(x_0\mathbf{I} - \mathbf{T}_k)$ is the characteristic polynomial evaluated at x_0 (Lemma 6.10.1), and two real polynomials that agree at every real number are equal (Theorem 5.1.5 (b)), so these identities hold as polynomials. They are the recurrence of Theorem 10.10.3 with the same starting values $p_0 = 1$, $p_1 = x - a_0$, so $D_k = p_k$ for every k by induction. The roots of $p_{\mathbf{T}_k}$ are the eigenvalues of $\mathbf{T}_k$ (Theorem 8.2.1), which are real because $\mathbf{T}_k$ is real symmetric (Theorem 11.2.1) and distinct by Lemma 16.4.5, whose hypothesis holds because every $\sqrt{b_i} > 0$.

(b) Write $\mathbf{T}_{k+1}$ in bordered form:

$$\mathbf{T}_{k+1} = \begin{pmatrix} \mathbf{T}_k & \sqrt{b_k}\,\mathbf{e}_k \\ \sqrt{b_k}\,\mathbf{e}_k^{\top} & a_k \end{pmatrix}, \qquad \mathbf{e}_k \in \mathbb{R}^k.$$

The border of $\mathbf{T}_{k+1}$ is $\mathbf{w} = \sqrt{b_k}\,\mathbf{e}_k$, whose k-th entry is $\sqrt{b_k}$. We call it $\mathbf{w}$ rather than $\mathbf{b}$ because b_k already names a recurrence coefficient. We check the two clauses of Theorem 16.4.4 (c) for $\mathbf{B} = \mathbf{T}_k$, with $\mathbf{w}$ in place of $\mathbf{b}$. By Lemma 16.4.5, $\mathbf{T}_k$ has k distinct eigenvalues. For each eigenvalue ν, the eigenspace $E_\nu(\mathbf{T}_k)$ is spanned by one unit vector $\mathbf{u}$, so $P_\nu \mathbf{w} = \langle \mathbf{w}, \mathbf{u} \rangle \mathbf{u} = \sqrt{b_k}\, u_k\, \mathbf{u}$, which is non-zero because $b_k > 0$ and $u_k \neq 0$ by the same lemma. So Theorem 16.4.4 (c) applies, and the eigenvalues of $\mathbf{T}_{k+1}$ and of $\mathbf{T}_k$ interlace strictly. By (a) these are the roots of p_{k+1} and of p_k. This proves the corollary.

■

Part (a) gives a second proof, with no integrals, that the roots of p_k are real and simple — half of Theorem 10.10.5. The other half, that they lie inside the interval of the weight, is not visible in the matrix and still needs the argument of Chapter 10. For the monic Legendre polynomials of Example (The monic Legendre polynomials, continued), $a_k = 0$, $b_1 = \frac{1}{3}$ and $b_2 = \frac{4}{15}$, so

$$\mathbf{T}_3 = \begin{pmatrix} 0 & 1/\sqrt{3} & 0 \\ 1/\sqrt{3} & 0 & 2/\sqrt{15} \\ 0 & 2/\sqrt{15} & 0 \end{pmatrix},$$

and expanding along the first row,

$$p_{\mathbf{T}_3}(x) = x^3 - \left(\tfrac{1}{3} + \tfrac{4}{15}\right)x = x^3 - \tfrac{3}{5}x = p_3.$$

Its leading corner $\mathbf{T}_2$ has characteristic polynomial $x^2 - \frac{1}{3} = p_2$ and unit eigenvectors $\frac{1}{\sqrt{2}}(1, \pm 1)$, both with non-zero last coordinate, so the border $\frac{2}{\sqrt{15}}\mathbf{e}_2$ meets both eigenspaces. The prediction is strict interlacing, and indeed

$$\sqrt{3/5} > 1/\sqrt{3} > 0 > -1/\sqrt{3} > -\sqrt{3/5},$$

that is $0.7746 > 0.5774 > 0 > -0.5774 > -0.7746$, where the strict comparisons $3/5 > 1/3$ and $1/\sqrt{3} > 0$ need no decimals.

16.4.4 A worked example

Example. (One matrix and all three of its corners)

Let

$$\mathbf{A} = \begin{pmatrix} 2 & 1 & 0 \\ 1 & 2 & 1 \\ 0 & 1 & 2 \end{pmatrix}.$$

Compute the eigenvalues of $\mathbf{A}$ and of each of its three 2×2 principal submatrices, exhibit the interlacing in each case, and explain the pattern of strict and non-strict inequalities using Theorem 16.4.4.

Solution. The eigenvalues of $\mathbf{A}$. Expanding $\det(x\mathbf{I} - \mathbf{A})$ along the first row,

$$\begin{aligned} p_{\mathbf{A}}(x) &= (x-2)\big[(x-2)^2 - 1\big] + 1\cdot\big[-(x-2)\big] \\ &= (x-2)\big[(x-2)^2 - 2\big], \end{aligned}$$

so

$$\lambda(\mathbf{A}) = \big(2+\sqrt{2},\ 2,\ 2-\sqrt{2}\big) \approx (3.41421,\ 2,\ 0.58579).$$

The three corners. With I the index set kept,

$$\mathbf{A}_{\{1,2\},\{1,2\}} = \begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix}, \quad \mathbf{A}_{\{1,3\},\{1,3\}} = \begin{pmatrix} 2 & 0 \\ 0 & 2 \end{pmatrix}, \quad \mathbf{A}_{\{2,3\},\{2,3\}} = \begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix}.$$

A matrix $\left(\begin{smallmatrix} 2 & 1 \\ 1 & 2 \end{smallmatrix}\right)$ has trace 4 and determinant 3, so its eigenvalues are 3 and 1; and $2\mathbf{I}_2$ has the eigenvalue 2 twice.

The interlacing. In all three cases Theorem 16.4.2 is confirmed:

$$\begin{aligned} I = \{1,2\}: &\quad 3.41421 > 3 > 2 > 1 > 0.58579, \\ I = \{1,3\}: &\quad 3.41421 > 2 = 2 = 2 > 0.58579, \\ I = \{2,3\}: &\quad 3.41421 > 3 > 2 > 1 > 0.58579. \end{aligned}$$

The first and third are strict everywhere; the second has two equalities in the middle. The exact comparisons need no decimals: $2+\sqrt{2} > 3$ is $\sqrt{2} > 1$, and $1 > 2-\sqrt{2}$ is $\sqrt{2} > 1$ again.

Why. Read $\mathbf{A}$ as a bordered matrix in each case, using the permutation remark above.

For $I = \{1,2\}$ the deleted index is already the last one, so $\mathbf{B} = \left(\begin{smallmatrix} 2 & 1 \\ 1 & 2 \end{smallmatrix}\right)$, $\mathbf{b} = (0,1)$ and $c = 2$. The eigenvalues 3 and 1 of $\mathbf{B}$ are distinct, with unit eigenvectors $\frac{1}{\sqrt{2}}(1,1)$ and $\frac{1}{\sqrt{2}}(1,-1)$. Both inner products with $\mathbf{b}$ are non-zero:

$$\langle \mathbf{b}, \tfrac{1}{\sqrt{2}}(1,1)\rangle = \tfrac{1}{\sqrt{2}}, \qquad \langle \mathbf{b}, \tfrac{1}{\sqrt{2}}(1,-1)\rangle = -\tfrac{1}{\sqrt{2}}.$$

So both clauses of Theorem 16.4.4 (c) hold and the interlacing is strict, as computed. The case $I = \{2,3\}$ is the same: moving index 1 to the end gives the corner $\left(\begin{smallmatrix} 2 & 1 \\ 1 & 2 \end{smallmatrix}\right)$ again, with border $(a_{21}, a_{31}) = (1,0)$, whose inner products with the two unit eigenvectors $\frac{1}{\sqrt{2}}(1,\pm 1)$ are both $\frac{1}{\sqrt{2}}$, non-zero.

For $I = \{1, 3\}$ the deleted index is 2. Conjugating by the permutation matrix that sends the coordinate order $(1, 2, 3)$ to $(1, 3, 2)$ turns $\mathbf{A}$ into

$$\begin{pmatrix} 2 & 0 & 1 \\ 0 & 2 & 1 \\ 1 & 1 & 2 \end{pmatrix}, \qquad \mathbf{B} = 2\mathbf{I}_2, \quad \mathbf{b} = (1, 1), \quad c = 2.$$

Here $\mathbf{b} \neq \mathbf{0}$ and $P_2\mathbf{b} = \mathbf{b} \neq \mathbf{0}$, so the first clause of Theorem 16.4.4 (c) is the one that fails: $\mathbf{B}$ has the repeated eigenvalue 2. Part (a) with $m_2 = 2$ then says that 2 is an eigenvalue of $\mathbf{A}$ of multiplicity exactly 1, which is visible in $p_{\mathbf{A}}$, and the interlacing collapses at the middle to $2 = 2 = 2$. This is exactly the situation of the warning above, occurring inside a perfectly ordinary integer matrix.

16.4.5 Inertia under compression

Interlacing controls not only where the eigenvalues are but how many of them have each sign, and that is a statement about inertia.

Corollary 16.4.7 — A Principal Submatrix Keeps Most of the Inertia

Let $\mathbf{A} \in M_n(F)$ be Hermitian, let $0 \leq m \leq n - 1$, let $|I| = n - m$ and $\mathbf{B} = \mathbf{A}_{I,I}$. Write $n_+(\mathbf{M})$ and $n_-(\mathbf{M})$ for the number of positive and of negative eigenvalues of a Hermitian $\mathbf{M}$, counted with multiplicity. Then

$$n_+(\mathbf{B}) \leq n_+(\mathbf{A}) \leq n_+(\mathbf{B}) + m, \qquad n_-(\mathbf{B}) \leq n_-(\mathbf{A}) \leq n_-(\mathbf{B}) + m.$$

In particular $\mathbf{A} \succeq 0$ implies $\mathbf{B} \succeq 0$, and $\mathbf{A} \succ 0$ implies $\mathbf{B} \succ 0$.

Proof. Write $r = n_+(\mathbf{B})$ and $s = n_+(\mathbf{A})$, and abbreviate $\lambda_i = \lambda_i(\mathbf{A})$, $\mu_i = \lambda_i(\mathbf{B})$. By Corollary 16.4.3, $\lambda_i \geq \mu_i \geq \lambda_{i+m}$ for $1 \leq i \leq n - m$.

($n_+(\mathbf{B}) \leq n_+(\mathbf{A})$) For $i \leq r$ we have $\mu_i > 0$, hence $\lambda_i \geq \mu_i > 0$. So $\mathbf{A}$ has at least r positive eigenvalues.

($n_+(\mathbf{A}) \leq n_+(\mathbf{B}) + m$) If $r + m \geq n$ there is nothing to prove, since $s \leq n$. Otherwise $r + 1 \leq n - m$, so the index $i = r + 1$ is admissible and $\mu_{r+1} \leq 0$ by the definition of r; hence $\lambda_{r+1+m} \leq \mu_{r+1} \leq 0$, and the eigenvalues $\lambda_{r+m+1}, \dots, \lambda_n$ are all ≤ 0 by the decreasing indexing. So $s \leq r + m$.

For the two statements about n_-, apply what has just been proved to $-\mathbf{A}$, whose principal submatrix on I is $-\mathbf{B}$. By Lemma 16.3.2 the eigenvalue lists are negated and reversed, so $n_+(-\mathbf{A}) = n_-(\mathbf{A})$ and $n_+(-\mathbf{B}) = n_-(\mathbf{B})$, and the two displayed chains are the same statement.

Finally, $\mathbf{A} \succeq 0$ means every eigenvalue of $\mathbf{A}$ is ≥ 0 (Theorem 12.1.4 (b)), that is, $n_-(\mathbf{A}) = 0$; then $n_-(\mathbf{B}) \leq n_-(\mathbf{A}) = 0$, so $\mathbf{B} \succeq 0$. And $\mathbf{A} \succ 0$ means $n_+(\mathbf{A}) = n$ (Theorem 12.1.5 (b)); then $n_+(\mathbf{B}) \geq n_+(\mathbf{A}) - m = n - m$, which is the size of $\mathbf{B}$, so every eigenvalue of $\mathbf{B}$ is positive and $\mathbf{B} \succ 0$. This proves the corollary. ∎

The last two sentences are a second proof of something Chapter 12 already knew. That a principal submatrix of a positive semidefinite matrix is positive semidefinite is the step (a) ⇒ (e) in the proof of Theorem 12.1.4, where it comes from the observation that a principal submatrix is what the quadratic form does to vectors supported on the corresponding coordinates — one line, needing no interlacing. What is new here is the quantitative form. Sylvester's law of inertia (Theorem 13.5.1) says that the triple of counts is an invariant of a real symmetric matrix up to congruence, and Theorem 13.5.3 identifies Chapter 13's counts with the eigenvalue counts n_+ and n_- used here; the corollary says that deleting m rows and the matching m columns can destroy at most m positive and at most m negative eigenvalues, and create none of either. Section 10 gives a second proof of Sylvester's law from Courant–Fischer, and bounds how far a low-rank perturbation can move the inertia.

16.4.6 Interlacing is a Hermitian phenomenon

Everything above rests on Theorem 16.2.3, which rests on the quadratic form being real. Without the Hermitian hypothesis, nothing survives — not a weakened interlacing, not even a bound.

Example. (A corner outside the spectrum)

Let

$$\mathbf{A} = \begin{pmatrix} 5 & 1 \\ -8 & -1 \end{pmatrix}.$$

Show that $\mathbf{A}$ has real eigenvalues, so that the conclusion of Theorem 16.4.2 can be stated for it, and that the conclusion is false.

Solution. $\operatorname{tr}\mathbf{A} = 4$ and $\det\mathbf{A} = 5(-1)-1(-8) = 3$, so $p_{\mathbf{A}}(x) = x^2-4x+3 = (x-3)(x-1)$ and the eigenvalues are 3 and 1, both real. The two 1×1 principal submatrices are $\mathbf{A}_{\{1\},\{1\}} = (5)$ and $\mathbf{A}_{\{2\},\{2\}} = (-1)$, with eigenvalues 5 and -1.

Interlacing would require $3 \geq 5 \geq 1$ in the first case and $3 \geq -1 \geq 1$ in the second. Both fail, and they fail on opposite sides: the diagonal entries 5 and -1 lie outside the interval $[1,3]$, which is the convex hull of the spectrum. For a Hermitian matrix that is impossible, by Example (The diagonal lies inside the spectrum).

Remark. The failure is total, not marginal. For any $a \in F$, the matrix

$$\mathbf{A}_a = \begin{pmatrix} a & 1 \\ -(a-1)(a-3) & 4-a \end{pmatrix}$$

has trace 4 and determinant $a(4-a)+(a-1)(a-3) = 4a-a^2+a^2-4a+3 = 3$, hence the same characteristic polynomial $(x-3)(x-1)$ as above. Its $(1,1)$ principal submatrix is (a). So a general matrix with spectrum $\{1,3\}$ can have any prescribed number whatsoever as its $(1,1)$ entry: the eigenvalue of a single principal submatrix is subject to no constraint at all. (The two diagonal entries together still add up to the trace, 4; that constraint holds for every matrix and has nothing to do with interlacing.) The choice $a = 5$ recovers $\mathbf{A}$, and $a = 0$ gives $\left(\begin{smallmatrix} 0 & 1 \\ -3 & 4 \end{smallmatrix}\right)$.

Warning. **Principal means the same index set on both sides.** Interlacing says nothing about a submatrix obtained by deleting row i and column j with $i \neq j$, even for a Hermitian $\mathbf{A}$. Take $\mathbf{A} = \left(\begin{smallmatrix} -10 & 1 \\ 1 & -10 \end{smallmatrix}\right)$, whose eigenvalues are -9 and -11. Deleting

row 1 and column 2 leaves the 1×1 matrix (1), and 1 is nowhere near $[-11, -9]$. The submatrix in Theorem 16.4.2 is $\mathbf{A}_{I,I}$, and the two I's are not decoration.

16.4.7 Exercises

16.4.7.1 A. Check your understanding

Exercise A1.

(a) State Theorem 16.4.2, and say which hypothesis on $\mathbf{A}$ and which hypothesis on the submatrix are used.

(b) Let $\mathbf{A} \in M_6(\mathbb{C})$ be Hermitian and let $\mathbf{B} = \mathbf{A}_{I,I}$ with $|I| = 4$. Which eigenvalues of $\mathbf{A}$ bound $\lambda_3(\mathbf{B})$ above and below?

(c) Determine whether the following is correct, and justify your answer: if $\mathbf{b} \neq \mathbf{0}$ then the interlacing between $\left(\begin{smallmatrix} \mathbf{B} & \mathbf{b} \\ \mathbf{b}^* & c \end{smallmatrix}\right)$ and $\mathbf{B}$ is strict.

(d) Explain why a principal submatrix of a positive semidefinite matrix is positive semidefinite, in one sentence, without using interlacing.

(e) Give a 2×2 matrix with real eigenvalues whose $(1,1)$ entry is larger than both of them.

Solution.

(a) See Theorem 16.4.2. The matrix $\mathbf{A}$ must be **Hermitian**, so that Theorem 16.2.3 applies and the eigenvalues are real and can be put in order; and $\mathbf{B}$ must be a **principal** submatrix, $\mathbf{B} = \mathbf{A}_{I,I}$ with the same index set on rows and columns, so that Lemma 16.4.1 identifies $R_{\mathbf{B}}$ with $R_{\mathbf{A}}$ restricted to a coordinate hyperplane.

(b) Here $n = 6$ and $m = 2$, so Corollary 16.4.3 gives $\lambda_3(\mathbf{A}) \geq \lambda_3(\mathbf{B}) \geq \lambda_5(\mathbf{A})$.

(c) Incorrect. The warning after Theorem 16.4.4 gives $\mathbf{B} = 2\mathbf{I}_2$, $\mathbf{b} = (1,1)$, $c = 2$, where $\mathbf{b} \neq \mathbf{0}$ and the interlacing is not strict, because $\mathbf{B}$ has a repeated eigenvalue. The correct criterion is Theorem 16.4.4 (c), which needs distinct eigenvalues of $\mathbf{B}$ as well as $P_\nu \mathbf{b} \neq \mathbf{0}$ for each ν.

(d) Because $\langle \mathbf{B}\mathbf{y}, \mathbf{y} \rangle = \langle \mathbf{A}\mathbf{x}, \mathbf{x} \rangle \geq 0$, where $\mathbf{x} \in F^n$ is $\mathbf{y}$ placed in the coordinates of I and 0 elsewhere (Lemma 16.4.1); this is how Theorem 12.1.4 obtained its clause (e).

(e) $\left(\begin{smallmatrix} 5 & 1 \\ -8 & -1 \end{smallmatrix}\right)$, with eigenvalues 3 and 1 and $(1,1)$ entry 5 (Example (A corner outside the spectrum)). It is necessarily non-Hermitian, by Example (The diagonal lies inside the spectrum).

16.4.7.2 B. Practice

Exercise B1: Interlacing in integers.

Let

$$\mathbf{A} = \begin{pmatrix} 0 & 1 & 2 \\ 1 & 0 & 2 \\ 2 & 2 & 3 \end{pmatrix}.$$

Compute the eigenvalues of $\mathbf{A}$ and of all three of its 2×2 principal submatrices, and

exhibit the interlacing in each case. Hence say, for each corner, whether the interlacing is strict.

Solution. The eigenvalues of $\mathbf{A}$. The vector $(1,-1,0)$ satisfies $\mathbf{A}(1,-1,0)=(-1,1,0)$, so -1 is an eigenvalue. Dividing, $p_{\mathbf{A}}(x)=x^3-3x^2-9x-5=(x-5)(x+1)^2$, so

$$\lambda(\mathbf{A})=(5,\ -1,\ -1).$$

(As a check, $\operatorname{tr}\mathbf{A}=3=5-1-1$, and expanding along the first row $\det\mathbf{A}=0-1(3-4)+2(2-0)=5=5\cdot(-1)\cdot(-1)$.)

The corners.

$$\mathbf{A}_{\{1,2\},\{1,2\}}=\begin{pmatrix}0&1\\1&0\end{pmatrix},\qquad \mathbf{A}_{\{1,3\},\{1,3\}}=\mathbf{A}_{\{2,3\},\{2,3\}}=\begin{pmatrix}0&2\\2&3\end{pmatrix}.$$

The first has trace 0 and determinant -1, so its eigenvalues are 1 and -1. The second has trace 3 and determinant -4, so its characteristic polynomial is $x^2-3x-4=(x-4)(x+1)$ and its eigenvalues are 4 and -1.

Interlacing.

$$\begin{aligned}I=\{1,2\}:&\quad 5>1>-1=-1=-1,\\ I=\{1,3\}:&\quad 5>4>-1=-1=-1,\\ I=\{2,3\}:&\quad 5>4>-1=-1=-1.\end{aligned}$$

No corner gives strict interlacing, and the reason is on the side of $\mathbf{A}$: whichever index is deleted, $\lambda_2(\mathbf{A})=\lambda_3(\mathbf{A})=-1$, so the chain $\lambda_2(\mathbf{A})\ge\lambda_2(\mathbf{B})\ge\lambda_3(\mathbf{A})$ squeezes $\lambda_2(\mathbf{B})$ to -1. Strict interlacing would make the combined chain strictly decreasing, and so would force $\mathbf{A}$ to have three distinct eigenvalues. Theorem 16.4.4 sees the same thing from the side of the corner. For $I=\{1,2\}$ the border is $\mathbf{b}=(2,2)$, orthogonal to $(1,-1)$, which spans $E_{-1}(\mathbf{B})$; so $P_{-1}\mathbf{b}=\mathbf{0}$, and part (b) predicts that -1 is an eigenvalue of $\mathbf{A}$. For $I=\{1,3\}$ the border is $(a_{12},a_{32})=(1,2)$, orthogonal to $(2,-1)$, which spans E_{-1} of $\left(\begin{smallmatrix}0&2\\2&3\end{smallmatrix}\right)$, with the same conclusion.

Exercise B2: Bounds without a characteristic polynomial.

Let $\mathbf{A}\in M_4(\mathbb{R})$ be symmetric with

$$\mathbf{A}=\begin{pmatrix}7&*&*&**&2&*&**&*&-3&**&*&*&1\end{pmatrix},$$

the entries marked $*$ being unknown.

(a) What do Corollary 16.4.3 and Example (The diagonal lies inside the spectrum) say about $\lambda_1(\mathbf{A})$ and $\lambda_4(\mathbf{A})$?

(b) Suppose in addition that $\mathbf{A}_{\{1,2\},\{1,2\}}=\left(\begin{smallmatrix}7&4\\4&2\end{smallmatrix}\right)$. Improve the lower bound on $\lambda_1(\mathbf{A})$, and give a lower bound on $\lambda_2(\mathbf{A})$.

Solution.

(a) Each diagonal entry is a 1×1 principal submatrix, so $\lambda_1(\mathbf{A})\ge\max\{7,2,-3,1\}=7$

and $\lambda_4(\mathbf{A}) \le \min\{7, 2, -3, 1\} = -3$. In particular $\mathbf{A}$ is indefinite whatever the unknown entries are.

(b) The submatrix $\mathbf{B} = \left(\begin{smallmatrix} 7 & 4 \\ 4 & 2 \end{smallmatrix}\right)$ has trace 9 and determinant $14 - 16 = -2$, so its characteristic polynomial is $x^2 - 9x - 2$ and its eigenvalues are

$$\lambda_1(\mathbf{B}) = \tfrac{9+\sqrt{89}}{2} \approx 9.2170, \qquad \lambda_2(\mathbf{B}) = \tfrac{9-\sqrt{89}}{2} \approx -0.2170.$$

Here $n = 4$ and $m = 2$, and the left-hand inequality $\lambda_i(\mathbf{A}) \ge \lambda_i(\mathbf{B})$ of Corollary 16.4.3 at $i = 1, 2$ gives

$$\lambda_1(\mathbf{A}) \ge \tfrac{9+\sqrt{89}}{2} \approx 9.2170, \qquad \lambda_2(\mathbf{A}) \ge \tfrac{9-\sqrt{89}}{2} \approx -0.2170.$$

The first improves the bound 7 from (a). The second is new: the diagonal entries alone say nothing about $\lambda_2(\mathbf{A})$. The right-hand inequalities $\lambda_i(\mathbf{B}) \ge \lambda_{i+2}(\mathbf{A})$ give $\lambda_3(\mathbf{A}) \le 9.2170$, which is true but of little use, and $\lambda_4(\mathbf{A}) \le -0.2170$, which is weaker than the bound $\lambda_4(\mathbf{A}) \le -3$ of (a). Each principal submatrix contributes what it can, and one keeps the best of the bounds.

Exercise B3: Deciding strictness.

For each of the following bordered matrices $\mathbf{A} = \left(\begin{smallmatrix} \mathbf{B} & \mathbf{b} \\ \mathbf{b}^{\top} & c \end{smallmatrix}\right)$, decide without computing $p_{\mathbf{A}}$ whether the interlacing between $\mathbf{A}$ and $\mathbf{B}$ is strict, and justify with Theorem 16.4.4.

(a) $\mathbf{B} = \operatorname{diag}(3, 1)$, $\mathbf{b} = (0, 1)$, $c = 0$.

(b) $\mathbf{B} = \operatorname{diag}(3, 1)$, $\mathbf{b} = (2, -1)$, $c = 5$.

(c) $\mathbf{B} = \left(\begin{smallmatrix} 4 & 0 \\ 0 & 4 \end{smallmatrix}\right)$, $\mathbf{b} = (1, 2)$, $c = 0$.

Solution. In each case $\mathbf{B}$ is diagonal, so the standard basis vectors are an orthonormal eigenbasis and $P_\nu \mathbf{b}$ is just the part of $\mathbf{b}$ in the coordinates where the diagonal entry equals ν.

(a) Not strict. The eigenvalues $3, 1$ of $\mathbf{B}$ are distinct, but $P_3\mathbf{b} = (0, 0) = \mathbf{0}$. By Theorem 16.4.4 (b), 3 is an eigenvalue of $\mathbf{A}$, so one of the inequalities $\lambda_1(\mathbf{A}) \ge 3 \ge \lambda_2(\mathbf{A})$ is an equality. (Indeed $p_{\mathbf{A}}(x) = (x - 3)(x^2 - x - 1)$.)

(b) Strict. The eigenvalues $3, 1$ are distinct and $P_3\mathbf{b} = (2, 0) \ne \mathbf{0}$, $P_1\mathbf{b} = (0, -1) \ne \mathbf{0}$. Both clauses of Theorem 16.4.4 (c) hold. (Indeed $p_{\mathbf{A}}(x) = (x - 2)(x^2 - 7x + 4)$, with roots $\tfrac{7+\sqrt{33}}{2} \approx 6.372$, 2 and $\tfrac{7-\sqrt{33}}{2} \approx 0.628$, and $6.372 > 3 > 2 > 1 > 0.628$.)

(c) Not strict. $P_4\mathbf{b} = \mathbf{b} = (1, 2) \ne \mathbf{0}$, so the second clause holds, but $\mathbf{B}$ has the repeated eigenvalue 4 and the first clause fails. By Theorem 16.4.4 (a) with $m_4 = 2$, the number 4 is an eigenvalue of $\mathbf{A}$ of multiplicity exactly 1, and the middle of the chain reads $4 \ge \lambda_2(\mathbf{A}) \ge 4$. (Indeed $p_{\mathbf{A}}(x) = (x - 5)(x - 4)(x + 1)$.)

16.4.7.3 C. Going deeper

Exercise C1: Rank under compression.

Let $\mathbf{A} \in M_n(F)$ be Hermitian of rank r, and let $\mathbf{B} = \mathbf{A}_{I,I}$ with $|I| = n - m$.

(a) Prove that $\operatorname{rank} \mathbf{B} \ge r - 2m$.

(b) Show that the bound is attained, by exhibiting for each n and each $m \le n/2$ a Hermitian $\mathbf{A}$ of rank $2m$ with a principal submatrix of size $n-m$ and rank 0.

Solution.

(a) For a Hermitian matrix $\mathbf{M}$, diagonalizing by the spectral theorem gives $\operatorname{rank}\mathbf{M} = n_+(\mathbf{M}) + n_-(\mathbf{M})$, the total number of non-zero eigenvalues. By Corollary 16.4.7, $n_+(\mathbf{B}) \ge n_+(\mathbf{A}) - m$ and $n_-(\mathbf{B}) \ge n_-(\mathbf{A}) - m$. Adding,

$$\operatorname{rank}\mathbf{B} = n_+(\mathbf{B}) + n_-(\mathbf{B}) \;\ge\; \big(n_+(\mathbf{A}) + n_-(\mathbf{A})\big) - 2m = r - 2m.$$

(b) Let $m \le n/2$ and let $I = \{m+1, m+2, \dots, n\}$, of size $n-m$. Define $\mathbf{A}$ by $a_{i,m+i} = a_{m+i,i} = 1$ for $1 \le i \le m$, and all other entries 0. Then $\mathbf{A}$ is real symmetric. It is a direct sum of m copies of $\left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$, acting on the coordinate pairs $\{i, m+i\}$, together with zeros on the remaining coordinates, so its eigenvalues are ± 1 each m times and 0 otherwise; hence $\operatorname{rank}\mathbf{A} = 2m$ and $n_+(\mathbf{A}) = n_-(\mathbf{A}) = m$. Every non-zero entry of $\mathbf{A}$ has one index in $\{1, \dots, m\}$, which I omits, so $\mathbf{A}_{I,I} = \mathbf{0}$ and $\operatorname{rank}\mathbf{A}_{I,I} = 0 = \operatorname{rank}\mathbf{A} - 2m$. The bound in (a) is therefore sharp for every m.

Exercise C2: The converse, in the smallest case.

Theorem 16.4.2 says that the spectrum of a corner interlaces the spectrum of the whole. This exercise asks whether every interlacing pattern occurs.

(a) Let $\lambda_1 > \mu_1 > \lambda_2$ be real numbers. Find $b \in \mathbb{R}$ and $c \in \mathbb{R}$ such that $\mathbf{A} = \left(\begin{smallmatrix} \mu_1 & b \\ b & c \end{smallmatrix}\right)$ has eigenvalues λ_1 and λ_2.

(b) Deduce that for $n = 2$ the interlacing condition of Theorem 16.4.2 is not merely necessary but also sufficient.

(c) Explain why the strict hypothesis $\lambda_1 > \mu_1 > \lambda_2$ may be relaxed to $\lambda_1 \ge \mu_1 \ge \lambda_2$.

Hint: match the trace and the determinant.

Solution.

(a) A real symmetric 2×2 matrix with eigenvalues λ_1, λ_2 must have $\operatorname{tr}\mathbf{A} = \lambda_1 + \lambda_2$ and $\det\mathbf{A} = \lambda_1\lambda_2$. The first forces

$$c = \lambda_1 + \lambda_2 - \mu_1,$$

and the second then forces $\mu_1 c - b^2 = \lambda_1\lambda_2$, that is,

$$b^2 = \mu_1(\lambda_1 + \lambda_2 - \mu_1) - \lambda_1\lambda_2 = -(\mu_1 - \lambda_1)(\mu_1 - \lambda_2) = (\lambda_1 - \mu_1)(\mu_1 - \lambda_2),$$

where the middle equality is the expansion $-(\mu_1^2 - (\lambda_1 + \lambda_2)\mu_1 + \lambda_1\lambda_2)$. The hypothesis $\lambda_1 > \mu_1 > \lambda_2$ makes both factors positive, so $b = \sqrt{(\lambda_1 - \mu_1)(\mu_1 - \lambda_2)}$ is a real number. With this b and c, the matrix $\mathbf{A}$ is real symmetric with the prescribed trace and determinant, hence with characteristic polynomial $x^2 - (\lambda_1 + \lambda_2)x + \lambda_1\lambda_2 = (x - \lambda_1)(x - \lambda_2)$, hence with eigenvalues λ_1 and λ_2.
For example $\lambda_1 = 4$, $\mu_1 = 2$, $\lambda_2 = 1$ gives $c = 3$ and $b^2 = 2$, that is $\mathbf{A} = \left(\begin{smallmatrix} 2 & \sqrt{2} \\ \sqrt{2} & 3 \end{smallmatrix}\right)$, whose trace is 5 and determinant $6 - 2 = 4$, as required.

(b) Necessity is Theorem 16.4.2 with $n = 2$ and $I = \{1\}$. Sufficiency is part (a): given any $\lambda_1 > \mu_1 > \lambda_2$, a Hermitian $\mathbf{A}$ with spectrum $\{\lambda_1, \lambda_2\}$ and $\mathbf{A}_{\{1\},\{1\}} = (\mu_1)$ exists.

(c) If $\mu_1 = \lambda_1$ or $\mu_1 = \lambda_2$ then the formula gives $b = 0$, and $\mathbf{A} = \operatorname{diag}(\mu_1, \lambda_1 + \lambda_2 - \mu_1)$ is diagonal with the two entries λ_1 and λ_2 in one order or the other. So the construction still works, with a zero border; consistently with Theorem 16.4.4, a zero border is exactly what makes the interlacing non-strict.

Exercise C3: How far apart can the extremes be.

Let $\mathbf{A} \in M_n(F)$ be Hermitian.

(a) Prove that $\lambda_1(\mathbf{A}) - \lambda_n(\mathbf{A}) \geq \max_{i,j} |a_{ii} - a_{jj}|$.

(b) Prove that $\lambda_1(\mathbf{A}) - \lambda_n(\mathbf{A}) \geq 2 \max_{i \neq j} |a_{ij}|$.

Hint for (b): look at a 2×2 principal submatrix.

Solution.

(a) By Example (The diagonal lies inside the spectrum), $\lambda_n(\mathbf{A}) \leq a_{kk} \leq \lambda_1(\mathbf{A})$ for every k. So for any i, j, both $a_{ii} - a_{jj}$ and $a_{jj} - a_{ii}$ are at most $\lambda_1(\mathbf{A}) - \lambda_n(\mathbf{A})$, which gives the bound after taking the maximum over i, j.

(b) Fix $i \neq j$ and let $I = \{i, j\}$, so that

$$\mathbf{B} = \mathbf{A}_{I,I} = \begin{pmatrix} a_{ii} & a_{ij} \\ \overline{a_{ij}} & a_{jj} \end{pmatrix}$$

is Hermitian of size 2. Its trace is $a_{ii} + a_{jj}$ and its determinant is $a_{ii}a_{jj} - |a_{ij}|^2$, so its eigenvalues are

$$\frac{a_{ii} + a_{jj}}{2} \pm \sqrt{\left(\frac{a_{ii} - a_{jj}}{2}\right)^2 + |a_{ij}|^2},$$

and their difference is $2\sqrt{((a_{ii} - a_{jj})/2)^2 + |a_{ij}|^2} \geq 2|a_{ij}|$. Now apply Corollary 16.4.3 with $m = n - 2$: it gives $\lambda_1(\mathbf{A}) \geq \lambda_1(\mathbf{B})$ and $\lambda_2(\mathbf{B}) \geq \lambda_{2+(n-2)}(\mathbf{A}) = \lambda_n(\mathbf{A})$, so

$$\lambda_1(\mathbf{A}) - \lambda_n(\mathbf{A}) \;\geq\; \lambda_1(\mathbf{B}) - \lambda_2(\mathbf{B}) \;\geq\; 2|a_{ij}|.$$

Taking the maximum over the pairs $i \neq j$ finishes the proof. (For $n = 2$ the step with $m = 0$ is the identity $\mathbf{B} = \mathbf{A}$, and the conclusion is the computation itself.)

16.5 Adding a Rank-One Matrix

Section 4 deleted a row and the matching column and found that the spectrum of the smaller matrix is pinned between the eigenvalues of the larger one. This section makes the opposite kind of change: it leaves the size alone and adds the simplest non-zero Hermitian matrix there is, a positive multiple of $\mathbf{v}\mathbf{v}^*$. The answer has the same shape — the new eigenvalues interlace the old ones — but here we can say more than that they interlace. Under one extra hypothesis the new eigenvalues are the roots of a single explicit scalar equation in one variable, and the

graph of that function shows at a glance where every one of them sits.

Throughout this section $F = \mathbb{R}$ or $F = \mathbb{C}$, the matrix $\mathbf{A} \in M_n(F)$ is Hermitian, and its eigenvalues are indexed decreasingly, $\lambda_1(\mathbf{A}) \geq \cdots \geq \lambda_n(\mathbf{A})$, as everywhere in this chapter. We fix $\mathbf{v} \in F^n$ and a real number τ, and study

$$\widetilde{\mathbf{A}} := \mathbf{A} + \tau \mathbf{v}\mathbf{v}^*.$$

The added term is Hermitian, since $(\mathbf{v}\mathbf{v}^*)^* = \mathbf{v}\mathbf{v}^*$ and τ is real, so $\widetilde{\mathbf{A}}$ is Hermitian too and its eigenvalues are indexed the same way. The added term has rank 1 when $\tau \neq 0$ and $\mathbf{v} \neq \mathbf{0}$, and is the zero matrix otherwise. For $\tau > 0$ it is positive semidefinite, because

$$\langle \tau \mathbf{v}\mathbf{v}^*\mathbf{x}, \mathbf{x} \rangle = \tau\, \mathbf{x}^*\mathbf{v}\, \mathbf{v}^*\mathbf{x} = \tau |\mathbf{v}^*\mathbf{x}|^2 \;\geq\; 0$$

for every $\mathbf{x}$, which is clause (P2) of Definition 12.1.1.

16.5.1 One bump, every eigenvalue up

Adding a positive semidefinite matrix can only raise the quadratic form, so no eigenvalue can go down. The content of the theorem is the ceiling: however large τ is, the i-th new eigenvalue cannot climb past the $(i-1)$-st old one. All the room created by the bump is spent at the top.

Theorem 16.5.1 — Interlacing for a Rank-One Update

Let $\mathbf{A} \in M_n(F)$ be Hermitian, let $\mathbf{v} \in F^n$, let $\tau \geq 0$, and put $\widetilde{\mathbf{A}} = \mathbf{A} + \tau \mathbf{v}\mathbf{v}^*$. Then

$$\lambda_i(\widetilde{\mathbf{A}}) \;\geq\; \lambda_i(\mathbf{A}) \;\geq\; \lambda_{i+1}(\widetilde{\mathbf{A}}) \qquad (1 \leq i \leq n-1),$$

and $\lambda_n(\widetilde{\mathbf{A}}) \geq \lambda_n(\mathbf{A})$. Written as one chain,

$$\begin{aligned} \lambda_1(\widetilde{\mathbf{A}}) \;\geq\; \lambda_1(\mathbf{A}) \;\geq\; \lambda_2(\widetilde{\mathbf{A}}) \;\geq\; \lambda_2(\mathbf{A}) \\ \geq\; \cdots \;\geq\; \lambda_n(\widetilde{\mathbf{A}}) \;\geq\; \lambda_n(\mathbf{A}). \end{aligned}$$

Idea. The two halves have different characters and different sources. The left-hand inequalities say the eigenvalues go **up**, and that is a statement about the quadratic form: on every vector, $\widetilde{\mathbf{A}}$ scores at least what $\mathbf{A}$ scores, so every max–min it competes in can only improve. The right-hand inequalities say the eigenvalues go up **by at most one index**, and that has nothing to do with the sign of τ: it is the rank of the perturbation doing the work, and Corollary 16.3.8 has already isolated exactly that.

Proof. If $\tau = 0$ or $\mathbf{v} = \mathbf{0}$ then $\widetilde{\mathbf{A}} = \mathbf{A}$ and every inequality is an equality, so assume $\tau > 0$ and $\mathbf{v} \neq \mathbf{0}$.

For the inequalities $\lambda_i(\widetilde{\mathbf{A}}) \geq \lambda_i(\mathbf{A})$, fix i and let $\mathbf{x} \neq \mathbf{0}$. By the computation above,

$$R_{\widetilde{\mathbf{A}}}(\mathbf{x}) = R_{\mathbf{A}}(\mathbf{x}) + \frac{\tau |\mathbf{v}^*\mathbf{x}|^2}{\|\mathbf{x}\|^2} \;\geq\; R_{\mathbf{A}}(\mathbf{x}),$$

using Definition 16.1.1 and $\tau > 0$. Multiplying through by $\|\mathbf{x}\|^2$, this says $\langle \widetilde{\mathbf{A}}\mathbf{x}, \mathbf{x} \rangle \geq \langle \mathbf{A}\mathbf{x}, \mathbf{x} \rangle$ for every $\mathbf{x}$, that is, $\widetilde{\mathbf{A}} \succeq \mathbf{A}$ in the Loewner order of Definition 12.5.1. So Corollary 16.2.4 gives $\lambda_i(\widetilde{\mathbf{A}}) \geq \lambda_i(\mathbf{A})$ for every i.

For the inequalities $\lambda_i(\mathbf{A}) \geq \lambda_{i+1}(\widetilde{\mathbf{A}})$, note that $\operatorname{rank}(\tau\mathbf{v}\mathbf{v}^*) = 1$, because every column of $\mathbf{v}\mathbf{v}^*$ is a multiple of $\mathbf{v} \neq \mathbf{0}$ and at least one of them is non-zero. So Corollary 16.3.8 applies with $\mathbf{B} = \tau\mathbf{v}\mathbf{v}^*$ and $r = 1$, and its first inequality reads

$$\lambda_{i+1}(\mathbf{A} + \tau\mathbf{v}\mathbf{v}^*) \;\leq\; \lambda_i(\mathbf{A})$$

for $1 \leq i \leq n-1$. This proves the theorem.

■

Two remarks on the proof. The first half used nothing about the rank: it is Corollary 16.2.4, the general fact that $\widetilde{\mathbf{A}} \succeq \mathbf{A}$ forces $\lambda_i(\widetilde{\mathbf{A}}) \geq \lambda_i(\mathbf{A})$ for every i, specialized to a rank-one increment. The second half used nothing about the sign: the eigenvalues of $\mathbf{A}+\mathbf{B}$ and of $\mathbf{A}$ are never more than $\operatorname{rank}\mathbf{B}$ indices apart. Interlacing is what happens when both restrictions apply at once.

The secular equation of the next subsection gives a sharper, **strict** version of the theorem — it locates each new eigenvalue exactly, strictly between consecutive old ones — but only under extra hypotheses (a diagonal $\mathbf{A}$ with distinct entries, and a $\mathbf{v}$ with no zero coordinate), so it is not a second proof of the general statement. The other short route to the general theorem is Cauchy interlacing (Theorem 16.4.2) applied to a suitable bordered matrix.

Example. (A bump on a diagonal matrix)

Let $\mathbf{A} = \operatorname{diag}(4, 1)$, $\mathbf{v} = (1, 2)$ and $\tau = 1$. Compute $\widetilde{\mathbf{A}}$ and its eigenvalues, and check Theorem 16.5.1.

Solution. Here $\mathbf{v}\mathbf{v}^{\top} = \left(\begin{smallmatrix} 1 & 2 \\ 2 & 4 \end{smallmatrix}\right)$, so

$$\widetilde{\mathbf{A}} = \begin{pmatrix} 4 & 0 \\ 0 & 1 \end{pmatrix} + \begin{pmatrix} 1 & 2 \\ 2 & 4 \end{pmatrix} = \begin{pmatrix} 5 & 2 \\ 2 & 5 \end{pmatrix}.$$

Its trace is 10 and its determinant is $25 - 4 = 21$, so its characteristic polynomial is $x^2 - 10x + 21 = (x-7)(x-3)$ and $\lambda_1(\widetilde{\mathbf{A}}) = 7$, $\lambda_2(\widetilde{\mathbf{A}}) = 3$. The chain of the theorem reads

$$7 \;\geq\; 4 \;\geq\; 3 \;\geq\; 1,$$

and all four inequalities are strict. Note the accounting: the two eigenvalues rose by 3 and by 2, a total of $5 = \|\mathbf{v}\|^2$. That is no coincidence, and the last result of this section says why.

Quick check. The matrix $\mathbf{A} = \operatorname{diag}(9, 5, 2)$ is bumped by $\tau\mathbf{v}\mathbf{v}^*$ with $\tau > 0$. Without knowing $\mathbf{v}$ or τ, what is the largest possible value of $\lambda_3(\mathbf{A} + \tau\mathbf{v}\mathbf{v}^*)$, and what is the smallest?

Solution. By Theorem 16.5.1, $\lambda_2(\mathbf{A}) \geq \lambda_3(\widetilde{\mathbf{A}}) \geq \lambda_3(\mathbf{A})$, that is, $5 \geq \lambda_3(\widetilde{\mathbf{A}}) \geq 2$. Both ends are reached: $\mathbf{v} = \mathbf{e}_3$ with τ large gives $\widetilde{\mathbf{A}} = \operatorname{diag}(9, 5, 2+\tau)$, whose third eigenvalue is 5 as soon as $\tau \geq 3$; and $\mathbf{v} = \mathbf{e}_1$ gives $\widetilde{\mathbf{A}} = \operatorname{diag}(9+\tau, 5, 2)$, whose third eigenvalue is 2. So the smallest eigenvalue can be pushed up as far as the *second* smallest of $\mathbf{A}$ and no further, no matter how big τ is.

16.5.2 Where the new eigenvalues actually are

Interlacing brackets each new eigenvalue in an interval. To pin it down we need an equation, and there is a cheap one: an eigenvalue of $\widetilde{\mathbf{A}}$ is a number λ making $\widetilde{\mathbf{A}} - \lambda\mathbf{I}$ singular, and $\widetilde{\mathbf{A}} - \lambda\mathbf{I} = (\mathbf{A} - \lambda\mathbf{I}) + \tau\mathbf{v}\mathbf{v}^*$ is a rank-one update of a matrix whose determinant we know. Chapter 7 computed the determinant of exactly such an update.

Divide the characteristic polynomial of the bumped matrix by that of the original one; what is left is a sum of n simple fractions.

Definition 16.5.1 — Secular function

Let $\mathbf{A} = \operatorname{diag}(d_1, \dots, d_n)$ with $d_1, \dots, d_n \in \mathbb{R}$, let $\mathbf{v} \in F^n$ and let $\tau \in \mathbb{R}$. The **secular function** of the update $\mathbf{A} + \tau\mathbf{v}\mathbf{v}^*$ is

$$f(\lambda) := 1 + \tau \sum_{i=1}^{n} \frac{|v_i|^2}{d_i - \lambda},$$

defined for every real λ **other than** $d_1, \dots, d_n$. The equation $f(\lambda) = 0$ is the **secular equation**.

In words: f is the constant 1 plus one simple pole at each diagonal entry of $\mathbf{A}$, weighted by τ times the squared modulus of the matching coordinate of $\mathbf{v}$. The name is inherited from celestial mechanics, where equations of this shape governed slow ("secular") drifts in planetary orbits.

Theorem 16.5.2 — Eigenvalues from the Secular Equation

Let $\mathbf{A} = \operatorname{diag}(d_1, \dots, d_n)$ with

$$d_1 > d_2 > \cdots > d_n$$

strictly decreasing and real, let $\tau > 0$, and let $\mathbf{v} \in F^n$ have **every** coordinate non-zero. Write $\widetilde{\mathbf{A}} = \mathbf{A} + \tau\mathbf{v}\mathbf{v}^*$ and let f be its secular function. Then:

(a) no d_i is an eigenvalue of $\widetilde{\mathbf{A}}$;

(b) a real number $\lambda \notin \{d_1, \dots, d_n\}$ is an eigenvalue of $\widetilde{\mathbf{A}}$ if and only if $f(\lambda) = 0$;

(c) f has exactly n roots $\mu_1 > \cdots > \mu_n$, one in each of the intervals

$$(d_1, \infty),\ (d_2, d_1),\ \dots,\ (d_n, d_{n-1}),$$

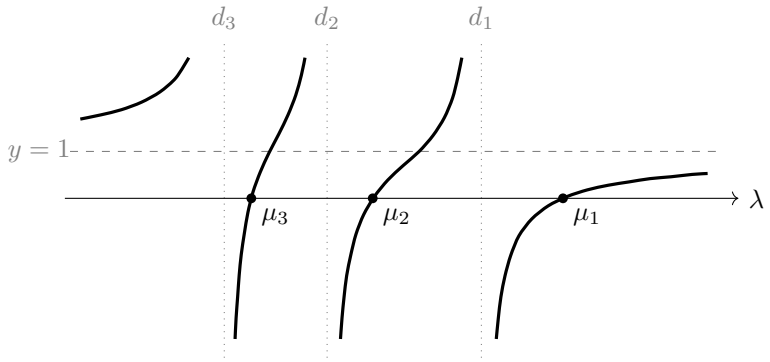
and none below d_n; these are the eigenvalues of $\widetilde{\mathbf{A}}$, each simple, and

$$\mu_1 > d_1 > \mu_2 > d_2 > \cdots > \mu_n > d_n;$$

(d) for each j, the vector $(\mathbf{A} - \mu_j\mathbf{I})^{-1}\mathbf{v}$ is an eigenvector of $\widetilde{\mathbf{A}}$ for μ_j.

Idea. Part (b) is one line of Chapter 7 once (a) has cleared the denominators out of the way. Part (c) is a picture. Each term $|v_i|^2/(d_i - \lambda)$ increases with λ on any interval that avoids d_i, so on each of the $n + 1$ open intervals into which the poles cut the line f climbs steadily from left to right. Just to the left of each pole f shoots up to $+\infty$;

just to the right it starts again from $-\infty$; and far out in either direction it settles at 1. Draw that, and the roots count themselves. The proof turns the picture into a count that needs no limits at all: the n eigenvalues turn out to be distinct, there are exactly n intervals where a root can live, and each holds at most one.



The dotted verticals are the poles, at the old eigenvalues $d_3 < d_2 < d_1$; the dashed horizontal is $y = 1$, the level f approaches at both ends. On the branch left of d_3 every term of the sum is positive, so the curve stays above 1 and never meets the axis. Each of the other three branches runs from $-\infty$ to $+\infty$ or from $-\infty$ to 1, increasing throughout, so each crosses the axis exactly once. Three branches, three roots, one strictly inside each gap and one above the top pole.

Proof. **(a)** Suppose $\widetilde{\mathbf{A}}\mathbf{x} = d_i\mathbf{x}$ for some $\mathbf{x} \neq \mathbf{0}$. Rearranging, $(\mathbf{A} - d_i\mathbf{I})\mathbf{x} = -\tau(\mathbf{v}^*\mathbf{x})\mathbf{v}$. The matrix $\mathbf{A} - d_i\mathbf{I}$ is diagonal with i-th diagonal entry 0, so the i-th coordinate of the left-hand side is 0; the i-th coordinate of the right-hand side is $-\tau(\mathbf{v}^*\mathbf{x})v_i$. Since $\tau \neq 0$ and $v_i \neq 0$, this forces $\mathbf{v}^*\mathbf{x} = 0$, and then $(\mathbf{A} - d_i\mathbf{I})\mathbf{x} = \mathbf{0}$. The diagonal entries d_j are distinct, so the only diagonal entry of $\mathbf{A} - d_i\mathbf{I}$ that vanishes is the i-th, and therefore $\mathbf{x} = c\mathbf{e}_i$ for some scalar c. But then $0 = \mathbf{v}^*\mathbf{x} = c\,\overline{v_i}$, and $v_i \neq 0$ gives $c = 0$, so $\mathbf{x} = \mathbf{0}$ — a contradiction.

(b) Let $\lambda \notin \{d_1, \dots, d_n\}$. Then $\mathbf{A} - \lambda\mathbf{I}$ is diagonal with non-zero diagonal entries, hence invertible, with

$$(\mathbf{A} - \lambda\mathbf{I})^{-1} = \operatorname{diag}\Big(\frac{1}{d_1 - \lambda}, \dots, \frac{1}{d_n - \lambda}\Big).$$

Apply the determinant statement of Corollary 7.3.6 — itself a 1×1 case of Theorem 7.3.2 — to the invertible matrix $\mathbf{A} - \lambda\mathbf{I}$, with the column $\tau\mathbf{v}$ and the row $\mathbf{v}^*$ — that is, with $\tau\mathbf{v}$ as its $\mathbf{u}$ and $\overline{\mathbf{v}}$ in place of its $\mathbf{v}$, so that its $\mathbf{v}^\top$ is our $\mathbf{v}^*$:

$$\begin{aligned}\det(\widetilde{\mathbf{A}} - \lambda\mathbf{I}) &= \det\big((\mathbf{A} - \lambda\mathbf{I}) + (\tau\mathbf{v})\mathbf{v}^*\big) \\ &= \det(\mathbf{A} - \lambda\mathbf{I})\,\big(1 + \tau\,\mathbf{v}^*(\mathbf{A} - \lambda\mathbf{I})^{-1}\mathbf{v}\big).\end{aligned}$$

The scalar in the second factor is $\sum_i |v_i|^2/(d_i - \lambda)$, since $\mathbf{v}^*\mathbf{D}\mathbf{v} = \sum_i \overline{v_i}\, d_{ii} v_i$ for diagonal $\mathbf{D}$. So

$$\det(\widetilde{\mathbf{A}} - \lambda\mathbf{I}) = \Big(\prod_{i=1}^{n}(d_i - \lambda)\Big) f(\lambda), \tag{$*$}$$

and the product is non-zero. Hence $\det(\widetilde{\mathbf{A}} - \lambda\mathbf{I}) = 0$ if and only if $f(\lambda) = 0$. Finally $\det(\lambda\mathbf{I} - \widetilde{\mathbf{A}}) = (-1)^n \det(\widetilde{\mathbf{A}} - \lambda\mathbf{I})$, since negating all n rows of a matrix multiplies its determinant by $(-1)^n$, by n applications of Theorem 6.5.1 (b); so the two determinants

vanish together, and by Theorem 6.10.4 (a) this happens exactly when λ is an eigenvalue of $\widetilde{\mathbf{A}}$.

(c) Let J be one of the $n+1$ open intervals into which $d_1, \dots, d_n$ cut the real line, and let $\lambda < \lambda'$ lie in J. For each i, the numbers $d_i - \lambda$ and $d_i - \lambda'$ are non-zero and have the same sign, because $d_i \notin J$; hence

$$\frac{1}{d_i - \lambda'} - \frac{1}{d_i - \lambda} = \frac{\lambda' - \lambda}{(d_i - \lambda)(d_i - \lambda')} \; > \; 0.$$

Multiplying by $\tau |v_i|^2 > 0$ and summing over i gives $f(\lambda') > f(\lambda)$. So f is **strictly increasing** on each such interval, and in particular has at most one root in each.

Next, every eigenspace of $\widetilde{\mathbf{A}}$ is one-dimensional. Let $\widetilde{\mathbf{A}}\mathbf{x} = \mu\mathbf{x}$. By (a), $\mu \notin \{d_1, \dots, d_n\}$, so $\mathbf{A} - \mu\mathbf{I}$ is invertible, and rearranging as in (a) gives $(\mathbf{A} - \mu\mathbf{I})\mathbf{x} = -\tau(\mathbf{v}^*\mathbf{x})\mathbf{v}$, that is,

$$\mathbf{x} = -\tau(\mathbf{v}^*\mathbf{x})\,(\mathbf{A} - \mu\mathbf{I})^{-1}\mathbf{v}.$$

So $\ker(\widetilde{\mathbf{A}} - \mu\mathbf{I}) \subseteq \operatorname{span}\big((\mathbf{A} - \mu\mathbf{I})^{-1}\mathbf{v}\big)$, a space of dimension 1. Now write $\widetilde{\mathbf{A}} = \mathbf{U}\mathbf{D}\mathbf{U}^*$ with $\mathbf{U}$ unitary and $\mathbf{D}$ diagonal carrying the eigenvalue list of $\widetilde{\mathbf{A}}$ with multiplicity (Corollary 11.4.3, or Corollary 11.5.2 over $\mathbb{R}$). Since $\mathbf{U}$ is invertible, $\ker(\widetilde{\mathbf{A}} - \mu\mathbf{I}) = \mathbf{U}\ker(\mathbf{D} - \mu\mathbf{I})$, and $\dim\ker(\mathbf{D} - \mu\mathbf{I})$ is the number of diagonal entries of $\mathbf{D}$ equal to μ. That number is therefore at most 1: the n eigenvalues of $\widetilde{\mathbf{A}}$ are **distinct**, and each is simple.

Now count. Call the eigenvalues $\mu_1 > \cdots > \mu_n$. By (b) each is a root of f, and by (a) none equals a d_i, so each lies in one of the $n+1$ open intervals. None lies in $(-\infty, d_n)$: there every $d_i - \lambda$ is positive, so every term of the sum is positive and $f(\lambda) > 1$. That leaves n intervals, each containing at most one root of f, to accommodate n distinct roots — so each of the intervals $(d_1, \infty), (d_2, d_1), \dots, (d_n, d_{n-1})$ contains exactly one of them, and since they are listed in decreasing order, $\mu_1 \in (d_1, \infty)$ and $\mu_{i+1} \in (d_{i+1}, d_i)$. Conversely every root of f is an eigenvalue by (b), so f has no roots besides these n. Reading the intervals in decreasing order gives the displayed chain.

(d) Fix j and put $\mathbf{x} = (\mathbf{A} - \mu_j\mathbf{I})^{-1}\mathbf{v}$, which is defined because $\mu_j \notin \{d_1, \dots, d_n\}$ and non-zero because $\mathbf{v} \neq \mathbf{0}$. As in (b),

$$\tau\,\mathbf{v}^*(\mathbf{A} - \mu_j\mathbf{I})^{-1}\mathbf{v} = \tau \sum_i \frac{|v_i|^2}{d_i - \mu_j} = f(\mu_j) - 1 = -1.$$

Therefore

$$\begin{aligned}(\widetilde{\mathbf{A}} - \mu_j\mathbf{I})\mathbf{x} &= (\mathbf{A} - \mu_j\mathbf{I})\mathbf{x} + \tau\mathbf{v}(\mathbf{v}^*\mathbf{x}) \\ &= \mathbf{v} + \mathbf{v}\left(\tau\,\mathbf{v}^*(\mathbf{A} - \mu_j\mathbf{I})^{-1}\mathbf{v}\right) = \mathbf{v} - \mathbf{v} = \mathbf{0}.\end{aligned}$$

This proves the theorem.

■

Identity $(*)$ is worth keeping on its own: it says that the characteristic polynomial of the bumped matrix is the characteristic polynomial of the original one multiplied by the secular function. The poles of f cancel the roots of the product exactly, and what survives is a polynomial of the same degree with its roots shifted one gap to the right.

Example. (A three-by-three update, found from its secular equation)

Let

$$\mathbf{A} = \operatorname{diag}(7, 1, -3), \qquad \mathbf{v} = (2, 1, 2), \qquad \tau = 1.$$

Write down $\widetilde{\mathbf{A}} = \mathbf{A} + \mathbf{v}\mathbf{v}^{\top}$ and its secular function, find all three eigenvalues from the secular equation, and confirm them independently.

Solution. The matrix. $\mathbf{v}\mathbf{v}^{\top}$ has (i, j) entry $v_i v_j$, so

$$\widetilde{\mathbf{A}} = \begin{pmatrix} 7 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -3 \end{pmatrix} + \begin{pmatrix} 4 & 2 & 4 \\ 2 & 1 & 2 \\ 4 & 2 & 4 \end{pmatrix} = \begin{pmatrix} 11 & 2 & 4 \\ 2 & 2 & 2 \\ 4 & 2 & 1 \end{pmatrix}.$$

The hypotheses of Theorem 16.5.2 hold: $7 > 1 > -3$ are distinct, $\tau = 1 > 0$, and no coordinate of $\mathbf{v}$ vanishes.

The secular function. With $|v_i|^2 = 4, 1, 4$,

$$f(\lambda) = 1 + \frac{4}{7 - \lambda} + \frac{1}{1 - \lambda} + \frac{4}{-3 - \lambda}.$$

The roots. Multiply through by $(7 - \lambda)(1 - \lambda)(-3 - \lambda)$, which by $(*)$ turns f into $\det(\widetilde{\mathbf{A}} - \lambda \mathbf{I})$:

$$\begin{aligned} &(7 - \lambda)(1 - \lambda)(-3 - \lambda) + 4(1 - \lambda)(-3 - \lambda) \\ &\quad + (7 - \lambda)(-3 - \lambda) + 4(7 - \lambda)(1 - \lambda) \\ &= -(\lambda - 13)(\lambda - 2)(\lambda + 1). \end{aligned}$$

So the eigenvalues are $\mu_1 = 13$, $\mu_2 = 2$, $\mu_3 = -1$. They sit where the theorem promised:

$$13 > 7 > 2 > 1 > -1 > -3.$$

It is quicker to check the three roots than to expand the product. At $\lambda = 13$,

$$f(13) = 1 - \tfrac{4}{6} - \tfrac{1}{12} - \tfrac{4}{16} = \tfrac{12 - 8 - 1 - 3}{12} = 0;$$

at $\lambda = 2$, $f(2) = 1 + \tfrac{4}{5} - 1 - \tfrac{4}{5} = 0$; at $\lambda = -1$, $f(-1) = 1 + \tfrac{1}{2} + \tfrac{1}{2} - 2 = 0$.

An independent confirmation. Part (d) of the theorem produces eigenvectors without any further elimination: $(\mathbf{A} - \mu \mathbf{I})^{-1}\mathbf{v}$ is diagonal applied to $\mathbf{v}$. For $\mu = 13$, $\mathbf{A} - 13\mathbf{I} = \operatorname{diag}(-6, -12, -16)$ and

$$(\mathbf{A} - 13\mathbf{I})^{-1}\mathbf{v} = \left(-\tfrac{1}{3}, -\tfrac{1}{12}, -\tfrac{1}{8}\right) \sim (8, 2, 3)$$

after scaling by -24. Multiplying out, $\widetilde{\mathbf{A}}(8, 2, 3) = (88 + 4 + 12,\ 16 + 4 + 6,\ 32 + 4 + 3) = (104, 26, 39) = 13\,(8, 2, 3)$. The same recipe gives $(2, -5, -2)$ for $\mu = 2$ and $(1, 2, -4)$ for $\mu = -1$, and both check by one matrix–vector product. Finally the trace: $11 + 2 + 1 = 14 = 13 + 2 - 1$, as Corollary 11.1.4 requires.

Warning. **Both extra hypotheses of Theorem 16.5.2 earn their place, and the sign of τ reverses the picture.**

A zero coordinate deflates. Take $\mathbf{A} = \operatorname{diag}(2, 1, 0)$ and $\mathbf{v} = (1, 0, 1)$, so $v_2 = 0$. Then $\mathbf{e}_2$ is an eigenvector of $\widetilde{\mathbf{A}} = \mathbf{A} + \mathbf{v}\mathbf{v}^{\top}$ with eigenvalue $1 = d_2$, because $\mathbf{v}^{*}\mathbf{e}_2 = 0$. So

conclusion (a) fails. The secular function $1 + 1/(2-\lambda) - 1/\lambda$ has only two poles and only two roots, $2 \pm \sqrt{2}$; the third eigenvalue, 1, is invisible to it. The eigenvalues still interlace, $2 + \sqrt{2} \geq 2 \geq 1 \geq 1 \geq 2 - \sqrt{2} \geq 0$, but not strictly.

A repeated d_i deflates too. If $d_1 = d_2$, any vector in $\operatorname{span}(\mathbf{e}_1, \mathbf{e}_2)$ orthogonal to $\mathbf{v}$ is an eigenvector of $\widetilde{\mathbf{A}}$ for d_1, for the same reason.

Negative τ reverses the interlacing. For $\tau < 0$ the matrix $\tau\mathbf{v}\mathbf{v}^*$ is negative semidefinite and every eigenvalue goes **down**: applying Theorem 16.5.1 to $\widetilde{\mathbf{A}}$ and $-\tau > 0$ gives $\lambda_i(\mathbf{A}) \geq \lambda_i(\widetilde{\mathbf{A}}) \geq \lambda_{i+1}(\mathbf{A})$. Reading the chain of the theorem in the wrong direction is the standard way to get this backwards.

16.5.3 The shifts add up

Interlacing says where each eigenvalue may go. One number says how far they all go together, and it costs a line.

Corollary 16.5.3 — Total Eigenvalue Shift

Let $\mathbf{A} \in M_n(F)$ be Hermitian, $\mathbf{v} \in F^n$, $\tau \in \mathbb{R}$, and $\widetilde{\mathbf{A}} = \mathbf{A} + \tau\mathbf{v}\mathbf{v}^*$. Then

$$\sum_{i=1}^{n} \bigl(\lambda_i(\widetilde{\mathbf{A}}) - \lambda_i(\mathbf{A})\bigr) = \tau\|\mathbf{v}\|^2.$$

Proof. By Theorem 0.9.6 (3) applied to the $n \times 1$ matrix $\mathbf{v}$ and the $1 \times n$ matrix $\mathbf{v}^*$,

$$\operatorname{tr}(\mathbf{v}\mathbf{v}^*) = \operatorname{tr}(\mathbf{v}^*\mathbf{v}) = \|\mathbf{v}\|^2.$$

Hence $\operatorname{tr}\widetilde{\mathbf{A}} = \operatorname{tr}\mathbf{A} + \tau\|\mathbf{v}\|^2$, by part (1) of the same theorem. Both $\mathbf{A}$ and $\widetilde{\mathbf{A}}$ are Hermitian, so Corollary 11.1.4 expresses each trace as the sum of the eigenvalues with multiplicity, and subtracting the two expressions gives the claim. ∎

So the whole budget for the movement is $\tau\|\mathbf{v}\|^2$, and for $\tau \geq 0$ Theorem 16.5.1 says how it may be spent: each eigenvalue takes a non-negative share, and no share except the top one is large enough to carry an eigenvalue past its old upper neighbor. In Example (A bump on a diagonal matrix) the budget 5 was split as $3 + 2$; in Example (A three-by-three update, found from its secular equation) the budget $\|\mathbf{v}\|^2 = 9$ was split as $6 + 1 + 2$.

Remark. The secular equation of Theorem 16.5.2 is not only a proof device. Because f is increasing between consecutive poles and the bracketing interval is known in advance, each root can be located by bisection on an interval that is guaranteed to contain exactly one of them — a far better-behaved problem than finding the roots of a characteristic polynomial. The secular equation is the engine of the divide-and-conquer eigenvalue algorithms for Hermitian matrices, which split the matrix into two halves joined by a rank-one term and solve one secular equation to merge their spectra. The deflation observed in the warning above, where a zero coordinate of $\mathbf{v}$ hands over an eigenvalue for free, is the same phenomenon that makes the algorithm fast in practice.

16.5.4 Exercises

16.5.4.1 A. Check your understanding

Exercise A1.

(a) State Theorem 16.5.1, including the hypothesis on τ.

(b) Write down the secular function of $\mathbf{A} + 2\mathbf{v}\mathbf{v}^{\top}$ for $\mathbf{A} = \operatorname{diag}(6, 2, -1)$ and $\mathbf{v} = (1, 3, 1)$.

(c) Explain in one sentence why no d_i is an eigenvalue of $\mathbf{A} + \tau\mathbf{v}\mathbf{v}^{*}$ under the hypotheses of Theorem 16.5.2.

(d) Determine whether the following is correct, and justify your answer: if $\tau < 0$ then $\lambda_i(\mathbf{A} + \tau\mathbf{v}\mathbf{v}^{*}) \geq \lambda_i(\mathbf{A})$ for every i.

(e) A Hermitian 4×4 matrix $\mathbf{A}$ has eigenvalues $8, 5, 5, 0$. What does Corollary 16.5.3 say about $\mathbf{A} + 3\mathbf{v}\mathbf{v}^{*}$ when $\|\mathbf{v}\| = 2$?

Solution.

(a) For Hermitian $\mathbf{A} \in M_n(F)$, $\mathbf{v} \in F^n$ and $\tau \geq 0$, the eigenvalues of $\widetilde{\mathbf{A}} = \mathbf{A} + \tau\mathbf{v}\mathbf{v}^{*}$ satisfy $\lambda_i(\widetilde{\mathbf{A}}) \geq \lambda_i(\mathbf{A}) \geq \lambda_{i+1}(\widetilde{\mathbf{A}})$ for $1 \leq i \leq n-1$, together with $\lambda_n(\widetilde{\mathbf{A}}) \geq \lambda_n(\mathbf{A})$. The hypothesis $\tau \geq 0$ is what makes the perturbation positive semidefinite; without it only the second family of inequalities survives.

(b) $f(\lambda) = 1 + 2\Big(\dfrac{1}{6-\lambda} + \dfrac{9}{2-\lambda} + \dfrac{1}{-1-\lambda}\Big)$.

(c) If $\widetilde{\mathbf{A}}\mathbf{x} = d_i\mathbf{x}$, comparing i-th coordinates in $(\mathbf{A} - d_i\mathbf{I})\mathbf{x} = -\tau(\mathbf{v}^{*}\mathbf{x})\mathbf{v}$ forces $\mathbf{v}^{*}\mathbf{x} = 0$ because $v_i \neq 0$; then $\mathbf{x}$ is a multiple of $\mathbf{e}_i$, and $\mathbf{v}^{*}\mathbf{x} = 0$ forces that multiple to be 0.

(d) Incorrect; the inequality goes the other way. For $\tau < 0$ the added matrix is negative semidefinite, and $\lambda_i(\mathbf{A}) \geq \lambda_i(\mathbf{A} + \tau\mathbf{v}\mathbf{v}^{*})$ for every i. Concretely, $\mathbf{A} = \operatorname{diag}(1, 0)$, $\tau = -1$, $\mathbf{v} = \mathbf{e}_1$ gives $\widetilde{\mathbf{A}} = \operatorname{diag}(0, 0)$ and λ_1 drops from 1 to 0.

(e) It says the four eigenvalues of $\mathbf{A} + 3\mathbf{v}\mathbf{v}^{*}$ sum to $8 + 5 + 5 + 0 + 3 \cdot 4 = 30$, that is, 12 more than those of $\mathbf{A}$. Combined with Theorem 16.5.1, which caps λ_2 at 8, λ_3 at 5 and λ_4 at 5, it forces $\lambda_1(\mathbf{A} + 3\mathbf{v}\mathbf{v}^{*}) \geq 30 - 18 = 12$.

16.5.4.2 B. Practice

Exercise B1: A secular equation, end to end.

Let $\mathbf{A} = \operatorname{diag}(7, 0, -3)$, $\mathbf{v} = (3, 2, 2)$ and $\tau = 1$.

(a) Write down $\widetilde{\mathbf{A}} = \mathbf{A} + \mathbf{v}\mathbf{v}^{\top}$ and the secular function f.

(b) Verify that 21, 2 and -2 are roots of f, and explain why these are all the eigenvalues of $\widetilde{\mathbf{A}}$.

(c) Exhibit the interlacing chain of Theorem 16.5.1 for this pair.

Solution.

(a) $\mathbf{v}\mathbf{v}^\top$ has entries $v_i v_j$, so

$$\widetilde{\mathbf{A}} = \begin{pmatrix} 7 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & -3 \end{pmatrix} + \begin{pmatrix} 9 & 6 & 6 \\ 6 & 4 & 4 \\ 6 & 4 & 4 \end{pmatrix} = \begin{pmatrix} 16 & 6 & 6 \\ 6 & 4 & 4 \\ 6 & 4 & 1 \end{pmatrix},$$

and $f(\lambda) = 1 + \dfrac{9}{7-\lambda} + \dfrac{4}{0-\lambda} + \dfrac{4}{-3-\lambda}$.

(b) At $\lambda = 21$: $1 - \frac{9}{14} - \frac{4}{21} - \frac{4}{24} = 1 - \frac{9}{14} - \frac{4}{21} - \frac{1}{6}$. Over 42 this is $(42 - 27 - 8 - 7)/42 = 0$. At $\lambda = 2$: $1 + \frac{9}{5} - 2 - \frac{4}{5} = (5 + 9 - 10 - 4)/5 = 0$. At $\lambda = -2$: $1 + 1 + 2 - 4 = 0$. The hypotheses of Theorem 16.5.2 hold — $7 > 0 > -3$ are distinct, $\tau = 1 > 0$, and every coordinate of $\mathbf{v}$ is non-zero — so by part (c) the secular function has exactly three roots and they are the eigenvalues. We have found three distinct roots, so there are no others.

(c) $21 \geq 7 \geq 2 \geq 0 \geq -2 \geq -3$, all strict, as part (c) of Theorem 16.5.2 predicts.

Exercise B2: Reading the chain backwards.

Let $\mathbf{B} = \begin{pmatrix} 5 & 2 \\ 2 & 5 \end{pmatrix}$ and $\mathbf{v} = (1, 2)$.

(a) Compute the eigenvalues of $\mathbf{B}$ and of $\mathbf{B} - \mathbf{v}\mathbf{v}^\top$.

(b) State which chain of inequalities Theorem 16.5.1 gives here, being careful about which matrix plays the role of $\mathbf{A}$.

Solution.

(a) $\mathbf{B}$ has trace 10 and determinant 21, so its characteristic polynomial is $x^2 - 10x + 21 = (x - 7)(x - 3)$ and its eigenvalues are 7 and 3. Also

$$\mathbf{B} - \mathbf{v}\mathbf{v}^\top = \begin{pmatrix} 5 & 2 \\ 2 & 5 \end{pmatrix} - \begin{pmatrix} 1 & 2 \\ 2 & 4 \end{pmatrix} = \begin{pmatrix} 4 & 0 \\ 0 & 1 \end{pmatrix},$$

with eigenvalues 4 and 1.

(b) Put $\mathbf{A} = \mathbf{B} - \mathbf{v}\mathbf{v}^\top = \mathrm{diag}(4, 1)$ and $\tau = 1$, so that $\mathbf{B} = \mathbf{A} + \tau\mathbf{v}\mathbf{v}^\top$ is the *bumped* matrix. The theorem then reads $\lambda_1(\mathbf{B}) \geq \lambda_1(\mathbf{A}) \geq \lambda_2(\mathbf{B}) \geq \lambda_2(\mathbf{A})$, that is, $7 \geq 4 \geq 3 \geq 1$. Taking $\mathbf{B}$ for $\mathbf{A}$ and $\tau = -1$ instead would give the reversed chain $\lambda_i(\mathbf{B}) \geq \lambda_i(\mathbf{B} - \mathbf{v}\mathbf{v}^\top) \geq \lambda_{i+1}(\mathbf{B})$, namely $7 \geq 4 \geq 3 \geq 1$ again: the same four numbers, read from the other side.

Exercise B3: The missing eigenvalue.

Let $\mathbf{A} = \mathrm{diag}(5, 3, 0)$, $\mathbf{v} = (2, 2, 2)$ and $\tau = 1$. It is given that two of the eigenvalues of $\widetilde{\mathbf{A}} = \mathbf{A} + \mathbf{v}\mathbf{v}^\top$ are 15 and 4. Find the third without computing a characteristic polynomial, and then confirm it from the secular equation.

Solution. By Corollary 16.5.3 the eigenvalues of $\widetilde{\mathbf{A}}$ sum to

$$(5 + 3 + 0) + \|\mathbf{v}\|^2 = 8 + 12 = 20.$$

Hence the third eigenvalue is $20 - 15 - 4 = 1$.

For the confirmation, $|v_i|^2 = 4$ for each i, so

$$f(\lambda) = 1 + \frac{4}{5-\lambda} + \frac{4}{3-\lambda} + \frac{4}{-\lambda},$$

and $f(1) = 1 + 1 + 2 - 4 = 0$. The hypotheses of Theorem 16.5.2 hold, and 1 lies in the interval $(0, 3)$ where part (c) puts the third root. As a check on the other two, $15 > 5$ and $4 \in (3, 5)$, exactly as the theorem requires.

16.5.4.3 C. Going deeper

Exercise C1: What a zero coordinate does.

Let $\mathbf{A} = \operatorname{diag}(d_1, \dots, d_n)$ with the d_i real, let $\tau \in \mathbb{R}$ and let $\mathbf{v} \in F^n$.

(a) Prove that if $v_i = 0$ then $\mathbf{e}_i$ is an eigenvector of $\mathbf{A} + \tau \mathbf{v}\mathbf{v}^*$ with eigenvalue d_i.

(b) Suppose $\tau > 0$, the d_i are strictly decreasing, and exactly one coordinate v_k vanishes. Show that the remaining $n - 1$ eigenvalues of $\mathbf{A} + \tau \mathbf{v}\mathbf{v}^*$ are the roots of the function obtained from the secular function by deleting the k-th term. *Hint: restrict to the coordinate subspace spanned by the $\mathbf{e}_i$ with $i \neq k$.*

(c) Illustrate both parts with $\mathbf{A} = \operatorname{diag}(2, 1, 0)$, $\mathbf{v} = (1, 0, 1)$ and $\tau = 1$.

Solution.

(a) $\mathbf{v}^* \mathbf{e}_i = \overline{v_i} = 0$, so $(\mathbf{A} + \tau \mathbf{v}\mathbf{v}^*)\mathbf{e}_i = \mathbf{A}\mathbf{e}_i + \tau \mathbf{v}(\mathbf{v}^* \mathbf{e}_i) = d_i \mathbf{e}_i$.

(b) Let $U = \operatorname{span}(\mathbf{e}_i : i \neq k)$, a subspace of dimension $n - 1$. Every column of $\mathbf{A}$ other than the k-th lies in U, and $\mathbf{v} \in U$ because $v_k = 0$; hence $(\mathbf{A} + \tau \mathbf{v}\mathbf{v}^*)U \subseteq U$. In the ordered basis $(\mathbf{e}_i)_{i \neq k}$ of U, the restriction of $\mathbf{A} + \tau \mathbf{v}\mathbf{v}^*$ to U has matrix $\mathbf{A}' + \tau \mathbf{v}'(\mathbf{v}')^*$, where $\mathbf{A}' = \operatorname{diag}(d_i : i \neq k)$ and $\mathbf{v}'$ is $\mathbf{v}$ with its k-th coordinate removed. Since $U \oplus \operatorname{span}(\mathbf{e}_k) = F^n$ and $\operatorname{span}(\mathbf{e}_k)$ is also invariant by (a), the eigenvalues of $\mathbf{A} + \tau \mathbf{v}\mathbf{v}^*$ are those of the restriction to U together with d_k. Now $\mathbf{A}'$ has strictly decreasing diagonal entries, $\tau > 0$, and $\mathbf{v}'$ has no zero coordinate, so Theorem 16.5.2 applies to $\mathbf{A}' + \tau \mathbf{v}'(\mathbf{v}')^*$: its $n - 1$ eigenvalues are exactly the roots of its secular function. That function is the secular function of the original update with the k-th term deleted, because that term was $\tau |v_k|^2 / (d_k - \lambda) = 0$ anyway.

(c) Here $v_2 = 0$, so $\mathbf{e}_2$ is an eigenvector with eigenvalue $d_2 = 1$ by (a). By (b) the other two eigenvalues are the roots of

$$1 + \frac{1}{2-\lambda} + \frac{1}{-\lambda} = 0,$$

that is, of $\lambda(2 - \lambda) + \lambda - (2 - \lambda) = 0$, i.e. $\lambda^2 - 4\lambda + 2 = 0$, with roots $2 \pm \sqrt{2}$. So the spectrum is $\{2 + \sqrt{2},\ 1,\ 2 - \sqrt{2}\}$. Directly,

$$\mathbf{A} + \mathbf{v}\mathbf{v}^{\top} = \begin{pmatrix} 3 & 0 & 1 \\ 0 & 1 & 0 \\ 1 & 0 & 1 \end{pmatrix},$$

whose second row and column confirm the eigenvalue 1, and whose remaining 2×2 block $\left(\begin{smallmatrix} 3 & 1 \\ 1 & 1 \end{smallmatrix}\right)$ has trace 4 and determinant 2.

Exercise C2: Only one eigenvalue can escape.

Let $\mathbf{A} \in M_n(F)$ be Hermitian, $\mathbf{v} \in F^n$, $\tau \in \mathbb{R}$, and $\widetilde{\mathbf{A}} = \mathbf{A} + \tau \mathbf{v}\mathbf{v}^*$.

(a) Prove that **at most one** eigenvalue of $\widetilde{\mathbf{A}}$ lies outside the closed interval $[\lambda_n(\mathbf{A}), \lambda_1(\mathbf{A})]$, and say which one it is and on which side, according to the sign of τ.

(b) Prove that the escaping eigenvalue moves by at most $|\tau|\|\mathbf{v}\|^2$, and show by examples with $n = 2$ that it may move by exactly that amount, and that it may not escape at all.

Solution.

(a) Suppose first $\tau \geq 0$. By Theorem 16.5.1, $\lambda_n(\widetilde{\mathbf{A}}) \geq \lambda_n(\mathbf{A})$, so no eigenvalue of $\widetilde{\mathbf{A}}$ falls below the interval; and for $i \geq 2$, $\lambda_i(\widetilde{\mathbf{A}}) \leq \lambda_{i-1}(\mathbf{A}) \leq \lambda_1(\mathbf{A})$, so only $\lambda_1(\widetilde{\mathbf{A}})$ can rise above it. So at most one eigenvalue escapes, namely the largest, and it escapes upwards.
For $\tau < 0$, the warning above gives $\lambda_i(\mathbf{A}) \geq \lambda_i(\widetilde{\mathbf{A}}) \geq \lambda_{i+1}(\mathbf{A})$ for $i \leq n-1$ and $\lambda_n(\mathbf{A}) \geq \lambda_n(\widetilde{\mathbf{A}})$. Hence $\lambda_1(\widetilde{\mathbf{A}}) \leq \lambda_1(\mathbf{A})$, and $\lambda_i(\widetilde{\mathbf{A}}) \geq \lambda_{i+1}(\mathbf{A}) \geq \lambda_n(\mathbf{A})$ for $i \leq n-1$. So only $\lambda_n(\widetilde{\mathbf{A}})$ can escape, and it escapes downwards.

(b) Take $\tau > 0$; the case $\tau < 0$ is the mirror image. By Theorem 16.5.1 every shift $\lambda_i(\widetilde{\mathbf{A}}) - \lambda_i(\mathbf{A})$ is ≥ 0, and by Corollary 16.5.3 they sum to $\tau\|\mathbf{v}\|^2$. So each shift, in particular that of λ_1, is at most $\tau\|\mathbf{v}\|^2$.

For equality, let $\mathbf{A} = \operatorname{diag}(2, 1)$, $\mathbf{v} = \mathbf{e}_1$, $\tau = 3$: then $\widetilde{\mathbf{A}} = \operatorname{diag}(5, 1)$, and λ_1 moves from 2 to 5, by exactly $\tau\|\mathbf{v}\|^2 = 3$. For no escape, let $\mathbf{v} = \mathbf{e}_2$ and $\tau = 1$: then $\widetilde{\mathbf{A}} = \operatorname{diag}(2, 2)$, whose eigenvalues both lie in $[1, 2]$. The whole budget went to λ_2, which Theorem 16.5.1 caps at $\lambda_1(\mathbf{A}) = 2$.

Exercise C3: Bumping along an eigenvector.

Let $\mathbf{A} \in M_n(F)$ be Hermitian with an orthonormal basis of eigenvectors $\mathbf{u}_1, \dots, \mathbf{u}_n$, where $\mathbf{A}\mathbf{u}_i = \lambda_i(\mathbf{A})\mathbf{u}_i$.

(a) Fix k and $\tau \in \mathbb{R}$. Prove that the eigenvalues of $\mathbf{A} + \tau\mathbf{u}_k\mathbf{u}_k^*$, listed with multiplicity but not necessarily in order, are $\lambda_k(\mathbf{A}) + \tau$ together with $\lambda_i(\mathbf{A})$ for $i \neq k$.

(b) Deduce that $\mathbf{A} - \lambda_1(\mathbf{A})\mathbf{u}_1\mathbf{u}_1^*$ has eigenvalue list $0, \lambda_2(\mathbf{A}), \dots, \lambda_n(\mathbf{A})$. (This is the **deflation** step: it removes the top eigenvalue and leaves the rest untouched, which is what makes it possible to find eigenvalues one at a time.)

(c) Explain why (a) does not contradict part (c) of Theorem 16.5.2.

Solution.

(a) For $i \neq k$, orthonormality gives $\mathbf{u}_k^*\mathbf{u}_i = 0$, so

$$(\mathbf{A} + \tau\mathbf{u}_k\mathbf{u}_k^*)\mathbf{u}_i = \mathbf{A}\mathbf{u}_i + \tau\mathbf{u}_k(\mathbf{u}_k^*\mathbf{u}_i) = \lambda_i(\mathbf{A})\mathbf{u}_i.$$

For $i = k$, $\mathbf{u}_k^*\mathbf{u}_k = 1$ gives $(\mathbf{A} + \tau\mathbf{u}_k\mathbf{u}_k^*)\mathbf{u}_k = (\lambda_k(\mathbf{A}) + \tau)\mathbf{u}_k$. So $(\mathbf{u}_1, \dots, \mathbf{u}_n)$ is a basis of F^n consisting of eigenvectors of $\mathbf{A} + \tau\mathbf{u}_k\mathbf{u}_k^*$, with the stated eigenvalues. A basis of eigenvectors exhibits the whole eigenvalue list with multiplicity.

(b) Take $k = 1$ and $\tau = -\lambda_1(\mathbf{A})$ in (a).

(c) There is no contradiction, because the hypothesis of Theorem 16.5.2 that fails here fails as badly as possible. Writing everything in the orthonormal eigenbasis, the update vector is $\mathbf{u}_k$, whose coordinate vector is $\mathbf{e}_k$: **all but one** of its coordinates are zero. Part (a) is the extreme case of Exercise (C1: What a zero coordinate does) (a), with $n-1$ coordinates deflating at once, and only one eigenvalue is left to move.

16.6 Subspaces and Sums of Eigenvalues

Section 4 deleted a row and the matching column, which is a coordinate-dependent operation, and got a coordinate-free conclusion: the spectra interlace. That is a hint. This section replaces "delete some coordinates" by "restrict to a subspace", which is the same operation with the accident of a basis removed, and the interlacing survives in a stronger form. Then it asks a question Courant–Fischer cannot answer one eigenvalue at a time: not "what is λ_2?" but "what is $\lambda_1+\lambda_2$?" That sum turns out to be a maximum over a set of subspaces, and the answer discharges a promise Chapter 12 made about singular values.

Throughout this section $F=\mathbb{R}$ or $F=\mathbb{C}$, every matrix whose eigenvalues are indexed is Hermitian, and the indexing is decreasing, $\lambda_1(\mathbf{A})\geq\cdots\geq\lambda_n(\mathbf{A})$.

16.6.1 Restricting a matrix to a subspace

A principal submatrix of $\mathbf{A}$ records what the quadratic form $\mathbf{x}\mapsto\langle\mathbf{Ax},\mathbf{x}\rangle$ does to vectors supported on a few coordinates. Nothing in that description needs the coordinates to be the standard ones: any subspace W and any orthonormal basis of it will do, and the matrix that results plays the same role.

Definition 16.6.1 — Compression to a subspace

Let $\mathbf{A}\in M_n(F)$, let $1\leq k\leq n$, and let $\mathbf{q}_1,\dots,\mathbf{q}_k$ be an **orthonormal** list in F^n, so that the matrix $\mathbf{Q}\in M_{n\times k}(F)$ with these columns satisfies $\mathbf{Q}^*\mathbf{Q}=\mathbf{I}_k$. The **compression** of $\mathbf{A}$ to $W=\operatorname{span}(\mathbf{q}_1,\dots,\mathbf{q}_k)$ with respect to this basis is the $k\times k$ matrix

$$\mathbf{Q}^*\mathbf{AQ},\qquad(\mathbf{Q}^*\mathbf{AQ})_{ij}=\langle\mathbf{Aq}_j,\mathbf{q}_i\rangle.$$

The entry formula is just $(\mathbf{Q}^*\mathbf{AQ})_{ij}=\mathbf{q}_i^*\mathbf{Aq}_j$, and $\mathbf{q}_i^*\mathbf{y}=\langle\mathbf{y},\mathbf{q}_i\rangle$ for the standard inner product. If $\mathbf{A}$ is Hermitian so is $\mathbf{Q}^*\mathbf{AQ}$, since $(\mathbf{Q}^*\mathbf{AQ})^*=\mathbf{Q}^*\mathbf{A}^*\mathbf{Q}=\mathbf{Q}^*\mathbf{AQ}$.

The eigenvalues do not depend on the basis chosen. Let $(\mathbf{q}'_1,\dots,\mathbf{q}'_k)$ be another orthonormal basis of the same W, with matrix $\mathbf{Q}'$. Each $\mathbf{q}'_j$ lies in $W=\operatorname{col}(\mathbf{Q})$, so $\mathbf{Q}'=\mathbf{QU}$ for some $\mathbf{U}\in M_k(F)$, and then $\mathbf{I}_k=(\mathbf{Q}')^*\mathbf{Q}'=\mathbf{U}^*\mathbf{Q}^*\mathbf{QU}=\mathbf{U}^*\mathbf{U}$, so $\mathbf{U}$ is unitary. Hence

$$(\mathbf{Q}')^*\mathbf{AQ}'=\mathbf{U}^*(\mathbf{Q}^*\mathbf{AQ})\mathbf{U},$$

a unitary similarity, which leaves the eigenvalues alone. So it is legitimate to speak of *the* eigenvalues of the compression of $\mathbf{A}$ to W, and we do.

Three cases to keep in mind.

- **Coordinate subspaces.** If $\mathbf{q}_j = \mathbf{e}_{i_j}$ for indices $i_1 < \cdots < i_k$, then $(\mathbf{Q}^*\mathbf{A}\mathbf{Q})_{lj} = a_{i_l i_j}$: the compression is the principal submatrix $\mathbf{A}_{I,I}$ of Definition 6.7.1 on the index set $I = \{i_1, \ldots, i_k\}$. Compression generalizes "delete rows and the matching columns".
- $k = n$**.** Then $\mathbf{Q}$ is a unitary matrix and $\mathbf{Q}^*\mathbf{A}\mathbf{Q}$ is unitarily similar to $\mathbf{A}$: nothing is lost and nothing is learned.
- $k = 1$**.** Then $\mathbf{Q}^*\mathbf{A}\mathbf{Q}$ is the 1×1 matrix $\langle \mathbf{A}\mathbf{q}_1, \mathbf{q}_1 \rangle = R_{\mathbf{A}}(\mathbf{q}_1)$, the Rayleigh quotient of Definition 16.1.1 at a unit vector. Everything below is a statement about k Rayleigh quotients at once.

Drop the orthonormality and the notion collapses. With $\mathbf{A} = \operatorname{diag}(1, 0)$ and the single column $\mathbf{Q} = (2, 0)^{\top}$, which has $\mathbf{Q}^*\mathbf{Q} = (4) \neq \mathbf{I}_1$, the "compression" is the 1×1 matrix (4), whose eigenvalue 4 is larger than every eigenvalue of $\mathbf{A}$. The clause that fails is $\mathbf{Q}^*\mathbf{Q} = \mathbf{I}_k$, and with it every conclusion of this section.

16.6.2 Interlacing without coordinates

Theorem 16.6.1 — Poincaré Separation Theorem

Let $\mathbf{A} \in M_n(F)$ be Hermitian, let $1 \le k \le n$, and let $\mathbf{B} = \mathbf{Q}^*\mathbf{A}\mathbf{Q}$ be the compression of $\mathbf{A}$ to a k-dimensional subspace $W \subseteq F^n$, as in Definition 16.6.1. Then

$$\lambda_i(\mathbf{A}) \;\ge\; \lambda_i(\mathbf{B}) \;\ge\; \lambda_{i+n-k}(\mathbf{A}) \qquad (1 \le i \le k).$$

Idea. Both inequalities come from the same observation, used twice. The map $\mathbf{y} \mapsto \mathbf{Q}\mathbf{y}$ carries F^k isometrically onto W, and it carries the Rayleigh quotient of $\mathbf{B}$ to the Rayleigh quotient of $\mathbf{A}$. So each of the two Courant–Fischer descriptions of $\lambda_i(\mathbf{B})$ — a maximum of minima, and a minimum of maxima — is the corresponding description of $\lambda_i(\mathbf{A})$ with the competing subspaces restricted to those lying inside W. A maximum over fewer competitors is smaller; a minimum over fewer competitors is larger. That is the whole proof; the only care needed is in matching the dimensions, and it is there that $n - k$ appears.

Proof. **Step 1: transport.** Throughout, $R_{\mathbf{A}}$ and $R_{\mathbf{B}}$ are the Rayleigh quotients of Definition 16.1.1. For $\mathbf{0} \neq \mathbf{y} \in F^k$ we have $\mathbf{Q}\mathbf{y} \neq \mathbf{0}$, since $\|\mathbf{Q}\mathbf{y}\|^2 = \mathbf{y}^*\mathbf{Q}^*\mathbf{Q}\mathbf{y} = \|\mathbf{y}\|^2$ and $\mathbf{y} \neq \mathbf{0}$. The same computation with $\mathbf{A}$ inserted gives

$$\langle \mathbf{B}\mathbf{y}, \mathbf{y} \rangle = \mathbf{y}^*\mathbf{Q}^*\mathbf{A}\mathbf{Q}\mathbf{y} = \langle \mathbf{A}(\mathbf{Q}\mathbf{y}), \mathbf{Q}\mathbf{y} \rangle,$$

so $R_{\mathbf{B}}(\mathbf{y}) = R_{\mathbf{A}}(\mathbf{Q}\mathbf{y})$. Moreover $\mathbf{y} \mapsto \mathbf{Q}\mathbf{y}$ is injective and linear, so it maps the subspaces of F^k of dimension j bijectively onto the subspaces of W of dimension j, for every j. Consequently, for each j,

$$\{\, R_{\mathbf{B}}(\mathbf{y}) : \mathbf{0} \neq \mathbf{y} \in S \,\} = \{\, R_{\mathbf{A}}(\mathbf{x}) : \mathbf{0} \neq \mathbf{x} \in \mathbf{Q}S \,\}$$

for every subspace $S \subseteq F^k$.

Step 2: the upper bound. By the max–min form of Theorem 16.2.3 applied to

$\mathbf{B} \in M_k(F)$,

$$\lambda_i(\mathbf{B}) = \max_{\substack{S \subseteq F^k \\ \dim S = i}} \min_{\mathbf{0} \neq \mathbf{y} \in S} R_{\mathbf{B}}(\mathbf{y}) = \max_{\substack{U \subseteq W \\ \dim U = i}} \min_{\mathbf{0} \neq \mathbf{x} \in U} R_{\mathbf{A}}(\mathbf{x}),$$

the second equality by Step 1. The subspaces $U \subseteq W$ of dimension i form a subfamily of the subspaces $U \subseteq F^n$ of dimension i, and enlarging the family over which a maximum is taken cannot decrease it. So by the max–min form of Theorem 16.2.3 applied to $\mathbf{A}$, the right-hand side is at most $\lambda_i(\mathbf{A})$.

Step 3: the lower bound. By the min–max form of Theorem 16.2.3 applied to $\mathbf{B} \in M_k(F)$, with the complementary dimension $k - i + 1$,

$$\lambda_i(\mathbf{B}) = \min_{\substack{S \subseteq F^k \\ \dim S = k-i+1}} \max_{\mathbf{0} \neq \mathbf{y} \in S} R_{\mathbf{B}}(\mathbf{y}) = \min_{\substack{U \subseteq W \\ \dim U = k-i+1}} \max_{\mathbf{0} \neq \mathbf{x} \in U} R_{\mathbf{A}}(\mathbf{x}),$$

again by Step 1. Put $l = i + n - k$, so that $1 \le l \le n$ and $n - l + 1 = k - i + 1$. The min–max form of Theorem 16.2.3 applied to $\mathbf{A}$ therefore reads

$$\lambda_l(\mathbf{A}) = \min_{\substack{U \subseteq F^n \\ \dim U = k-i+1}} \max_{\mathbf{0} \neq \mathbf{x} \in U} R_{\mathbf{A}}(\mathbf{x}),$$

a minimum over a **larger** family than the one above, hence no larger. So $\lambda_i(\mathbf{B}) \ge \lambda_{i+n-k}(\mathbf{A})$. This proves the theorem.

■

Remark. Taking W to be the coordinate hyperplane $\operatorname{span}(\mathbf{e}_j : j \neq l)$ makes $\mathbf{B}$ the principal submatrix obtained by deleting row l and column l, and $k = n - 1$ turns the conclusion into $\lambda_i(\mathbf{A}) \ge \lambda_i(\mathbf{B}) \ge \lambda_{i+1}(\mathbf{A})$. That is Theorem 16.4.2. What the present theorem adds is that the coordinates played no part, and that deleting $n - k$ dimensions at once costs exactly $n - k$ indices.

Example. (A compression of a diagonal matrix)

Let $\mathbf{A} = \operatorname{diag}(5, 3, -2)$ and let

$$\mathbf{q}_1 = \tfrac{1}{3}(2, 2, 1), \qquad \mathbf{q}_2 = \tfrac{1}{3}(-2, 1, 2).$$

Check that $(\mathbf{q}_1, \mathbf{q}_2)$ is orthonormal, compute the compression $\mathbf{B}$ of $\mathbf{A}$ to $W = \operatorname{span}(\mathbf{q}_1, \mathbf{q}_2)$ and its eigenvalues, and verify Theorem 16.6.1.

Solution. Orthonormality. $\|\mathbf{q}_1\|^2 = (4 + 4 + 1)/9 = 1$ and $\|\mathbf{q}_2\|^2 = (4 + 1 + 4)/9 = 1$, while $9\langle \mathbf{q}_1, \mathbf{q}_2 \rangle = -4 + 2 + 2 = 0$.

The compression. Multiplying by the diagonal matrix, $3\mathbf{A}\mathbf{q}_1 = (10, 6, -2)$ and $3\mathbf{A}\mathbf{q}_2 =$

$(-10, 3, -4)$. Hence

$$b_{11} = \tfrac{1}{9}(2,2,1)\cdot(10,6,-2) = \tfrac{20+12-2}{9} = \tfrac{10}{3},$$
$$b_{21} = \tfrac{1}{9}(-2,1,2)\cdot(10,6,-2) = \tfrac{-20+6-4}{9} = -2,$$
$$b_{22} = \tfrac{1}{9}(-2,1,2)\cdot(-10,3,-4) = \tfrac{20+3-8}{9} = \tfrac{5}{3},$$

and $b_{12} = b_{21}$ because $\mathbf{B}$ is symmetric. So

$$\mathbf{B} = \begin{pmatrix} 10/3 & -2 \\ -2 & 5/3 \end{pmatrix}.$$

Its eigenvalues. $\operatorname{tr}\mathbf{B} = 5$ and $\det\mathbf{B} = \tfrac{50}{9} - 4 = \tfrac{14}{9}$, so the characteristic polynomial is $x^2 - 5x + \tfrac{14}{9}$, that is $9x^2 - 45x + 14$. Its discriminant is $2025 - 504 = 1521 = 39^2$, so the roots are $(45 \pm 39)/18$, namely $\lambda_1(\mathbf{B}) = \tfrac{14}{3}$ and $\lambda_2(\mathbf{B}) = \tfrac{1}{3}$.

The separation. Here $n = 3$ and $k = 2$, so the theorem says $\lambda_i(\mathbf{A}) \geq \lambda_i(\mathbf{B}) \geq \lambda_{i+1}(\mathbf{A})$ for $i = 1, 2$:

$$5 \;\geq\; \tfrac{14}{3} \;\geq\; 3 \;\geq\; \tfrac{1}{3} \;\geq\; -2,$$

and every inequality is strict. Note also $\operatorname{tr}\mathbf{B} = 5 \leq 5 + 3 = \lambda_1(\mathbf{A}) + \lambda_2(\mathbf{A})$; the next theorem says that this is no accident and that 8 is the best possible ceiling.

Quick check. Let $\mathbf{A}$ be Hermitian $n \times n$ and let $\mathbf{B}$ be its compression to a k-dimensional subspace. Which single inequality of Theorem 16.6.1 says that a compression of a positive semidefinite matrix is positive semidefinite?

Solution. The case $i = k$ of the lower bound: $\lambda_k(\mathbf{B}) \geq \lambda_{k+n-k}(\mathbf{A}) = \lambda_n(\mathbf{A})$. If $\mathbf{A} \succeq 0$ then $\lambda_n(\mathbf{A}) \geq 0$ by Theorem 12.1.4 (b), so every eigenvalue of $\mathbf{B}$ is ≥ 0, and $\mathbf{B}$ is Hermitian, so $\mathbf{B} \succeq 0$ by the same theorem. (A direct proof is also one line: $\langle \mathbf{B}\mathbf{y}, \mathbf{y}\rangle = \langle \mathbf{A}\mathbf{Q}\mathbf{y}, \mathbf{Q}\mathbf{y}\rangle \geq 0$. The point of the check is to locate the statement inside the interlacing.)

16.6.3 The top eigenvalues, summed

Chapter 12 described λ_1 as a maximum over the unit sphere (Lemma 12.5.2), and Section 1 pointed out that λ_2 is not the "second largest value" of anything. But $\lambda_1 + \lambda_2$ is a maximum again — over pairs of orthonormal vectors rather than single ones. The pattern continues for every k, and it is the sum, never the individual eigenvalue, that behaves.

Theorem 16.6.2 — Ky Fan Maximum Principle

Let $\mathbf{A} \in M_n(F)$ be Hermitian and let $1 \leq k \leq n$. Then

$$\sum_{i=1}^{k} \lambda_i(\mathbf{A}) = \max\Big\{ \sum_{i=1}^{k} \langle \mathbf{A}\mathbf{q}_i, \mathbf{q}_i\rangle \;:\; \mathbf{q}_1, \dots, \mathbf{q}_k \text{ orthonormal} \Big\}$$
$$= \max\big\{ \operatorname{tr}(\mathbf{Q}^*\mathbf{A}\mathbf{Q}) \;:\; \mathbf{Q} \in M_{n\times k}(F),\; \mathbf{Q}^*\mathbf{Q} = \mathbf{I}_k \big\},$$

and the maximum is attained by $\mathbf{Q} = (\mathbf{u}_1 \;\dots\; \mathbf{u}_k)$ for any orthonormal basis $(\mathbf{u}_1, \dots, \mathbf{u}_n)$

of F^n with $\mathbf{A}\mathbf{u}_i = \lambda_i(\mathbf{A})\mathbf{u}_i$.

Idea. The two right-hand sides are the same number written twice, since the diagonal entries of $\mathbf{Q}^*\mathbf{A}\mathbf{Q}$ are exactly the k numbers $\langle \mathbf{A}\mathbf{q}_i, \mathbf{q}_i\rangle$. That reformulation is the whole idea: the quantity to be maximized is the **trace of a compression**, and Theorem 16.6.1 already bounds every eigenvalue of a compression by the matching eigenvalue of $\mathbf{A}$. Add k such bounds and read the left-hand side as a trace. The maximizing $\mathbf{Q}$ is the one that makes the compression diagonal with the top eigenvalues on it, and there is no cleverness in guessing it.

Proof. Write $\mathbf{B} = \mathbf{Q}^*\mathbf{A}\mathbf{Q}$ for a matrix $\mathbf{Q}$ with orthonormal columns $\mathbf{q}_1, \dots, \mathbf{q}_k$. Its diagonal entries are $b_{ii} = \langle \mathbf{A}\mathbf{q}_i, \mathbf{q}_i\rangle$ by Definition 16.6.1, so

$$\operatorname{tr}\mathbf{B} = \sum_{i=1}^{k} \langle \mathbf{A}\mathbf{q}_i, \mathbf{q}_i\rangle,$$

and the two sets over which the maxima are taken consist of the same numbers. It therefore suffices to prove the statement for $\operatorname{tr}(\mathbf{Q}^*\mathbf{A}\mathbf{Q})$.

The bound. Let $\mathbf{Q}^*\mathbf{Q} = \mathbf{I}_k$ and put $\mathbf{B} = \mathbf{Q}^*\mathbf{A}\mathbf{Q}$, a Hermitian matrix in $M_k(F)$. By Corollary 11.1.4, $\operatorname{tr}\mathbf{B} = \sum_{i=1}^{k} \lambda_i(\mathbf{B})$. By Theorem 16.6.1, $\lambda_i(\mathbf{B}) \le \lambda_i(\mathbf{A})$ for every $1 \le i \le k$. Summing these k inequalities,

$$\operatorname{tr}(\mathbf{Q}^*\mathbf{A}\mathbf{Q}) = \sum_{i=1}^{k} \lambda_i(\mathbf{B}) \;\le\; \sum_{i=1}^{k} \lambda_i(\mathbf{A}).$$

Attainment. Since $\mathbf{A}$ is Hermitian, Corollary 11.4.3 (for $F = \mathbb{C}$) or Corollary 11.5.2 (for $F = \mathbb{R}$) provides an orthonormal basis $(\mathbf{u}_1, \dots, \mathbf{u}_n)$ of F^n of eigenvectors, in any prescribed order; take the order with $\mathbf{A}\mathbf{u}_i = \lambda_i(\mathbf{A})\mathbf{u}_i$. Let $\mathbf{Q}$ have columns $\mathbf{u}_1, \dots, \mathbf{u}_k$; these are orthonormal, so $\mathbf{Q}^*\mathbf{Q} = \mathbf{I}_k$. Then

$$\langle \mathbf{A}\mathbf{u}_i, \mathbf{u}_i\rangle = \lambda_i(\mathbf{A})\langle \mathbf{u}_i, \mathbf{u}_i\rangle = \lambda_i(\mathbf{A}),$$

so $\operatorname{tr}(\mathbf{Q}^*\mathbf{A}\mathbf{Q}) = \sum_{i \le k} \lambda_i(\mathbf{A})$.

The bound is therefore attained, so the supremum is a maximum and equals $\sum_{i \le k} \lambda_i(\mathbf{A})$. This proves the theorem.

■

For $k = 1$ this is Lemma 12.5.2 of Chapter 12: λ_1 is the largest value of $\langle \mathbf{A}\mathbf{x}, \mathbf{x}\rangle$ on the unit sphere. For $k = n$ it degenerates in an instructive way: every $\mathbf{Q}$ is unitary, every $\mathbf{Q}^*\mathbf{A}\mathbf{Q}$ is unitarily similar to $\mathbf{A}$, and the "maximum" is attained everywhere, at the common value $\operatorname{tr}\mathbf{A}$. The content is in between.

Example. (Which pairs of directions capture the most)

Let

$$\mathbf{A} = \begin{pmatrix} 2 & 1 & 0 \\ 1 & 2 & 0 \\ 0 & 0 & -1 \end{pmatrix}.$$

Find $\max\{\operatorname{tr}(\mathbf{Q}^\top \mathbf{A}\mathbf{Q}) : \mathbf{Q}^\top\mathbf{Q} = \mathbf{I}_2\}$ and a maximizer, and compare the values at $\mathbf{Q} = (\mathbf{e}_1\ \mathbf{e}_2)$ and $\mathbf{Q} = (\mathbf{e}_1\ \mathbf{e}_3)$.

Solution. The eigenvalues: $\mathbf{e}_3$ is an eigenvector for -1, and the top-left block $\left(\begin{smallmatrix} 2 & 1 \\ 1 & 2 \end{smallmatrix}\right)$ has eigenvectors $(1,1)$ and $(1,-1)$ for 3 and 1. So $\lambda_1 = 3$, $\lambda_2 = 1$, $\lambda_3 = -1$, with orthonormal eigenvectors $\mathbf{u}_1 = \frac{1}{\sqrt{2}}(1,1,0)$, $\mathbf{u}_2 = \frac{1}{\sqrt{2}}(1,-1,0)$, $\mathbf{u}_3 = \mathbf{e}_3$. By Theorem 16.6.2 the maximum is $3+1=4$, attained at $\mathbf{Q} = (\mathbf{u}_1\ \mathbf{u}_2)$.

At $\mathbf{Q} = (\mathbf{e}_1\ \mathbf{e}_2)$ the trace is $a_{11}+a_{22} = 4$: this is also a maximizer. That is no accident — $\operatorname{span}(\mathbf{e}_1, \mathbf{e}_2) = \operatorname{span}(\mathbf{u}_1, \mathbf{u}_2)$, and the trace of a compression, like its eigenvalues, depends only on the subspace. At $\mathbf{Q} = (\mathbf{e}_1\ \mathbf{e}_3)$ the trace is $2 + (-1) = 1$, well below the ceiling, as Theorem 16.6.2 requires.

The simplest competitors are the standard basis vectors, and they give a statement about the diagonal of $\mathbf{A}$ for free.

Corollary 16.6.3 — Partial Sums of the Diagonal

Let $\mathbf{A} \in M_n(F)$ be Hermitian with diagonal entries $a_{11}, \dots, a_{nn}$, and let $1 \le i_1 < \cdots < i_k \le n$. Then

$$\sum_{j=1}^{k} a_{i_j i_j} \ \le\ \sum_{i=1}^{k} \lambda_i(\mathbf{A}),$$

with equality for $k = n$.

Proof. The list $(\mathbf{e}_{i_1}, \dots, \mathbf{e}_{i_k})$ is orthonormal, and $\langle \mathbf{A}\mathbf{e}_i, \mathbf{e}_i\rangle = a_{ii}$. Apply Theorem 16.6.2. For $k = n$ both sides equal $\operatorname{tr}\mathbf{A}$, by Corollary 11.1.4.

■

Quick check. Can a Hermitian 3×3 matrix with diagonal entries $5, 1, 0$ have eigenvalues $4, 2, 0$? Can it have eigenvalues $6, 0, 0$?

Solution. Not the first: the case $k = 1$ of Corollary 16.6.3 says every diagonal entry is at most λ_1, and $5 > 4$. The second passes every test — $5 \le 6$, $5+1 \le 6$, $6 = 6$ — and is realized: with $\mathbf{v} = (\sqrt{5}, 1, 0)$, the matrix $\mathbf{v}\mathbf{v}^\top$ has diagonal $5, 1, 0$; it sends $\mathbf{v}$ to $\|\mathbf{v}\|^2\mathbf{v} = 6\mathbf{v}$ and kills the plane orthogonal to $\mathbf{v}$, so its eigenvalues are $6, 0, 0$. Whether passing every test is always enough is the converse question, which Section 8 takes up.

16.6.4 The promise from Chapter 12

Chapter 12 §10 proved a bound on how much of a matrix an orthonormal list can capture (Lemma 12.10.2), and said of it: it "is the extreme case of a family of statements about sums of the largest eigenvalues of a Hermitian matrix; Chapter 16 develops the family through the Courant–Fischer min–max theorem". Theorem 16.6.2 is that family. Here is the lemma, recovered from it in four lines.

Corollary 16.6.4 — The Capture Bound as a Case of Ky Fan

Let $\mathbf{A} \in M_{m\times n}(F)$ with singular values $\sigma_1 \geq \cdots \geq \sigma_p$, $p = \min(m,n)$, extended by $\sigma_i = 0$ for $p < i \leq m$, and let $\mathbf{q}_1, \dots, \mathbf{q}_s$ be an orthonormal list in F^m. Then

$$\sum_{j=1}^{s} \|\mathbf{A}^*\mathbf{q}_j\|^2 \;\leq\; \sum_{i=1}^{s} \sigma_i^2.$$

Proof. If $s = 0$ both sides are empty sums, equal to 0; so assume $s \geq 1$. Put $\mathbf{M} = \mathbf{A}\mathbf{A}^* \in M_m(F)$, which is Hermitian. For each j,

$$\|\mathbf{A}^*\mathbf{q}_j\|^2 = (\mathbf{A}^*\mathbf{q}_j)^*(\mathbf{A}^*\mathbf{q}_j) = \mathbf{q}_j^*\mathbf{M}\mathbf{q}_j = \langle \mathbf{M}\mathbf{q}_j, \mathbf{q}_j\rangle.$$

Fix a singular value decomposition $\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^*$ (Theorem 12.8.1). Since $\mathbf{V}^*\mathbf{V} = \mathbf{I}_n$,

$$\mathbf{M} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^*\mathbf{V}\mathbf{\Sigma}^*\mathbf{U}^* = \mathbf{U}(\mathbf{\Sigma}\mathbf{\Sigma}^*)\mathbf{U}^*,$$

and $\mathbf{\Sigma}\mathbf{\Sigma}^*$ is the $m \times m$ diagonal matrix with diagonal $\sigma_1^2, \dots, \sigma_p^2$ followed by $m - p$ zeros — that is, $\sigma_1^2 \geq \cdots \geq \sigma_m^2$ in the extended notation. So this display is a unitary diagonalization of $\mathbf{M}$, and Corollary 11.4.3 identifies its diagonal as the eigenvalue list: $\lambda_i(\mathbf{M}) = \sigma_i^2$ for $1 \leq i \leq m$. Now Theorem 16.6.2 applied to $\mathbf{M}$ with $k = s$ gives

$$\sum_{j=1}^{s} \langle \mathbf{M}\mathbf{q}_j, \mathbf{q}_j\rangle \;\leq\; \sum_{i=1}^{s} \lambda_i(\mathbf{M}) = \sum_{i=1}^{s} \sigma_i^2,$$

which is the claim. ∎

This is Lemma 12.10.2 exactly, hypotheses and conclusion, so the debt is paid. Two things are worth saying about the shape of the payment.

First, Chapter 12 had to prove the inequality by hand, weight by weight, because it had no min–max theorem; the argument there is a careful estimate on a weighted sum of a decreasing sequence. Here the same estimate is invisible: it has been absorbed into Theorem 16.2.3, whose proof is a dimension count, and passed on through Theorem 16.6.1.

Second, the words "extreme case". Strictly, the lemma is a *special* case of the family rather than an extreme one: it is the instance in which the Hermitian matrix is a product $\mathbf{A}\mathbf{A}^*$, so that every eigenvalue is a squared singular value. Its crudest instance, $s = 1$, says $\|\mathbf{A}^*\mathbf{q}\|^2 \leq \sigma_1^2$ for a unit $\mathbf{q}$, that is, $\|\mathbf{A}^*\|_2 = \sigma_1$. The same one line of Ky Fan, run with the other product — Theorem 16.6.2 with $k = 1$ applied to the Hermitian matrix $\mathbf{A}^*\mathbf{A} \in M_n(F)$ — whose largest eigenvalue is σ_1^2 by Definition 12.8.1 — gives

$$\max_{\|\mathbf{x}\|=1} \|\mathbf{A}\mathbf{x}\|^2 = \max_{\|\mathbf{x}\|=1} \langle \mathbf{A}^*\mathbf{A}\mathbf{x}, \mathbf{x}\rangle = \lambda_1(\mathbf{A}^*\mathbf{A}) = \sigma_1^2.$$

So the largest singular value is the largest stretching factor, which is Theorem 15.3.3 (c), $\|\mathbf{A}\|_2 = \sigma_1(\mathbf{A})$. Chapter 15 proved that from the singular value decomposition; here it is one line of Ky Fan.

16.6.5 Sums are convex; individual eigenvalues are not

Corollary 16.6.5 — Subadditivity of the Top Partial Sums

Let $\mathbf{A}, \mathbf{B} \in M_n(F)$ be Hermitian and let $1 \le k \le n$. Then

$$\sum_{i=1}^{k} \lambda_i(\mathbf{A}+\mathbf{B}) \;\le\; \sum_{i=1}^{k} \lambda_i(\mathbf{A}) + \sum_{i=1}^{k} \lambda_i(\mathbf{B}).$$

Proof. By Theorem 16.6.2 applied to the Hermitian matrix $\mathbf{A}+\mathbf{B}$, there is a $\mathbf{Q} \in M_{n\times k}(F)$ with $\mathbf{Q}^*\mathbf{Q} = \mathbf{I}_k$ attaining the maximum, so that

$$\sum_{i=1}^{k} \lambda_i(\mathbf{A}+\mathbf{B}) = \operatorname{tr}\big(\mathbf{Q}^*(\mathbf{A}+\mathbf{B})\mathbf{Q}\big).$$

By Theorem 0.9.6 (1) the right-hand side is $\operatorname{tr}(\mathbf{Q}^*\mathbf{A}\mathbf{Q}) + \operatorname{tr}(\mathbf{Q}^*\mathbf{B}\mathbf{Q})$. This one $\mathbf{Q}$ is a competitor in each of the two maximization problems of Theorem 16.6.2, for $\mathbf{A}$ and for $\mathbf{B}$, so each summand is at most the corresponding maximum. Adding the two bounds proves the corollary. ∎

Write $s_k(\mathbf{A}) = \sum_{i\le k} \lambda_i(\mathbf{A})$ for the function just bounded. Two properties have now been proved: it is **subadditive**, $s_k(\mathbf{A}+\mathbf{B}) \le s_k(\mathbf{A}) + s_k(\mathbf{B})$, and it is **positively homogeneous**, $s_k(t\mathbf{A}) = t s_k(\mathbf{A})$ for $t \ge 0$, since multiplying a Hermitian matrix by $t \ge 0$ multiplies each eigenvalue by t without disturbing the order. Together these say that for $t \in [0,1]$,

$$s_k\big(t\mathbf{A} + (1-t)\mathbf{B}\big) \;\le\; t s_k(\mathbf{A}) + (1-t) s_k(\mathbf{B}) :$$

s_k is a **convex** function on the real vector space of Hermitian matrices. That is exactly what one expects of a maximum of linear functions, which is what Theorem 16.6.2 says s_k is: each fixed $\mathbf{Q}$ makes $\mathbf{A} \mapsto \operatorname{tr}(\mathbf{Q}^*\mathbf{A}\mathbf{Q})$ linear, and s_k is the pointwise maximum of this family. Chapter 17 studies convex functions in general, and the observation that a pointwise supremum of linear functions is convex is one of its basic facts.

Corollary 16.6.6 — The Bottom Partial Sums as a Minimum

Let $\mathbf{A} \in M_n(F)$ be Hermitian and let $1 \le k \le n$. Then

$$\sum_{i=n-k+1}^{n} \lambda_i(\mathbf{A}) = \min\big\{\operatorname{tr}(\mathbf{Q}^*\mathbf{A}\mathbf{Q}) : \mathbf{Q}^*\mathbf{Q} = \mathbf{I}_k\big\},$$

the minimum being attained at the bottom k eigenvectors.

Proof. The eigenvalues of $-\mathbf{A}$, with multiplicity, are the negatives of those of $\mathbf{A}$, and negation reverses order, so

$$\lambda_i(-\mathbf{A}) = -\lambda_{n+1-i}(\mathbf{A}) \qquad (1 \le i \le n).$$

Apply Theorem 16.6.2 to $-\mathbf{A}$. Its left-hand side is

$$\sum_{i=1}^{k} \lambda_i(-\mathbf{A}) = -\sum_{i=1}^{k} \lambda_{n+1-i}(\mathbf{A}) = -\sum_{i=n-k+1}^{n} \lambda_i(\mathbf{A}),$$

the last step re-indexing the sum. Its right-hand side is

$$\max_{\mathbf{Q}^*\mathbf{Q}=\mathbf{I}_k} \operatorname{tr}\big(\mathbf{Q}^*(-\mathbf{A})\mathbf{Q}\big) = -\min_{\mathbf{Q}^*\mathbf{Q}=\mathbf{I}_k} \operatorname{tr}(\mathbf{Q}^*\mathbf{A}\mathbf{Q}),$$

using Theorem 0.9.6 (1) and the fact that maximizing $-g$ is minimizing g. Negating both sides gives the claim, and the maximizer for $-\mathbf{A}$ is a list of top eigenvectors of $-\mathbf{A}$, which are bottom eigenvectors of $\mathbf{A}$.

■

Warning. **Only the sums are convex. A single eigenvalue λ_k with $1 < k < n$ is neither convex nor concave in $\mathbf{A}$.** Both failures happen among 3×3 diagonal matrices, where λ_2 is just the middle entry; for general n and $1 < k < n$, take the direct sum of each witness with $2\mathbf{I}_{k-2}$ above and $-\mathbf{I}_{n-k-1}$ below, which moves the middle entry to position k without changing the computation.

Not convex. Take $\mathbf{A} = \operatorname{diag}(1, 0, 0)$ and $\mathbf{B} = \operatorname{diag}(0, 1, 0)$, so $\lambda_2(\mathbf{A}) = \lambda_2(\mathbf{B}) = 0$. Their midpoint is $\frac{1}{2}(\mathbf{A} + \mathbf{B}) = \operatorname{diag}(\frac{1}{2}, \frac{1}{2}, 0)$, with $\lambda_2 = \frac{1}{2}$. Convexity would require $\frac{1}{2} \le 0$.

Not concave. Take $\mathbf{A} = \operatorname{diag}(1, 1, 0)$ and $\mathbf{B} = \operatorname{diag}(1, 0, 1)$, so $\lambda_2(\mathbf{A}) = \lambda_2(\mathbf{B}) = 1$. Their midpoint is $\operatorname{diag}(1, \frac{1}{2}, \frac{1}{2})$, with $\lambda_2 = \frac{1}{2}$. Concavity would require $\frac{1}{2} \ge 1$.

The partial sum s_2 satisfies the **convexity** inequality on both pairs, as it must: in the first pair its values at the two matrices and their midpoint are $1, 1, 1$, and in the second $2, 2, \frac{3}{2}$. The moral is that $\lambda_k = s_k - s_{k-1}$ is a **difference** of two convex functions, and a difference of convex functions has, in general, no convexity property at all. This is why the sharpest statements in this chapter are about sums, and why a statement about a single intermediate eigenvalue usually has to be proved as a statement about two sums.

16.6.6 Exercises

16.6.6.1 A. Check your understanding

Exercise A1.

(a) Define the compression of $\mathbf{A}$ to a subspace, and say what has to be checked before the phrase "the eigenvalues of the compression" makes sense.

(b) State Theorem 16.6.2, including where the maximum is attained.

(c) Explain why the maximum in Theorem 16.6.2 does not need an appeal to compactness.

(d) Is $\mathbf{A} \mapsto \lambda_1(\mathbf{A})$ convex on the Hermitian matrices? Is $\mathbf{A} \mapsto \lambda_n(\mathbf{A})$? Justify each answer.

(e) State Theorem 16.6.1 and say which case of it is Theorem 16.4.2.

Solution.

(a) For an orthonormal list $\mathbf{q}_1, \dots, \mathbf{q}_k$ with matrix $\mathbf{Q}$, the compression of $\mathbf{A}$ to $W = \operatorname{span}(\mathbf{q}_1, \dots, \mathbf{q}_k)$ is $\mathbf{Q}^*\mathbf{A}\mathbf{Q}$, the $k \times k$ matrix with entries $\langle \mathbf{A}\mathbf{q}_j, \mathbf{q}_i \rangle$. What must be checked is that changing the orthonormal basis of W changes $\mathbf{Q}^*\mathbf{A}\mathbf{Q}$ only by a unitary similarity, so the eigenvalues depend on W alone.

(b) For Hermitian $\mathbf{A} \in M_n(F)$ and $1 \le k \le n$, $\sum_{i \le k} \lambda_i(\mathbf{A})$ is the maximum of $\operatorname{tr}(\mathbf{Q}^*\mathbf{A}\mathbf{Q})$ over all $\mathbf{Q} \in M_{n \times k}(F)$ with $\mathbf{Q}^*\mathbf{Q} = \mathbf{I}_k$, equivalently the maximum of $\sum_{i \le k} \langle \mathbf{A}\mathbf{q}_i, \mathbf{q}_i \rangle$ over orthonormal lists. It is attained at $\mathbf{Q} = (\mathbf{u}_1 \ \dots \ \mathbf{u}_k)$ for an orthonormal eigenbasis ordered with $\mathbf{A}\mathbf{u}_i = \lambda_i(\mathbf{A})\mathbf{u}_i$.

(c) Because the proof exhibits both a bound valid for every competitor and a competitor achieving it. A supremum that is achieved is a maximum, whatever the topology of the competing set.

(d) Incorrect. Take $\mathbf{A} = \operatorname{diag}(1,0,0)$ and $\mathbf{B} = \operatorname{diag}(0,1,0)$ as in the warning: $\lambda_2(\mathbf{A}) = \lambda_2(\mathbf{B}) = 0$ while $\mathbf{A} + \mathbf{B} = \operatorname{diag}(1,1,0)$ has $\lambda_2 = 1$. What is true is the statement about sums, Corollary 16.6.5: here $\lambda_1 + \lambda_2$ of the sum is 2, and $(1+0)+(1+0) = 2$.

(e) If $\mathbf{B}$ is the compression of the Hermitian $\mathbf{A} \in M_n(F)$ to a k-dimensional subspace, then $\lambda_i(\mathbf{A}) \ge \lambda_i(\mathbf{B}) \ge \lambda_{i+n-k}(\mathbf{A})$ for $1 \le i \le k$. Cauchy interlacing is the case $k = n - 1$ with the subspace a coordinate hyperplane.

16.6.6.2 B. Practice

Exercise B1: A compression, and two bounds.

Let $\mathbf{A} = \operatorname{diag}(5, 0, -2)$ and let $\mathbf{q}_1 = \frac{1}{3}(1,2,2)$, $\mathbf{q}_2 = \frac{1}{3}(2,1,-2)$.

(a) Verify that $(\mathbf{q}_1, \mathbf{q}_2)$ is orthonormal and compute the compression $\mathbf{B}$ of $\mathbf{A}$ to $\operatorname{span}(\mathbf{q}_1, \mathbf{q}_2)$.

(b) Find the eigenvalues of $\mathbf{B}$ and verify Theorem 16.6.1.

(c) Compare $\operatorname{tr}\mathbf{B}$ with the bound of Theorem 16.6.2, and say how far this subspace is from optimal.

Solution.

(a) $\|\mathbf{q}_1\|^2 = (1+4+4)/9 = 1$, $\|\mathbf{q}_2\|^2 = (4+1+4)/9 = 1$ and $9\langle \mathbf{q}_1, \mathbf{q}_2 \rangle = 2+2-4 = 0$. Next $3\mathbf{A}\mathbf{q}_1 = (5,0,-4)$ and $3\mathbf{A}\mathbf{q}_2 = (10,0,4)$, so

$$b_{11} = \tfrac{1}{9}(1,2,2)\cdot(5,0,-4) = \tfrac{5-8}{9} = -\tfrac{1}{3},$$
$$b_{12} = \tfrac{1}{9}(1,2,2)\cdot(10,0,4) = \tfrac{10+8}{9} = 2,$$
$$b_{22} = \tfrac{1}{9}(2,1,-2)\cdot(10,0,4) = \tfrac{20-8}{9} = \tfrac{4}{3},$$

so $\mathbf{B} = \begin{pmatrix} -1/3 & 2 \\ 2 & 4/3 \end{pmatrix}$.

(b) $\operatorname{tr}\mathbf{B} = 1$ and $\det\mathbf{B} = -\frac{4}{9} - 4 = -\frac{40}{9}$, so $9x^2 - 9x - 40 = 0$, with discriminant $81 + 1440 = 1521 = 39^2$ and roots $(9 \pm 39)/18$. Hence $\lambda_1(\mathbf{B}) = \frac{8}{3}$ and $\lambda_2(\mathbf{B}) = -\frac{5}{3}$. The separation $\lambda_i(\mathbf{A}) \ge \lambda_i(\mathbf{B}) \ge \lambda_{i+1}(\mathbf{A})$ reads

$$5 \ \ge \ \tfrac{8}{3} \ \ge \ 0 \ \ge \ -\tfrac{5}{3} \ \ge \ -2,$$

all strict.

(c) $\operatorname{tr}\mathbf{B} = 1$, while Theorem 16.6.2 gives $\lambda_1(\mathbf{A}) + \lambda_2(\mathbf{A}) = 5 + 0 = 5$ as the maximum, attained at $\operatorname{span}(\mathbf{e}_1, \mathbf{e}_2)$. So this subspace scores 1 out of a possible 5; it is far from optimal, and one can see why. Between them $\mathbf{q}_1$ and $\mathbf{q}_2$ put weight $\frac{4}{9} + \frac{4}{9} = \frac{8}{9}$ on the third coordinate, where $\mathbf{A}$ is -2, and only $\frac{1}{9} + \frac{4}{9} = \frac{5}{9}$ on the first, where it is 5: indeed $5 \cdot \frac{5}{9} + 0 - 2 \cdot \frac{8}{9} = 1$.

Exercise B2: Reading the sums off the spectrum.

A Hermitian $\mathbf{A} \in M_4(\mathbb{R})$ has eigenvalues $6, 4, 1, -3$.

(a) Compute $\max\{\operatorname{tr}(\mathbf{Q}^\top \mathbf{A}\mathbf{Q}) : \mathbf{Q}^\top \mathbf{Q} = \mathbf{I}_k\}$ for $k = 1, 2, 3, 4$.

(b) Compute the corresponding minima, using Corollary 16.6.6.

(c) For $\mathbf{A} = \operatorname{diag}(6, 4, 1, -3)$ and $\mathbf{q}_1 = \frac{1}{\sqrt{2}}(1, 1, 0, 0)$, $\mathbf{q}_2 = \frac{1}{\sqrt{2}}(0, 0, 1, 1)$, compute $\operatorname{tr}(\mathbf{Q}^\top \mathbf{A}\mathbf{Q})$ and check it against (a) and (b).

Solution.

(a) By Theorem 16.6.2 the maxima are the partial sums from the top: 6, 10, 11, 8.

(b) By Corollary 16.6.6 the minima are the partial sums from the bottom: -3, -2, 2, 8. The two agree at $k = 4$, as they must, both being $\operatorname{tr}\mathbf{A}$.

(c) $\langle \mathbf{A}\mathbf{q}_1, \mathbf{q}_1 \rangle = \frac{1}{2}(6 + 4) = 5$ and $\langle \mathbf{A}\mathbf{q}_2, \mathbf{q}_2 \rangle = \frac{1}{2}(1 - 3) = -1$, so $\operatorname{tr}(\mathbf{Q}^\top \mathbf{A}\mathbf{Q}) = 4$. Indeed $-2 \le 4 \le 10$, as (a) and (b) require for $k = 2$.

Exercise B3: Subadditivity, and how loose it can be.

Let

$$\mathbf{A} = \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix}, \qquad \mathbf{B} = \begin{pmatrix} 1 & -1 \\ -1 & 1 \end{pmatrix}.$$

(a) Compute the eigenvalues of $\mathbf{A}$, of $\mathbf{B}$ and of $\mathbf{A} + \mathbf{B}$.

(b) Verify Corollary 16.6.5 for $k = 1$ and $k = 2$, and say for which k it is strict.

(c) Give a pair of Hermitian 2×2 matrices for which the $k = 1$ inequality is an equality.

Solution.

(a) $\mathbf{A}$ has trace 2 and determinant 0, so its eigenvalues are $2, 0$; the same for $\mathbf{B}$. And $\mathbf{A} + \mathbf{B} = 2\mathbf{I}_2$ has eigenvalues $2, 2$.

(b) For $k = 1$: $\lambda_1(\mathbf{A} + \mathbf{B}) = 2$ and $\lambda_1(\mathbf{A}) + \lambda_1(\mathbf{B}) = 4$, so $2 \le 4$, strictly. For $k = 2$: $4 \le 2 + 2 = 4$, an equality — as it must be, since for $k = n$ both sides are traces and Theorem 0.9.6 (1) makes the trace additive.

(c) Take $\mathbf{A} = \mathbf{B} = \operatorname{diag}(1, 0)$. Then $\mathbf{A} + \mathbf{B} = \operatorname{diag}(2, 0)$ and $\lambda_1(\mathbf{A} + \mathbf{B}) = 2 = 1 + 1$. More generally equality holds at $k = 1$ whenever $\mathbf{A}$ and $\mathbf{B}$ have a common top eigenvector, because then that one vector attains all three maxima at once.

16.6.6.3 C. Going deeper

Exercise C1: The Loewner order and the partial sums.

Let $\mathbf{A}, \mathbf{B} \in M_n(F)$ be Hermitian.

(a) Prove that $\mathbf{A} \succeq \mathbf{B}$ implies $\sum_{i \le k} \lambda_i(\mathbf{A}) \ge \sum_{i \le k} \lambda_i(\mathbf{B})$ for every k. *Hint: compare the two maximization problems of Theorem 16.6.2 competitor by competitor.*

(b) Show that the converse fails: give Hermitian $\mathbf{A}, \mathbf{B}$ satisfying all n of these inequalities with $\mathbf{A} \not\succeq \mathbf{B}$.

Solution.

(a) Let $\mathbf{Q}^*\mathbf{Q} = \mathbf{I}_k$ with columns $\mathbf{q}_1, \dots, \mathbf{q}_k$. Since $\mathbf{A} - \mathbf{B} \succeq 0$, clause (P2) of Definition 12.1.1 gives $\langle (\mathbf{A} - \mathbf{B})\mathbf{q}_i, \mathbf{q}_i \rangle \ge 0$ for each i, that is, $\langle \mathbf{A}\mathbf{q}_i, \mathbf{q}_i \rangle \ge \langle \mathbf{B}\mathbf{q}_i, \mathbf{q}_i \rangle$. Summing over i,

$$\operatorname{tr}(\mathbf{Q}^*\mathbf{A}\mathbf{Q}) \;\ge\; \operatorname{tr}(\mathbf{Q}^*\mathbf{B}\mathbf{Q}).$$

Now take $\mathbf{Q}$ to be a maximizer for $\mathbf{B}$ in Theorem 16.6.2. Then

$$\sum_{i \le k} \lambda_i(\mathbf{B}) = \operatorname{tr}(\mathbf{Q}^*\mathbf{B}\mathbf{Q}) \le \operatorname{tr}(\mathbf{Q}^*\mathbf{A}\mathbf{Q}) \le \sum_{i \le k} \lambda_i(\mathbf{A}),$$

the last step because $\mathbf{Q}$ is one competitor in the maximization for $\mathbf{A}$.

(b) Take $\mathbf{A} = \operatorname{diag}(2, 0)$ and $\mathbf{B} = \operatorname{diag}(1, 1)$. The partial sums are $2 \ge 1$ for $k = 1$ and $2 \ge 2$ for $k = 2$. But $\mathbf{A} - \mathbf{B} = \operatorname{diag}(1, -1)$ has a negative eigenvalue, so $\mathbf{A} - \mathbf{B} \not\succeq 0$ by Theorem 12.1.4 (b), and $\mathbf{A} \not\succeq \mathbf{B}$. Concretely, $\langle (\mathbf{A} - \mathbf{B})\mathbf{e}_2, \mathbf{e}_2 \rangle = -1 < 0$.

Exercise C2: Partial sums that behave like a norm.

For positive semidefinite $\mathbf{A} \in M_n(F)$ and $1 \le k \le n$, consider $s_k(\mathbf{A}) = \sum_{i \le k} \lambda_i(\mathbf{A})$, the partial sum of this section, now restricted to the positive semidefinite matrices.

(a) Prove that $N_k(\mathbf{A}) \ge 0$, with equality if and only if $\mathbf{A} = \mathbf{0}$.

(b) Prove that $N_k(c\mathbf{A}) = cN_k(\mathbf{A})$ for every real $c \ge 0$, and that $N_k(\mathbf{A} + \mathbf{B}) \le N_k(\mathbf{A}) + N_k(\mathbf{B})$ for positive semidefinite $\mathbf{A}, \mathbf{B}$.

(c) The positive semidefinite matrices form a **cone**, not a vector space, so a norm cannot be defined on them. Deduce instead that s_k is positive, positively homogeneous and subadditive on this cone. Which step of your argument for (a) uses positive semidefiniteness, and what goes wrong without it?

Solution.

(a) By Theorem 12.1.4 (b) every eigenvalue of $\mathbf{A}$ is ≥ 0, so $N_k(\mathbf{A}) \ge \lambda_1(\mathbf{A}) \ge 0$ for $k \ge 1$. If $N_k(\mathbf{A}) = 0$ then in particular $\lambda_1(\mathbf{A}) = 0$, so every eigenvalue is 0; by Corollary 11.4.3 (or Corollary 11.5.2) $\mathbf{A} = \mathbf{U}\mathbf{0}\mathbf{U}^* = \mathbf{0}$. Conversely $N_k(\mathbf{0}) = 0$.

(b) Multiplying a Hermitian matrix by $c \ge 0$ multiplies each eigenvalue by c and preserves the decreasing order, so $\lambda_i(c\mathbf{A}) = c\lambda_i(\mathbf{A})$ and the first claim follows by summing. The second is Corollary 16.6.5, which needs no positivity at all.

(c) Positivity with $N_k(\mathbf{A}) = 0$ only for $\mathbf{A} = \mathbf{0}$ is (a); homogeneity under scalars $c \ge 0$ is (b); subadditivity is (b). So N_k behaves as a norm wherever it is defined. It cannot be extended to all Hermitian matrices by the same formula: for $\mathbf{A} = \operatorname{diag}(0, -1)$

and $k = 1$ we get $N_1(\mathbf{A}) = 0$ with $\mathbf{A} \neq \mathbf{0}$, so the positivity clause fails, and for $c = -1$ the value $N_1(-\mathbf{A}) = 1$ differs from $|c|N_1(\mathbf{A}) = 0$. The repair is to apply N_k to the singular values instead of the eigenvalues, which is what Chapter 20 does.

Exercise C3: How much of a matrix a subspace holds.

Let $\mathbf{A} \in M_{m\times n}(F)$ with singular values $\sigma_1 \geq \cdots \geq \sigma_p$ extended by zeros as in Corollary 16.6.4, let $S \subseteq F^m$ have dimension k, and let $\mathbf{Q}$ have as columns an orthonormal basis of S, so that $P_S = \mathbf{Q}\mathbf{Q}^*$ by Theorem 10.3.3 (a).

(a) Prove that $\|P_S\mathbf{A}\|_F^2 = \operatorname{tr}(\mathbf{Q}^*\mathbf{A}\mathbf{A}^*\mathbf{Q})$.

(b) Deduce from Theorem 16.6.2 that $\|P_S\mathbf{A}\|_F^2 \leq \sigma_1^2 + \cdots + \sigma_k^2$, with equality when S is spanned by the first k left singular vectors.

(c) Hence recover the value $\sum_{i>k}\sigma_i^2$ of the minimum in Corollary 12.10.4. *Hint:* $\mathbf{a} - P_S\mathbf{a}$ *is orthogonal to* $P_S\mathbf{a}$.

Solution.

(a) The Frobenius norm satisfies $\|\mathbf{X}\|_F^2 = \operatorname{tr}(\mathbf{X}^*\mathbf{X})$, because the (j,j) entry of $\mathbf{X}^*\mathbf{X}$ is the squared length of the j-th column of $\mathbf{X}$. With $P_S = \mathbf{Q}\mathbf{Q}^*$, which is Hermitian and satisfies $P_S^2 = \mathbf{Q}(\mathbf{Q}^*\mathbf{Q})\mathbf{Q}^* = P_S$,

$$\|P_S\mathbf{A}\|_F^2 = \operatorname{tr}(\mathbf{A}^*P_S^*P_S\mathbf{A}) = \operatorname{tr}(\mathbf{A}^*\mathbf{Q}\mathbf{Q}^*\mathbf{A}) = \operatorname{tr}(\mathbf{Q}^*\mathbf{A}\mathbf{A}^*\mathbf{Q}),$$

the last step by Theorem 0.9.6 (3) applied to $\mathbf{A}^*\mathbf{Q}$ and $\mathbf{Q}^*\mathbf{A}$.

(b) The matrix $\mathbf{M} = \mathbf{A}\mathbf{A}^*$ is Hermitian with $\lambda_i(\mathbf{M}) = \sigma_i^2$, as computed in the proof of Corollary 16.6.4. By Theorem 16.6.2 with k columns,

$$\operatorname{tr}(\mathbf{Q}^*\mathbf{M}\mathbf{Q}) \leq \sum_{i\leq k}\lambda_i(\mathbf{M}) = \sum_{i\leq k}\sigma_i^2,$$

with equality when the columns of $\mathbf{Q}$ are top eigenvectors of $\mathbf{M}$. From $\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^*$ the columns $\mathbf{u}_1, \ldots, \mathbf{u}_m$ of $\mathbf{U}$ are exactly such an eigenbasis, so equality holds for $S = \operatorname{span}(\mathbf{u}_1, \ldots, \mathbf{u}_k)$.

(c) Write $\mathbf{a}_1, \ldots, \mathbf{a}_n$ for the columns of $\mathbf{A}$. For each j the vectors $P_S\mathbf{a}_j$ and $\mathbf{a}_j - P_S\mathbf{a}_j$ are orthogonal, so Theorem 10.1.3 gives $\|\mathbf{a}_j\|^2 = \|P_S\mathbf{a}_j\|^2 + \|\mathbf{a}_j - P_S\mathbf{a}_j\|^2$. Summing over j,

$$\sum_j d(\mathbf{a}_j, S)^2 = \|\mathbf{A}\|_F^2 - \|P_S\mathbf{A}\|_F^2.$$

By Lemma 12.10.1, $\|\mathbf{A}\|_F^2 = \sum_i \sigma_i^2$. By (b) the subtracted term is at most $\sum_{i\leq k}\sigma_i^2$, with equality for $S = \operatorname{span}(\mathbf{u}_1, \ldots, \mathbf{u}_k)$. Hence the total squared distance is at least $\sum_{i>k}\sigma_i^2$, and equals it for that S; a subspace of smaller dimension $k' < k$ does no better, since the same argument bounds what it captures by $\sum_{i\leq k'}\sigma_i^2 \leq \sum_{i\leq k}\sigma_i^2$ — which is Corollary 12.10.4, now read as a statement about a maximum of traces rather than a minimum of distances.

16.7 Arbitrary Index Sets

The Courant–Fischer theorem describes one eigenvalue at a time, and Ky Fan's theorem describes the sum of the top k. Between those two lies every other sum, for instance $\lambda_2 + \lambda_4$, and §06 ended by warning that the sharpest statements about eigenvalues tend to be statements about sums. This section describes the sum over an **arbitrary** index set as a max–min, which is Wielandt's theorem. It then uses that description to compare two Hermitian matrices across any index set at once, which is Lidskii's inequality. The price of the generality is that single subspaces are replaced by nested chains of them, and the proof takes some care.

Throughout, $F = \mathbb{R}$ or $F = \mathbb{C}$, every matrix whose eigenvalues are indexed is Hermitian, and the indexing is decreasing, $\lambda_1(\mathbf{A}) \geq \cdots \geq \lambda_n(\mathbf{A})$, with multiplicity. An **index set** of size k is a list of integers $1 \leq i_1 < i_2 < \cdots < i_k \leq n$.

16.7.1 What adding up the min–max gives

Here is the question that drives the section. Let $\mathbf{A}$ and $\mathbf{B}$ be Hermitian and fix an index set. How large can

$$\sum_{j=1}^{k} \lambda_{i_j}(\mathbf{A}) - \sum_{j=1}^{k} \lambda_{i_j}(\mathbf{B})$$

be, in terms of $\mathbf{A} - \mathbf{B}$? One answer is immediate. By Corollary 16.3.4, applied to $\mathbf{B}$ and the Hermitian matrix $\mathbf{A} - \mathbf{B}$, each single difference satisfies $\lambda_i(\mathbf{A}) - \lambda_i(\mathbf{B}) \leq \lambda_1(\mathbf{A} - \mathbf{B})$. Adding k of these gives the bound $k\,\lambda_1(\mathbf{A} - \mathbf{B})$.

That bound is poor, and a rank-one example shows by how much. Let $\mathbf{A} = \mathbf{B} + \mathbf{u}\mathbf{u}^*$ with $\|\mathbf{u}\| = 1$. By Theorem 16.5.1 every shift $\lambda_i(\mathbf{A}) - \lambda_i(\mathbf{B})$ is ≥ 0, and by Corollary 16.5.3 the shifts add up to exactly $\|\mathbf{u}\|^2 = 1$. So **every** partial sum of shifts is at most 1, whatever the index set. The eigenvalues of $\mathbf{u}\mathbf{u}^*$ are $1, 0, \ldots, 0$, so $1 = \lambda_1 + \cdots + \lambda_k$ of $\mathbf{A} - \mathbf{B}$ for every k. The summed Weyl bound says k, which is wrong by a factor of k.

The bound we would like is therefore

$$\sum_{j=1}^{k} \lambda_{i_j}(\mathbf{A}) - \sum_{j=1}^{k} \lambda_{i_j}(\mathbf{B}) \;\leq\; \sum_{j=1}^{k} \lambda_j(\mathbf{A} - \mathbf{B}),$$

and the obstruction is visible in the proof of Weyl's inequality. That proof finds, for each index, **one** good vector. Summing k such bounds uses k unrelated vectors, and the only control over $\sum_j \langle (\mathbf{A} - \mathbf{B})\mathbf{x}_j, \mathbf{x}_j \rangle$ for unrelated unit vectors is $k\,\lambda_1(\mathbf{A} - \mathbf{B})$. If the $\mathbf{x}_j$ were **orthonormal**, Theorem 16.6.2 would bound the same sum by $\lambda_1 + \cdots + \lambda_k$ of $\mathbf{A} - \mathbf{B}$. So we need a single orthonormal list $\mathbf{x}_1, \ldots, \mathbf{x}_k$ that is simultaneously good for $\mathbf{A}$ and good for $\mathbf{B}$:

$$\sum_j \langle \mathbf{A}\mathbf{x}_j, \mathbf{x}_j \rangle \;\geq\; \sum_j \lambda_{i_j}(\mathbf{A}), \qquad \sum_j \langle \mathbf{B}\mathbf{x}_j, \mathbf{x}_j \rangle \;\leq\; \sum_j \lambda_{i_j}(\mathbf{B}).$$

The first requirement is easy to meet: it will hold whenever each $\mathbf{x}_j$ lies in the span W_j of the top i_j eigenvectors of $\mathbf{A}$. Those spans are nested, $W_1 \subset W_2 \subset \cdots \subset W_k$, and from $\mathbf{B}$'s point of view they are an arbitrary nested chain of subspaces. The second requirement is then a question about $\mathbf{B}$ alone: **inside any nested chain of subspaces of these dimensions, is there an orthonormal list whose sum for $\mathbf{B}$ is small?** Wielandt's theorem answers yes, and the chain needs a name.

16.7.2 Flags and adapted lists

Chapter 8 §07 called a chain $U_1 \subset U_2 \subset \cdots \subset U_n = V$ with $\dim U_k = k$ a **flag**, and a basis whose first k members span U_k a basis adapted to it. We need chains that skip dimensions, and lists that meet each member of the chain once.

A flag of type $(i_1, \dots, i_k)$ is a nested chain of subspaces with prescribed dimensions; an adapted list takes its j-th vector from the j-th subspace and is orthonormal.

Definition 16.7.1 — Flags of a given type, and adapted lists

Let $F = \mathbb{R}$ or $\mathbb{C}$, and let $1 \le i_1 < \cdots < i_k \le n$ be an index set. A **flag of type** $(i_1, \dots, i_k)$ in F^n is a list $\mathcal{W} = (W_1, \dots, W_k)$ of subspaces of F^n with

$$W_1 \subseteq W_2 \subseteq \cdots \subseteq W_k \qquad \text{and} \qquad \dim W_j = i_j \ \text{ for every } j.$$

A list $(\mathbf{x}_1, \dots, \mathbf{x}_k)$ of vectors of F^n is **adapted to** $\mathcal{W}$ if it is **orthonormal** and $\mathbf{x}_j \in W_j$ for **every** j.

In words. The subspaces are nested, and the j-th one has dimension equal to the j-th **index** i_j, not to j; since the indices strictly increase, so do the dimensions, and each inclusion is proper. An adapted list has exactly one vector per subspace; the j-th vector may be taken anywhere in W_j, including in the smaller $W_1, \dots, W_{j-1}$, but the whole list must be orthonormal.

Every flag has an adapted list. Choose a basis of W_1, extend it to a basis of W_2 (Theorem 1.6.5), then to W_3, and so on up to W_k. This gives a basis $\mathbf{v}_1, \dots, \mathbf{v}_{i_k}$ of W_k whose first i_j members span W_j. Applying Theorem 10.2.2 yields an orthonormal list $\mathbf{e}_1, \dots, \mathbf{e}_{i_k}$ with $\operatorname{span}(\mathbf{e}_1, \dots, \mathbf{e}_{i_j}) = W_j$ for each j, and $(\mathbf{e}_{i_1}, \dots, \mathbf{e}_{i_k})$ is adapted to $\mathcal{W}$.

Four cases to keep in mind.

- **One index.** For $k = 1$ a flag is a single subspace W_1 of dimension i_1, and an adapted list is a single unit vector in it.
- **An initial segment.** For the index set $(1, 2, \dots, k)$, W_j has dimension j. An adapted list is then an orthonormal basis of W_k whose first j vectors span W_j, since j orthonormal vectors in the j-dimensional W_j span it. With $k = n$ this is Chapter 8's complete flag.
- **The eigenflag.** Let $(\mathbf{u}_1, \dots, \mathbf{u}_n)$ be an orthonormal basis of F^n with $\mathbf{A}\mathbf{u}_p = \lambda_p(\mathbf{A})\mathbf{u}_p$, and put $W_j = \operatorname{span}(\mathbf{u}_1, \dots, \mathbf{u}_{i_j})$. This is a flag of type $(i_1, \dots, i_k)$, and $(\mathbf{u}_{i_1}, \dots, \mathbf{u}_{i_k})$ is adapted to it, since $\mathbf{u}_{i_j}$ is among the vectors spanning W_j.
- **The degenerate case $k = n$.** Then $i_j = j$ is forced, $W_n = F^n$, and an adapted list is an orthonormal basis of F^n whose first j vectors span W_j.

A minimal change breaks adaptedness. For the eigenflag of type $(1, 3)$ in F^3, namely $\operatorname{span}(\mathbf{u}_1) \subset F^3$, the list $(\mathbf{u}_1, \mathbf{u}_3)$ is adapted. Swap the two vectors to get $(\mathbf{u}_3, \mathbf{u}_1)$. It is still orthonormal and its members still lie in $W_2 = F^3$, but the clause $\mathbf{x}_1 \in W_1$ fails: $\mathbf{u}_3 \notin \operatorname{span}(\mathbf{u}_1)$.

Why this definition? Orthonormality is what makes $\sum_j \langle \mathbf{A}\mathbf{x}_j, \mathbf{x}_j \rangle$ the trace of a compression, which is what Theorem 16.6.2 controls. The nesting will let us orthonormalize a list by Gram–Schmidt without moving any vector out of its own subspace, since Gram–Schmidt keeps the j-th vector in the span of the first j.

Quick check. In $\mathbb{R}^3$, take the flag $W_1 = \operatorname{span}(\mathbf{e}_1) \subset W_2 = \operatorname{span}(\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3)$, of type $(1, 3)$. Which of these lists are adapted to it: (a) $(\mathbf{e}_1, \mathbf{e}_3)$; (b) $(\mathbf{e}_3, \mathbf{e}_1)$; (c) $(\mathbf{e}_1, \mathbf{e}_1 + \mathbf{e}_2)$; (d) $(-\mathbf{e}_1, \frac{1}{\sqrt{2}}(\mathbf{e}_2 - \mathbf{e}_3))$?

Solution.

(a) Yes: orthonormal, $\mathbf{e}_1 \in W_1$ and $\mathbf{e}_3 \in W_2$. (b) No: $\mathbf{x}_1 = \mathbf{e}_3$ is not in W_1. (c) No: the list is not orthonormal, since $\langle \mathbf{e}_1, \mathbf{e}_1 + \mathbf{e}_2 \rangle = 1$ and $\|\mathbf{e}_1 + \mathbf{e}_2\| = \sqrt{2}$. (d) Yes: $-\mathbf{e}_1 \in W_1$, the second vector has length 1 and is orthogonal to $\mathbf{e}_1$, and every vector lies in $W_2 = \mathbb{R}^3$.

16.7.3 Wielandt's minimax principle

The eigenflag guarantees every adapted list a large sum, and no flag of the same type can guarantee more. That is the statement; the second half is the hard one.

Theorem 16.7.1 — Wielandt's Minimax Principle

Let $\mathbf{A} \in M_n(F)$ be Hermitian, with $F = \mathbb{R}$ or $\mathbb{C}$, and let $1 \le i_1 < \cdots < i_k \le n$.

(a) For **every** flag $\mathcal{W}$ of type $(i_1, \dots, i_k)$ there is a list $(\mathbf{x}_1, \dots, \mathbf{x}_k)$ adapted to $\mathcal{W}$ with

$$\sum_{j=1}^{k} \langle \mathbf{A}\mathbf{x}_j, \mathbf{x}_j \rangle \;\le\; \sum_{j=1}^{k} \lambda_{i_j}(\mathbf{A}).$$

(b) Let $(\mathbf{u}_1, \dots, \mathbf{u}_n)$ be an orthonormal basis with $\mathbf{A}\mathbf{u}_p = \lambda_p(\mathbf{A})\mathbf{u}_p$ for every p, and let $\mathcal{W}^{\mathbf{A}}$ be the flag $W_j = \operatorname{span}(\mathbf{u}_1, \dots, \mathbf{u}_{i_j})$. Then **every** list $(\mathbf{x}_1, \dots, \mathbf{x}_k)$ adapted to $\mathcal{W}^{\mathbf{A}}$ satisfies

$$\sum_{j=1}^{k} \langle \mathbf{A}\mathbf{x}_j, \mathbf{x}_j \rangle \;\ge\; \sum_{j=1}^{k} \lambda_{i_j}(\mathbf{A}),$$

with equality for $\mathbf{x}_j = \mathbf{u}_{i_j}$.

(c) Consequently

$$\sum_{j=1}^{k} \lambda_{i_j}(\mathbf{A}) = \max_{\mathcal{W}} \min_{(\mathbf{x}_1, \dots, \mathbf{x}_k)} \sum_{j=1}^{k} \langle \mathbf{A}\mathbf{x}_j, \mathbf{x}_j \rangle,$$

where $\mathcal{W}$ runs over all flags of type $(i_1, \dots, i_k)$ in F^n, and for each $\mathcal{W}$ the list runs over all lists adapted to $\mathcal{W}$. The inner minimum exists for every $\mathcal{W}$, and the outer maximum is attained at $\mathcal{W}^{\mathbf{A}}$.

Idea. Two inequalities of different characters, as in Theorem 16.2.3. In both, the sum $\sum_j \langle \mathbf{A}\mathbf{x}_j, \mathbf{x}_j \rangle$ is the trace of the compression $\mathbf{B}$ of $\mathbf{A}$ to the span of the list, so it is $\sum_j \lambda_j(\mathbf{B})$. Both parts therefore come down to comparing $\lambda_j(\mathbf{B})$ with $\lambda_{i_j}(\mathbf{A})$, one j at a time, by Courant–Fischer applied to the small matrix $\mathbf{B}$.

For (b), the first j vectors of the list lie in $\operatorname{span}(\mathbf{u}_1, \dots, \mathbf{u}_{i_j})$, where $R_{\mathbf{A}} \ge \lambda_{i_j}(\mathbf{A})$, so $\lambda_j(\mathbf{B}) \ge \lambda_{i_j}(\mathbf{A})$.

For (a), we need a list whose span X meets each bottom span $L_{i_j} = \operatorname{span}(\mathbf{u}_{i_j}, \dots, \mathbf{u}_n)$

in dimension at least $k-j+1$, since $R_{\mathbf{A}} \le \lambda_{i_j}(\mathbf{A})$ there. For a **single** j, Lemma 16.2.1 gives such a meeting. For all j at once, with one X, it does not: the vectors chosen for different j can collide, and the example after the proof shows that they do. The remedy is to count in coordinates. Record, for each vector, the first eigenvector coordinate at which it is non-zero; vectors with different first coordinates are independent; and a greedy choice of these first coordinates achieves every count at once.

Step roadmap. A preliminary claim turns bounds on $R_{\mathbf{A}}$ over subspaces into bounds on the eigenvalues of a compression. **Step 1** proves (b). **Step 2** introduces leading indices and makes the greedy selection. **Step 3** orthonormalizes the selected vectors and proves (a). **Step 4** proves that the inner minimum exists, which is the only place analysis enters, and deduces (c).

Proof. Let $(\mathbf{u}_1, \dots, \mathbf{u}_n)$ be an orthonormal basis of F^n with $\mathbf{A}\mathbf{u}_p = \lambda_p(\mathbf{A})\mathbf{u}_p$ for every p; such a basis exists by Corollary 11.4.3 over $\mathbb{C}$ or Corollary 11.5.2 over $\mathbb{R}$. For part (b) take the basis named there; for part (a) any such basis will do. Abbreviate $\lambda_p = \lambda_p(\mathbf{A})$. For $1 \le p \le n$ put

$$L_p = \operatorname{span}(\mathbf{u}_p, \mathbf{u}_{p+1}, \dots, \mathbf{u}_n), \qquad L_{n+1} = \{\mathbf{0}\}.$$

By Lemma 16.3.1, $R_{\mathbf{A}}(\mathbf{x}) \le \lambda_p$ for every non-zero $\mathbf{x} \in L_p$, and $R_{\mathbf{A}}(\mathbf{x}) \ge \lambda_p$ for every non-zero $\mathbf{x} \in \operatorname{span}(\mathbf{u}_1, \dots, \mathbf{u}_p)$.

Claim. **Claim 1 (compression bounds).** Let $(\mathbf{y}_1, \dots, \mathbf{y}_k)$ be orthonormal, let Y be its span, let $\mathbf{Q} \in M_{n\times k}(F)$ have columns $\mathbf{y}_1, \dots, \mathbf{y}_k$, and let $\mathbf{B} = \mathbf{Q}^*\mathbf{A}\mathbf{Q}$ be the compression of Definition 16.6.1. Let $1 \le m \le k$ and $c \in \mathbb{R}$.

(i) If $S \subseteq Y$ is a subspace with $\dim S = m$ and $R_{\mathbf{A}}(\mathbf{x}) \ge c$ for every non-zero $\mathbf{x} \in S$, then $\lambda_m(\mathbf{B}) \ge c$.

(ii) If $S \subseteq Y$ is a subspace with $\dim S = k-m+1$ and $R_{\mathbf{A}}(\mathbf{x}) \le c$ for every non-zero $\mathbf{x} \in S$, then $\lambda_m(\mathbf{B}) \le c$.

Moreover $\sum_{j=1}^{k} \langle \mathbf{A}\mathbf{y}_j, \mathbf{y}_j \rangle = \operatorname{tr} \mathbf{B} = \sum_{j=1}^{k} \lambda_j(\mathbf{B})$.

Proof. The matrix $\mathbf{B}$ is Hermitian, and the map $\mathbf{c} \mapsto \mathbf{Qc}$ is a linear bijection $F^k \to Y$ with $R_{\mathbf{B}}(\mathbf{c}) = R_{\mathbf{A}}(\mathbf{Qc})$ for $\mathbf{c} \neq \mathbf{0}$, as computed in the proof of Lemma 16.2.2. Let $S' = \{\mathbf{c} \in F^k : \mathbf{Qc} \in S\}$; it is a subspace, and $\mathbf{c} \mapsto \mathbf{Qc}$ maps it bijectively onto S, so $\dim S' = \dim S$.

(i) By the max–min line of Theorem 16.2.3 for $\mathbf{B} \in M_k(F)$, $\lambda_m(\mathbf{B})$ is the largest of the numbers $\min_{\mathbf{0}\neq\mathbf{c}\in T} R_{\mathbf{B}}(\mathbf{c})$ over subspaces $T \subseteq F^k$ of dimension m. Taking $T = S'$,

$$\lambda_m(\mathbf{B}) \;\geq\; \min_{\mathbf{0}\neq\mathbf{c}\in S'} R_{\mathbf{B}}(\mathbf{c}) = \min_{\mathbf{0}\neq\mathbf{x}\in S} R_{\mathbf{A}}(\mathbf{x}) \;\geq\; c.$$

(ii) By the min–max line of Theorem 16.2.3 for $\mathbf{B}$, with $T = S'$ of dimension $k - m + 1$,

$$\lambda_m(\mathbf{B}) \;\leq\; \max_{\mathbf{0}\neq\mathbf{c}\in S'} R_{\mathbf{B}}(\mathbf{c}) = \max_{\mathbf{0}\neq\mathbf{x}\in S} R_{\mathbf{A}}(\mathbf{x}) \;\leq\; c.$$

Finally, the diagonal entries of $\mathbf{B}$ are $\langle \mathbf{A}\mathbf{y}_j, \mathbf{y}_j\rangle$ by Definition 16.6.1, and the trace of the Hermitian $\mathbf{B}$ is the sum of its eigenvalues by Corollary 11.1.4.

■

Step 1. The eigenflag guarantees the sum: part (b). Let $(\mathbf{x}_1, \dots, \mathbf{x}_k)$ be adapted to $\mathcal{W}^{\mathbf{A}}$, so $\mathbf{x}_j \in W_j = \operatorname{span}(\mathbf{u}_1, \dots, \mathbf{u}_{i_j})$. Fix j and put $S = \operatorname{span}(\mathbf{x}_1, \dots, \mathbf{x}_j)$. The list is orthonormal, hence independent, so $\dim S = j$. Each $\mathbf{x}_m$ with $m \leq j$ lies in $W_m \subseteq W_j$, so $S \subseteq W_j$, where $R_{\mathbf{A}} \geq \lambda_{i_j}$. By Claim 1 (i) with $m = j$, $\lambda_j(\mathbf{B}) \geq \lambda_{i_j}$, where $\mathbf{B}$ is the compression to the span of the list. Summing over j and using the last line of Claim 1,

$$\sum_{j=1}^{k} \langle \mathbf{A}\mathbf{x}_j, \mathbf{x}_j\rangle = \sum_{j=1}^{k} \lambda_j(\mathbf{B}) \;\geq\; \sum_{j=1}^{k} \lambda_{i_j}.$$

For $\mathbf{x}_j = \mathbf{u}_{i_j}$ each term is $\langle \mathbf{A}\mathbf{u}_{i_j}, \mathbf{u}_{i_j}\rangle = \lambda_{i_j}$, so equality holds. This proves (b).

Step 2. Leading indices, and a selection. Let $\mathcal{W} = (W_1, \dots, W_k)$ be an arbitrary flag of type $(i_1, \dots, i_k)$. For $\mathbf{x} \in F^n$ write $c_p(\mathbf{x}) = \langle \mathbf{x}, \mathbf{u}_p\rangle$, so that $\mathbf{x} = \sum_p c_p(\mathbf{x})\mathbf{u}_p$ by Theorem 10.2.1 (a). Then $\mathbf{x} \in L_p$ exactly when $c_1(\mathbf{x}) = \cdots = c_{p-1}(\mathbf{x}) = 0$. The **leading index** $\ell(\mathbf{x})$ of a non-zero $\mathbf{x}$ is the smallest p with $c_p(\mathbf{x}) \neq 0$, so that

$$\mathbf{x} \in L_p \iff \ell(\mathbf{x}) \geq p \qquad (\mathbf{x} \neq \mathbf{0}).$$

For a subspace $V \subseteq F^n$, let $J(V)$ be the set of $p \in \{1, \dots, n\}$ with $V \cap L_{p+1} \neq V \cap L_p$. These are the indices at which the chain $V = V \cap L_1 \supseteq V \cap L_2 \supseteq \cdots \supseteq V \cap L_{n+1} = \{\mathbf{0}\}$ gets strictly smaller.

Claim. **Claim 2 (the jumps count the dimension).** For every subspace $V \subseteq F^n$ and every $1 \leq p \leq n + 1$,

$$\dim(V \cap L_p) = \big|J(V) \cap \{p, p+1, \dots, n\}\big|.$$

In particular $|J(V)| = \dim V$. Moreover, for each $p \in J(V)$ there is $\mathbf{x} \in V$ with $\ell(\mathbf{x}) = p$.

Proof. Fix $p \le n$. The map $\varphi_p \colon V \cap L_p \to F$, $\mathbf{x} \mapsto c_p(\mathbf{x})$, is linear. A vector of $V \cap L_p$ already has $c_1 = \cdots = c_{p-1} = 0$, so it lies in L_{p+1} exactly when also $c_p = 0$; hence $\ker \varphi_p = V \cap L_{p+1}$. By Theorem 3.3.1,

$$\dim(V \cap L_p) - \dim(V \cap L_{p+1}) = \operatorname{rank} \varphi_p,$$

and $\operatorname{rank} \varphi_p \le \dim F = 1$. The rank is 1 exactly when $\ker \varphi_p \neq V \cap L_p$, that is, when $p \in J(V)$. Adding these equations for $p, p+1, \dots, n$, the left side telescopes to $\dim(V \cap L_p) - \dim(V \cap L_{n+1}) = \dim(V \cap L_p)$, and the right side counts the elements of $J(V)$ that are $\ge p$. This proves the formula, which for $p = n+1$ reads $0 = 0$. At $p = 1$, $L_1 = F^n$ gives $|J(V)| = \dim V$. Finally, if $p \in J(V)$, pick $\mathbf{x} \in (V \cap L_p) \setminus L_{p+1}$; then $c_1(\mathbf{x}) = \cdots = c_{p-1}(\mathbf{x}) = 0 \neq c_p(\mathbf{x})$, so $\ell(\mathbf{x}) = p$.

■

Claim. **Claim 3 (distinct leading indices force independence).** Non-zero vectors $\mathbf{x}_1, \dots, \mathbf{x}_r$ whose leading indices are pairwise distinct are linearly independent.

Proof. Suppose $\sum_m a_m \mathbf{x}_m = \mathbf{0}$ with not all a_m zero. Among the m with $a_m \neq 0$, let m_0 be the one with the smallest leading index, $q = \ell(\mathbf{x}_{m_0})$. Apply c_q. Every other $\mathbf{x}_m$ with $a_m \neq 0$ has $\ell(\mathbf{x}_m) > q$, so $c_q(\mathbf{x}_m) = 0$. Hence $0 = a_{m_0} c_q(\mathbf{x}_{m_0})$, a product of two non-zero numbers, which is a contradiction.

■

Claim. **Claim 4 (a greedy selection).** There are non-zero vectors $\mathbf{x}_1, \dots, \mathbf{x}_k$ with $\mathbf{x}_m \in W_m$, with pairwise distinct leading indices $q_m = \ell(\mathbf{x}_m)$, and such that for every j,

$$\#\{\, m : q_m \ge i_j \,\} \;\ge\; k - j + 1.$$

Proof. Choose $q_1, \dots, q_k$ in turn: q_m is the **largest** element of $J(W_m)$ not among $q_1, \dots, q_{m-1}$. This is possible, because $J(W_m)$ has $\dim W_m = i_m \ge m$ elements by Claim 2, so at most $m-1$ of them are used. By the last part of Claim 2, pick $\mathbf{x}_m \in W_m$ with $\ell(\mathbf{x}_m) = q_m$. The q_m are distinct by construction.

Fix j, and for $m \ge j-1$ let N_m be the number of $l \le m$ with $q_l \ge i_j$. We show $N_m \ge m - j + 1$ by induction on m. For $m = j-1$ this says $N_{j-1} \ge 0$, which is true. Let $m \ge j$ and assume $N_{m-1} \ge m - j$.

Case 1: $q_m \ge i_j$. Then $N_m = N_{m-1} + 1 \ge m - j + 1$.

Case 2: $q_m < i_j$. By Claim 2, $J(W_m)$ has i_m elements, of which at most $i_j - 1$ are smaller than i_j. So at least $i_m - i_j + 1$ of them are $\ge i_j$, and $i_m - i_j \ge m - j$ because the indices are strictly increasing integers. Every element of $J(W_m)$ that is $\ge i_j$ exceeds q_m, so by the choice of q_m as the largest unused element, each of them is already among $q_1, \dots, q_{m-1}$. These are at least $i_m - i_j + 1 \ge m - j + 1$ of the earlier q_l, all $\ge i_j$, so $N_{m-1} \ge m - j + 1$. Hence $N_m = N_{m-1} \ge m - j + 1$.

At $m = k$ this gives $N_k \ge k - j + 1$, which is the claim.

■

Step 3. An adapted list with a small sum: part (a). Take $\mathbf{x}_1, \dots, \mathbf{x}_k$ from Claim 4. They are linearly independent by Claim 3, so Theorem 10.2.2 applies and produces an orthonormal list $(\mathbf{y}_1, \dots, \mathbf{y}_k)$ with $\operatorname{span}(\mathbf{y}_1, \dots, \mathbf{y}_j) = \operatorname{span}(\mathbf{x}_1, \dots, \mathbf{x}_j)$ for each j. Since $\mathbf{x}_m \in W_m \subseteq W_j$ for $m \le j$, the vector $\mathbf{y}_j$ lies in W_j. So $(\mathbf{y}_1, \dots, \mathbf{y}_k)$ is adapted to $\mathcal{W}$.

Let $X = \operatorname{span}(\mathbf{y}_1, \dots, \mathbf{y}_k) = \operatorname{span}(\mathbf{x}_1, \dots, \mathbf{x}_k)$, and let $\mathbf{B}$ be the compression of $\mathbf{A}$ to it with respect to the $\mathbf{y}_j$. Fix j. By Claim 4 at least $k - j + 1$ of the $\mathbf{x}_m$ have $q_m \ge i_j$; each of them lies in L_{i_j}, and any $k - j + 1$ of them are independent by Claim 3. Let S be the span of $k - j + 1$ of them, so $S \subseteq X \cap L_{i_j}$ and $\dim S = k - j + 1$. On $S \subseteq L_{i_j}$ we have $R_{\mathbf{A}} \le \lambda_{i_j}$, so Claim 1 (ii) with $m = j$ gives $\lambda_j(\mathbf{B}) \le \lambda_{i_j}$. Summing over j and using the last line of Claim 1,

$$\sum_{j=1}^{k} \langle \mathbf{A}\mathbf{y}_j, \mathbf{y}_j \rangle = \sum_{j=1}^{k} \lambda_j(\mathbf{B}) \;\le\; \sum_{j=1}^{k} \lambda_{i_j}.$$

This proves (a).

Step 4. The minimum exists, and the max–min formula: part (c). Fix a flag $\mathcal{W}$. Identify a list $(\mathbf{x}_1, \dots, \mathbf{x}_k)$ with the column of F^{nk} obtained by stacking the $\mathbf{x}_j$; its Euclidean norm is $(\sum_j \|\mathbf{x}_j\|^2)^{1/2}$. Let $\mathcal{O}$ be the set of lists adapted to $\mathcal{W}$. It is non-empty, by the paragraph after Definition 16.7.1. It is bounded, since every element has norm $\sqrt{k}$. And it contains the limit of each of its convergent sequences. Indeed, the conditions $\langle \mathbf{x}_i, \mathbf{x}_j \rangle = \delta_{ij}$ are equations between sums of products of the entries and their conjugates, which pass to limits. Each condition $\mathbf{x}_j \in W_j$ says $\mathbf{M}_j \mathbf{x}_j = \mathbf{0}$ for a matrix $\mathbf{M}_j$ whose null space is W_j, for instance the matrix whose rows are the conjugate transposes of a basis of $W_j^{\perp}$ (the zero matrix if $W_j = F^n$), and this passes to limits too. So by fact (A3) of Chapter 15's introduction, every sequence in $\mathcal{O}$ has a subsequence converging to a point of $\mathcal{O}$. The function $(\mathbf{x}_1, \dots, \mathbf{x}_k) \mapsto \sum_j \langle \mathbf{A}\mathbf{x}_j, \mathbf{x}_j \rangle$ is built from the real and imaginary parts of the entries by sums and products, so it is continuous, and it is real-valued since $\mathbf{A}$ is Hermitian. By fact (A4) it attains a minimum on $\mathcal{O}$.

Call that minimum $v(\mathcal{W})$. By (a), some adapted list has sum $\le \sum_j \lambda_{i_j}$, so $v(\mathcal{W}) \le \sum_j \lambda_{i_j}$ for every $\mathcal{W}$. By (b), every list adapted to $\mathcal{W}^{\mathbf{A}}$ has sum $\ge \sum_j \lambda_{i_j}$, with equality at $(\mathbf{u}_{i_1}, \dots, \mathbf{u}_{i_k})$, so $v(\mathcal{W}^{\mathbf{A}}) = \sum_j \lambda_{i_j}$. Hence the largest value of $v(\mathcal{W})$ over all flags of the type exists, is attained at $\mathcal{W}^{\mathbf{A}}$, and equals $\sum_j \lambda_{i_j}$. This proves (c), and the theorem. ∎

Remark. **Where the analysis went.** Parts (a) and (b) are pure algebra: a dimension count, Gram–Schmidt, and Courant–Fischer for a small matrix. The only analytic input is in Step 4, facts (A3) and (A4) of Chapter 15's introduction. This is the first time in the chapter that an item of that list is used rather than merely mentioned, and it is used only so that the word "min" in (c) refers to a value that is attained. Every later *result* in this section uses (a) and (b) alone, so no later result depends on analysis; only the exercises that quote (c), such as A1(b), lean on the attained minimum.

Two index sets give back what we already have. For $k = 1$ a flag is a single subspace W of dimension i_1, an adapted list is a unit vector $\mathbf{x} \in W$, and $\langle \mathbf{A}\mathbf{x}, \mathbf{x} \rangle = R_{\mathbf{A}}(\mathbf{x})$. So (c) reads $\lambda_{i_1}(\mathbf{A}) = \max_{\dim W = i_1} \min_{\mathbf{0} \ne \mathbf{x} \in W} R_{\mathbf{A}}(\mathbf{x})$, the max–min line of Theorem 16.2.3. For the initial segment $(1, \dots, k)$, an adapted list is an orthonormal basis of the k-dimensional W_k, and conversely every orthonormal basis $(\mathbf{x}_1, \dots, \mathbf{x}_k)$ of a k-dimensional subspace is adapted to the flag

$\operatorname{span}(\mathbf{x}_1) \subset \operatorname{span}(\mathbf{x}_1, \mathbf{x}_2) \subset \dots$. The sum $\sum_j \langle \mathbf{A}\mathbf{x}_j, \mathbf{x}_j \rangle$ is the trace of the compression to W_k. That trace does not depend on the orthonormal basis, because §06 showed that a change of orthonormal basis changes the compression by a unitary similarity. So the inner minimum is constant, and (c) says that $\sum_{j \le k} \lambda_j(\mathbf{A})$ is the largest trace of a compression to a k-dimensional subspace, which is Theorem 16.6.2. What is new is everything in between: index sets with gaps, such as $(2, 4)$, and index sets that do not start at 1.

Example. (The selection at work, and why it is needed)

Let $\mathbf{A} = \operatorname{diag}(4, 2, 1, -1) \in M_4(\mathbb{R})$, take the index set $(2, 4)$, and take the flag

$$W_1 = \operatorname{span}\big((1, 1, 0, 0),\ \mathbf{e}_4\big) \ \subset \ W_2 = \mathbb{R}^4,$$

of type $(2, 4)$. Show that the naive attempt, choosing $\mathbf{x}_j \in W_j \cap L_{i_j}$ for each j separately, cannot produce an adapted list. Then follow the proof of part (a) to produce one with sum at most $\lambda_2(\mathbf{A}) + \lambda_4(\mathbf{A})$.

Solution. Here the eigenvectors are $\mathbf{u}_p = \mathbf{e}_p$, so $L_p = \operatorname{span}(\mathbf{e}_p, \dots, \mathbf{e}_4)$ is the set of vectors whose first $p - 1$ entries vanish, and the target is $\lambda_2 + \lambda_4 = 2 + (-1) = 1$.

The naive attempt. A vector $a(1, 1, 0, 0) + b\mathbf{e}_4$ of W_1 lies in L_2 exactly when its first entry a is 0, so $W_1 \cap L_2 = \operatorname{span}(\mathbf{e}_4)$. Also $W_2 \cap L_4 = L_4 = \operatorname{span}(\mathbf{e}_4)$. Both vectors would have to be multiples of $\mathbf{e}_4$, and two such vectors are never orthonormal. Each of the two intersections is non-zero, as Lemma 16.2.1 promises, but the two choices collide.

The selection. The vectors of W_1 have the form $(a, a, 0, b)$. They lie in L_2, L_3 or L_4 exactly when $a = 0$, and in $L_5 = \{\mathbf{0}\}$ only when also $b = 0$. So the dimensions of $W_1 \cap L_p$ for $p = 1, \dots, 5$ are $2, 1, 1, 1, 0$, and the chain drops at $p = 1$ and $p = 4$: $J(W_1) = \{1, 4\}$. For $W_2 = \mathbb{R}^4$ the dimensions are $4, 3, 2, 1, 0$, so $J(W_2) = \{1, 2, 3, 4\}$. The greedy rule takes $q_1 = \max J(W_1) = 4$, with $\mathbf{x}_1 = \mathbf{e}_4 \in W_1$. It then takes $q_2 = \max\big(J(W_2) \backslash \{4\}\big) = 3$, with $\mathbf{x}_2 = \mathbf{e}_3$.

The counts of Claim 4. For $j = 1$, $i_1 = 2$, and both $q_1 = 4$ and $q_2 = 3$ are ≥ 2: the count is $2 \ge 2$. For $j = 2$, $i_2 = 4$, and only $q_1 = 4$ is ≥ 4: the count is $1 \ge 1$. Notice that the requirement for $j = 2$ is met by $\mathbf{x}_1$, not by $\mathbf{x}_2$; insisting that $\mathbf{x}_2$ itself lie in L_4 is exactly the naive attempt that failed.

The list and its sum. $(\mathbf{e}_4, \mathbf{e}_3)$ is already orthonormal, so Gram–Schmidt leaves it alone, and it is adapted: $\mathbf{e}_4 \in W_1$, $\mathbf{e}_3 \in W_2$. Its sum is $\langle \mathbf{A}\mathbf{e}_4, \mathbf{e}_4 \rangle + \langle \mathbf{A}\mathbf{e}_3, \mathbf{e}_3 \rangle = -1 + 1 = 0 \le 1$. The compression to $X = \operatorname{span}(\mathbf{e}_4, \mathbf{e}_3)$ is $\operatorname{diag}(-1, 1)$, with eigenvalues $1 \le \lambda_2(\mathbf{A}) = 2$ and $-1 \le \lambda_4(\mathbf{A}) = -1$, as Step 3 predicts one index at a time.

Quick check. Suppose "orthonormal" is weakened to "each $\mathbf{x}_j$ is a unit vector" in the definition of an adapted list. Show that the formula (c) of Theorem 16.7.1 remains true. Why is this weaker version useless for comparing two matrices?

Solution. With the $\mathbf{x}_j$ chosen independently, the inner minimum splits as $\sum_j \min_{\mathbf{0} \ne \mathbf{x} \in W_j} R_{\mathbf{A}}(\mathbf{x})$, one term per subspace. By Theorem 16.2.3 each term is at most $\lambda_{i_j}(\mathbf{A})$, since $\dim W_j = i_j$, and the eigenflag makes every term equal to $\lambda_{i_j}(\mathbf{A})$ at once. So the max–min is still $\sum_j \lambda_{i_j}(\mathbf{A})$; it is just Courant–Fischer added up. But the lists it produces are not orthonormal, so Theorem 16.6.2 cannot be applied to them. Comparing $\mathbf{A}$ with $\mathbf{B}$ through

such lists gives only the summed Weyl bound $k\,\lambda_1(\mathbf{A}-\mathbf{B})$ of the first subsection. The whole content of Wielandt's theorem is that orthonormality costs nothing.

16.7.4 Lidskii's inequality

The plan of the first subsection can now be carried out.

Theorem 16.7.2 — Lidskii's Inequality

Let $\mathbf{A},\mathbf{B}\in M_n(F)$ be Hermitian, with $F=\mathbb{R}$ or $\mathbb{C}$. Then for every index set $1\le i_1<\cdots<i_k\le n$,

$$\sum_{j=1}^{k}\lambda_{i_j}(\mathbf{A})-\sum_{j=1}^{k}\lambda_{i_j}(\mathbf{B})\;\le\;\sum_{j=1}^{k}\lambda_j(\mathbf{A}-\mathbf{B}).$$

Idea. Find one orthonormal list that is good for both matrices. Take the eigenflag of $\mathbf{A}$. Part (b) of Theorem 16.7.1 says that **every** list adapted to it is good for $\mathbf{A}$. Part (a), applied to $\mathbf{B}$ and this same flag, produces **one** adapted list that is good for $\mathbf{B}$. Subtract the two sums. What remains is $\sum_j\langle(\mathbf{A}-\mathbf{B})\mathbf{x}_j,\mathbf{x}_j\rangle$ over an orthonormal list, which Theorem 16.6.2 bounds by the top k eigenvalues of $\mathbf{A}-\mathbf{B}$.

Proof. Let $(\mathbf{u}_1,\dots,\mathbf{u}_n)$ be an orthonormal basis of F^n with $\mathbf{A}\mathbf{u}_p=\lambda_p(\mathbf{A})\mathbf{u}_p$, which exists by Corollary 11.4.3 or Corollary 11.5.2, and let $\mathcal{W}^{\mathbf{A}}$ be the flag $W_j=\operatorname{span}(\mathbf{u}_1,\dots,\mathbf{u}_{i_j})$, of type $(i_1,\dots,i_k)$. By Theorem 16.7.1 (a) applied to the Hermitian matrix $\mathbf{B}$ and the flag $\mathcal{W}^{\mathbf{A}}$, there is a list $(\mathbf{x}_1,\dots,\mathbf{x}_k)$ adapted to $\mathcal{W}^{\mathbf{A}}$ with

$$\sum_{j=1}^{k}\langle\mathbf{B}\mathbf{x}_j,\mathbf{x}_j\rangle\;\le\;\sum_{j=1}^{k}\lambda_{i_j}(\mathbf{B}).$$

By Theorem 16.7.1 (b) applied to $\mathbf{A}$, the same list satisfies

$$\sum_{j=1}^{k}\langle\mathbf{A}\mathbf{x}_j,\mathbf{x}_j\rangle\;\ge\;\sum_{j=1}^{k}\lambda_{i_j}(\mathbf{A}).$$

Subtracting the first inequality from the second, and using that the inner product is linear in its first slot,

$$\sum_{j=1}^{k}\lambda_{i_j}(\mathbf{A})-\sum_{j=1}^{k}\lambda_{i_j}(\mathbf{B})\;\le\;\sum_{j=1}^{k}\langle(\mathbf{A}-\mathbf{B})\mathbf{x}_j,\mathbf{x}_j\rangle.$$

The matrix $\mathbf{A}-\mathbf{B}$ is Hermitian and $\mathbf{x}_1,\dots,\mathbf{x}_k$ are orthonormal, so Theorem 16.6.2 bounds the right-hand side by $\sum_{j=1}^{k}\lambda_j(\mathbf{A}-\mathbf{B})$. This proves the theorem. ∎

For the rank-one example of the first subsection, the right-hand side is $\lambda_1+\cdots+\lambda_k$ of $\mathbf{u}\mathbf{u}^*$, which is 1 for every k: the theorem gives exactly the bound that the interlacing argument found there, and it gives it for every Hermitian $\mathbf{A}-\mathbf{B}$, whatever its rank. One feature of the statement

deserves a warning.

Warning. **The left side compares the two spectra at the same indices; the right side always uses the top k eigenvalues of $\mathbf{A}-\mathbf{B}$, whatever the index set.** The tempting "index-by-index" version

$$\lambda_i(\mathbf{A}) - \lambda_i(\mathbf{B}) \;\le\; \lambda_i(\mathbf{A}-\mathbf{B})$$

is false. Take $\mathbf{A} = \operatorname{diag}(1,1)$ and $\mathbf{B} = \operatorname{diag}(1,0)$, so $\mathbf{A}-\mathbf{B} = \operatorname{diag}(0,1)$ with $\lambda_1(\mathbf{A}-\mathbf{B}) = 1$ and $\lambda_2(\mathbf{A}-\mathbf{B}) = 0$. At $i=2$ the left side is $1-0=1$, which exceeds $\lambda_2(\mathbf{A}-\mathbf{B}) = 0$. Lidskii's bound is $\lambda_1(\mathbf{A}-\mathbf{B}) = 1$, and it is attained.

Example. (All seven index sets)

Let

$$\mathbf{A} = \begin{pmatrix} 0 & 2 & 0 \\ 2 & 1 & 2 \\ 0 & 2 & 2 \end{pmatrix}, \qquad \mathbf{B} = \operatorname{diag}(0,2,-1).$$

Find the three spectra, check Theorem 16.7.2 for every index set, and compare with the summed Weyl bound $k\,\lambda_1(\mathbf{A}-\mathbf{B})$.

Solution. The spectra. The vectors $(1,2,2)$, $(2,1,-2)$, $(2,-2,1)$ are eigenvectors of $\mathbf{A}$: for instance $\mathbf{A}(1,2,2) = (4, 2+2+4, 4+4) = 4(1,2,2)$, and the other two give the eigenvalues 1 and -2 in the same way. So $\boldsymbol{\lambda}(\mathbf{A}) = (4,1,-2)$, writing $\boldsymbol{\lambda}(\mathbf{A})$ for the vector of eigenvalues in decreasing order. Sorting the diagonal of $\mathbf{B}$ gives $\boldsymbol{\lambda}(\mathbf{B}) = (2,0,-1)$. Next,

$$\mathbf{A}-\mathbf{B} = \begin{pmatrix} 0 & 2 & 0 \\ 2 & -1 & 2 \\ 0 & 2 & 3 \end{pmatrix}$$

has eigenvectors $(1,2,4)$, $(-2,-1,1)$, $(2,-3,1)$. For example $(\mathbf{A}-\mathbf{B})(1,2,4) = (4,\ 2-2+8,\ 4+12) = 4(1,2,4)$. So $\boldsymbol{\lambda}(\mathbf{A}-\mathbf{B}) = (4,1,-3)$, whose running totals from the top are $4, 5, 2$.

The inequalities. The differences at equal indices are $\lambda_i(\mathbf{A}) - \lambda_i(\mathbf{B}) = 2, 1, -1$ for $i = 1,2,3$.

index set	left side	Lidskii bound	summed Weyl bound
(1), (2), (3)	$2,\ 1,\ -1$	4	4
$(1,2)$, $(1,3)$, $(2,3)$	$3,\ 1,\ 0$	5	8
$(1,2,3)$	2	2	12

Every inequality holds. For $k=3$ it is an equality, and must be: both sides are then $\operatorname{tr}\mathbf{A} - \operatorname{tr}\mathbf{B} = \operatorname{tr}(\mathbf{A}-\mathbf{B})$, by Corollary 11.1.4 and Theorem 0.9.6 (1). The summed Weyl bound grows like $k\,\lambda_1(\mathbf{A}-\mathbf{B})$, while Lidskii's bound can even decrease, because the eigenvalue -3 of $\mathbf{A}-\mathbf{B}$ enters the sum as soon as $k=3$.

The index sets that give the results we already have are the two families from the discussion of Wielandt's theorem, now at the level of two matrices.

Corollary 16.7.3 — Weyl and Ky Fan as Cases of Lidskii

Let $\mathbf{A}, \mathbf{B} \in M_n(F)$ be Hermitian.

(a) **(One index.)** For every i,

$$\lambda_n(\mathbf{A}-\mathbf{B}) \;\le\; \lambda_i(\mathbf{A}) - \lambda_i(\mathbf{B}) \;\le\; \lambda_1(\mathbf{A}-\mathbf{B}),$$

and in particular $|\lambda_i(\mathbf{A}) - \lambda_i(\mathbf{B})| \le \|\mathbf{A}-\mathbf{B}\|_2$.

(b) **(An initial segment.)** For every k,

$$\sum_{i=1}^{k} \lambda_i(\mathbf{A}) - \sum_{i=1}^{k} \lambda_i(\mathbf{B}) \;\le\; \sum_{i=1}^{k} \lambda_i(\mathbf{A}-\mathbf{B}).$$

Idea. Both are Theorem 16.7.2 with a particular index set, the lower bound in (a) coming from the same theorem with $\mathbf{A}$ and $\mathbf{B}$ exchanged.

Proof.

(a) The upper bound is Theorem 16.7.2 with $k = 1$ and the index set (i). Exchanging $\mathbf{A}$ and $\mathbf{B}$ in the same case gives $\lambda_i(\mathbf{B}) - \lambda_i(\mathbf{A}) \le \lambda_1(\mathbf{B}-\mathbf{A})$. By Lemma 16.3.2 with $p = 1$, $\lambda_1(\mathbf{B}-\mathbf{A}) = \lambda_1(-(\mathbf{A}-\mathbf{B})) = -\lambda_n(\mathbf{A}-\mathbf{B})$, and multiplying by -1 gives the lower bound. So $\lambda_i(\mathbf{A}) - \lambda_i(\mathbf{B})$ lies between $\lambda_n(\mathbf{A}-\mathbf{B})$ and $\lambda_1(\mathbf{A}-\mathbf{B})$, and its absolute value is at most $\max\big(\lambda_1(\mathbf{A}-\mathbf{B}), -\lambda_n(\mathbf{A}-\mathbf{B})\big)$, which is $\|\mathbf{A}-\mathbf{B}\|_2$ by Lemma 16.3.5.

(b) This is Theorem 16.7.2 with the index set $(1, 2, \dots, k)$.

■

Read with $\mathbf{A} = \mathbf{X}+\mathbf{Y}$ and $\mathbf{B} = \mathbf{X}$, part (a) is Corollary 16.3.4 for the pair $\mathbf{X}, \mathbf{Y}$; read with $\mathbf{B} = \mathbf{Y}$ instead, it is the same corollary with $\mathbf{X}$ and $\mathbf{Y}$ exchanged. Together these are the cases of Theorem 16.3.3 in which one of the two indices on the right is 1 (in part (a) of that theorem) or n (in its part (b)); applied to negated pairs, the one-index case gives a few more, as the remark below explains. The last clause of part (a) is Corollary 16.3.6. Part (b), read the same way, is Corollary 16.6.5. Here is the hierarchy, one row per index set.

index set	Theorem 16.7.1 gives	Theorem 16.7.2 gives
(i), one index	Theorem 16.2.3, max–min line	Theorem 16.3.3 with one index 1 or n (and, through negation, with $i+j-1=n$); Corollary 16.3.6
$(1, \dots, k)$	Theorem 16.6.2	Corollary 16.6.5
any other, such as $(2, 4)$	new	new

Remark. **Not all of Weyl's inequalities are cases of Lidskii's.** To test this fairly, Theorem 16.7.2 must be allowed every pair it can see: all pairs of matrices among $\pm\mathbf{X}$, $\pm\mathbf{Y}$, $\pm(\mathbf{X}+\mathbf{Y})$ whose difference is another of the six. Negation matters. With it, the one-index case already reaches some Weyl inequalities with both indices inside: applied to $\mathbf{A} = -\mathbf{X}$, $\mathbf{B} = \mathbf{Y}$, whose difference is $-(\mathbf{X}+\mathbf{Y})$, and read through Lemma 16.3.2, it

gives $\lambda_n(\mathbf{X}+\mathbf{Y}) \le \lambda_{n+1-i}(\mathbf{X}) + \lambda_i(\mathbf{Y})$ for every i, which is exactly the Weyl inequality (a) with $i+j-1=n$. So a small example that ignores negation can look like a counterexample and not be one.

Even with every signed pair allowed, the family does not contain all of Weyl's. Take $n=4$ and the candidate spectra

$$\boldsymbol{\lambda}(\mathbf{X}) = (2,0,0,-1), \qquad \boldsymbol{\lambda}(\mathbf{Y}) = (2,0,0,0),$$
$$\boldsymbol{\lambda}(\mathbf{X}+\mathbf{Y}) = (2,1,1,-1).$$

The totals agree, $1+2=3$, and a direct check of every index set shows that all twelve signed pairs satisfy every inequality of Theorem 16.7.2. Yet Weyl's inequality with $i=j=2$ demands $\lambda_3(\mathbf{X}+\mathbf{Y}) \le \lambda_2(\mathbf{X}) + \lambda_2(\mathbf{Y}) = 0$, and here $\lambda_3(\mathbf{X}+\mathbf{Y}) = 1$. Since Theorem 16.3.3 is a theorem, no Hermitian $\mathbf{X}$, $\mathbf{Y}$ have these spectra: the lists are ruled out by Weyl and not by Lidskii.

Remark. **The majorization form.** Section 8 introduces the language that turns this family of inequalities into a single statement. We record the translation here, together with exactly what has been proved. For a real vector $\mathbf{x} \in \mathbb{R}^n$, the sum of its k largest entries is the largest value of $\sum_{i\in S} x_i$ over the sets S of k positions: sorting the entries shows that the k largest do best. Apply this to $\mathbf{x} = \boldsymbol{\lambda}(\mathbf{A}) - \boldsymbol{\lambda}(\mathbf{B})$, whose i-th entry is $\lambda_i(\mathbf{A}) - \lambda_i(\mathbf{B})$ and which need not be decreasing. Then Theorem 16.7.2, over all index sets of size k, says that the k largest entries of $\boldsymbol{\lambda}(\mathbf{A}) - \boldsymbol{\lambda}(\mathbf{B})$ add up to at most $\sum_{j\le k} \lambda_j(\mathbf{A}-\mathbf{B})$, for every k. The two vectors also have the same total, $\operatorname{tr}\mathbf{A} - \operatorname{tr}\mathbf{B} = \operatorname{tr}(\mathbf{A}-\mathbf{B})$. In the notation of Section 8 this is

$$\boldsymbol{\lambda}(\mathbf{A}) - \boldsymbol{\lambda}(\mathbf{B}) \;\prec\; \boldsymbol{\lambda}(\mathbf{A}-\mathbf{B}).$$

Proved here: every inequality in this majorization, namely Theorem 16.7.2 for every index set, and the equality of totals, which is the trace. **Not proved here, and left to Chapter 20:** the general consequences of a majorization $\mathbf{x} \prec \mathbf{y}$, namely $\sum_i \phi(x_i) \le \sum_i \phi(y_i)$ for every convex $\phi\colon \mathbb{R} \to \mathbb{R}$, together with the matching statement for the unitarily invariant norms of that chapter. Applied to the display above, they bound $\sum_i \phi\big(\lambda_i(\mathbf{A}) - \lambda_i(\mathbf{B})\big)$ by $\sum_i \phi\big(\lambda_i(\mathbf{A}-\mathbf{B})\big)$ for every convex ϕ. One case, $\phi(t) = |t|$, follows from this section directly, and exercise C2 proves it. Nothing in this chapter uses the general case.

16.7.5 What the flags bought

Courant–Fischer turned each eigenvalue into an optimization that two matrices can share, and the comparison theorems of §§02–05 followed one index at a time. Ky Fan did the same for the top partial sums. Wielandt's theorem does it for every sum, at the price of optimizing over flags instead of subspaces, and Lidskii's inequality is what the shared optimization yields: the eigenvalue shifts $\lambda_i(\mathbf{A}) - \lambda_i(\mathbf{B})$, summed over **any** k indices, never exceed the top k eigenvalues of $\mathbf{A}-\mathbf{B}$. The single idea behind it is the one the first subsection isolated. A comparison of sums needs one orthonormal list that serves both matrices, and a flag is exactly the structure that lets such a list be found by counting.

16.7.6 Exercises

16.7.6.1 A. Check your understanding

Exercise A1.

(a) Define a flag of type $(i_1, \dots, i_k)$ in F^n and a list adapted to it.

(b) State the max–min formula of Theorem 16.7.1, and name the index sets for which it reduces to Theorem 16.2.3 and to Theorem 16.6.2.

(c) Determine whether the following is true, and justify your answer: if $(\mathbf{x}_1, \dots, \mathbf{x}_k)$ is adapted to a flag $(W_1, \dots, W_k)$, then $\operatorname{span}(\mathbf{x}_1, \dots, \mathbf{x}_j) = W_j$ for every j.

(d) Determine whether the following is true for all Hermitian $\mathbf{A}, \mathbf{B} \in M_n(F)$, and justify your answer: $\lambda_2(\mathbf{A}) - \lambda_2(\mathbf{B}) \le \lambda_2(\mathbf{A} - \mathbf{B})$.

(e) In the proof of Theorem 16.7.2, which part of Theorem 16.7.1 is applied to $\mathbf{A}$, which to $\mathbf{B}$, and with which flag?

Solution.

(a) For an index set $1 \le i_1 < \cdots < i_k \le n$, a flag of that type is a list $(W_1, \dots, W_k)$ of subspaces of F^n with $W_1 \subseteq \cdots \subseteq W_k$ and $\dim W_j = i_j$. A list $(\mathbf{x}_1, \dots, \mathbf{x}_k)$ is adapted to it if it is orthonormal and $\mathbf{x}_j \in W_j$ for every j.

(b) $\sum_j \lambda_{i_j}(\mathbf{A})$ is the maximum over flags $\mathcal{W}$ of type $(i_1, \dots, i_k)$ of the minimum of $\sum_j \langle \mathbf{A}\mathbf{x}_j, \mathbf{x}_j \rangle$ over lists adapted to $\mathcal{W}$. For $k = 1$, with index set (i), it is the max–min line of Courant–Fischer for λ_i. For the initial segment $(1, \dots, k)$ it is Ky Fan's theorem for $\sum_{j \le k} \lambda_j$.

(c) False in general. The span of j orthonormal vectors has dimension j, while $\dim W_j = i_j$, which exceeds j unless $i_j = j$. For instance, with $k = 1$ and the flag $W_1 = \mathbb{R}^2$ of type (2), the adapted list $(\mathbf{e}_1)$ spans a line. What is true is $\operatorname{span}(\mathbf{x}_1, \dots, \mathbf{x}_j) \subseteq W_j$.

(d) False. With $\mathbf{A} = \operatorname{diag}(1, 1)$ and $\mathbf{B} = \operatorname{diag}(1, 0)$, the left side is $1 - 0 = 1$ and $\lambda_2(\mathbf{A} - \mathbf{B}) = \lambda_2(\operatorname{diag}(0, 1)) = 0$. The correct bound, from Theorem 16.7.2 with $k = 1$, is $\lambda_1(\mathbf{A} - \mathbf{B})$.

(e) The flag is the eigenflag $\mathcal{W}^{\mathbf{A}}$ of $\mathbf{A}$ for the given index set. Part (b) is applied to $\mathbf{A}$: every list adapted to $\mathcal{W}^{\mathbf{A}}$ has $\mathbf{A}$-sum at least $\sum_j \lambda_{i_j}(\mathbf{A})$. Part (a) is applied to $\mathbf{B}$ with the same flag: some adapted list has $\mathbf{B}$-sum at most $\sum_j \lambda_{i_j}(\mathbf{B})$.

16.7.6.2 B. Practice

Exercise B1: Running the selection.

Let $\mathbf{A} = \operatorname{diag}(4, 1, -1) \in M_3(\mathbb{R})$, take the index set $(1, 3)$, and let $\mathcal{W}$ be the flag $W_1 = \operatorname{span}\big((1, 1, 1)\big) \subset W_2 = \mathbb{R}^3$.

(a) Compute $\lambda_1(\mathbf{A}) + \lambda_3(\mathbf{A})$, and show directly that every list adapted to the eigenflag $\operatorname{span}(\mathbf{e}_1) \subset \mathbb{R}^3$ has sum at least this number.

(b) Follow the proof of Theorem 16.7.1 (a) for $\mathcal{W}$: find $J(W_1)$ and $J(W_2)$, select $\mathbf{x}_1, \mathbf{x}_2$, apply Gram–Schmidt, and compute $\sum_j \langle \mathbf{A}\mathbf{y}_j, \mathbf{y}_j \rangle$.

(c) Compute the compression $\mathbf{B}$ of $\mathbf{A}$ to $\operatorname{span}(\mathbf{y}_1, \mathbf{y}_2)$ and its eigenvalues, and check $\lambda_j(\mathbf{B}) \le \lambda_{i_j}(\mathbf{A})$ for $j = 1, 2$.

(d) Find the minimum of $\sum_j \langle \mathbf{A}\mathbf{x}_j, \mathbf{x}_j \rangle$ over all lists adapted to $\mathcal{W}$. Is it the value found in (b)?

Solution.

(a) The eigenvalues are $4, 1, -1$ with eigenvectors $\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3$, so $\lambda_1 + \lambda_3 = 3$, and $\operatorname{span}(\mathbf{e}_1) \subset \mathbb{R}^3$ is the eigenflag of type $(1, 3)$. An adapted list has $\mathbf{x}_1 = \pm\mathbf{e}_1$, the unit vectors of the line, so $\langle \mathbf{A}\mathbf{x}_1, \mathbf{x}_1 \rangle = 4$. Its $\mathbf{x}_2$ is a unit vector orthogonal to $\mathbf{e}_1$, so $\mathbf{x}_2 = (0, b, c)$ with $b^2 + c^2 = 1$, and $\langle \mathbf{A}\mathbf{x}_2, \mathbf{x}_2 \rangle = b^2 - c^2 \ge -1$. The sum is at least $4 - 1 = 3$, with equality at $\mathbf{x}_2 = \pm\mathbf{e}_3$, as part (b) of the theorem says.

(b) Here $L_p = \operatorname{span}(\mathbf{e}_p, \dots, \mathbf{e}_3)$. The line W_1 is spanned by $\mathbf{w} = (1, 1, 1)$, whose first entry is non-zero, so $W_1 \cap L_2 = \{\mathbf{0}\}$ and $J(W_1) = \{1\}$. For $W_2 = \mathbb{R}^3$, $J(W_2) = \{1, 2, 3\}$. The greedy rule gives $q_1 = 1$ with $\mathbf{x}_1 = \mathbf{w}$, and $q_2 = \max\{2, 3\} = 3$ with $\mathbf{x}_2 = \mathbf{e}_3$. The counts of Claim 4 hold: for $j = 1$, both q's are $\ge i_1 = 1$; for $j = 2$, $q_2 = 3 \ge i_2 = 3$. Gram–Schmidt gives $\mathbf{y}_1 = \frac{1}{\sqrt{3}}(1, 1, 1)$ and

$$\mathbf{e}_3 - \langle \mathbf{e}_3, \mathbf{y}_1 \rangle \mathbf{y}_1 = \tfrac{1}{3}(-1, -1, 2), \qquad \mathbf{y}_2 = \tfrac{1}{\sqrt{6}}(-1, -1, 2).$$

Then $\langle \mathbf{A}\mathbf{y}_1, \mathbf{y}_1 \rangle = \frac{1}{3}(4 + 1 - 1) = \frac{4}{3}$ and $\langle \mathbf{A}\mathbf{y}_2, \mathbf{y}_2 \rangle = \frac{1}{6}(4 + 1 - 4) = \frac{1}{6}$, so the sum is $\frac{3}{2} \le 3$, as the theorem requires.

(c) The off-diagonal entry is $\langle \mathbf{A}\mathbf{y}_2, \mathbf{y}_1 \rangle = \frac{1}{\sqrt{18}}(-4 - 1 - 2) = -\frac{7}{3\sqrt{2}}$, so

$$\mathbf{B} = \begin{pmatrix} 4/3 & -7/(3\sqrt{2}) \\ -7/(3\sqrt{2}) & 1/6 \end{pmatrix}, \qquad \operatorname{tr} \mathbf{B} = \tfrac{3}{2}, \quad \det \mathbf{B} = \tfrac{2}{9} - \tfrac{49}{18} = -\tfrac{5}{2}.$$

The characteristic polynomial is $t^2 - \frac{3}{2}t - \frac{5}{2}$, that is $\frac{1}{2}(2t - 5)(t + 1)$, so $\lambda_1(\mathbf{B}) = \frac{5}{2} \le 4 = \lambda_1(\mathbf{A})$ and $\lambda_2(\mathbf{B}) = -1 \le -1 = \lambda_3(\mathbf{A})$. The second is an equality, as it must be: Theorem 16.6.1 with $n = 3$, $k = 2$ gives the reverse bound $\lambda_2(\mathbf{B}) \ge \lambda_3(\mathbf{A})$.

(d) An adapted list has $\mathbf{x}_1 = \pm\mathbf{y}_1$, contributing $\frac{4}{3}$, and $\mathbf{x}_2$ is any unit vector of $\mathbf{w}^\perp$. By Lemma 16.2.2 the smallest value of $\langle \mathbf{A}\mathbf{x}_2, \mathbf{x}_2 \rangle$ there is the smallest eigenvalue of the compression of $\mathbf{A}$ to $\mathbf{w}^\perp$. With the orthonormal basis $\frac{1}{\sqrt{2}}(1, -1, 0)$, $\frac{1}{\sqrt{6}}(1, 1, -2)$ of $\mathbf{w}^\perp$, that compression is

$$\begin{pmatrix} 5/2 & \sqrt{3}/2 \\ \sqrt{3}/2 & 1/6 \end{pmatrix},$$

with trace $\frac{8}{3}$, determinant $\frac{5}{12} - \frac{3}{4} = -\frac{1}{3}$, and characteristic polynomial $\frac{1}{3}(3t^2 - 8t - 1)$. Its smaller eigenvalue is $\frac{1}{3}(4 - \sqrt{19})$. So the minimum over lists adapted to $\mathcal{W}$ is

$$\tfrac{4}{3} + \tfrac{1}{3}(4 - \sqrt{19}) = \tfrac{1}{3}(8 - \sqrt{19}) \approx 1.214.$$

This is smaller than $\frac{3}{2}$. The construction in the proof finds **an** adapted list below the bound 3, which is all part (a) asks; it need not find the best one. Both numbers are below 3, the value at the eigenflag, as part (c) requires.

Exercise B2: A complex pair.

Let
$$\mathbf{A} = \begin{pmatrix} 2 & 1+i \\ 1-i & 1 \end{pmatrix}, \qquad \mathbf{B} = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \quad \text{in } M_2(\mathbb{C}).$$

(a) Check that $\mathbf{A}$ and $\mathbf{B}$ are Hermitian, and compute $\boldsymbol{\lambda}(\mathbf{A})$, $\boldsymbol{\lambda}(\mathbf{B})$ and $\boldsymbol{\lambda}(\mathbf{A}-\mathbf{B})$.

(b) Verify Theorem 16.7.2 for all three index sets, and say which inequality is an equality and why it had to be.

(c) Verify both bounds of Corollary 16.7.3 (a), and explain why here every $\lambda_i(\mathbf{A}) - \lambda_i(\mathbf{B})$ had to be non-negative.

Solution.

(a) The diagonal of $\mathbf{A}$ is real and $a_{21} = 1 - i = \overline{a_{12}}$, so $\mathbf{A}^* = \mathbf{A}$; $\mathbf{B}$ is real diagonal. For $\mathbf{A}$, $\operatorname{tr}\mathbf{A} = 3$ and $\det\mathbf{A} = 2-(1+i)(1-i) = 2-2 = 0$, so $\boldsymbol{\lambda}(\mathbf{A}) = (3,0)$. Next, $\boldsymbol{\lambda}(\mathbf{B}) = (1,-1)$. Finally
$$\mathbf{A}-\mathbf{B} = \begin{pmatrix} 1 & 1+i \\ 1-i & 2 \end{pmatrix}$$
has trace 3 and determinant $2-2=0$, so $\boldsymbol{\lambda}(\mathbf{A}-\mathbf{B}) = (3,0)$.

(b) The differences at equal indices are $3-1=2$ and $0-(-1)=1$. For (1): $2 \le 3$. For (2): $1 \le 3$. For $(1,2)$: $3 \le 3+0=3$, an equality. It had to be one, since for the full index set both sides equal $\operatorname{tr}\mathbf{A} - \operatorname{tr}\mathbf{B} = \operatorname{tr}(\mathbf{A}-\mathbf{B})$.

(c) The bounds are $\lambda_2(\mathbf{A}-\mathbf{B}) = 0 \le 2 \le 3$ and $0 \le 1 \le 3$. The lower bound $\lambda_n(\mathbf{A}-\mathbf{B}) = 0$ is non-negative because $\mathbf{A}-\mathbf{B} \succeq 0$: it is Hermitian with eigenvalues $3, 0 \ge 0$ (Theorem 12.1.4). So $\mathbf{A} \succeq \mathbf{B}$, and Corollary 16.2.4 already forces $\lambda_i(\mathbf{A}) \ge \lambda_i(\mathbf{B})$ for each i.

Exercise B3: The lower bound.

Let $\mathbf{A}, \mathbf{B} \in M_n(F)$ be Hermitian and $1 \le i_1 < \cdots < i_k \le n$. Prove that
$$\sum_{j=1}^{k} \lambda_{i_j}(\mathbf{A}) - \sum_{j=1}^{k} \lambda_{i_j}(\mathbf{B}) \;\ge\; \sum_{j=n-k+1}^{n} \lambda_j(\mathbf{A}-\mathbf{B}),$$
that is, the shifts over any k indices add up to at least the k **smallest** eigenvalues of $\mathbf{A}-\mathbf{B}$. Check the result on Example (All seven index sets).

Solution. Apply Theorem 16.7.2 with the roles of $\mathbf{A}$ and $\mathbf{B}$ exchanged:
$$\sum_{j=1}^{k} \lambda_{i_j}(\mathbf{B}) - \sum_{j=1}^{k} \lambda_{i_j}(\mathbf{A}) \;\le\; \sum_{j=1}^{k} \lambda_j(\mathbf{B}-\mathbf{A}).$$
Since $\mathbf{B}-\mathbf{A} = -(\mathbf{A}-\mathbf{B})$, Lemma 16.3.2 gives $\lambda_j(\mathbf{B}-\mathbf{A}) = -\lambda_{n+1-j}(\mathbf{A}-\mathbf{B})$. As j runs over $1,\dots,k$, the index $n+1-j$ runs over $n,\dots,n-k+1$, so the right-hand side is $-\sum_{j=n-k+1}^{n}\lambda_j(\mathbf{A}-\mathbf{B})$. Multiplying the inequality by -1 gives the claim.

In Example (All seven index sets), $\boldsymbol{\lambda}(\mathbf{A}-\mathbf{B}) = (4,1,-3)$, whose bottom partial sums are -3, -2, 2 for $k=1,2,3$. The left sides are $2, 1, -1$ for $k=1$, then $3, 1, 0$ for $k=2$, then 2 for $k=3$. Each is at least the corresponding bottom sum.

16.7.6.3 C. Going deeper

Exercise C1: A second proof of Lidskii's inequality.

Let $\mathbf{A}, \mathbf{B} \in M_n(F)$ be Hermitian, put $\mathbf{C} = \mathbf{A} - \mathbf{B}$, and fix an index set $1 \le i_1 < \cdots < i_k \le n$.

(a) Let $c \in \mathbb{R}$. Show that replacing $\mathbf{A}$ by $\mathbf{A} - c\mathbf{I}$, with $\mathbf{B}$ unchanged, lowers both sides of Theorem 16.7.2 by kc. Deduce that it suffices to prove the inequality when $\lambda_k(\mathbf{C}) = 0$.

(b) Assume $\lambda_k(\mathbf{C}) = 0$. Write $\mathbf{C} = \mathbf{U}\mathbf{D}\mathbf{U}^*$ with $\mathbf{U}$ unitary and $\mathbf{D} = \operatorname{diag}(\lambda_1(\mathbf{C}), \dots, \lambda_n(\mathbf{C}))$, and put $\mathbf{C}_+ = \mathbf{U}\mathbf{D}_+\mathbf{U}^*$, where $\mathbf{D}_+$ replaces each negative diagonal entry of $\mathbf{D}$ by 0. Prove that $\mathbf{C}_+ \succeq \mathbf{C}$, $\mathbf{C}_+ \succeq 0$ and $\operatorname{tr} \mathbf{C}_+ = \sum_{j \le k} \lambda_j(\mathbf{C})$.

(c) Prove that $\lambda_i(\mathbf{A}) \le \lambda_i(\mathbf{B} + \mathbf{C}_+)$ and $\lambda_i(\mathbf{B} + \mathbf{C}_+) \ge \lambda_i(\mathbf{B})$ for every i, and deduce Theorem 16.7.2.

(d) Which of the ingredients of this proof were available before this section? What does this proof not give that Theorem 16.7.1 does?

Hint: *Corollary 16.2.4*.

Solution.

(a) For every Hermitian $\mathbf{M}$ and real c, $\lambda_i(\mathbf{M} - c\mathbf{I}) = \lambda_i(\mathbf{M}) - c$ for all i. Indeed, if $\mathbf{M} = \mathbf{U}\mathbf{D}\mathbf{U}^*$ with $\mathbf{U}$ unitary and $\mathbf{D}$ real diagonal (Corollary 11.4.3, or Corollary 11.5.2 over $\mathbb{R}$), then $\mathbf{M} - c\mathbf{I} = \mathbf{U}(\mathbf{D} - c\mathbf{I})\mathbf{U}^*$, and subtracting c from every diagonal entry keeps the order. Replacing $\mathbf{A}$ by $\mathbf{A} - c\mathbf{I}$ lowers each $\lambda_{i_j}(\mathbf{A})$ by c, so the left side drops by kc. It also replaces $\mathbf{C}$ by $\mathbf{C} - c\mathbf{I}$, so each $\lambda_j(\mathbf{C})$ drops by c and the right side drops by kc. So the inequality for $(\mathbf{A} - c\mathbf{I}, \mathbf{B})$ is equivalent to the one for $(\mathbf{A}, \mathbf{B})$. With $c = \lambda_k(\mathbf{C})$, the new difference $\mathbf{C} - c\mathbf{I}$ has $\lambda_k = 0$.

(b) $\mathbf{C}_+ - \mathbf{C} = \mathbf{U}(\mathbf{D}_+ - \mathbf{D})\mathbf{U}^*$, and $\mathbf{D}_+ - \mathbf{D}$ is diagonal with entries $\max(-\lambda_i(\mathbf{C}), 0) \ge 0$. So $\mathbf{C}_+ - \mathbf{C}$ is Hermitian with non-negative eigenvalues, hence $\mathbf{C}_+ - \mathbf{C} \succeq 0$ by Theorem 12.1.4, that is, $\mathbf{C}_+ \succeq \mathbf{C}$. In the same way $\mathbf{C}_+ \succeq 0$, since the entries of $\mathbf{D}_+$ are ≥ 0. For the trace, $\operatorname{tr} \mathbf{C}_+ = \operatorname{tr} \mathbf{D}_+ = \sum_i \max(\lambda_i(\mathbf{C}), 0)$ by Theorem 0.9.6 (3). For $i \le k$, $\lambda_i(\mathbf{C}) \ge \lambda_k(\mathbf{C}) = 0$, so the term is $\lambda_i(\mathbf{C})$. For $i > k$, $\lambda_i(\mathbf{C}) \le 0$, so the term is 0. Hence $\operatorname{tr} \mathbf{C}_+ = \sum_{j \le k} \lambda_j(\mathbf{C})$.

(c) $\mathbf{A} = \mathbf{B} + \mathbf{C} \preceq \mathbf{B} + \mathbf{C}_+$ by (b), and $\mathbf{B} + \mathbf{C}_+ \succeq \mathbf{B}$ because $\mathbf{C}_+ \succeq 0$. Corollary 16.2.4 turns both into the stated eigenvalue inequalities. Therefore

$$\begin{aligned} \sum_{j=1}^{k} \big(\lambda_{i_j}(\mathbf{A}) - \lambda_{i_j}(\mathbf{B})\big) &\le \sum_{j=1}^{k} \big(\lambda_{i_j}(\mathbf{B} + \mathbf{C}_+) - \lambda_{i_j}(\mathbf{B})\big) \\ &\le \sum_{i=1}^{n} \big(\lambda_i(\mathbf{B} + \mathbf{C}_+) - \lambda_i(\mathbf{B})\big), \end{aligned}$$

the second step adding the $n - k$ omitted terms, each ≥ 0. The last sum is $\operatorname{tr}(\mathbf{B} + \mathbf{C}_+) - \operatorname{tr} \mathbf{B} = \operatorname{tr} \mathbf{C}_+$, by Corollary 11.1.4 and Theorem 0.9.6 (1), and $\operatorname{tr} \mathbf{C}_+ = \sum_{j \le k} \lambda_j(\mathbf{C})$ by (b).

(d) Everything used here was available after §02: the spectral theorem, the characterization of positive semidefiniteness by eigenvalues, the trace, and Corollary 16.2.4. The proof never looks at a flag. What it does not give is the variational description

itself. Theorem 16.7.1 expresses $\sum_j \lambda_{i_j}(\mathbf{A})$ as an optimization involving $\mathbf{A}$ alone, and like Courant–Fischer and Ky Fan before it, such a description can be reused for other comparisons. This proof is a clever route to one consequence of that description.

Exercise C2: The total absolute shift.

Let $\mathbf{A}, \mathbf{B} \in M_n(F)$ be Hermitian.

(a) Prove that
$$\sum_{i=1}^{n} \big|\lambda_i(\mathbf{A}) - \lambda_i(\mathbf{B})\big| \;\le\; \sum_{i=1}^{n} \big|\lambda_i(\mathbf{A} - \mathbf{B})\big|.$$

(b) Show that equality holds when $\mathbf{A} \succeq \mathbf{B}$. Compute both sides for Example (All seven index sets), and compare with the bound $n\|\mathbf{A} - \mathbf{B}\|_2$ obtained by adding the bounds of Corollary 16.3.6.

Hint for (a): use the set of indices at which $\lambda_i(\mathbf{A}) > \lambda_i(\mathbf{B})$.

Solution.

(a) Write $d_i = \lambda_i(\mathbf{A}) - \lambda_i(\mathbf{B})$ and $\mu_j = \lambda_j(\mathbf{A} - \mathbf{B})$. Let $S = \{i : d_i > 0\}$ and $k = |S|$. Then
$$\sum_{i=1}^{n} |d_i| = \sum_{i \in S} d_i - \sum_{i \notin S} d_i = 2\sum_{i \in S} d_i - \sum_{i=1}^{n} d_i.$$
The total is $\sum_i d_i = \operatorname{tr}\mathbf{A} - \operatorname{tr}\mathbf{B} = \operatorname{tr}(\mathbf{A} - \mathbf{B}) = \sum_j \mu_j$, by Corollary 11.1.4 and Theorem 0.9.6 (1). If $k \ge 1$, Theorem 16.7.2 with the elements of S as index set gives $\sum_{i \in S} d_i \le \sum_{j \le k} \mu_j$; if $k = 0$ both sides of this inequality are the empty sum 0. In either case
$$\sum_{i=1}^{n} |d_i| \;\le\; 2\sum_{j \le k} \mu_j - \sum_{j=1}^{n} \mu_j = \sum_{j \le k} \mu_j - \sum_{j > k} \mu_j \;\le\; \sum_{j=1}^{n} |\mu_j|,$$
the last step because $\pm\mu_j \le |\mu_j|$ for each j.

(b) If $\mathbf{A} \succeq \mathbf{B}$ then every $d_i \ge 0$ by Corollary 16.2.4, and every $\mu_j \ge 0$ by Theorem 12.1.4. Both sides then equal their plain sums, and those are equal, both being $\operatorname{tr}(\mathbf{A} - \mathbf{B})$.

In Example (All seven index sets), the d_i are $2, 1, -1$, so the left side is 4; the μ_j are $4, 1, -3$, so the right side is 8. By Lemma 16.3.5, $\|\mathbf{A} - \mathbf{B}\|_2 = \max(4, 3) = 4$, and adding the three bounds of Corollary 16.3.6 gives $3 \cdot 4 = 12$. The bound of (a) is never worse than this one: each $|\mu_j| \le \|\mathbf{A} - \mathbf{B}\|_2$, so the right side of (a) is at most $n\|\mathbf{A} - \mathbf{B}\|_2$, and it is often much smaller.

16.8 The Diagonal and the Spectrum

A Hermitian matrix carries two lists of n real numbers: its diagonal entries, read off at a glance, and its eigenvalues, computed with effort. Since Chapter 8 we have known that the two lists have the same sum, the trace. This section asks what else the eigenvalues force on the diagonal, and answers the question completely. The answer needs a name, **majorization**. One half of it, Schur's theorem, is §06's bound on partial sums of the diagonal in the new language. The other half, Horn's theorem, says that nothing more is forced; it is proved by an induction driven by a single 2×2 rotation. The section ends with a short second proof of Hadamard's determinant inequality.

Throughout, the field is $\mathbb{R}$ or $\mathbb{C}$, and every matrix whose eigenvalues are indexed is Hermitian, with its eigenvalues real and listed **decreasingly** with multiplicity, $\lambda_1(\mathbf{A}) \geq \cdots \geq \lambda_n(\mathbf{A})$. Two vectors in $\mathbb{R}^n$ are attached to such an $\mathbf{A} \in M_n(F)$:

$$\mathbf{d}(\mathbf{A}) = (a_{11}, a_{22}, \ldots, a_{nn}),$$
$$\boldsymbol{\lambda}(\mathbf{A}) = \big(\lambda_1(\mathbf{A}), \lambda_2(\mathbf{A}), \ldots, \lambda_n(\mathbf{A})\big).$$

The first is the **diagonal vector**, in the order the entries sit on the diagonal; the second is the **eigenvalue vector**, always in decreasing order. The diagonal entries are real because $\mathbf{A}^* = \mathbf{A}$ gives $a_{ii} = \overline{a_{ii}}$, and the eigenvalues are real by Theorem 11.2.1. The bold $\mathbf{d}(\mathbf{A})$ is a vector, not the diagonal matrix $\operatorname{diag}(a_{11}, \ldots, a_{nn})$.

Two facts about a Hermitian $\mathbf{A}$ are used below. The spectral theorem (Corollary 11.4.3 over $\mathbb{C}$, Corollary 11.5.2 over $\mathbb{R}$) makes $\mathbf{A}$ similar to the real diagonal matrix of its eigenvalues, so its characteristic polynomial splits as $\prod_i (x - \lambda_i(\mathbf{A}))$. Then Theorem 8.3.3 gives

$$\operatorname{tr} \mathbf{A} = \sum_{i=1}^{n} \lambda_i(\mathbf{A}), \qquad \det \mathbf{A} = \prod_{i=1}^{n} \lambda_i(\mathbf{A}).$$

16.8.1 What the diagonal already knows

Start with the smallest interesting case. The matrix

$$\mathbf{A} = \begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix}$$

has $\mathbf{d}(\mathbf{A}) = (2, 2)$ and eigenvalues 3 and 1, with eigenvectors $(1, 1)$ and $(1, -1)$, so $\boldsymbol{\lambda}(\mathbf{A}) = (3, 1)$. The totals agree, $2 + 2 = 4 = 3 + 1$. But the two lists are not alike: the diagonal is perfectly even, while the spectrum is spread out.

A larger example shows the pattern better. The tridiagonal matrix

$$\mathbf{A} = \begin{pmatrix} 3 & 2 & 0 \\ 2 & 4 & 2 \\ 0 & 2 & 5 \end{pmatrix}$$

has eigenvectors $(1, 2, 2)$, $(-2, -1, 2)$ and $(2, -2, 1)$, with eigenvalues 7, 4 and 1. To check the first, $\mathbf{A}(1, 2, 2) = (3 + 4,\ 2 + 8 + 4,\ 4 + 10) = (7, 14, 14)$; the other two are checked the same way. So $\boldsymbol{\lambda}(\mathbf{A}) = (7, 4, 1)$, while $\mathbf{d}(\mathbf{A}) = (3, 4, 5)$. Sort the diagonal decreasingly to $(5, 4, 3)$ and compare the running totals of the two lists:

k	1	2	3
largest k diagonal entries	5	9	12
largest k eigenvalues	7	11	12

Each running total of the eigenvalues is at least the matching running total of the diagonal, and at $k = n$ the two are equal. None of this is new. Corollary 16.6.3 says that any k diagonal entries add up to at most $\lambda_1(\mathbf{A}) + \cdots + \lambda_k(\mathbf{A})$, with equality at $k = n$, and the k largest diagonal entries are one such choice. What is new is the point of view: to ask which diagonals are **possible**, the corollary's list of inequalities has to be read as a single relation between two vectors.

Two features of this comparison deserve notice. First, the diagonal had to be **sorted**, and this is forced. For a permutation matrix $\mathbf{P}_\sigma$ (Definition 2.6.2), $\mathbf{P}_\sigma^\top = \mathbf{P}_\sigma^{-1}$ by Lemma 2.6.6 (b), so $\mathbf{P}_\sigma^\top \mathbf{A} \mathbf{P}_\sigma$ is Hermitian with the same eigenvalues as $\mathbf{A}$, and its (j, j) entry is $\mathbf{e}_{\sigma(j)}^\top \mathbf{A} \mathbf{e}_{\sigma(j)} = a_{\sigma(j)\sigma(j)}$. Relabeling the basis shuffles the diagonal and fixes the spectrum, so any true relation between $\mathbf{d}(\mathbf{A})$ and $\boldsymbol{\lambda}(\mathbf{A})$ must ignore the order of the diagonal. Second, the comparison is between **running totals from the top**, and it measures how unevenly a fixed total is spread.

16.8.2 Majorization

One vector is majorized by another when the two have the same total but the second piles more of it onto its largest entries: every "top k" sum of the second is at least that of the first.

The sorting step gets a notation first. For $\mathbf{x} = (x_1, \ldots, x_n) \in \mathbb{R}^n$, the **decreasing rearrangement** $\mathbf{x}^\downarrow = (x_1^\downarrow, \ldots, x_n^\downarrow)$ is the vector with the same entries, repeated as often as in $\mathbf{x}$, listed so that $x_1^\downarrow \geq x_2^\downarrow \geq \cdots \geq x_n^\downarrow$. For example, $(0, 3, 1, 3)^\downarrow = (3, 3, 1, 0)$. In this notation, $\boldsymbol{\lambda}(\mathbf{A}) = \boldsymbol{\lambda}(\mathbf{A})^\downarrow$ by convention, while $\mathbf{d}(\mathbf{A})$ usually needs sorting.

Definition 16.8.1 — Majorization

Let $n \geq 1$ and let $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$ be **real** vectors with the **same number** of entries. We say that $\mathbf{x}$ is **majorized by** $\mathbf{y}$, and write $\mathbf{x} \prec \mathbf{y}$, if

(M1) $\displaystyle\sum_{i=1}^{k} x_i^\downarrow \leq \sum_{i=1}^{k} y_i^\downarrow$ for **every** $k = 1, \ldots, n-1$; and

(M2) $\displaystyle\sum_{i=1}^{n} x_i = \sum_{i=1}^{n} y_i$ (**equal totals**).

We say that $\mathbf{x}$ is **weakly majorized by** $\mathbf{y}$, and write $\mathbf{x} \prec_w \mathbf{y}$, if the inequality in (M1) holds for **every** $k = 1, \ldots, n$, including $k = n$, and (M2) is dropped.

In words, clause by clause. (M1) sorts both vectors and compares their **running totals from the top**: the largest entry of $\mathbf{x}$ is at most the largest entry of $\mathbf{y}$, the two largest of $\mathbf{x}$ add up to at most the two largest of $\mathbf{y}$, and so on up to $k = n - 1$. The word **every** matters: one failing k refutes $\mathbf{x} \prec \mathbf{y}$. (M2) says the totals are equal; a sum does not care about order, so no sorting is needed there. Weak majorization keeps (M1), adds its case $k = n$, which reads $\sum_i x_i \leq \sum_i y_i$, and asks nothing more. Comparing the definitions: $\mathbf{x} \prec \mathbf{y}$ holds **exactly when** $\mathbf{x} \prec_w \mathbf{y}$ and the totals are equal.

There is an equivalent way to read (M1) from the bottom. Subtracting the k-th running total from the equal totals of (M2) gives

$$\sum_{i=k+1}^{n} x_i^\downarrow \geq \sum_{i=k+1}^{n} y_i^\downarrow \qquad (k = 1, \ldots, n-1),$$

so under (M2), the $n-k$ **smallest** entries of $\mathbf{x}$ add up to at least the $n-k$ smallest entries of $\mathbf{y}$. The vector $\mathbf{y}$ is more extreme at both ends: its top is heavier and its bottom is lighter.

The definition makes sense because $\mathbf{x}^{\downarrow}$ is determined by $\mathbf{x}$: when two entries are equal, it does not matter which is written first. A consequence worth recording: **the relation sees only which numbers occur in each vector and how often, not where they sit.** If $\mathbf{x}'$ is a rearrangement of $\mathbf{x}$ and $\mathbf{y}'$ of $\mathbf{y}$, then $\mathbf{x} \prec \mathbf{y}$ if and only if $\mathbf{x}' \prec \mathbf{y}'$, because the rearrangements have the same decreasing rearrangements and the same totals.

Example. (A chain, the two extremes, and size one)

Check each claim against Definition 16.8.1.

(a) $(1,1,1) \prec (2,1,0) \prec (3,0,0)$.

(b) For every $\mathbf{x} \in \mathbb{R}^n$ with mean $m = \frac{1}{n}\sum_i x_i$, the **flat vector** $m\mathbf{1} = (m,\dots,m)$ satisfies $m\mathbf{1} \prec \mathbf{x}$.

(c) For every $\mathbf{x} \in \mathbb{R}^n$ with **non-negative** entries and total $s = \sum_i x_i$, $\mathbf{x} \prec (s,0,\dots,0)$.

(d) For $n = 1$, $\mathbf{x} \prec \mathbf{y}$ if and only if $\mathbf{x} = \mathbf{y}$.

Solution.

(a) All three vectors are already decreasing, and all have total 3, so (M2) holds for both pairs. Their running totals are

$$(1,1,1)\colon\ 1,\ 2,\ 3; \qquad (2,1,0)\colon\ 2,\ 3,\ 3; \qquad (3,0,0)\colon\ 3,\ 3,\ 3.$$

At $k = 1$ and $k = 2$ the first row is at most the second ($1 \le 2$, $2 \le 3$), and the second is at most the third ($2 \le 3$, $3 \le 3$). So (M1) holds for both pairs.

(b) The totals are $nm = \sum_i x_i$, so (M2) holds. For (M1), fix k and let $a = \frac{1}{k}\sum_{i\le k} x_i^{\downarrow}$ be the average of the k largest entries. Each of these is at least $x_k^{\downarrow}$, so $a \ge x_k^{\downarrow}$. Every remaining entry $x_j^{\downarrow}$ with $j > k$ is at most $x_k^{\downarrow}$, hence at most a. Therefore

$$nm = \sum_{i\le k} x_i^{\downarrow} + \sum_{j>k} x_j^{\downarrow} \le ka + (n-k)a = na,$$

so $m \le a$, and multiplying by k gives $km \le \sum_{i\le k} x_i^{\downarrow}$. The left side is the k-th running total of $m\mathbf{1}$. This is (M1).

(c) The totals are both s. Every running total of $(s,0,\dots,0)$ equals s, and $\sum_{i\le k} x_i^{\downarrow} \le s$ because the omitted entries $x_{k+1}^{\downarrow},\dots,x_n^{\downarrow}$ are ≥ 0. This is (M1). Non-negativity is really needed: $(1,-1)$ has total 0, but $(1,-1) \prec (0,0)$ fails at $k = 1$, since $1 > 0$.

(d) For $n = 1$ there are no values of k in (M1), since k runs from 1 to 0. So only (M2) remains, and it says $x_1 = y_1$.

Parts (b) and (c) are the two ends of the order: among vectors with a given total, the flat vector is the most evenly spread, and among non-negative ones, the vector that puts everything in one entry is the least. Part (d) is the degenerate case: with a single entry there is nothing to spread, and the relation collapses to equality.

The chain in (a) might suggest that any two vectors with the same total can be ranked this way. They cannot.

Example. (Neither majorizes the other)

Show that $\mathbf{x} = (4, 1, 1)$ and $\mathbf{y} = (3, 3, 0)$ have the same total, that neither $\mathbf{x} \prec \mathbf{y}$ nor $\mathbf{y} \prec \mathbf{x}$, and that both are majorized by $(4, 2, 0)$.

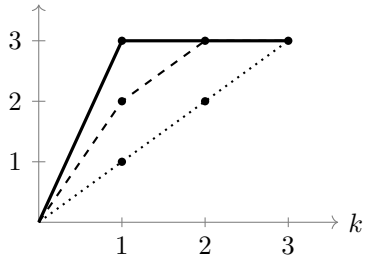
Solution. Both totals are 6, and both vectors are already decreasing. Their running totals are

$$\mathbf{x}\colon\ 4,\ 5,\ 6; \qquad \mathbf{y}\colon\ 3,\ 6,\ 6.$$

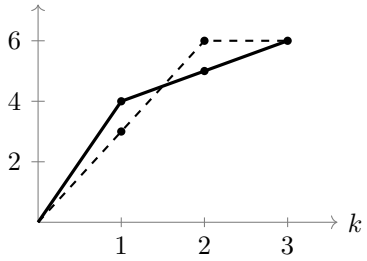
At $k = 1$, $4 > 3$, so (M1) fails for $\mathbf{x} \prec \mathbf{y}$. At $k = 2$, $6 > 5$, so (M1) fails for $\mathbf{y} \prec \mathbf{x}$. The vector $(4, 2, 0)$ has total 6 and running totals $4, 6, 6$, which are at least both $4, 5$ and $3, 6$ at $k = 1, 2$. So $\mathbf{x} \prec (4, 2, 0)$ and $\mathbf{y} \prec (4, 2, 0)$.

This is the non-example by minimal change. Start from the comparable pair $(4, 1, 1) \prec (4, 2, 0)$, move one unit in the second vector from its top entry to its middle entry to get $(3, 3, 0)$, and the pair becomes incomparable. (M2) still holds; what fails is (M1), at a **different** k in each direction. Spreading is not a single number.

The picture makes this visible. Plot the running totals of a sorted vector against k, joined by segments, starting from $(0, 0)$. Then $\mathbf{x} \prec \mathbf{y}$ says that the curve of $\mathbf{y}$ lies on or above the curve of $\mathbf{x}$ and ends at the same height. Two curves can also cross.



solid: $(3, 0, 0)$
dashed: $(2, 1, 0)$
dotted: $(1, 1, 1)$
nested, same endpoint



solid: $(4, 1, 1)$
dashed: $(3, 3, 0)$
the curves cross:
incomparable

Why this definition. Each clause earns its place, and changing any one of them changes the subject.

- *Sorting.* Relabeling a basis shuffles $\mathbf{d}(\mathbf{A})$ and fixes $\boldsymbol{\lambda}(\mathbf{A})$, so a relation comparing unsorted entries would answer a question the matrix does not pose.
- *Running totals from the top, with* $\leq$. These are the quantities that Theorem 16.6.2 and Corollary 16.6.3 control: the top k eigenvalues sum to a maximum. Totals from the bottom add nothing new, as shown above, because under (M2) they are the same information.
- *Equal totals.* This is the trace. Dropping it gives weak majorization, the right notion when there is no conservation law to enforce: $(1, 0) \prec_w (2, 0)$, but $(1, 0) \not\prec (2, 0)$, because the totals differ.

Warning. **$\mathbf{x} \prec \mathbf{y}$ does not mean $x_i \leq y_i$, not even after sorting both vectors.** In $(1, 1, 1) \prec (2, 1, 0)$, the third entries are 1 and 0, and $1 > 0$. This is no accident: subtracting (M1) at $k = n - 1$ from (M2) gives $x_n^{\downarrow} \geq y_n^{\downarrow}$ whenever $\mathbf{x} \prec \mathbf{y}$, so at the

bottom the inequality always runs the other way. Majorization compares **sums of the largest entries**, not entries one at a time.

Quick check. Arrange the five vectors $(2,1,1,0)$, $(4,0,0,0)$, $(1,1,1,1)$, $(3,1,0,0)$ and $(2,2,0,0)$ in a chain $\mathbf{x}^{(1)} \prec \mathbf{x}^{(2)} \prec \cdots \prec \mathbf{x}^{(5)}$.

Solution. All five are decreasing and all have total 4. Their running totals at $k = 1, 2, 3$ are

$$\begin{aligned} &(1,1,1,1)\colon\ 1,\ 2,\ 3; \qquad &&(2,1,1,0)\colon\ 2,\ 3,\ 4;\\ &(2,2,0,0)\colon\ 2,\ 4,\ 4; \qquad &&(3,1,0,0)\colon\ 3,\ 4,\ 4;\\ &(4,0,0,0)\colon\ 4,\ 4,\ 4. \end{aligned}$$

Read in this order, each triple is entrywise at most the next, so

$$(1,1,1,1) \prec (2,1,1,0) \prec (2,2,0,0) \prec (3,1,0,0) \prec (4,0,0,0).$$

The ends are the flat vector and the concentrated vector of Example (A chain, the two extremes, and size one) (b) and (c), as they must be. These five happen to be comparable in pairs, but Example (Neither majorizes the other) shows that this is not always so.

16.8.3 Majorization is an order

The first small result is that $\prec$ behaves like an order, and it says precisely how it falls short of being a partial order on $\mathbb{R}^n$.

Proposition 16.8.1 — Basic Properties of Majorization

Let $\mathbf{x}, \mathbf{y}, \mathbf{z} \in \mathbb{R}^n$.

(a) $\mathbf{x} \prec \mathbf{x}$.

(b) If $\mathbf{x} \prec \mathbf{y}$ and $\mathbf{y} \prec \mathbf{z}$, then $\mathbf{x} \prec \mathbf{z}$.

(c) If $\mathbf{x} \prec \mathbf{y}$ and $\mathbf{y} \prec \mathbf{x}$, then $\mathbf{x}^{\downarrow} = \mathbf{y}^{\downarrow}$; that is, $\mathbf{y}$ is a rearrangement of $\mathbf{x}$.

Statements (a) and (b) hold with $\prec_w$ in place of $\prec$.

Proof. For $k = 1, \dots, n$, write $X_k = \sum_{i \le k} x_i^{\downarrow}$, and define Y_k and Z_k in the same way. Since $X_n = \sum_i x_i$, Definition 16.8.1 says that $\mathbf{x} \prec \mathbf{y}$ means $X_k \le Y_k$ for $k < n$ and $X_n = Y_n$.

(a) $X_k \le X_k$ for every k, and $X_n = X_n$.

(b) For $k < n$, $X_k \le Y_k \le Z_k$. At $k = n$, $X_n = Y_n = Z_n$. Hence $\mathbf{x} \prec \mathbf{z}$.

(c) The hypotheses give $X_k \le Y_k$ and $Y_k \le X_k$ for $k < n$, and $X_n = Y_n$, so $X_k = Y_k$ for every $k = 1, \dots, n$. Put $X_0 = Y_0 = 0$. Then for each k,

$$x_k^{\downarrow} = X_k - X_{k-1} = Y_k - Y_{k-1} = y_k^{\downarrow},$$

so $\mathbf{x}^{\downarrow} = \mathbf{y}^{\downarrow}$. Two vectors with the same decreasing rearrangement contain the same numbers, each the same number of times, so each is a rearrangement of the other.

For $\prec_w$, the arguments for (a) and (b) are the same with every $k \le n$ treated like $k < n$. This proves the proposition.

■

So $\prec$ is reflexive and transitive. A relation with these two properties is called a **preorder**. Part (c) is antisymmetry up to rearrangement, and no more: $(1,0) \prec (0,1) \prec (1,0)$, yet $(1,0) \neq (0,1)$. So $\prec$ is **not** a partial order on $\mathbb{R}^n$. Restricted to **decreasing** vectors, where a rearrangement is the vector itself, (c) is exact antisymmetry, and there $\prec$ is a partial order. By Example (Neither majorizes the other) it is **not total**, not even among non-negative decreasing vectors with the same total. Like the Loewner order of Chapter 12 (Proposition 12.5.1), it leaves many pairs uncompared.

16.8.4 Schur's theorem

The running totals in the 3×3 example were not a coincidence. Restated in the language of majorization, §06's Corollary 16.6.3 says that for every Hermitian matrix the diagonal is more evenly spread than the spectrum:

Theorem 16.8.2 — Schur's Majorization Theorem

Let $F = \mathbb{R}$ or $F = \mathbb{C}$, and let $\mathbf{A} \in M_n(F)$ be Hermitian. Then

$$\mathbf{d}(\mathbf{A}) \prec \boldsymbol{\lambda}(\mathbf{A}).$$

Explicitly, if $\mathbf{d}(\mathbf{A})^{\downarrow} = (a_1^{\downarrow}, \dots, a_n^{\downarrow})$ lists the diagonal entries of $\mathbf{A}$ decreasingly, then

$$\begin{aligned} a_1^{\downarrow} + \cdots + a_k^{\downarrow} &\le \lambda_1(\mathbf{A}) + \cdots + \lambda_k(\mathbf{A}) \qquad (1 \le k \le n-1), \\ a_1^{\downarrow} + \cdots + a_n^{\downarrow} &= \lambda_1(\mathbf{A}) + \cdots + \lambda_n(\mathbf{A}). \end{aligned}$$

Proof. Both vectors lie in $\mathbb{R}^n$, as noted at the start of the section. Fix k with $1 \le k \le n$. List the positions $1, \dots, n$ in an order in which the diagonal entries decrease, breaking ties arbitrarily, and let $i_1 < \cdots < i_k$ be the first k positions of that list, written in increasing order. Then $a_{i_1 i_1}, \dots, a_{i_k i_k}$ are $a_1^{\downarrow}, \dots, a_k^{\downarrow}$ in some order, so Corollary 16.6.3 gives

$$a_1^{\downarrow} + \cdots + a_k^{\downarrow} = \sum_{j=1}^{k} a_{i_j i_j} \le \lambda_1(\mathbf{A}) + \cdots + \lambda_k(\mathbf{A}),$$

with equality when $k = n$. For $k \le n-1$ this is (M1). For $k = n$ it is (M2), since a sum does not depend on the order of its terms. This proves the theorem.

■

So Schur's theorem is Corollary 16.6.3 restated. What the restatement adds is a relation between two vectors, and a relation has a converse that can be asked about. Read from the bottom, (M1) says that the $n-k$ smallest diagonal entries add up to **at least** the $n-k$ smallest eigenvalues. At the two ends of Example (A chain, the two extremes, and size one), a **diagonal** matrix has $\mathbf{d}(\mathbf{A})$ a rearrangement of $\boldsymbol{\lambda}(\mathbf{A})$, the most spread a diagonal can be; a **constant** diagonal t is the flat vector $t\mathbf{1}$, where Schur's theorem says only that $nt = \lambda_1(\mathbf{A}) + \cdots + \lambda_n(\mathbf{A})$.

Example. (Coordinate vectors against eigenvectors)

For the matrix

$$\mathbf{A} = \begin{pmatrix} 3 & 2 & 0 \\ 2 & 4 & 2 \\ 0 & 2 & 5 \end{pmatrix}$$

from the start of the section, whose running totals were tabulated there, exhibit for $k = 2$ the coordinate pair that the proof of Corollary 16.6.3 feeds to Theorem 16.6.2 and an orthonormal pair that attains the maximum in Theorem 16.6.2. Account for the difference between the two sums.

Solution. We found $\boldsymbol{\lambda}(\mathbf{A}) = (7, 4, 1)$, with unit eigenvectors $\mathbf{u}_1 = \frac{1}{3}(1, 2, 2)$, $\mathbf{u}_2 = \frac{1}{3}(-2, -1, 2)$ and $\mathbf{u}_3 = \frac{1}{3}(2, -2, 1)$. They are pairwise orthogonal (for instance $\langle (1, 2, 2), (-2, -1, 2) \rangle = -2 - 2 + 4 = 0$), and each vector in parentheses has length 3.

For $k = 2$ the proof uses the two largest diagonal entries, $a_{33} = 5$ and $a_{22} = 4$, so the coordinate pair is $(\mathbf{e}_2, \mathbf{e}_3)$, and $\langle \mathbf{A}\mathbf{e}_2, \mathbf{e}_2 \rangle + \langle \mathbf{A}\mathbf{e}_3, \mathbf{e}_3 \rangle = 9$. The pair $(\mathbf{u}_1, \mathbf{u}_2)$ gives $\langle \mathbf{A}\mathbf{u}_1, \mathbf{u}_1 \rangle + \langle \mathbf{A}\mathbf{u}_2, \mathbf{u}_2 \rangle = 7 + 4 = 11$, since $\langle \mathbf{A}\mathbf{u}_i, \mathbf{u}_i \rangle = \lambda_i \|\mathbf{u}_i\|^2 = \lambda_i$. The coordinate pair falls short of the eigenvector pair by 2, and that shortfall is exactly the slack in Schur's theorem at $k = 2$. Ky Fan's maximum is attained by eigenvectors, and the diagonal only ever sees coordinate vectors.

Quick check. A Hermitian 3×3 matrix $\mathbf{A}$ has diagonal entries $4, -1, 2$. Without knowing anything else about $\mathbf{A}$, what does Theorem 16.8.2 say about $\lambda_1(\mathbf{A})$, about $\lambda_1(\mathbf{A}) + \lambda_2(\mathbf{A})$, and about $\lambda_3(\mathbf{A})$?

Solution. Sorted, $\mathbf{d}(\mathbf{A})^{\downarrow} = (4, 2, -1)$, with running totals $4, 6, 5$. So $\lambda_1(\mathbf{A}) \geq 4$, $\lambda_1(\mathbf{A}) + \lambda_2(\mathbf{A}) \geq 6$, and $\lambda_1(\mathbf{A}) + \lambda_2(\mathbf{A}) + \lambda_3(\mathbf{A}) = 5$. Subtracting the middle inequality from the last equality gives $\lambda_3(\mathbf{A}) \leq 5 - 6 = -1$. In particular $\mathbf{A}$ is indefinite, since $\lambda_1(\mathbf{A}) > 0 > \lambda_3(\mathbf{A})$, and that was visible without computing any eigenvalue.

16.8.5 Horn's converse

Schur's theorem gives a **necessary** condition on a diagonal. Is it also sufficient? Given $\mathbf{d} \prec \boldsymbol{\lambda}$, is there a Hermitian matrix with eigenvalues $\lambda_1, \ldots, \lambda_n$ and diagonal entries $d_1, \ldots, d_n$, in the given order? For $n = 2$ a rotation answers the question. Turning the eigenbasis of $\operatorname{diag}(\lambda_1, \lambda_2)$ moves its first diagonal entry through every value between λ_2 and λ_1, and the trace fixes the second entry.

Lemma 16.8.3 — The Two-by-Two Rotation

Let $\lambda_1 \geq \lambda_2$ and t be real numbers with $\lambda_2 \leq t \leq \lambda_1$. Put $b = \sqrt{(\lambda_1 - t)(t - \lambda_2)}$. Then there is an orthogonal $\mathbf{R} \in \mathrm{O}(2)$ with

$$\mathbf{R} \operatorname{diag}(\lambda_1, \lambda_2) \mathbf{R}^{\top} = \begin{pmatrix} t & b \\ b & \lambda_1 + \lambda_2 - t \end{pmatrix}.$$

Idea. If the first row of $\mathbf{R}$ is $(c, -s)$ with $c^2+s^2=1$, the $(1,1)$ entry of $\mathbf{R}\,\mathrm{diag}(\lambda_1,\lambda_2)\mathbf{R}^\top$ is $c^2\lambda_1 + s^2\lambda_2$, an average of λ_1 and λ_2 with weights c^2 and s^2. Every t between them is such an average, and solving for the weights gives c and s.

Proof. If $\lambda_1 = \lambda_2$, then $t = \lambda_1 = \lambda_2$ and $b = 0$, and $\mathbf{R} = \mathbf{I}$ works. Otherwise $\lambda_1 - \lambda_2 > 0$, and

$$c = \sqrt{\frac{t-\lambda_2}{\lambda_1-\lambda_2}}, \qquad s = \sqrt{\frac{\lambda_1 - t}{\lambda_1-\lambda_2}}$$

are real numbers, because both radicands are ≥ 0 by the hypothesis on t. They satisfy $c^2+s^2=1$. Let $\mathbf{R} = \left(\begin{smallmatrix} c & -s \\ s & c \end{smallmatrix}\right)$. Then $\mathbf{R}^\top\mathbf{R} = (c^2+s^2)\mathbf{I} = \mathbf{I}$, so $\mathbf{R} \in \mathrm{O}(2)$. Multiplying out,

$$\mathbf{R}\,\mathrm{diag}(\lambda_1,\lambda_2)\mathbf{R}^\top = \begin{pmatrix} c^2\lambda_1 + s^2\lambda_2 & cs(\lambda_1-\lambda_2) \\ cs(\lambda_1-\lambda_2) & s^2\lambda_1 + c^2\lambda_2 \end{pmatrix}.$$

Since $s^2 = 1-c^2$, the $(1,1)$ entry is $\lambda_2 + c^2(\lambda_1-\lambda_2) = \lambda_2 + (t-\lambda_2) = t$. The two diagonal entries add up to $(c^2+s^2)(\lambda_1+\lambda_2) = \lambda_1+\lambda_2$, so the $(2,2)$ entry is $\lambda_1+\lambda_2-t$. Finally $cs(\lambda_1-\lambda_2) = \sqrt{(t-\lambda_2)(\lambda_1-t)} = b$. This proves the lemma. ∎

This is the converse for $n=2$: if $\lambda_1 \geq \lambda_2$ and $(d_1,d_2) \prec (\lambda_1,\lambda_2)$, then $d_1, d_2 \leq d_1^{\downarrow} \leq \lambda_1$ by (M1), so by (M2) $d_1 = \lambda_1+\lambda_2-d_2 \geq \lambda_2$, so $t = d_1$ is allowed. For larger n, the lemma is used once, on a well-chosen pair of eigenvalues, to put d_1 in the corner, and induction does the rest.

Theorem 16.8.4 — Horn's Theorem

Let $n \geq 1$, and let $\mathbf{d} = (d_1,\ldots,d_n)$ and $\boldsymbol{\lambda} = (\lambda_1,\ldots,\lambda_n)$ be vectors in $\mathbb{R}^n$ with $\mathbf{d} \prec \boldsymbol{\lambda}$. Then there is an orthogonal $\mathbf{Q} \in \mathrm{O}(n)$ such that the matrix

$$\mathbf{A} = \mathbf{Q}\,\mathrm{diag}(\lambda_1,\ldots,\lambda_n)\mathbf{Q}^\top$$

has diagonal entries $d_1, d_2, \ldots, d_n$, **in this order**. So $\mathbf{A}$ is a real symmetric matrix with $\mathbf{d}(\mathbf{A}) = \mathbf{d}$ and $\boldsymbol{\lambda}(\mathbf{A}) = \boldsymbol{\lambda}^{\downarrow}$.

Idea. Induction on n, one diagonal entry at a time.

① Permutation matrices are orthogonal and shuffle diagonal entries, so it is enough to treat $\mathbf{d}$ and $\boldsymbol{\lambda}$ both decreasing. ② The top and bottom clauses of majorization put d_1 between λ_n and λ_1, hence between two **consecutive** eigenvalues, $\lambda_k \geq d_1 \geq \lambda_{k+1}$. The lemma rotates that pair so that d_1 sits in the corner, with $\eta = \lambda_k + \lambda_{k+1} - d_1$ next to it. ③ The Claim: what is left over, the diagonal $d_2,\ldots,d_n$ and the spectrum with λ_k, λ_{k+1} replaced by η, satisfies the hypothesis again, in size $n-1$. ④ Induction rotates the lower $(n-1)\times(n-1)$ block into place without touching the corner.

Step ③ is where the choice of k matters.

Proof. For every $\mathbf{Q} \in \mathrm{O}(n)$, the matrix $\mathbf{A} = \mathbf{Q}\,\mathrm{diag}(\lambda_1,\ldots,\lambda_n)\mathbf{Q}^\top$ is real and symmetric, and by Corollary 11.5.2 its eigenvalues, with multiplicity, are $\lambda_1,\ldots,\lambda_n$; listed decreasingly they form $\boldsymbol{\lambda}^{\downarrow}$. So only the diagonal needs work. We use two facts repeatedly. A product of orthogonal matrices is orthogonal, since $(\mathbf{XY})^\top\mathbf{XY} = \mathbf{Y}^\top\mathbf{X}^\top\mathbf{XY} = \mathbf{I}$. And

for a permutation $\pi \in S_n$ and any $\mathbf{M} \in M_n(\mathbb{R})$, Definition 2.6.2 gives

$$(\mathbf{P}_\pi^\top \mathbf{M} \mathbf{P}_\pi)_{ij} = \mathbf{e}_{\pi(i)}^\top \mathbf{M} \mathbf{e}_{\pi(j)} = m_{\pi(i)\pi(j)}, \tag{$\dagger$}$$

where $\mathbf{P}_\pi$ is orthogonal by Lemma 2.6.6 (b).

Step 1: reduction to decreasing vectors. Suppose the theorem holds whenever $\mathbf{d}$ and $\boldsymbol{\lambda}$ are both decreasing, and let $\mathbf{d} \prec \boldsymbol{\lambda}$ be arbitrary. Majorization sees only rearrangements (as noted after Definition 16.8.1), so $\mathbf{d}^\downarrow \prec \boldsymbol{\lambda}^\downarrow$, and there is $\mathbf{Q}_0 \in \mathrm{O}(n)$ such that $\mathbf{B} = \mathbf{Q}_0 \operatorname{diag}(\boldsymbol{\lambda}^\downarrow)\mathbf{Q}_0^\top$ has diagonal $\mathbf{d}^\downarrow$. Here $\operatorname{diag}(\boldsymbol{\lambda}^\downarrow)$ is the diagonal matrix with diagonal $\lambda_1^\downarrow, \dots, \lambda_n^\downarrow$. Since $\boldsymbol{\lambda}^\downarrow$ is a rearrangement of $\boldsymbol{\lambda}$, and $\mathbf{d}^\downarrow$ of $\mathbf{d}$, there are permutations $\sigma, \tau \in S_n$ with $\lambda_{\sigma(i)} = \lambda_i^\downarrow$ and $d_{\tau(j)}^\downarrow = d_j$ for all i, j. By ($\dagger$), $\mathbf{P}_\sigma^\top \operatorname{diag}(\lambda_1, \dots, \lambda_n)\mathbf{P}_\sigma = \operatorname{diag}(\boldsymbol{\lambda}^\downarrow)$, and the (j, j) entry of $\mathbf{P}_\tau^\top \mathbf{B} \mathbf{P}_\tau$ is $b_{\tau(j)\tau(j)} = d_{\tau(j)}^\downarrow = d_j$. So $\mathbf{Q} = \mathbf{P}_\tau^\top \mathbf{Q}_0 \mathbf{P}_\sigma^\top$ is orthogonal and

$$\begin{aligned} \mathbf{Q} \operatorname{diag}(\lambda_1, \dots, \lambda_n)\mathbf{Q}^\top &= \mathbf{P}_\tau^\top \mathbf{Q}_0 \operatorname{diag}(\boldsymbol{\lambda}^\downarrow)\mathbf{Q}_0^\top \mathbf{P}_\tau \\ &= \mathbf{P}_\tau^\top \mathbf{B} \mathbf{P}_\tau \end{aligned}$$

has diagonal $\mathbf{d}$. It therefore suffices to prove the theorem for decreasing $\mathbf{d}$ and $\boldsymbol{\lambda}$, and we do so by induction on n.

Step 2: the corner. For $n = 1$, $\mathbf{d} \prec \boldsymbol{\lambda}$ means $d_1 = \lambda_1$ (Example (A chain, the two extremes, and size one) (d)), and $\mathbf{Q} = (1)$ works. Let $n \geq 2$, assume the theorem for $n - 1$ (for vectors in any order, by Step 1), and let $\mathbf{d}$ and $\boldsymbol{\lambda}$ be decreasing with $\mathbf{d} \prec \boldsymbol{\lambda}$. By (M1) at $k = 1$, $d_1 \leq \lambda_1$. Subtracting (M1) at $k = n - 1$ from (M2) gives $d_n \geq \lambda_n$, so $d_1 \geq d_n \geq \lambda_n$. Let k be the smallest index in $\{1, \dots, n - 1\}$ with $\lambda_{k+1} \leq d_1$; one exists, since $\lambda_n \leq d_1$. Then $\lambda_k \geq d_1$: for $k = 1$ this is $d_1 \leq \lambda_1$, and for $k \geq 2$ the minimality of k gives $\lambda_k > d_1$. So

$$\lambda_k \geq d_1 \geq \lambda_{k+1}.$$

By Lemma 16.8.3 with $t = d_1$, there are $\mathbf{R} \in \mathrm{O}(2)$ and a real b with

$$\mathbf{R} \operatorname{diag}(\lambda_k, \lambda_{k+1})\mathbf{R}^\top = \begin{pmatrix} d_1 & b \\ b & \eta \end{pmatrix}, \qquad \eta = \lambda_k + \lambda_{k+1} - d_1.$$

Moreover $\lambda_{k+1} \leq \eta \leq \lambda_k$, since $\eta - \lambda_{k+1} = \lambda_k - d_1 \geq 0$ and $\lambda_k - \eta = d_1 - \lambda_{k+1} \geq 0$.

Step 3: the leftover data. Put

$$\begin{aligned} \mathbf{d}' &= (d_2, \dots, d_n), \\ \boldsymbol{\lambda}' &= (\eta, \lambda_1, \dots, \lambda_{k-1}, \lambda_{k+2}, \dots, \lambda_n), \end{aligned}$$

two vectors in $\mathbb{R}^{n-1}$. So $\boldsymbol{\lambda}'$ is $\boldsymbol{\lambda}$ with the pair λ_k, λ_{k+1} replaced by the single number η, written first.

Claim. $\mathbf{d}' \prec \boldsymbol{\lambda}'$.

Proof. By Step 2, $\lambda_{k-1} \geq \lambda_k \geq \eta \geq \lambda_{k+1} \geq \lambda_{k+2}$, for those of these indices that exist. So

$$(\mu_1, \dots, \mu_{n-1}) = (\lambda_1, \dots, \lambda_{k-1}, \eta, \lambda_{k+2}, \dots, \lambda_n)$$

is $(\boldsymbol{\lambda}')^{\downarrow}$, and $\mathbf{d}'$ is already decreasing. For (M2), $\sum_i d'_i = \sum_i d_i - d_1 = \sum_i \lambda_i - d_1 = \sum_i \lambda'_i$, by (M2) for $\mathbf{d} \prec \boldsymbol{\lambda}$ and the definition of η. For (M1), fix m with $1 \leq m \leq n-2$; when $n = 2$ there is nothing to check.

Case $m \leq k-1$. Then $\mu_i = \lambda_i$ for $i \leq m$. For each such i, $d_{i+1} \leq d_1 \leq \lambda_k \leq \lambda_i$, because $\mathbf{d}$ and $\boldsymbol{\lambda}$ are decreasing and $i < k$. Summing over $i \leq m$ gives $d_2 + \cdots + d_{m+1} \leq \mu_1 + \cdots + \mu_m$.

Case $m \geq k$. The first m entries of $(\boldsymbol{\lambda}')^{\downarrow}$ are $\lambda_1, \dots, \lambda_{k-1}$, then η, then $\lambda_{k+2}, \dots, \lambda_{m+1}$. So

$$\begin{aligned} \mu_1 + \cdots + \mu_m &= (\lambda_1 + \cdots + \lambda_{m+1}) - \lambda_k - \lambda_{k+1} + \eta \\ &= (\lambda_1 + \cdots + \lambda_{m+1}) - d_1. \end{aligned}$$

Since $m + 1 \leq n - 1$, (M1) for $\mathbf{d} \prec \boldsymbol{\lambda}$ applies at $m + 1$ and gives

$$\begin{aligned} d_2 + \cdots + d_{m+1} &= (d_1 + \cdots + d_{m+1}) - d_1 \\ &\leq (\lambda_1 + \cdots + \lambda_{m+1}) - d_1 = \mu_1 + \cdots + \mu_m. \end{aligned}$$

In both cases (M1) holds, which proves the claim. ∎

Step 4: assembly. Let $\sigma \in S_n$ list the indices $k, k+1$ first and the others after them in increasing order: $\sigma(1) = k$, $\sigma(2) = k+1$, and $\sigma(3), \dots, \sigma(n)$ are $1, \dots, k-1, k+2, \dots, n$. By (†),

$$\mathbf{P}_\sigma^\top \operatorname{diag}(\lambda_1, \dots, \lambda_n) \mathbf{P}_\sigma = \begin{pmatrix} \operatorname{diag}(\lambda_k, \lambda_{k+1}) & \mathbf{0} \\ \mathbf{0} & \mathbf{D}_1 \end{pmatrix},$$

where $\mathbf{D}_1 = \operatorname{diag}(\lambda_1, \dots, \lambda_{k-1}, \lambda_{k+2}, \dots, \lambda_n) \in M_{n-2}(\mathbb{R})$; when $n = 2$ the blocks involving $\mathbf{D}_1$ are absent. Let $\mathbf{R}_1 = \left(\begin{smallmatrix} \mathbf{R} & \mathbf{0} \\ \mathbf{0} & \mathbf{I}_{n-2} \end{smallmatrix}\right)$. Multiplying blocks and using Step 2,

$$\mathbf{M} = \mathbf{R}_1 \mathbf{P}_\sigma^\top \operatorname{diag}(\lambda_1, \dots, \lambda_n) \mathbf{P}_\sigma \mathbf{R}_1^\top = \begin{pmatrix} d_1 & b & \mathbf{0} \\ b & \eta & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{D}_1 \end{pmatrix} = \begin{pmatrix} d_1 & b\,\mathbf{e}_1^\top \\ b\,\mathbf{e}_1 & \mathbf{E} \end{pmatrix},$$

where $\mathbf{e}_1$ is the first standard basis vector of $\mathbb{R}^{n-1}$ and $\mathbf{E} = \operatorname{diag}(\eta, \lambda_1, \dots, \lambda_{k-1}, \lambda_{k+2}, \dots, \lambda_n)$ is the diagonal matrix of $\boldsymbol{\lambda}'$. By the Claim and the inductive hypothesis, there is $\mathbf{W} \in \mathrm{O}(n-1)$ such that $\mathbf{W}\mathbf{E}\mathbf{W}^\top$ has diagonal entries $d_2, \dots, d_n$. Let $\mathbf{W}_1 = \left(\begin{smallmatrix} 1 & \mathbf{0}^\top \\ \mathbf{0} & \mathbf{W} \end{smallmatrix}\right)$. Then

$$\mathbf{W}_1 \mathbf{M} \mathbf{W}_1^\top = \begin{pmatrix} d_1 & b\,(\mathbf{W}\mathbf{e}_1)^\top \\ b\,\mathbf{W}\mathbf{e}_1 & \mathbf{W}\mathbf{E}\mathbf{W}^\top \end{pmatrix},$$

whose diagonal entries are $d_1, d_2, \dots, d_n$. The block matrices $\mathbf{R}_1$ and $\mathbf{W}_1$ are orthogonal, since $\mathbf{R}_1^\top \mathbf{R}_1$ and $\mathbf{W}_1^\top \mathbf{W}_1$ are block diagonal with blocks $\mathbf{R}^\top \mathbf{R} = \mathbf{I}$, $\mathbf{I}$, and 1, $\mathbf{W}^\top \mathbf{W} = \mathbf{I}$. So $\mathbf{Q} = \mathbf{W}_1 \mathbf{R}_1 \mathbf{P}_\sigma^\top$ is orthogonal, and $\mathbf{Q} \operatorname{diag}(\lambda_1, \dots, \lambda_n) \mathbf{Q}^\top = \mathbf{W}_1 \mathbf{M} \mathbf{W}_1^\top$. This completes the induction and proves the theorem.

■

Over $\mathbb{C}$ nothing more is needed, because an orthogonal matrix is unitary and a real symmetric matrix is Hermitian. Together with Schur's theorem, this settles the question the section began with.

Theorem 16.8.5 — Schur–Horn Theorem

Let $F = \mathbb{R}$ or $F = \mathbb{C}$, and let $\mathbf{d}, \boldsymbol{\lambda} \in \mathbb{R}^n$. There is a Hermitian $\mathbf{A} \in M_n(F)$ with $\boldsymbol{\lambda}(\mathbf{A}) = \boldsymbol{\lambda}^{\downarrow}$ and $\mathbf{d}(\mathbf{A}) = \mathbf{d}$ if and only if $\mathbf{d} \prec \boldsymbol{\lambda}$. In words: the diagonals of the Hermitian matrices with spectrum $\boldsymbol{\lambda}$ are **exactly** the vectors majorized by $\boldsymbol{\lambda}$, and real symmetric matrices already give all of them.

Proof. ($\Rightarrow$) By Theorem 16.8.2, $\mathbf{d} = \mathbf{d}(\mathbf{A}) \prec \boldsymbol{\lambda}(\mathbf{A}) = \boldsymbol{\lambda}^{\downarrow}$. Since majorization sees only rearrangements, $\mathbf{d} \prec \boldsymbol{\lambda}$.

($\Leftarrow$) Theorem 16.8.4 gives a real symmetric $\mathbf{A} \in M_n(\mathbb{R}) \subseteq M_n(F)$ with $\mathbf{d}(\mathbf{A}) = \mathbf{d}$ and $\boldsymbol{\lambda}(\mathbf{A}) = \boldsymbol{\lambda}^{\downarrow}$, and a real symmetric matrix is Hermitian.

■

Example. (Building a matrix from its diagonal and spectrum)

Find a real symmetric matrix with eigenvalues $6, 1, 0$ and diagonal $(4, 2, 1)$.

Solution. Both vectors are decreasing, and $(4,2,1) \prec (6,1,0)$: the running totals are $4, 6$ against $6, 7$, and both totals are 7. Follow the proof of Theorem 16.8.4.

The corner. $d_1 = 4$ lies between $\lambda_1 = 6$ and $\lambda_2 = 1$, so $k = 1$, $\eta = 6 + 1 - 4 = 3$, and Lemma 16.8.3 gives $b = \sqrt{(6-4)(4-1)} = \sqrt{6}$. After the first rotation the matrix is

$$\mathbf{M} = \begin{pmatrix} 4 & \sqrt{6} & 0 \\ \sqrt{6} & 3 & 0 \\ 0 & 0 & 0 \end{pmatrix}.$$

The leftover. $\mathbf{d}' = (2,1)$ and $\boldsymbol{\lambda}' = (3,0)$, with $2 \le 3$ and $2+1 = 3+0$, so $\mathbf{d}' \prec \boldsymbol{\lambda}'$, as the Claim promises. The lemma with $t = 2$ gives $c = \sqrt{2/3}$, $s = \sqrt{1/3}$, and

$$\mathbf{W}\,\mathrm{diag}(3,0)\mathbf{W}^{\top} = \begin{pmatrix} 2 & \sqrt{2} \\ \sqrt{2} & 1 \end{pmatrix}, \qquad \mathbf{W}\mathbf{e}_1 = (c, s).$$

Assembly. The first row becomes $\big(4,\ \sqrt{6}\,c,\ \sqrt{6}\,s\big) = (4, 2, \sqrt{2})$, so

$$\mathbf{A} = \begin{pmatrix} 4 & 2 & \sqrt{2} \\ 2 & 2 & \sqrt{2} \\ \sqrt{2} & \sqrt{2} & 1 \end{pmatrix}.$$

Check directly: $\mathbf{A}(3,2,\sqrt{2}) = (18,12,6\sqrt{2}) = 6\,(3,2,\sqrt{2})$, $\mathbf{A}(-\sqrt{2},\sqrt{2},1) = (-\sqrt{2},\sqrt{2},1)$, and $\mathbf{A}(0,-1,\sqrt{2}) = (0,0,0)$. Three eigenvectors with distinct eigenvalues $6,1,0$ give the whole spectrum, and the diagonal is $(4,2,1)$.

16.8.6 Hadamard's inequality from the diagonal

Chapter 12 §06 proved Theorem 12.6.4: for a positive semidefinite $\mathbf{A}$, $\det \mathbf{A} \le a_{11}a_{22}\cdots a_{nn}$, with equality if and only if $\mathbf{A}$ is diagonal or some $a_{ii} = 0$. That proof inducts on the size through Fischer's inequality (Corollary 12.6.3). A much shorter route scales $\mathbf{A}$ so that its diagonal is flat, and then compares the product of the eigenvalues with their sum. That comparison is the inequality between the arithmetic and geometric means, which the book has not yet proved; it is pure algebra, and it comes first.

Lemma 16.8.6 — The Arithmetic–Geometric Mean Inequality

Let $n \ge 1$ and let $t_1, \dots, t_n$ be **non-negative** real numbers. Then

$$t_1 t_2 \cdots t_n \le \left(\frac{t_1 + t_2 + \cdots + t_n}{n}\right)^n,$$

with equality if and only if $t_1 = t_2 = \cdots = t_n$.

Idea. Scale so that the mean is 1. If the numbers are not all 1, one of them lies above 1 and another below. Merge that pair into the single number $t_j + t_k - 1$. This leaves $n-1$ non-negative numbers with mean 1, so induction applies to them. The merge can only increase the product, because

$$(t_j + t_k - 1) - t_j t_k = (t_j - 1)(1 - t_k),$$

and both factors are positive. So the original product is at most, and when it is non-zero strictly less than, a product that induction bounds by 1.

Proof. **Step 1: mean 1.** We prove by induction on $n \ge 1$: if $t_1, \dots, t_n \ge 0$ and $t_1 + \cdots + t_n = n$, then $t_1 \cdots t_n \le 1$, with equality only when every $t_i = 1$. For $n = 1$ the hypothesis says $t_1 = 1$, and the product is 1.

Let $n \ge 2$ and assume the claim for $n-1$ numbers. If every $t_i = 1$, the product is 1. Otherwise some $t_j > 1$: if every $t_i \le 1$ with at least one strictly smaller, the sum would be less than n. Similarly some $t_k < 1$, since if every $t_i \ge 1$ with at least one strictly larger, the sum would exceed n. Then $j \ne k$. Neither the sum nor the product depends on the order of the numbers, so we may relabel so that $j = n-1$ and $k = n$. Put

$$s = t_{n-1} + t_n - 1.$$

Then $s > 0$, since $t_{n-1} > 1$ and $t_n \ge 0$. The $n-1$ numbers $t_1, \dots, t_{n-2}, s$ are non-negative and add up to $n-1$. So by the inductive hypothesis $p\,s \le 1$, where $p = t_1 \cdots t_{n-2} \ge 0$ (with $p = 1$ when $n = 2$). Moreover

$$s - t_{n-1}t_n = (t_{n-1} - 1)(1 - t_n) > 0.$$

If $p = 0$, then $t_1 \cdots t_n = 0 < 1$. If $p > 0$, then $t_1 \cdots t_n = p\,t_{n-1}t_n < p\,s \le 1$. In either

case the product is strictly less than 1 when the t_i are not all 1. This completes the induction.

Step 2: the general case. Let $m = \frac{1}{n}(t_1 + \cdots + t_n) \geq 0$. If $m = 0$, then every $t_i = 0$, since non-negative numbers with sum 0 are all 0. Both sides are then 0, and the t_i are all equal. If $m > 0$, the numbers t_i/m are non-negative with sum n. By Step 1,

$$\frac{t_1}{m} \cdots \frac{t_n}{m} \leq 1, \qquad \text{that is,} \qquad t_1 \cdots t_n \leq m^n,$$

with equality if and only if every $t_i/m = 1$, that is, every $t_i = m$. Numbers that are all equal to some c have mean $m = c$, so "every $t_i = m$" is the same as "all the t_i are equal". This proves the lemma.

■

In the language of this section, the lemma says that among non-negative vectors with a fixed total, the **flat** vector, which is the bottom of the majorization order (Example (A chain, the two extremes, and size one) (b)), has the largest product.

Corollary 16.8.7 — Hadamard's Inequality, Second Proof

Let $F = \mathbb{R}$ or $F = \mathbb{C}$, and let $\mathbf{A} \in M_n(F)$ with $\mathbf{A} \succeq 0$. Then

$$\det \mathbf{A} \leq a_{11} a_{22} \cdots a_{nn},$$

with equality if and only if $\mathbf{A}$ is diagonal or some $a_{ii} = 0$.

This is Theorem 12.6.4 (a) again, with the same hypothesis and the same equality condition. What is new is the proof.

Idea. Suppose first that every diagonal entry equals 1. Then $\operatorname{tr} \mathbf{A} = n$, so the eigenvalues, which are non-negative, add up to n, and Lemma 16.8.6 gives $\det \mathbf{A} = \prod_i \lambda_i(\mathbf{A}) \leq 1 = \prod_i a_{ii}$. A general diagonal is made flat by a diagonal congruence $\mathbf{A} \mapsto \mathbf{SAS}$ with $\mathbf{S} = \operatorname{diag}(a_{11}^{-1/2}, \ldots, a_{nn}^{-1/2})$. This congruence preserves positivity and divides both sides of the inequality by the same number $a_{11} \cdots a_{nn}$. Zero diagonal entries, where $\mathbf{S}$ does not exist, are handled first and separately.

Proof. Each $a_{ii} = \langle \mathbf{A}\mathbf{e}_i, \mathbf{e}_i \rangle \geq 0$ by Definition 12.1.1, and each $\lambda_i(\mathbf{A}) \geq 0$ by Theorem 12.1.4 (b).

Case 1: some $a_{ii} = 0$. The right-hand side is 0. Suppose $\det \mathbf{A} \neq 0$. By Theorem 8.3.3, $\det \mathbf{A} = \prod_j \lambda_j(\mathbf{A})$, so every $\lambda_j(\mathbf{A})$ is non-zero, hence positive. By Theorem 12.1.5 (b), $\mathbf{A} \succ 0$, so $a_{ii} = \langle \mathbf{A}\mathbf{e}_i, \mathbf{e}_i \rangle > 0$, a contradiction. Hence $\det \mathbf{A} = 0$, and the inequality holds with equality, as the statement says it should when some $a_{ii} = 0$.

Case 2: every $a_{ii} > 0$. Let $\mathbf{S} = \operatorname{diag}(a_{11}^{-1/2}, \ldots, a_{nn}^{-1/2})$, a real diagonal matrix with non-zero diagonal, so $\mathbf{S}^* = \mathbf{S}$ and $\mathbf{S}$ is invertible. Put $\mathbf{B} = \mathbf{S}^*\mathbf{AS} = \mathbf{SAS}$. By Proposition 12.1.2 (a), $\mathbf{B} \succeq 0$. Its entries are $b_{ij} = a_{ij}/\sqrt{a_{ii}a_{jj}}$, so $b_{ii} = 1$ for every i, and $\operatorname{tr} \mathbf{B} = n$. By Theorem 8.3.3,

$$\lambda_1(\mathbf{B}) + \cdots + \lambda_n(\mathbf{B}) = n.$$

The $\lambda_i(\mathbf{B})$ are non-negative by Theorem 12.1.4 (b). So Lemma 16.8.6 and Theorem 8.3.3 give

$$\det \mathbf{B} = \prod_{i=1}^{n} \lambda_i(\mathbf{B}) \le \left(\frac{n}{n}\right)^n = 1,$$

with equality if and only if all $\lambda_i(\mathbf{B})$ are equal, hence all equal to 1. By Theorem 6.5.4, and since $\det \mathbf{S} = (a_{11} \cdots a_{nn})^{-1/2}$,

$$\det \mathbf{B} = (\det \mathbf{S})^2 \det \mathbf{A} = \frac{\det \mathbf{A}}{a_{11} a_{22} \cdots a_{nn}}.$$

Multiplying $\det \mathbf{B} \le 1$ by the positive number $a_{11} \cdots a_{nn}$ gives $\det \mathbf{A} \le a_{11} \cdots a_{nn}$.

For equality in Case 2: equality holds exactly when every $\lambda_i(\mathbf{B}) = 1$. If so, the spectral theorem (Corollary 11.4.3, or Corollary 11.5.2 over $\mathbb{R}$) gives $\mathbf{B} = \mathbf{U}\mathbf{I}\mathbf{U}^* = \mathbf{I}$ for some unitary (or orthogonal) $\mathbf{U}$. Then $\mathbf{A} = \mathbf{S}^{-1}\mathbf{B}\mathbf{S}^{-1} = \mathbf{S}^{-2} = \operatorname{diag}(a_{11}, \ldots, a_{nn})$ is diagonal. Conversely, if $\mathbf{A}$ is diagonal, then $\mathbf{B} = \mathbf{S}\mathbf{A}\mathbf{S} = \mathbf{I}$, and every $\lambda_i(\mathbf{B}) = 1$. So in Case 2, equality holds if and only if $\mathbf{A}$ is diagonal. Together with Case 1, this is the stated equality condition. This proves the corollary.

■

For the matrix of Example (Coordinate vectors against eigenvectors), which is positive definite since its eigenvalues are $7, 4, 1$, the inequality reads $\det \mathbf{A} = 7 \cdot 4 \cdot 1 = 28 \le 60 = 3 \cdot 4 \cdot 5$.

The two proofs show different things. The first proves more along the way: Fischer's inequality for blocks of any sizes. The second shows that once the diagonal is scaled flat, the trace and the arithmetic–geometric mean inequality suffice. Of $\mathbf{d}(\mathbf{B}) \prec \boldsymbol{\lambda}(\mathbf{B})$ it uses only clause (M2), which for a matrix is just the trace.

Remark. A proof by majorization in earnest would use all of $\mathbf{d}(\mathbf{A}) \prec \boldsymbol{\lambda}(\mathbf{A})$, without scaling, together with the fact that for vectors with **non-negative** entries, $\mathbf{x} \prec \mathbf{y}$ implies $x_1 \cdots x_n \ge y_1 \cdots y_n$ (the product is **Schur-concave**). That fact is true but **not proved in this book yet**; Chapter 20 proves it, for the whole class of functions that reverse majorization.

Majorization is the language this chapter's eigenvalue inequalities were already using, and the Schur–Horn theorem shows that it fits the diagonal problem exactly. The same language compresses the inequality of Section 7 for arbitrary index sets, Theorem 16.7.2, into one line. The k largest entries of the vector $\boldsymbol{\lambda}(\mathbf{A}) - \boldsymbol{\lambda}(\mathbf{B})$ add up to the largest value of $\sum_j \big(\lambda_{i_j}(\mathbf{A}) - \lambda_{i_j}(\mathbf{B})\big)$ over index sets of size k, and the totals are $\operatorname{tr} \mathbf{A} - \operatorname{tr} \mathbf{B} = \operatorname{tr}(\mathbf{A} - \mathbf{B})$. So a bound of every such sum by $\sum_{j \le k} \lambda_j(\mathbf{A} - \mathbf{B})$ says exactly that

$$\boldsymbol{\lambda}(\mathbf{A}) - \boldsymbol{\lambda}(\mathbf{B}) \prec \boldsymbol{\lambda}(\mathbf{A} - \mathbf{B}).$$

The diagonal of a Hermitian matrix and the eigenvalues of a difference are both controlled by one ordering of vectors in $\mathbb{R}^n$.

16.8.7 Exercises

16.8.7.1 A. Check your understanding

Exercise A1.

(a) State the definitions of $\mathbf{x} \prec \mathbf{y}$ and $\mathbf{x} \prec_w \mathbf{y}$ for $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$.

(b) Decide whether $(2,1,1) \prec (2,2,0)$, and whether $(2,2,0) \prec (2,1,1)$.

(c) True or false: if $\mathbf{x} \prec \mathbf{y}$, then $x_1 \le y_1$. Justify your answer.

(d) State Theorem 16.8.2. Which result of §06 is it a restatement of?

(e) State Theorem 16.8.5. Which half is proved by induction on n, and which lemma does each step of that induction use?

Solution.

(a) $\mathbf{x} \prec \mathbf{y}$ means that $\sum_{i \le k} x_i^{\downarrow} \le \sum_{i \le k} y_i^{\downarrow}$ for every $k = 1, \dots, n-1$, and $\sum_{i=1}^{n} x_i = \sum_{i=1}^{n} y_i$ (Definition 16.8.1). $\mathbf{x} \prec_w \mathbf{y}$ means that the same inequality holds for every $k = 1, \dots, n$, with no condition on the totals.

(b) Both vectors are decreasing with total 4. Their running totals at $k = 1, 2$ are $2, 3$ and $2, 4$. Since $2 \le 2$ and $3 \le 4$, $(2,1,1) \prec (2,2,0)$. The reverse fails at $k = 2$, since $4 > 3$.

(c) False. The definition compares **sorted** vectors, so the unsorted first entries can go either way. Take $\mathbf{x} = (1,0)$ and $\mathbf{y} = (0,1)$. Both have decreasing rearrangement $(1,0)$, so (M1) at $k = 1$ reads $1 \le 1$, and both totals are 1; hence $\mathbf{x} \prec \mathbf{y}$. But $x_1 = 1 > 0 = y_1$. What is true is $x_1^{\downarrow} \le y_1^{\downarrow}$, which is (M1) at $k = 1$.

(d) For a Hermitian $\mathbf{A} \in M_n(F)$, $F = \mathbb{R}$ or $\mathbb{C}$, $\mathbf{d}(\mathbf{A}) \prec \boldsymbol{\lambda}(\mathbf{A})$. It restates Corollary 16.6.3: applied to the positions of the k largest diagonal entries, the corollary gives (M1), and its equality at $k = n$ gives (M2).

(e) For $\mathbf{d}, \boldsymbol{\lambda} \in \mathbb{R}^n$, there is a Hermitian matrix over $\mathbb{R}$ or $\mathbb{C}$ with diagonal $\mathbf{d}$, in the given order, and eigenvalues $\lambda_1, \dots, \lambda_n$ if and only if $\mathbf{d} \prec \boldsymbol{\lambda}$. The half "$\mathbf{d} \prec \boldsymbol{\lambda}$ implies such a matrix exists" is Horn's theorem, Theorem 16.8.4, proved by induction on n. Each step uses Lemma 16.8.3, applied to a pair of consecutive eigenvalues $\lambda_k \ge d_1 \ge \lambda_{k+1}$, to put d_1 in the corner. The other half is Schur's theorem.

16.8.7.2 B. Practice

Exercise B1: Determine which pairs are comparable.

For each pair, determine whether $\mathbf{x} \prec \mathbf{y}$ and whether $\mathbf{x} \prec_w \mathbf{y}$. Where a relation fails, name the exact clause and the value of k at which it fails. Justify your answer.

(a) $\mathbf{x} = (2,2,1,1)$, $\mathbf{y} = (3,2,1,0)$.

(b) $\mathbf{x} = (0,3,1)$, $\mathbf{y} = (4,0,0)$.

(c) $\mathbf{x} = (1,1,0)$, $\mathbf{y} = (2,1,0)$.

(d) $\mathbf{x} = (-1,2,2)$, $\mathbf{y} = (3,0,0)$.

(e) $\mathbf{x} = (3,1,1,1)$, $\mathbf{y} = (2,2,2,0)$; decide also whether $\mathbf{y} \prec \mathbf{x}$.

Solution. In each case, sort first, then compare running totals.

(a) Both are decreasing with total 6. Running totals: $2, 4, 5, 6$ and $3, 5, 6, 6$. Every entry of the first list is at most the matching entry of the second, so $\mathbf{x} \prec \mathbf{y}$ and

hence $\mathbf{x} \prec_w \mathbf{y}$.

(b) $\mathbf{x}^{\downarrow} = (3, 1, 0)$ with running totals $3, 4, 4$, and $\mathbf{y}$ has running totals $4, 4, 4$. The totals agree and $3 \le 4$, $4 \le 4$, so $\mathbf{x} \prec \mathbf{y}$ and $\mathbf{x} \prec_w \mathbf{y}$. This is Example (A chain, the two extremes, and size one) (c), applied after sorting.

(c) Running totals $1, 2, 2$ and $2, 3, 3$. Every inequality holds, including at $k = 3$, so $\mathbf{x} \prec_w \mathbf{y}$. But the totals are $2 \neq 3$, so **(M2) fails** and $\mathbf{x} \not\prec \mathbf{y}$.

(d) $\mathbf{x}^{\downarrow} = (2, 2, -1)$ with running totals $2, 4, 3$, and $\mathbf{y}$ has running totals $3, 3, 3$. The totals agree, but at $k = 2$, $4 > 3$, so **(M1) fails at** $k = 2$. Neither $\mathbf{x} \prec \mathbf{y}$ nor $\mathbf{x} \prec_w \mathbf{y}$ holds.

(e) Both are decreasing with total 6. Running totals: $3, 4, 5, 6$ and $2, 4, 6, 6$. At $k = 1$, $3 > 2$, so **(M1) fails at** $k = 1$ and $\mathbf{x} \not\prec \mathbf{y}$, and also $\mathbf{x} \not\prec_w \mathbf{y}$. For $\mathbf{y} \prec \mathbf{x}$, the inequalities $2 \le 3$ and $4 \le 4$ hold, but $6 > 5$ at $k = 3$, so **(M1) fails at** $k = 3$. The pair is incomparable, like Example (Neither majorizes the other).

Exercise B2: Schur's theorem for one matrix.

Let

$$\mathbf{A} = \begin{pmatrix} 3 & 2 & 2 \\ 2 & 4 & 0 \\ 2 & 0 & 7 \end{pmatrix}.$$

(a) Verify that $(2, 1, 4)$, $(-1, -2, 1)$ and $(-3, 2, 1)$ are eigenvectors of $\mathbf{A}$, and find $\boldsymbol{\lambda}(\mathbf{A})$.

(b) Write down $\mathbf{d}(\mathbf{A})$ and verify every clause of $\mathbf{d}(\mathbf{A}) \prec \boldsymbol{\lambda}(\mathbf{A})$.

(c) Hence verify Hadamard's inequality (Theorem 12.6.4) for $\mathbf{A}$.

Solution.

(a) Multiply out:

$$\begin{aligned} \mathbf{A}(2, 1, 4) &= (6 + 2 + 8,\ 4 + 4,\ 4 + 28) = (16, 8, 32) = 8\,(2, 1, 4), \\ \mathbf{A}(-1, -2, 1) &= (-3 - 4 + 2,\ -2 - 8,\ -2 + 7) = (-5, -10, 5) = 5\,(-1, -2, 1), \\ \mathbf{A}(-3, 2, 1) &= (-9 + 4 + 2,\ -6 + 8,\ -6 + 7) = (-3, 2, 1) = 1\,(-3, 2, 1). \end{aligned}$$

Three distinct eigenvalues of a 3×3 matrix account for the whole spectrum, so $\boldsymbol{\lambda}(\mathbf{A}) = (8, 5, 1)$.

(b) $\mathbf{d}(\mathbf{A}) = (3, 4, 7)$, and $\mathbf{d}(\mathbf{A})^{\downarrow} = (7, 4, 3)$. (M1): at $k = 1$, $7 \le 8$; at $k = 2$, $7 + 4 = 11 \le 13 = 8 + 5$. (M2): $3 + 4 + 7 = 14 = 8 + 5 + 1$. Hence $\mathbf{d}(\mathbf{A}) \prec \boldsymbol{\lambda}(\mathbf{A})$, as Theorem 16.8.2 requires.

(c) All eigenvalues are positive, so $\mathbf{A} \succ 0$ by Theorem 12.1.5 (b), and Corollary 16.8.7 applies. By Theorem 8.3.3, $\det \mathbf{A} = 8 \cdot 5 \cdot 1 = 40$, while $a_{11}a_{22}a_{33} = 3 \cdot 4 \cdot 7 = 84$. Hence $40 \le 84$. The inequality is strict, as it must be, since $\mathbf{A}$ is not diagonal and no diagonal entry is 0.

Exercise B3: Which diagonals are ruled out?.

A Hermitian 3×3 matrix has eigenvalues $5, 1, 0$. For each proposed list of diagonal entries, determine whether Theorem 16.8.2 rules it out. Justify your answer.

(a) $4, 2, 0$.
(b) $6, 0, 0$.
(c) $3, 3, 1$.
(d) $2, 2, 2$.
(e) $-1, 4, 3$.

For the lists that are not ruled out, what does Theorem 16.8.5 add?

Solution. Here $\boldsymbol{\lambda} = (5, 1, 0)$, with running totals $5, 6$ and total 6.

(a) Running totals $4, 6$, total 6. Since $4 \le 5$ and $6 \le 6$, the list is **not** ruled out.
(b) At $k = 1$, $6 > 5$. **Ruled out.** No diagonal entry can exceed λ_1.
(c) The total is $7 \neq 6$. **Ruled out** by (M2): the trace would be wrong.
(d) This is the flat vector with total 6, which is majorized by every vector with total 6 (Example (A chain, the two extremes, and size one) (b)). **Not** ruled out.
(e) Sorted, it is $(4, 3, -1)$, with running totals $4, 7$ and total 6. At $k = 2$, $7 > 6$. **Ruled out.** Independently, $-1 < 0 = \lambda_3$ contradicts the bottom-end inequality of the warning.

Schur's theorem is only a necessary condition, so for (a) and (d) it shows only that nothing forbids these diagonals. Theorem 16.8.5 adds that they occur: for each of them there is a real symmetric matrix with eigenvalues $5, 1, 0$ and that diagonal.

16.8.7.3 C. Going deeper

Exercise C1: Majorization squeezes the range.

(a) Prove that if $\mathbf{x} \prec \mathbf{y}$, then $y_n^{\downarrow} \le x_n^{\downarrow} \le x_1^{\downarrow} \le y_1^{\downarrow}$.
(b) Deduce that every diagonal entry of a Hermitian $\mathbf{A}$ lies in $[\lambda_n(\mathbf{A}), \lambda_1(\mathbf{A})]$.
(c) Show that the conclusion of (b), together with equal totals, does **not** imply majorization. Prove that no Hermitian matrix has eigenvalues $4, 1, 1, 0$ and diagonal entries $3, 3, 0, 0$, although every one of these entries lies in $[0, 4]$ and the totals agree.

Solution.

(a) The inequality $x_1^{\downarrow} \le y_1^{\downarrow}$ is (M1) at $k = 1$ (for $n = 1$, $\mathbf{x} = \mathbf{y}$ by Example (A chain, the two extremes, and size one) (d), and there is nothing to prove). The middle inequality holds because $\mathbf{x}^{\downarrow}$ is decreasing. For the left inequality, subtract (M1) at $k = n - 1$ from (M2):

$$\begin{aligned} x_n^{\downarrow} &= \sum_{i=1}^{n} x_i - \sum_{i=1}^{n-1} x_i^{\downarrow} \\ &\ge \sum_{i=1}^{n} y_i - \sum_{i=1}^{n-1} y_i^{\downarrow} = y_n^{\downarrow}. \end{aligned}$$

(b) By Theorem 16.8.2, $\mathbf{d}(\mathbf{A}) \prec \boldsymbol{\lambda}(\mathbf{A})$. Apply (a) with $\mathbf{x} = \mathbf{d}(\mathbf{A})$ and $\mathbf{y} = \boldsymbol{\lambda}(\mathbf{A})$, using $\boldsymbol{\lambda}(\mathbf{A})^{\downarrow} = \boldsymbol{\lambda}(\mathbf{A})$. Every diagonal entry lies between the smallest and the

largest diagonal entry, which (a) places between $\lambda_n(\mathbf{A})$ and $\lambda_1(\mathbf{A})$. (This also follows from Lemma 12.5.2 at $\mathbf{x} = \mathbf{e}_i$. The point of (a) is that it is a property of majorization itself.)

(c) The vector $(3,3,0,0)$ has running totals $3,6,6$, and $(4,1,1,0)$ has $4,5,6$. At $k=2$, $6 > 5$, so $(3,3,0,0) \not\prec (4,1,1,0)$, and by Theorem 16.8.2 no Hermitian matrix has this diagonal and this spectrum. Yet $0 \le 3,3,0,0 \le 4$, and both totals are 6. The range condition controls only the running totals at $k=1$ and $k=n-1$, while majorization constrains the middle ones too, which is why the example needs $n \ge 4$.

Exercise C2: A weaker determinant bound.

Let $\mathbf{A} \in M_n(F)$ with $\mathbf{A} \succeq 0$.

(a) Prove that $\det \mathbf{A} \le \left(\frac{1}{n}\operatorname{tr}\mathbf{A}\right)^n$, with equality if and only if $\mathbf{A} = c\mathbf{I}$ for some real $c \ge 0$.

(b) Prove that $a_{11}\cdots a_{nn} \le \left(\frac{1}{n}\operatorname{tr}\mathbf{A}\right)^n$. Deduce that Hadamard's inequality (Theorem 12.6.4) always implies the bound in (a).

(c) For

$$\mathbf{A} = \begin{pmatrix} 2 & 0 & 2 \\ 0 & 5 & 2 \\ 2 & 2 & 6 \end{pmatrix},$$

whose eigenvectors are $(1,2,3)$, $(1,-2,1)$ and $(-4,-1,2)$, compute the three numbers $\det \mathbf{A}$, $a_{11}a_{22}a_{33}$ and $\left(\frac{1}{3}\operatorname{tr}\mathbf{A}\right)^3$.

Solution.

(a) The eigenvalues $\lambda_i(\mathbf{A})$ are non-negative by Theorem 12.1.4 (b). By Theorem 8.3.3 and Lemma 16.8.6,

$$\det \mathbf{A} = \prod_i \lambda_i(\mathbf{A}) \le \left(\frac{1}{n}\sum_i \lambda_i(\mathbf{A})\right)^n = \left(\frac{1}{n}\operatorname{tr}\mathbf{A}\right)^n.$$

Equality holds if and only if all $\lambda_i(\mathbf{A})$ equal a common value $c \ge 0$. By the spectral theorem this happens if and only if $\mathbf{A} = \mathbf{U}(c\mathbf{I})\mathbf{U}^* = c\mathbf{I}$. Conversely, $\mathbf{A} = c\mathbf{I}$ gives equality directly.

(b) The a_{ii} are non-negative (as in the proof of Corollary 16.8.7) and add up to $\operatorname{tr}\mathbf{A}$. So Lemma 16.8.6 gives $\prod_i a_{ii} \le (\frac{1}{n}\operatorname{tr}\mathbf{A})^n$. Combined with Corollary 16.8.7, this gives $\det \mathbf{A} \le \prod_i a_{ii} \le (\frac{1}{n}\operatorname{tr}\mathbf{A})^n$, so the Hadamard bound always sits between $\det \mathbf{A}$ and the bound of (a). The bound in (a) sees only the total of the diagonal, while Hadamard's bound sees each entry, and so it is never worse.

(c) Check the eigenvectors: $\mathbf{A}(1,2,3) = (2+6,\ 10+6,\ 2+4+18) = (8,16,24)$; $\mathbf{A}(1,-2,1) = (2+2,\ -10+2,\ 2-4+6) = (4,-8,4)$; $\mathbf{A}(-4,-1,2) = (-8+$

$4,\ -5+4,\ -8-2+12) = (-4,-1,2)$. So $\boldsymbol{\lambda}(\mathbf{A}) = (8,4,1)$, and $\mathbf{A} \succ 0$. Then

$$\det \mathbf{A} = 8 \cdot 4 \cdot 1 = 32, \qquad a_{11}a_{22}a_{33} = 2 \cdot 5 \cdot 6 = 60,$$
$$\left(\frac{\operatorname{tr}\mathbf{A}}{3}\right)^3 = \left(\frac{13}{3}\right)^3 = \frac{2197}{27} \approx 81.4,$$

and $32 \le 60 \le 81.4$, with both inequalities strict.

Exercise C3: The possible diagonals form a convex set.

For $\mathbf{x} \in \mathbb{R}^n$ and $1 \le k \le n$, write $s_k(\mathbf{x}) = x_1^{\downarrow} + \cdots + x_k^{\downarrow}$.

(a) Prove that $s_k(\mathbf{x}) = \max\{\sum_{i\in I} x_i : I \subseteq \{1,\dots,n\},\ |I| = k\}$.

(b) Deduce that $s_k(\mathbf{x}+\mathbf{y}) \le s_k(\mathbf{x}) + s_k(\mathbf{y})$ for all $\mathbf{x},\mathbf{y} \in \mathbb{R}^n$.

(c) Let $\boldsymbol{\lambda} \in \mathbb{R}^n$. Prove that if $\mathbf{d} \prec \boldsymbol{\lambda}$ and $\mathbf{d}' \prec \boldsymbol{\lambda}$, then $t\mathbf{d} + (1-t)\mathbf{d}' \prec \boldsymbol{\lambda}$ for every $0 \le t \le 1$.

(d) Hence show that if $\mathbf{A}$ and $\mathbf{B}$ are Hermitian $n \times n$ matrices with the same eigenvalues, then for every $0 \le t \le 1$ there is a real symmetric matrix with those eigenvalues and diagonal $t\,\mathbf{d}(\mathbf{A}) + (1-t)\,\mathbf{d}(\mathbf{B})$.

Hint for (a): if $v_1 \ge \cdots \ge v_k$ are the entries x_i, $i \in I$, in decreasing order, count how many entries of $\mathbf{x}$ are at least v_j.

Solution.

(a) Let $|I| = k$, and list the entries x_i, $i \in I$, decreasingly as $v_1 \ge \cdots \ge v_k$. For each $j \le k$, the entries $v_1,\dots,v_j$ sit at j different positions of $\mathbf{x}$ and are all $\ge v_j$. If $x_j^{\downarrow} < v_j$, then, since $\mathbf{x}^{\downarrow}$ is decreasing, only $x_1^{\downarrow},\dots,x_{j-1}^{\downarrow}$ could be $\ge v_j$, which is fewer than j entries. Hence $v_j \le x_j^{\downarrow}$ for every j, and summing gives $\sum_{i\in I} x_i \le s_k(\mathbf{x})$. The bound is attained by the positions of the k largest entries, chosen as in the proof of Theorem 16.8.2. This proves (a).

(b) Let I be a set of k positions at which $\mathbf{x}+\mathbf{y}$ attains the maximum in (a). Applying (a) three times,

$$s_k(\mathbf{x}+\mathbf{y}) = \sum_{i\in I} x_i + \sum_{i\in I} y_i \le s_k(\mathbf{x}) + s_k(\mathbf{y}).$$

(c) Put $\mathbf{z} = t\mathbf{d} + (1-t)\mathbf{d}'$. Its total is $t\sum_i \lambda_i + (1-t)\sum_i \lambda_i = \sum_i \lambda_i$, by (M2) for both hypotheses. For a scalar $c \ge 0$, multiplying by c does not change the order of the entries, so $s_k(c\mathbf{x}) = c\,s_k(\mathbf{x})$. For $1 \le k \le n-1$, (b) and (M1) for both hypotheses give

$$s_k(\mathbf{z}) \le t\,s_k(\mathbf{d}) + (1-t)\,s_k(\mathbf{d}') \le t\,s_k(\boldsymbol{\lambda}) + (1-t)\,s_k(\boldsymbol{\lambda}) = s_k(\boldsymbol{\lambda}).$$

So $\mathbf{z} \prec \boldsymbol{\lambda}$.

(d) Let $\boldsymbol{\lambda} = \boldsymbol{\lambda}(\mathbf{A}) = \boldsymbol{\lambda}(\mathbf{B})$. By Theorem 16.8.2, $\mathbf{d}(\mathbf{A}) \prec \boldsymbol{\lambda}$ and $\mathbf{d}(\mathbf{B}) \prec \boldsymbol{\lambda}$. By (c), $t\,\mathbf{d}(\mathbf{A}) + (1-t)\,\mathbf{d}(\mathbf{B}) \prec \boldsymbol{\lambda}$. By Theorem 16.8.4 there is a real symmetric matrix with eigenvalues $\boldsymbol{\lambda}$ and exactly this diagonal. So among Hermitian matrices with a fixed spectrum, the set of diagonals contains the segment between any two of its points: it is **convex**.

16.9 The Same Theory for Singular Values

Everything so far in this chapter has been about Hermitian matrices, and it had to be: a general square matrix need not have real eigenvalues to order, and a rectangular matrix has none at all. But every matrix has singular values, they are real and non-negative, and Chapter 12 listed them decreasingly from the moment it defined them. This section carries the apparatus across — a min–max description, a perturbation bound, an interlacing theorem — and then spends the rest of its length paying debts that earlier chapters recorded and could not settle.

Throughout, $F = \mathbb{R}$ **or** $F = \mathbb{C}$, $\mathbf{A} \in M_{m\times n}(F)$, $p = \min(m, n)$, and $\sigma_1(\mathbf{A}) \geq \cdots \geq \sigma_p(\mathbf{A}) \geq 0$ are the singular values of $\mathbf{A}$ (Definition 12.8.1). Nothing here is assumed Hermitian and nothing is assumed square; where a matrix must be square, or invertible, the statement says so. Vector norms are Euclidean, and $\|\mathbf{A}\|_2$ is the spectral norm of Definition 15.3.2, which Theorem 15.3.3 (c) computes as $\sigma_1(\mathbf{A})$.

One convention, stated once and used everywhere below. We set

$$\sigma_i(\mathbf{A}) \coloneqq 0 \qquad \text{for } p < i \leq n.$$

This is not new: Theorem 12.8.2 (a) already makes it, and records what it buys. With it in force, if $\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^*$ is a singular value decomposition (Theorem 12.8.1) with columns $\mathbf{v}_1, \ldots, \mathbf{v}_n$ of $\mathbf{V}$, then

$$\mathbf{A}^*\mathbf{A}\,\mathbf{v}_i = \sigma_i(\mathbf{A})^2\,\mathbf{v}_i \qquad (1 \leq i \leq n), \tag{16.9.1}$$

so that $\mathbf{v}_1, \ldots, \mathbf{v}_n$ is an orthonormal eigenbasis of $\mathbf{A}^*\mathbf{A}$ whose eigenvalues $\sigma_1^2 \geq \cdots \geq \sigma_n^2 \geq 0$ are already sorted. In the notation of this chapter,

$$\lambda_i(\mathbf{A}^*\mathbf{A}) = \sigma_i(\mathbf{A})^2 \qquad (1 \leq i \leq n).$$

Every statement in this section is that identity, pushed through a theorem about Hermitian matrices.

16.9.1 The stretch ratio is a Rayleigh quotient

Chapter 12 introduced the singular values by an algebraic route — take $\mathbf{A}^*\mathbf{A}$, diagonalize it, take square roots. Their geometric meaning is stretching: how much longer $\mathbf{A}\mathbf{x}$ is than $\mathbf{x}$. The bridge between the two descriptions is one line of algebra, and it is the only computation this section needs before the theorems start.

For $\mathbf{x} \neq \mathbf{0}$ in F^n, the matrix $\mathbf{A}^*\mathbf{A}$ is Hermitian, so its Rayleigh quotient (Definition 16.1.1) is defined, and

$$R_{\mathbf{A}^*\mathbf{A}}(\mathbf{x}) = \frac{\langle \mathbf{A}^*\mathbf{A}\mathbf{x}, \mathbf{x}\rangle}{\langle \mathbf{x}, \mathbf{x}\rangle} = \frac{\mathbf{x}^*\mathbf{A}^*\mathbf{A}\mathbf{x}}{\mathbf{x}^*\mathbf{x}} = \frac{(\mathbf{A}\mathbf{x})^*(\mathbf{A}\mathbf{x})}{\mathbf{x}^*\mathbf{x}} = \frac{\|\mathbf{A}\mathbf{x}\|^2}{\|\mathbf{x}\|^2}. \tag{16.9.2}$$

The Rayleigh quotient of $\mathbf{A}^*\mathbf{A}$ *is the squared stretching factor of* $\mathbf{A}$.

So a statement about the Rayleigh quotient of $\mathbf{A}^*\mathbf{A}$ is a statement about the function $\mathbf{x} \mapsto \|\mathbf{A}\mathbf{x}\|/\|\mathbf{x}\|$, and conversely. Nothing is lost in passing between them, because $t \mapsto \sqrt{t}$ is a

strictly increasing bijection of $[0,\infty)$ onto itself: it carries maxima to maxima and minima to minima, over any set whatever.

Before the min–max theorem, it is worth writing down what the singular value decomposition says about this function in coordinates. The computation is three lines, and it is used four times below — for the witness subspaces in every proof of the section — so it gets a label.

Lemma 16.9.1 — Stretching in the Right Singular Basis

Let $\mathbf{A} \in M_{m\times n}(F)$ have a singular value decomposition $\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^*$ (Theorem 12.8.1), with $\mathbf{v}_1, \dots, \mathbf{v}_n$ the columns of $\mathbf{V}$, and write $\sigma_i = \sigma_i(\mathbf{A})$ with the convention above. Then for $\mathbf{x} = \sum_{i=1}^{n} c_i \mathbf{v}_i$,

$$\|\mathbf{A}\mathbf{x}\|^2 = \sum_{i=1}^{n} \sigma_i^2 \, |c_i|^2, \qquad \|\mathbf{x}\|^2 = \sum_{i=1}^{n} |c_i|^2.$$

Consequently, for each $1 \le k \le n$:

(a) on the **tail** subspace $T_k = \operatorname{span}(\mathbf{v}_k, \dots, \mathbf{v}_n)$, of dimension $n - k + 1$,

$$\max\left\{ \tfrac{\|\mathbf{A}\mathbf{x}\|}{\|\mathbf{x}\|} : \mathbf{0} \neq \mathbf{x} \in T_k \right\} = \sigma_k,$$

attained at $\mathbf{x} = \mathbf{v}_k$;

(b) on the **head** subspace $H_k = \operatorname{span}(\mathbf{v}_1, \dots, \mathbf{v}_k)$, of dimension k,

$$\min\left\{ \tfrac{\|\mathbf{A}\mathbf{x}\|}{\|\mathbf{x}\|} : \mathbf{0} \neq \mathbf{x} \in H_k \right\} = \sigma_k,$$

attained at $\mathbf{x} = \mathbf{v}_k$.

Idea. In the right singular basis $\mathbf{A}$ does nothing but scale: it sends $\mathbf{v}_i$ to $\sigma_i \mathbf{u}_i$, and the $\mathbf{u}_i$ are orthonormal. So measuring $\mathbf{A}\mathbf{x}$ is Pythagoras applied to the scaled coordinates, and every claim about how much $\mathbf{A}$ can stretch a subspace becomes a claim about a weighted sum of $|c_i|^2$.

Proof. By Eq. 16.9.1 the list $(\mathbf{v}_1, \dots, \mathbf{v}_n)$ is an orthonormal basis of F^n consisting of eigenvectors of $\mathbf{A}^*\mathbf{A}$, with $\mathbf{A}^*\mathbf{A}\mathbf{v}_i = \sigma_i^2 \mathbf{v}_i$. Hence, for $\mathbf{x} = \sum_i c_i \mathbf{v}_i$, using Eq. 16.9.2 in the form $\|\mathbf{A}\mathbf{x}\|^2 = \mathbf{x}^*\mathbf{A}^*\mathbf{A}\mathbf{x}$ and expanding with orthonormality,

$$\|\mathbf{A}\mathbf{x}\|^2 = \Big(\sum_i c_i \mathbf{v}_i\Big)^* \Big(\sum_j c_j \sigma_j^2 \mathbf{v}_j\Big) = \sum_{i=1}^{n} \sigma_i^2 |c_i|^2,$$

the cross terms vanishing because $\mathbf{v}_i^* \mathbf{v}_j = \delta_{ij}$. The second identity is the same expansion with $\mathbf{A}$ removed.

(a) For $\mathbf{0} \neq \mathbf{x} \in T_k$ we have $c_i = 0$ for $i < k$, so $\|\mathbf{A}\mathbf{x}\|^2 = \sum_{i\ge k} \sigma_i^2 |c_i|^2 \le \sigma_k^2 \sum_{i\ge k} |c_i|^2 = \sigma_k^2 \|\mathbf{x}\|^2$, since $\sigma_i \le \sigma_k$ for $i \ge k$ and the singular values are non-negative. Taking square roots gives $\|\mathbf{A}\mathbf{x}\|/\|\mathbf{x}\| \le \sigma_k$, and $\mathbf{x} = \mathbf{v}_k$ gives $\|\mathbf{A}\mathbf{v}_k\| = \sigma_k = \sigma_k \|\mathbf{v}_k\|$, so the bound is attained.

(b) For $\mathbf{0} \neq \mathbf{x} \in H_k$ we have $c_i = 0$ for $i > k$, so $\|\mathbf{A}\mathbf{x}\|^2 = \sum_{i\le k} \sigma_i^2 |c_i|^2 \ge \sigma_k^2 \|\mathbf{x}\|^2$, since now $\sigma_i \ge \sigma_k$ for $i \le k$; and $\mathbf{x} = \mathbf{v}_k$ attains equality. This proves the lemma.

■

In words: the tail subspace is a place where $\mathbf{A}$ stretches **no more** than σ_k, and the head subspace is a place where it stretches **no less**. The min–max theorem says that these two subspaces are optimal.

16.9.2 Each singular value as an optimization

Theorem 16.9.2 — Min–Max for Singular Values

Let $\mathbf{A} \in M_{m\times n}(F)$ and let $1 \le k \le n$, with $\sigma_k(\mathbf{A}) = 0$ read by convention when $k > p$. Then

$$\sigma_k(\mathbf{A}) = \min_{\substack{W \le F^n \\ \dim W = n-k+1}} \max_{\mathbf{0}\neq\mathbf{x}\in W} \frac{\|\mathbf{A}\mathbf{x}\|}{\|\mathbf{x}\|}$$

$$= \max_{\substack{W \le F^n \\ \dim W = k}} \min_{\mathbf{0}\neq\mathbf{x}\in W} \frac{\|\mathbf{A}\mathbf{x}\|}{\|\mathbf{x}\|}.$$

The outer minimum is attained at $W = \operatorname{span}(\mathbf{v}_k, \dots, \mathbf{v}_n)$ and the outer maximum at $W = \operatorname{span}(\mathbf{v}_1, \dots, \mathbf{v}_k)$, for the right singular vectors of any singular value decomposition of $\mathbf{A}$.

Idea. There is nothing to discover: Eq. 16.9.2 turns the objective function into the Rayleigh quotient of the Hermitian matrix $\mathbf{A}^*\mathbf{A}$, Theorem 16.2.3 applies to that matrix, and the square root — increasing, hence order-preserving — moves through the minima and maxima without changing which subspace attains them.

Proof. Put $\mathbf{B} = \mathbf{A}^*\mathbf{A} \in M_n(F)$, which is Hermitian, and fix $1 \le k \le n$. By Eq. 16.9.1, $\lambda_k(\mathbf{B}) = \sigma_k(\mathbf{A})^2$. By Theorem 16.2.3 applied to $\mathbf{B}$,

$$\sigma_k(\mathbf{A})^2 = \lambda_k(\mathbf{B}) = \min_{\dim W = n-k+1} \max_{\mathbf{0}\neq\mathbf{x}\in W} R_{\mathbf{B}}(\mathbf{x}),$$

and by Eq. 16.9.2, $R_{\mathbf{B}}(\mathbf{x}) = \big(\|\mathbf{A}\mathbf{x}\|/\|\mathbf{x}\|\big)^2$ for every $\mathbf{x} \neq \mathbf{0}$.

Fix a subspace W. The function $\mathbf{x} \mapsto \|\mathbf{A}\mathbf{x}\|/\|\mathbf{x}\|$ takes only non-negative values, and $t \mapsto t^2$ is strictly increasing on $[0, \infty)$; so a vector of W maximizes $R_{\mathbf{B}}$ over W exactly when it maximizes $\|\mathbf{A}\mathbf{x}\|/\|\mathbf{x}\|$, and

$$\max_{\mathbf{0}\neq\mathbf{x}\in W} R_{\mathbf{B}}(\mathbf{x}) = \Big(\max_{\mathbf{0}\neq\mathbf{x}\in W} \frac{\|\mathbf{A}\mathbf{x}\|}{\|\mathbf{x}\|}\Big)^2.$$

(Both maxima exist: by homogeneity the quotient may be taken over the unit sphere of W, which is compact by fact (A3) of Chapter 15's introduction, and the function is continuous, so the extreme value theorem — fact (A4) of Chapter 15's introduction — applies. This is the same appeal Theorem 16.2.3 makes.) Taking square roots, and using once more that $t \mapsto \sqrt{t}$ is increasing, so that it commutes with a minimum over the family of subspaces,

$$\sigma_k(\mathbf{A}) = \sqrt{\lambda_k(\mathbf{B})} = \min_{\dim W = n-k+1} \max_{\mathbf{0}\neq\mathbf{x}\in W} \frac{\|\mathbf{A}\mathbf{x}\|}{\|\mathbf{x}\|}.$$

The max–min form follows from the second equality of Theorem 16.2.3 by the same two steps.

For the attainment claims, Lemma 16.9.1 (a) says that the tail subspace T_k, of dimension $n-k+1$, has inner maximum exactly $\sigma_k(\mathbf{A})$, which is therefore the outer minimum; and part (b) says the head subspace H_k, of dimension k, has inner minimum exactly $\sigma_k(\mathbf{A})$. This proves the theorem.

■

Two things are worth noticing. First, the subspaces W live in F^n, the **domain**, whatever m is; the theorem compares two matrices with the same number of columns without caring how many rows they have. Second, the extremal subspaces are named, and they are spans of right singular vectors: the theorem is not only an identity but a recipe.

There is a second route to the same theorem, and it is worth recording because it converts a statement about a rectangular matrix into a statement about a Hermitian one, which is what the later chapters will want.

Proposition 16.9.3 — The Hermitian Dilation

Let $\mathbf{A} \in M_{m\times n}(F)$ and put

$$\mathcal{H}(\mathbf{A}) \coloneqq \begin{pmatrix} \mathbf{0} & \mathbf{A} \\ \mathbf{A}^* & \mathbf{0} \end{pmatrix} \in M_{m+n}(F).$$

Then $\mathcal{H}(\mathbf{A})$ is Hermitian, and its eigenvalues, with multiplicity, are

$$\sigma_1(\mathbf{A}), \dots, \sigma_p(\mathbf{A}),\ -\sigma_1(\mathbf{A}), \dots, -\sigma_p(\mathbf{A}),\ \underbrace{0, \dots, 0}_{m+n-2p}.$$

Idea. Guess the eigenvectors from the SVD. The pair $(\mathbf{u}_i, \mathbf{v}_i)$, stacked, is sent by $\mathcal{H}(\mathbf{A})$ to $(\mathbf{A}\mathbf{v}_i, \mathbf{A}^*\mathbf{u}_i) = \sigma_i(\mathbf{u}_i, \mathbf{v}_i)$; flipping the sign of the second half flips the sign of the eigenvalue. That accounts for $2p$ orthonormal eigenvectors, and what is left over is a kernel whose dimension is a count.

Proof. Writing out the conjugate transpose block by block, $\mathcal{H}(\mathbf{A})^* = \left(\begin{smallmatrix} \mathbf{0} & (\mathbf{A}^*)^* \\ \mathbf{A}^* & \mathbf{0} \end{smallmatrix}\right) = \mathcal{H}(\mathbf{A})$, so $\mathcal{H}(\mathbf{A})$ is Hermitian.

Fix a singular value decomposition $\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^*$ (Theorem 12.8.1), with columns $\mathbf{u}_1, \dots, \mathbf{u}_m$ of $\mathbf{U}$ and $\mathbf{v}_1, \dots, \mathbf{v}_n$ of $\mathbf{V}$. Since $\mathbf{V}^*\mathbf{v}_i = \mathbf{e}_i$ and $\mathbf{\Sigma}\mathbf{e}_i = \sigma_i\mathbf{e}_i$ for $i \le p$ while $\mathbf{\Sigma}\mathbf{e}_j = \mathbf{0}$ for $p < j \le n$, and symmetrically for $\mathbf{A}^* = \mathbf{V}\mathbf{\Sigma}^*\mathbf{U}^*$,

$$\mathbf{A}\mathbf{v}_i = \sigma_i\mathbf{u}_i, \quad \mathbf{A}^*\mathbf{u}_i = \sigma_i\mathbf{v}_i \ \ (i \le p), \qquad \mathbf{A}\mathbf{v}_j = \mathbf{0}, \quad \mathbf{A}^*\mathbf{u}_j = \mathbf{0} \ \ (j > p).$$

For $i \le p$ put

$$\mathbf{w}_i^{\pm} = \tfrac{1}{\sqrt{2}} \begin{pmatrix} \mathbf{u}_i \\ \pm\mathbf{v}_i \end{pmatrix} \in F^{m+n}.$$

Then $\mathcal{H}(\mathbf{A})\mathbf{w}_i^{\pm} = \frac{1}{\sqrt{2}}\big(\pm\mathbf{A}\mathbf{v}_i,\ \mathbf{A}^*\mathbf{u}_i\big) = \frac{1}{\sqrt{2}}\big(\pm\sigma_i\mathbf{u}_i,\ \sigma_i\mathbf{v}_i\big) = \pm\sigma_i\,\mathbf{w}_i^{\pm}$. Likewise $\mathcal{H}(\mathbf{A})(\mathbf{u}_j, \mathbf{0}) = (\mathbf{0}, \mathbf{A}^*\mathbf{u}_j) = \mathbf{0}$ for $j > p$, and $\mathcal{H}(\mathbf{A})(\mathbf{0}, \mathbf{v}_j) = (\mathbf{A}\mathbf{v}_j, \mathbf{0}) = \mathbf{0}$ for $j > p$.

These $2p+(m-p)+(n-p)=m+n$ vectors are orthonormal: the $\mathbf{w}_i^{\pm}$ are unit vectors because $\mathbf{u}_i$ and $\mathbf{v}_i$ are, and any two distinct vectors in the list pair to 0, since $(\mathbf{w}_i^{+})^{*}\mathbf{w}_i^{-}=\frac{1}{2}(1-1)=0$ and all other pairs have orthogonal $\mathbf{u}$-parts or orthogonal $\mathbf{v}$-parts. So they form an orthonormal eigenbasis of F^{m+n} with the stated eigenvalues, which are therefore the eigenvalue list of $\mathcal{H}(\mathbf{A})$ with multiplicity. This proves the proposition.

■

Applying Theorem 16.2.3 to $\mathcal{H}(\mathbf{A})$ instead of $\mathbf{A}^{*}\mathbf{A}$ gives Theorem 16.9.2 again, with subspaces of F^{m+n} in place of F^{n}. We took the shorter road; the dilation is recorded because it turns *any* theorem about Hermitian eigenvalues into one about singular values, which Section 10's exercises and Chapter 19 both exploit.

16.9.3 Perturbation, with no hypothesis at all

For Hermitian matrices, Corollary 16.3.6 says that $|\lambda_i(\mathbf{A}+\mathbf{E})-\lambda_i(\mathbf{A})|\le\|\mathbf{E}\|_2$ — provided $\mathbf{A}$ and $\mathbf{E}$ are Hermitian. That proviso is not decoration: Chapter 15's Example (A Jordan block's eigenvalues move like $\varepsilon^{1/k}$) shows the conclusion failing spectacularly without it. The corresponding statement for singular values needs no proviso whatsoever.

Theorem 16.9.4 — Weyl's Inequalities for Singular Values

Let $\mathbf{A},\mathbf{B}\in M_{m\times n}(F)$ and let $i,j\ge 1$ with $i+j-1\le n$. Then

$$\sigma_{i+j-1}(\mathbf{A}+\mathbf{B})\le\sigma_i(\mathbf{A})+\sigma_j(\mathbf{B}).$$

Idea. Put $k=i+j-1$. The min–max form of Theorem 16.9.2 bounds $\sigma_k(\mathbf{A}+\mathbf{B})$ from above as soon as we produce **one** subspace of dimension $n-k+1$ on which $\mathbf{A}+\mathbf{B}$ stretches by at most $\sigma_i(\mathbf{A})+\sigma_j(\mathbf{B})$. Each summand supplies a subspace where it is individually small — the tail subspaces of Lemma 16.9.1 — and the dimensions are chosen so that the two subspaces must overlap in something of the required size. On the overlap the triangle inequality finishes it.

Proof. Put $k=i+j-1\le n$. Let $T=\operatorname{span}(\mathbf{v}_i,\dots,\mathbf{v}_n)$ for the right singular vectors of $\mathbf{A}$ and $T'=\operatorname{span}(\mathbf{v}'_j,\dots,\mathbf{v}'_n)$ for those of $\mathbf{B}$, so that $\dim T=n-i+1$, $\dim T'=n-j+1$, and by Lemma 16.9.1 (a),

$$\|\mathbf{A}\mathbf{x}\|\le\sigma_i(\mathbf{A})\|\mathbf{x}\|\ \ (\mathbf{x}\in T),\qquad \|\mathbf{B}\mathbf{x}\|\le\sigma_j(\mathbf{B})\|\mathbf{x}\|\ \ (\mathbf{x}\in T').$$

By the dimension formula (Theorem 1.7.3) and $\dim(T+T')\le n$,

$$\begin{aligned}\dim(T\cap T')&\ge(n-i+1)+(n-j+1)-n\\&=n-(i+j-1)+1=n-k+1,\end{aligned}$$

which is at least 1 because $k\le n$. Choose a subspace $W\subseteq T\cap T'$ with $\dim W=n-k+1$ exactly; this is possible because every subspace has a subspace of each smaller dimension, obtained by truncating a basis. For $\mathbf{0}\ne\mathbf{x}\in W$, the triangle inequality (Corollary 10.1.6) gives

$$\|(\mathbf{A}+\mathbf{B})\mathbf{x}\|\le\|\mathbf{A}\mathbf{x}\|+\|\mathbf{B}\mathbf{x}\|\le\big(\sigma_i(\mathbf{A})+\sigma_j(\mathbf{B})\big)\|\mathbf{x}\|.$$

Hence the inner maximum over W is at most $\sigma_i(\mathbf{A}) + \sigma_j(\mathbf{B})$, and since $\sigma_k(\mathbf{A}+\mathbf{B})$ is the **minimum** of that inner maximum over all subspaces of dimension $n-k+1$ (Theorem 16.9.2), we get $\sigma_k(\mathbf{A}+\mathbf{B}) \le \sigma_i(\mathbf{A}) + \sigma_j(\mathbf{B})$. This proves the theorem.

■

Corollary 16.9.5 — Singular Values Are Perfectly Conditioned

Let $\mathbf{A}, \mathbf{E} \in M_{m\times n}(F)$. Then

$$|\sigma_i(\mathbf{A}+\mathbf{E}) - \sigma_i(\mathbf{A})| \le \|\mathbf{E}\|_2 \qquad \text{for every } 1 \le i \le n.$$

No hypothesis is placed on $\mathbf{A}$ or on $\mathbf{E}$.

Idea. Put $j = 1$ in the Weyl inequality for singular values: one index passes through unchanged, and the other matrix contributes only its largest singular value, which is $\|\mathbf{E}\|_2$. That bounds $\sigma_i(\mathbf{A}+\mathbf{E})$ from above; writing $\mathbf{A} = (\mathbf{A}+\mathbf{E}) + (-\mathbf{E})$ and doing it again bounds it from below.

Proof. Take $j = 1$ in Theorem 16.9.4, so that $i + j - 1 = i \le n$:

$$\sigma_i(\mathbf{A}+\mathbf{E}) \le \sigma_i(\mathbf{A}) + \sigma_1(\mathbf{E}) = \sigma_i(\mathbf{A}) + \|\mathbf{E}\|_2,$$

using Theorem 15.3.3 (c) for the last equality. Now apply the same inequality with $\mathbf{A}+\mathbf{E}$ in place of $\mathbf{A}$ and $-\mathbf{E}$ in place of $\mathbf{E}$, noting $\|-\mathbf{E}\|_2 = \|\mathbf{E}\|_2$ by homogeneity (Theorem 15.3.2 (b)):

$$\sigma_i(\mathbf{A}) = \sigma_i\big((\mathbf{A}+\mathbf{E}) + (-\mathbf{E})\big) \le \sigma_i(\mathbf{A}+\mathbf{E}) + \|\mathbf{E}\|_2.$$

The two inequalities together are the claim.

■

This is a Lipschitz bound with constant 1, exactly as Corollary 16.3.6 is for Hermitian eigenvalues, and with no dependence on n, on the conditioning of $\mathbf{A}$, or on the gaps between the singular values. What is new is the absence of hypotheses. It is worth seeing the contrast on the very matrix Chapter 15 used to show that eigenvalues have no such bound.

Example. (The Jordan block again, measured by its singular values)

Let $k \ge 2$, let $0 < \varepsilon < 1$, and let

$$\mathbf{A} = \mathbf{J}_k(0), \qquad \mathbf{A}_\varepsilon = \mathbf{J}_k(0) + \varepsilon \mathbf{E}_{k1}$$

be the matrices of Example (A Jordan block's eigenvalues move like $\varepsilon^{1/k}$). Compute the singular values of both, and compare how far they move with how far the eigenvalues move.

Solution. The columns of $\mathbf{A}_\varepsilon$ are $\varepsilon\mathbf{e}_k$ in position 1, and $\mathbf{e}_{j-1}$ in position j for $2 \le j \le k$.

These k columns are pairwise orthogonal, with norms $\varepsilon, 1, \dots, 1$, so

$$\mathbf{A}_\varepsilon^* \mathbf{A}_\varepsilon = \operatorname{diag}(\varepsilon^2, 1, \dots, 1),$$

whose eigenvalues in decreasing order are 1 with multiplicity $k-1$ and then ε^2, since $\varepsilon < 1$. By Definition 12.8.1 the singular values of $\mathbf{A}_\varepsilon$ are

$$\sigma_1 = \cdots = \sigma_{k-1} = 1, \qquad \sigma_k = \varepsilon.$$

Setting $\varepsilon = 0$ in the same computation, the singular values of $\mathbf{A} = \mathbf{J}_k(0)$ are $1, \dots, 1, 0$.

So every singular value moves by at most ε, and exactly one of them — the last — moves by exactly ε. The perturbation has $\|\varepsilon \mathbf{E}_{k1}\|_2 = \varepsilon$, computed in Example (A Jordan block's eigenvalues move like $\varepsilon^{1/k}$), so Corollary 16.9.5 is attained here and not merely satisfied.

Meanwhile Example (A Jordan block's eigenvalues move like $\varepsilon^{1/k}$) computed that the **eigenvalues** of the same two matrices are 0 (with multiplicity k) and the k-th roots of ε, all of modulus $\varepsilon^{1/k}$. For $k = 10$ and $\varepsilon = 10^{-10}$: the singular values move by 10^{-10}, and the eigenvalues move by 10^{-1}, a factor of a billion more. The same matrix, the same perturbation, two spectra — one of them stable and one of them not.

This is not a paradox. The singular values of $\mathbf{A}$ are the square roots of the eigenvalues of the Hermitian matrix $\mathbf{A}^*\mathbf{A}$, and Hermitian eigenvalues are stable; the eigenvalues of $\mathbf{A}$ itself are roots of a polynomial, and a repeated root is fragile. The instability lives in the passage from $\mathbf{A}$ to its eigenvalues, not in $\mathbf{A}$ — which is why a question that can be phrased in singular values should be.

Warning. **Weyl's inequality does not say $\sigma_k(\mathbf{A}+\mathbf{B}) \le \sigma_k(\mathbf{A}) + \sigma_k(\mathbf{B})$.** The index bookkeeping $i + j - 1$ is the content, not a technicality. Take

$$\mathbf{A} = \operatorname{diag}(1, 0), \qquad \mathbf{B} = \operatorname{diag}(0, 1).$$

Then $\sigma(\mathbf{A}) = \sigma(\mathbf{B}) = (1, 0)$, while $\mathbf{A} + \mathbf{B} = \mathbf{I}_2$ has $\sigma(\mathbf{I}_2) = (1, 1)$. So $\sigma_2(\mathbf{A}+\mathbf{B}) = 1$ while $\sigma_2(\mathbf{A}) + \sigma_2(\mathbf{B}) = 0$. What Theorem 16.9.4 does give here, with $i = j = 1$, is $\sigma_1(\mathbf{A}+\mathbf{B}) \le \sigma_1(\mathbf{A}) + \sigma_1(\mathbf{B}) = 2$, which holds. Only $i = 1$ or $j = 1$ lets an index pass through unchanged, which is why Corollary 16.9.5 is the case $j = 1$.

16.9.4 The best approximation of low rank

Chapter 12 §10 proved that the truncated singular value decomposition $\mathbf{A}_k$ of Definition 12.10.1 is the closest matrix of rank at most k to $\mathbf{A}$ in the Frobenius norm (Theorem 12.10.3), and then wrote, in the remark that closes its main proof:

> The same matrix $\mathbf{A}_k$ is also optimal in the **spectral norm** $\|\cdot\|_2$, where the minimum value is σ_{k+1} rather than $\left(\sum_{i>k} \sigma_i^2\right)^{1/2}$. We cannot state that here, because the spectral norm is defined only in Chapter 15.

Chapter 15 supplied the norm and then, in its closing ledger, handed the theorem to this chapter: "the theorem itself waits for Chapter 16, which proves it from the min–max description of the singular values." That description now exists. Here is the theorem.

Theorem 16.9.6 — Eckart–Young Theorem, Spectral Case

Let $\mathbf{A} \in M_{m\times n}(F)$ and let $0 \le k < n$. Then for **every** $\mathbf{B} \in M_{m\times n}(F)$ with $\operatorname{rank}\mathbf{B} \le k$,

$$\|\mathbf{A}-\mathbf{B}\|_2 \;\ge\; \sigma_{k+1}(\mathbf{A}),$$

and equality holds for the truncation $\mathbf{B} = \mathbf{A}_k$ of Definition 12.10.1. In words: $\mathbf{A}_k$ minimizes $\|\mathbf{A}-\mathbf{B}\|_2$ over all matrices of rank at most k, and the minimum value is $\sigma_{k+1}(\mathbf{A})$.

Idea. A matrix $\mathbf{B}$ of rank at most k has a large null space — dimension at least $n-k$ — and on that null space $\mathbf{A}-\mathbf{B}$ acts exactly as $\mathbf{A}$ does. The head subspace $H_{k+1} = \operatorname{span}(\mathbf{v}_1,\dots,\mathbf{v}_{k+1})$ is a place where $\mathbf{A}$ stretches by at least σ_{k+1}, and it has dimension $k+1$. Two subspaces of F^n of dimensions $n-k$ and $k+1$ cannot avoid each other, by Lemma 16.2.1, and a vector in both settles the matter in one line.

Proof. The lower bound. Let $\operatorname{rank}\mathbf{B} \le k$. By Rank–Nullity for matrices (Theorem 2.5.7), $\dim\operatorname{nul}(\mathbf{B}) = n - \operatorname{rank}\mathbf{B} \ge n-k$. Let $H = \operatorname{span}(\mathbf{v}_1,\dots,\mathbf{v}_{k+1})$, where $\mathbf{v}_1,\dots,\mathbf{v}_n$ are the right singular vectors of a fixed singular value decomposition of $\mathbf{A}$; then $\dim H = k+1$. Since

$$\dim\operatorname{nul}(\mathbf{B}) + \dim H \;\ge\; (n-k)+(k+1) = n+1 > n,$$

Lemma 16.2.1 gives a vector $\mathbf{x} \neq \mathbf{0}$ with $\mathbf{x} \in \operatorname{nul}(\mathbf{B}) \cap H$. For that $\mathbf{x}$, $\mathbf{B}\mathbf{x} = \mathbf{0}$, so $(\mathbf{A}-\mathbf{B})\mathbf{x} = \mathbf{A}\mathbf{x}$, and by Lemma 16.9.1 (b) applied with $k+1$ in place of k,

$$\|(\mathbf{A}-\mathbf{B})\mathbf{x}\| = \|\mathbf{A}\mathbf{x}\| \;\ge\; \sigma_{k+1}(\mathbf{A})\,\|\mathbf{x}\|.$$

Since $\mathbf{x} \neq \mathbf{0}$, dividing by $\|\mathbf{x}\|$ and using Theorem 15.3.2 (a), which says $\|\mathbf{A}-\mathbf{B}\|_2$ is the largest such ratio, gives $\|\mathbf{A}-\mathbf{B}\|_2 \ge \sigma_{k+1}(\mathbf{A})$.

Equality at the truncation. If $k \ge p$, then $\mathbf{A}_k = \mathbf{A}$ by Definition 12.10.1 and $\sigma_{k+1}(\mathbf{A}) = 0$ by our convention, so equality holds trivially; assume $k < p$. By Definition 12.10.1, $\mathbf{A}_k = \sum_{i\le k}\sigma_i\mathbf{u}_i\mathbf{v}_i^*$ has rank $\min(k, \operatorname{rank}\mathbf{A}) \le k$, and

$$\mathbf{A}-\mathbf{A}_k = \sum_{i>k}\sigma_i\mathbf{u}_i\mathbf{v}_i^* = \mathbf{U}\boldsymbol{\Sigma}^{(k)}\mathbf{V}^*,$$

where $\boldsymbol{\Sigma}^{(k)}$ is $\boldsymbol{\Sigma}$ with its first k diagonal entries replaced by 0. Since $\mathbf{U}$ is unitary, $(\mathbf{A}-\mathbf{A}_k)^*(\mathbf{A}-\mathbf{A}_k) = \mathbf{V}\,(\boldsymbol{\Sigma}^{(k)})^*\boldsymbol{\Sigma}^{(k)}\,\mathbf{V}^*$, which is similar to the diagonal matrix $(\boldsymbol{\Sigma}^{(k)})^*\boldsymbol{\Sigma}^{(k)}$; its eigenvalues are therefore $\sigma_{k+1}^2,\dots,\sigma_p^2$ together with zeros. By Definition 12.8.1 the singular values of $\mathbf{A}-\mathbf{A}_k$ are $\sigma_{k+1} \ge \sigma_{k+2} \ge \dots$ followed by zeros, the largest being σ_{k+1}. Hence $\|\mathbf{A}-\mathbf{A}_k\|_2 = \sigma_{k+1}(\mathbf{A})$ by Theorem 15.3.3 (c). This proves the theorem. ∎

So the *minimizer* is the same matrix in both norms, and only the *minimum value* changes: σ_{k+1} for the spectral norm, $\left(\sum_{i>k}\sigma_i^2\right)^{1/2}$ for the Frobenius norm. That the same $\mathbf{A}_k$ works for both is not a coincidence — it is optimal in every unitarily invariant norm at once, which is Chapter 20's theorem and needs machinery neither this section nor Chapter 12 has.

Example. (One matrix, two norms)

Let

$$\mathbf{A} = \begin{pmatrix} 3 & 1 & 0 \\ 1 & 3 & 0 \\ 0 & 0 & 1 \end{pmatrix} \in M_3(\mathbb{R}).$$

Find the best approximations of rank 1 and rank 2, and compute the error in both the spectral and the Frobenius norm.

Solution. $\mathbf{A}$ is symmetric and block diagonal. The 2×2 block $\left(\begin{smallmatrix} 3 & 1 \\ 1 & 3 \end{smallmatrix}\right)$ has trace 6 and determinant 8, hence eigenvalues 4 and 2, with orthonormal eigenvectors $\frac{1}{\sqrt{2}}(1,1)$ and $\frac{1}{\sqrt{2}}(1,-1)$; the third eigenvalue is 1, with eigenvector $\mathbf{e}_3$. All three eigenvalues are positive, so $\mathbf{A} \succ 0$ and its singular values are those eigenvalues (Theorem 12.1.5; $\mathbf{A}^*\mathbf{A} = \mathbf{A}^2$ has eigenvalues their squares):

$$\sigma_1 = 4, \quad \sigma_2 = 2, \quad \sigma_3 = 1,$$

with $\mathbf{u}_i = \mathbf{v}_i$ the unit eigenvectors $\frac{1}{\sqrt{2}}(1,1,0)$, $\frac{1}{\sqrt{2}}(1,-1,0)$, $\mathbf{e}_3$.

Truncating,

$$\mathbf{A}_1 = 4\mathbf{v}_1\mathbf{v}_1^\top = \begin{pmatrix} 2 & 2 & 0 \\ 2 & 2 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \qquad \mathbf{A}_2 = \begin{pmatrix} 3 & 1 & 0 \\ 1 & 3 & 0 \\ 0 & 0 & 0 \end{pmatrix},$$

the second because $4\mathbf{v}_1\mathbf{v}_1^\top + 2\mathbf{v}_2\mathbf{v}_2^\top$ restores the 2×2 block exactly. The error matrices are

$$\mathbf{A} - \mathbf{A}_1 = \begin{pmatrix} 1 & -1 & 0 \\ -1 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}, \qquad \mathbf{A} - \mathbf{A}_2 = \operatorname{diag}(0,0,1).$$

For $k = 1$: $\|\mathbf{A} - \mathbf{A}_1\|_2 = \sigma_2 = 2$ and $\|\mathbf{A} - \mathbf{A}_1\|_F = \sqrt{\sigma_2^2 + \sigma_3^2} = \sqrt{5} \approx 2.236$. Check the first directly: $\mathbf{A} - \mathbf{A}_1$ is symmetric with the 2×2 block $\left(\begin{smallmatrix} 1 & -1 \\ -1 & 1 \end{smallmatrix}\right)$, of eigenvalues 2 and 0, and the entry 1, so its largest eigenvalue in modulus is 2. Check the second directly: the sum of the squares of the five non-zero entries is $4 \cdot 1 + 1 = 5$.

For $k = 2$: both norms of $\operatorname{diag}(0,0,1)$ equal $1 = \sigma_3$, and the two formulas agree because only one singular value is discarded.

Quick check. A matrix has singular values $6, 3, 2, 1$. What is the smallest spectral-norm error of a rank-2 approximation, and how does it compare with the Frobenius-norm error found in Exercise (B1: Errors from the singular values alone)?

Solution. By Theorem 16.9.6 with $k = 2$, the minimum is $\sigma_3 = 2$. By Theorem 12.10.3 the Frobenius minimum is $\sqrt{\sigma_3^2 + \sigma_4^2} = \sqrt{5} \approx 2.236$. The Frobenius error is the larger of the two, as it must be: it counts every discarded singular value, while the spectral error counts only the largest one.

16.9.5 How far an invertible matrix is from being singular

Take $k = n-1$ in Theorem 16.9.6, with $\mathbf{A}$ square. A matrix of rank at most $n-1$ is precisely a singular matrix, so the theorem computes the distance from $\mathbf{A}$ to the set of singular matrices. That is the geometric content of Chapter 15's condition number, and it is the best payoff in this chapter.

Corollary 16.9.7 — The Distance to Singularity

Let $\mathbf{A} \in M_n(F)$ be invertible. Then

$$\min\{\|\mathbf{A}-\mathbf{B}\|_2 : \mathbf{B} \in M_n(F) \text{ singular}\} = \sigma_n(\mathbf{A}) = \frac{1}{\|\mathbf{A}^{-1}\|_2},$$

the minimum being attained at $\mathbf{B} = \mathbf{A}_{n-1}$. Consequently the **relative** distance from $\mathbf{A}$ to the nearest singular matrix is

$$\frac{\min\{\|\mathbf{A}-\mathbf{B}\|_2 : \mathbf{B} \text{ singular}\}}{\|\mathbf{A}\|_2} = \frac{\sigma_n(\mathbf{A})}{\sigma_1(\mathbf{A})} = \frac{1}{\kappa_2(\mathbf{A})},$$

the reciprocal of the spectral condition number of Definition 15.8.1.

Idea. A singular matrix has rank at most $n-1$, so this is the spectral Eckart–Young theorem with $k = n-1$, and the answer is the next singular value, σ_n. The formula $1/\|\mathbf{A}^{-1}\|_2$ is the same number read through the inverse, whose largest singular value is $1/\sigma_n$.

Proof. A matrix $\mathbf{B} \in M_n(F)$ is singular if and only if $\operatorname{rank}\mathbf{B} \le n-1$ (Theorem 2.4.4). So the set over which the minimum is taken is exactly the set appearing in Theorem 16.9.6 with $k = n-1$, and that theorem gives the value $\sigma_{(n-1)+1}(\mathbf{A}) = \sigma_n(\mathbf{A})$, attained at $\mathbf{A}_{n-1}$. The matrix $\mathbf{A}_{n-1}$ is singular because its rank is $\min(n-1, \operatorname{rank}\mathbf{A}) = n-1 < n$.

For the second expression: since $\operatorname{rank}\mathbf{A} = n$, exactly n singular values of $\mathbf{A}$ are nonzero (Theorem 12.8.1), so $\sigma_n(\mathbf{A}) > 0$. By Definition 15.8.1 and Proposition 15.8.2 (d), $\|\mathbf{A}\|_2\|\mathbf{A}^{-1}\|_2 = \kappa_2(\mathbf{A}) = \sigma_1(\mathbf{A})/\sigma_n(\mathbf{A})$, and $\|\mathbf{A}\|_2 = \sigma_1(\mathbf{A})$ by Theorem 15.3.3 (c); dividing, $\|\mathbf{A}^{-1}\|_2 = 1/\sigma_n(\mathbf{A})$. Dividing the minimum $\sigma_n(\mathbf{A})$ by $\|\mathbf{A}\|_2 = \sigma_1(\mathbf{A})$ gives $\sigma_n/\sigma_1 = 1/\kappa_2(\mathbf{A})$, the last display. This proves the corollary. ∎

What this settles. Chapter 15 defined $\kappa(\mathbf{A}) = \|\mathbf{A}\|\|\mathbf{A}^{-1}\|$ as the worst factor by which $\mathbf{A}$ magnifies a relative error, proved that the factor is attained, and described it geometrically through Lemma 15.8.1 as the ratio of the largest to the smallest stretch $\|\mathbf{A}\mathbf{x}\|$ over unit vectors $\mathbf{x}$. That is a statement about what $\mathbf{A}$ *does*. Corollary 16.9.7 is a statement about where $\mathbf{A}$ *is*: it says that $1/\kappa_2(\mathbf{A})$ measures the distance from $\mathbf{A}$ to the boundary of the invertible matrices, relative to the size of $\mathbf{A}$. A matrix with $\kappa_2 = 10^6$ is not merely a matrix that magnifies errors by a million; it is a matrix that a relative perturbation of one part in a million can make singular. "Ill-conditioned" and "nearly singular" are the same property, and this is the theorem that identifies them.

Two earlier exercises reached for this. Exercise (C1: How far is a matrix from being singular?) found the same distance in the Frobenius norm — also σ_n, since only one singular value is discarded when $k = n - 1$. Exercise (C2: The condition number is the reciprocal distance to singularity) obtained the spectral statement by hand, with a Neumann-series lower bound and the truncation as witness. Nothing above rests on either. What is new is that the distance to singularity is now the case $k = n-1$ of one theorem covering every rank, proved by a dimension count and stated as an attained minimum.

Example. (The nearest singular matrix, exactly and approximately)

(a) For the matrix $\mathbf{A}$ of Example (One matrix, two norms), find the nearest singular matrix and the relative distance to it.

(b) Do the same, to three significant figures, for $\mathbf{C} = \left(\begin{smallmatrix} 1 & 1 \\ 1 & 1.01 \end{smallmatrix}\right)$, the ill-conditioned matrix of Example (A system where the bound is attained).

Solution.

(a) The singular values are $4, 2, 1$, so by Corollary 16.9.7 the nearest singular matrix is at distance $\sigma_3 = 1$, and it is

$$\mathbf{A}_2 = \begin{pmatrix} 3 & 1 & 0 \\ 1 & 3 & 0 \\ 0 & 0 & 0 \end{pmatrix},$$

computed in Example (One matrix, two norms); it is singular because its last row is zero. Here $\kappa_2(\mathbf{A}) = 4/1 = 4$, so the relative distance is $\frac{1}{4}$: a perturbation of a quarter of the size of $\mathbf{A}$ is needed, and $\mathbf{A}$ is very well conditioned.

(b) $\mathbf{C}$ is symmetric with $\operatorname{tr}\mathbf{C} = \frac{201}{100}$ and $\det\mathbf{C} = \frac{1}{100}$, so its eigenvalues are

$$\frac{201 \pm \sqrt{201^2 - 400}}{200} = \frac{201 \pm \sqrt{40001}}{200},$$

both positive, hence equal to the singular values: $\sigma_1 \approx 2.00501$ and $\sigma_2 \approx 0.0049875$. So $\kappa_2(\mathbf{C}) \approx 402.0$ and the nearest singular matrix is at distance $\sigma_2 \approx 0.00499$, a **relative** distance of $1/\kappa_2(\mathbf{C}) \approx 0.00249$, about a quarter of one percent. The nearest singular matrix itself is $\mathbf{C}_1 = \sigma_1 \mathbf{v}_1 \mathbf{v}_1^{\top}$, which to five decimals is

$$\mathbf{C}_1 \approx \begin{pmatrix} 0.99749 & 1.00249 \\ 1.00249 & 1.00752 \end{pmatrix};$$

it is singular, and each entry differs from the corresponding entry of $\mathbf{C}$ by about 0.0025. Changing $\mathbf{C}$ in its third decimal place destroys its invertibility. That is what $\kappa_2 \approx 402$ means.

Warning. **The distance to singularity is not measured by the determinant.** Chapter 15 §08 warned that no threshold on $|\det\mathbf{A}|$ detects ill-conditioning, and Corollary 16.9.7 says exactly why: the quantity that decides nearness to singularity is σ_n, and $|\det\mathbf{A}| = \sigma_1\sigma_2\cdots\sigma_n$ is a product in which a tiny σ_n can be hidden by large partners, or a healthy σ_n buried by many small ones. For $\mathbf{A} = 10^{-6}\mathbf{I}_{10}$ all singular values are 10^{-6}, so $|\det\mathbf{A}| = 10^{-60}$ while the relative distance to singularity is $1/\kappa_2 = 1$, the largest it can ever be. For $\mathbf{A} = \operatorname{diag}(10^6, 10^{-6})$, $|\det\mathbf{A}| = 1$ while the relative distance is 10^{-12}. Only the *smallest* singular value knows.

16.9.6 Deleting a row

The last transfer is Cauchy interlacing. For a Hermitian matrix the operation was deleting a row **and** the matching column; for a general matrix there is no matching, and deleting a single row is enough.

Theorem 16.9.8 — Interlacing Under Deletion of a Row or a Column

Let $\mathbf{A} \in M_{m\times n}(F)$ with $m \geq 2$, and let $\mathbf{B} \in M_{(m-1)\times n}(F)$ be obtained from $\mathbf{A}$ by deleting one row. Then

$$\sigma_i(\mathbf{B}) \leq \sigma_i(\mathbf{A}) \quad (1 \leq i \leq n), \qquad \sigma_{i+1}(\mathbf{A}) \leq \sigma_i(\mathbf{B}) \quad (1 \leq i \leq n-1),$$

singular values beyond the p-th being read as 0. If instead $n \geq 2$ and $\mathbf{B} \in M_{m\times(n-1)}(F)$ is obtained from $\mathbf{A}$ by deleting one **column**, the same two chains hold, both over $1 \leq i \leq n-1$; written out, $\sigma_1(\mathbf{A}) \geq \sigma_1(\mathbf{B}) \geq \sigma_2(\mathbf{A}) \geq \cdots \geq \sigma_{n-1}(\mathbf{B}) \geq \sigma_n(\mathbf{A})$.

Idea. Deleting a row removes one term from the sum $\|\mathbf{Ax}\|^2 = \sum_{\text{rows}} |\text{row} \cdot \mathbf{x}|^2$. So $\|\mathbf{Bx}\| \leq \|\mathbf{Ax}\|$ for every $\mathbf{x}$, which gives the first chain from the min–max formula at once, because both matrices are compared over the same subspaces of F^n. For the second chain, the two norms **agree** on the hyperplane where the deleted row vanishes; intersecting a good subspace for $\mathbf{B}$ with that hyperplane costs one dimension, and one dimension is exactly one index.

Proof. Say row r of $\mathbf{A}$ is deleted, and write $\mathbf{r}^* \in M_{1\times n}(F)$ for that row. Summing squares of entries coordinate by coordinate,

$$\|\mathbf{Ax}\|^2 = \|\mathbf{Bx}\|^2 + |\mathbf{r}^*\mathbf{x}|^2 \qquad (\mathbf{x} \in F^n), \tag{16.9.3}$$

since the entries of $\mathbf{Ax}$ are those of $\mathbf{Bx}$ together with $\mathbf{r}^*\mathbf{x}$.

First chain. By Eq. 16.9.3, $\|\mathbf{Bx}\|/\|\mathbf{x}\| \leq \|\mathbf{Ax}\|/\|\mathbf{x}\|$ for every $\mathbf{x} \neq \mathbf{0}$. Both $\mathbf{A}$ and $\mathbf{B}$ have n columns, so Theorem 16.9.2 describes $\sigma_i(\mathbf{A})$ and $\sigma_i(\mathbf{B})$ as a minimum over the *same* family of subspaces of F^n, of a maximum of these two objective functions. A pointwise smaller function has a smaller maximum on each subspace and hence a smaller minimum over the family, so $\sigma_i(\mathbf{B}) \leq \sigma_i(\mathbf{A})$ for every $i \leq n$.

Second chain. Fix $1 \leq i \leq n-1$. Let $\mathbf{w}_1, \ldots, \mathbf{w}_n$ be the right singular vectors of a singular value decomposition of $\mathbf{B}$, and put $T = \operatorname{span}(\mathbf{w}_i, \ldots, \mathbf{w}_n)$, of dimension $n - i + 1$; by Lemma 16.9.1 (a) applied to $\mathbf{B}$,

$$\|\mathbf{Bx}\| \leq \sigma_i(\mathbf{B})\|\mathbf{x}\| \qquad (\mathbf{x} \in T).$$

Let $H = \{\mathbf{x} \in F^n : \mathbf{r}^*\mathbf{x} = 0\} = \operatorname{nul}(\mathbf{r}^*)$. Since $\mathbf{r}^*$ has at most one non-zero row, $\operatorname{rank}\mathbf{r}^* \leq 1$, so $\dim H \geq n-1$ by Rank–Nullity for matrices (Theorem 2.5.7). By the dimension formula (Theorem 1.7.3),

$$\dim(T \cap H) \;\geq\; (n-i+1) + (n-1) - n = n - i \;\geq\; 1.$$

Choose $W \subseteq T \cap H$ with $\dim W = n - i = n - (i+1) + 1$. For $\mathbf{0} \neq \mathbf{x} \in W$ we have $\mathbf{r}^*\mathbf{x} = 0$, so Eq. 16.9.3 gives $\|\mathbf{A}\mathbf{x}\| = \|\mathbf{B}\mathbf{x}\| \leq \sigma_i(\mathbf{B})\|\mathbf{x}\|$. Hence the inner maximum over W is at most $\sigma_i(\mathbf{B})$, and $\sigma_{i+1}(\mathbf{A})$, being the minimum of that inner maximum over all subspaces of dimension $n-(i+1)+1$ (Theorem 16.9.2), is at most $\sigma_i(\mathbf{B})$.

Columns. Deleting column c of $\mathbf{A}$ is deleting row c of $\mathbf{A}^*$. Taking conjugate transposes in $\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^*$ gives $\mathbf{A}^* = \mathbf{V}\mathbf{\Sigma}^*\mathbf{U}^*$, in which $\mathbf{\Sigma}^*$ has the same diagonal $\sigma_1, \ldots, \sigma_p$; so by Theorem 12.8.2, $\sigma_i(\mathbf{A}^*) = \sigma_i(\mathbf{A})$ for every $i \leq p$, and the same holds for $\mathbf{B}$ and $\mathbf{B}^*$. Both $\mathbf{A}^*$ and $\mathbf{B}^*$ have m columns, so the row statement applied to them gives $\sigma_i(\mathbf{B}) \leq \sigma_i(\mathbf{A})$ for $i \leq m$ and $\sigma_{i+1}(\mathbf{A}) \leq \sigma_i(\mathbf{B})$ for $i \leq m-1$. The remaining indices are free: if $i > m$ then i exceeds $\min(m, n-1)$, so $\sigma_i(\mathbf{B}) = 0$ and the first inequality is trivial; and if $i \geq m$ then $i+1 > p$, so $\sigma_{i+1}(\mathbf{A}) = 0$ and the second is trivial. Hence both chains hold on the stated ranges. This proves the theorem.

■

Example. (Interlacing on a 3 × 2 matrix)

Let $\mathbf{A} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \\ 1 & 1 \end{pmatrix}$, the matrix of Example (The best rank-one approximation of a 3 × 2 matrix). Verify Theorem 16.9.8 for each of the three rows that could be deleted.

Solution. Example (The best rank-one approximation of a 3 × 2 matrix) computed $\mathbf{A}^\top\mathbf{A} = \left(\begin{smallmatrix} 2 & 1 \\ 1 & 2 \end{smallmatrix}\right)$, with eigenvalues 3 and 1, so $\sigma_1(\mathbf{A}) = \sqrt{3} \approx 1.732$ and $\sigma_2(\mathbf{A}) = 1$.

Deleting row 1 or row 2. The remaining matrix is $\left(\begin{smallmatrix} 0 & 1 \\ 1 & 1 \end{smallmatrix}\right)$ or $\left(\begin{smallmatrix} 1 & 0 \\ 1 & 1 \end{smallmatrix}\right)$. In both cases $\mathbf{B}^\top\mathbf{B} = \left(\begin{smallmatrix} 1 & 1 \\ 1 & 2 \end{smallmatrix}\right)$, with trace 3 and determinant 1, hence eigenvalues $(3 \pm \sqrt{5})/2$. Their square roots are $(1+\sqrt{5})/2 \approx 1.618$ and $(\sqrt{5}-1)/2 \approx 0.618$ — the two are reciprocal, since $(3+\sqrt{5})/2 \cdot (3-\sqrt{5})/2 = 1$. The interlacing reads

$$1.732 \;\geq\; 1.618 \;\geq\; 1 \;\geq\; 0.618,$$

that is $\sigma_1(\mathbf{A}) \geq \sigma_1(\mathbf{B}) \geq \sigma_2(\mathbf{A}) \geq \sigma_2(\mathbf{B})$, as the theorem requires.

Deleting row 3. The remaining matrix is $\mathbf{I}_2$, with $\sigma_1 = \sigma_2 = 1$, and the chain reads $1.732 \geq 1 \geq 1 \geq 1$. Here the second inequality of the first chain and the inequality of the second chain are both equalities: deleting the row that carried all the interaction between the two columns leaves a perfectly conditioned matrix.

Everything in this section came from one move: a singular value is the square root of an eigenvalue of a Hermitian matrix, so the min–max theory transfers wholesale. What the transfer bought is worth listing. The spectral half of the Eckart–Young theorem, which Chapter 12 could state only in the Frobenius norm, is now proved. The condition number of Chapter 15 has a geometric meaning: $1/\kappa_2(\mathbf{A})$ is how far, relatively, $\mathbf{A}$ sits from the nearest singular matrix. And singular values turned out to be perfectly conditioned with no hypothesis at all, which the Jordan block showed eigenvalues are not. The Hermitian dilation $\mathcal{H}(\mathbf{A})$ is the other bridge from singular values to Hermitian eigenvalues; Section 10's exercises use it, and Chapter 19 leans on it for perturbation bounds.

16.9.7 Exercises

16.9.7.1 A. Check your understanding

Exercise A1.

(a) State the min–max description of $\sigma_k(\mathbf{A})$, naming the dimension of the subspaces in each of the two forms.

(b) Explain in one sentence why the identity $\|\mathbf{Ax}\|^2/\|\mathbf{x}\|^2 = R_{\mathbf{A}^*\mathbf{A}}(\mathbf{x})$ is what makes the whole section possible.

(c) State the bound of Corollary 16.9.5 and say precisely which hypotheses it needs, comparing with Corollary 16.3.6.

(d) What is $\min\{\|\mathbf{A}-\mathbf{B}\|_2 : \operatorname{rank}\mathbf{B} \le k\}$, and what is the corresponding Frobenius-norm minimum? Which of the two is larger, and why?

(e) Decide whether the statement is correct, and justify: "a square matrix with a very small determinant is close to a singular matrix".

Solution.

(a) See Theorem 16.9.2: $\sigma_k(\mathbf{A})$ is the minimum, over subspaces $W \le F^n$ of dimension $n-k+1$, of $\max\{\|\mathbf{Ax}\|/\|\mathbf{x}\| : \mathbf{0} \ne \mathbf{x} \in W\}$; equivalently the maximum, over subspaces of dimension k, of the corresponding minimum.

(b) It converts a statement about the rectangular matrix $\mathbf{A}$, which has no eigenvalues, into a statement about the Hermitian matrix $\mathbf{A}^*\mathbf{A}$, which has the whole of Sections 1 to 8 available; and the conversion loses nothing, because the square root is increasing.

(c) $|\sigma_i(\mathbf{A}+\mathbf{E}) - \sigma_i(\mathbf{A})| \le \|\mathbf{E}\|_2$, for **arbitrary** $\mathbf{A}, \mathbf{E} \in M_{m\times n}(F)$ — no symmetry, no smallness, no squareness. Corollary 16.3.6 is the same bound for eigenvalues, but it requires both $\mathbf{A}$ and $\mathbf{E}$ to be Hermitian, and Example (A Jordan block's eigenvalues move like $\varepsilon^{1/k}$) shows the bound is false without that.

(d) $\sigma_{k+1}(\mathbf{A})$ in the spectral norm (Theorem 16.9.6) and $\left(\sum_{i>k}\sigma_i^2\right)^{1/2}$ in the Frobenius norm (Theorem 12.10.3). The Frobenius value is the larger, since $\sum_{i>k}\sigma_i^2 \ge \sigma_{k+1}^2$; it charges for every discarded singular value, the spectral norm only for the biggest.

(e) Incorrect. Nearness to singularity is measured by σ_n, not by det (Corollary 16.9.7). The matrix $10^{-6}\mathbf{I}_{10}$ has determinant 10^{-60} and relative distance 1 to the singular matrices, the largest possible value. The determinant is the product of all the singular values and cannot report the smallest one.

16.9.7.2 B. Practice

Exercise B1: Two norms, one list of singular values.

A matrix $\mathbf{A} \in M_{5\times 4}(\mathbb{R})$ has singular values $8, 4, 4, 1$.

(a) Compute $\min\{\|\mathbf{A}-\mathbf{B}\|_2 : \operatorname{rank}\mathbf{B} \le k\}$ for $k = 0, 1, 2, 3$.

(b) Compute the corresponding Frobenius minima and say for which k the two agree.

(c) Compute $\kappa_2(\mathbf{A})$ and the relative distance from $\mathbf{A}$ to the set of matrices of rank at most 3.

Solution.

(a) By Theorem 16.9.6 the minimum is σ_{k+1}, so the four values are $8, 4, 4, 1$ for $k = 0, 1, 2, 3$.

(b) By Theorem 12.10.3 the minimum is $\left(\sum_{i>k} \sigma_i^2\right)^{1/2}$:

$$\sqrt{64+16+16+1} = \sqrt{97}, \quad \sqrt{33}, \quad \sqrt{17}, \quad 1$$

for $k = 0, 1, 2, 3$, approximately $9.849,\ 5.745,\ 4.123,\ 1$. They agree only at $k = 3$, where exactly one singular value is discarded.

(c) $\mathbf{A}$ has rank 4 and full column rank, so Definition 15.8.1 gives $\kappa_2(\mathbf{A}) = \sigma_1/\sigma_4 = 8$. The distance to the matrices of rank at most 3 is $\sigma_4 = 1$ and $\|\mathbf{A}\|_2 = 8$, so the relative distance is $\frac{1}{8} = 1/\kappa_2(\mathbf{A})$ — the rectangular analogue of Corollary 16.9.7, and for the same reason.

Exercise B2: The nearest singular matrix.

Let $\mathbf{A} = \begin{pmatrix} 2 & 1 \\ 1 & 1 \end{pmatrix}$, whose condition number $\kappa_2(\mathbf{A}) = \frac{7+3\sqrt{5}}{2} \approx 6.854$ was computed in Example (Three condition numbers of one matrix).

(a) Find the singular values of $\mathbf{A}$ and the distance from $\mathbf{A}$ to the nearest singular matrix.

(b) Write down a singular matrix at exactly that distance, and check that it is singular.

(c) Compute the relative distance and compare it with $1/\kappa_2(\mathbf{A})$.

Solution.

(a) $\mathbf{A}$ is symmetric with $\operatorname{tr}\mathbf{A} = 3$ and $\det\mathbf{A} = 1$, so its eigenvalues are $(3 \pm \sqrt{5})/2$, both positive; hence these are also its singular values,

$$\sigma_1 = \tfrac{3+\sqrt{5}}{2} \approx 2.618, \qquad \sigma_2 = \tfrac{3-\sqrt{5}}{2} \approx 0.382.$$

By Corollary 16.9.7 the distance to the nearest singular matrix is $\sigma_2 = (3-\sqrt{5})/2$.

(b) The witness is $\mathbf{A}_1 = \sigma_1 \mathbf{v}_1 \mathbf{v}_1^{\top}$, where $\mathbf{v}_1$ is a unit eigenvector for σ_1. From $(2-\sigma_1)x_1 + x_2 = 0$ we may take $\mathbf{v}_1$ parallel to $(2, \sqrt{5}-1)$, whose squared length is $4 + (6-2\sqrt{5}) = 10 - 2\sqrt{5}$. Hence

$$\mathbf{A}_1 = \frac{3+\sqrt{5}}{2} \cdot \frac{1}{10-2\sqrt{5}} \begin{pmatrix} 4 & 2(\sqrt{5}-1) \\ 2(\sqrt{5}-1) & 6-2\sqrt{5} \end{pmatrix} = \begin{pmatrix} 1+\frac{2\sqrt{5}}{5} & \frac{1}{2}+\frac{3\sqrt{5}}{10} \\ \frac{1}{2}+\frac{3\sqrt{5}}{10} & \frac{1}{2}+\frac{\sqrt{5}}{10} \end{pmatrix},$$

approximately $\left(\begin{smallmatrix} 1.894 & 1.171 \\ 1.171 & 0.724 \end{smallmatrix}\right)$. It is singular: it is a scalar multiple of $\mathbf{v}_1\mathbf{v}_1^{\top}$, which has rank 1, so its determinant is 0. (Directly: $1.894 \times 0.724 - 1.171^2 = 0$ to three decimals.)

(c) $\|\mathbf{A}\|_2 = \sigma_1$, so the relative distance is

$$\frac{\sigma_2}{\sigma_1} = \frac{3-\sqrt{5}}{3+\sqrt{5}} = \frac{(3-\sqrt{5})^2}{4} = \frac{7-3\sqrt{5}}{2} \approx 0.1459,$$

using $(3-\sqrt{5})(3+\sqrt{5}) = 4$. And $1/\kappa_2(\mathbf{A}) = 2/(7+3\sqrt{5}) = (7-3\sqrt{5})/2$, since $(7+3\sqrt{5})(7-3\sqrt{5}) = 49-45 = 4$. The two agree, as Corollary 16.9.7 says.

Exercise B3: Interlacing by hand.

Let $\mathbf{A} = \begin{pmatrix} 2 & 0 \\ 0 & 1 \\ 0 & 2 \end{pmatrix}$.

(a) Compute the singular values of $\mathbf{A}$.

(b) Compute the singular values of each of the three matrices obtained by deleting one row, and check Theorem 16.9.8 in each case.

Solution.

(a) $\mathbf{A}^\top\mathbf{A} = \left(\begin{smallmatrix} 4 & 0 \\ 0 & 5 \end{smallmatrix}\right)$, so the eigenvalues are 5 and 4 and $\sigma_1(\mathbf{A}) = \sqrt{5} \approx 2.236$, $\sigma_2(\mathbf{A}) = 2$.

(b) Deleting row 1 leaves $\left(\begin{smallmatrix} 0 & 1 \\ 0 & 2 \end{smallmatrix}\right)$, with $\mathbf{B}^\top\mathbf{B} = \operatorname{diag}(0,5)$, so $\sigma_1 = \sqrt{5}$, $\sigma_2 = 0$; the chain reads $\sqrt{5} \geq \sqrt{5} \geq 2 \geq 0$.

Deleting row 2 leaves $\left(\begin{smallmatrix} 2 & 0 \\ 0 & 2 \end{smallmatrix}\right)$, with singular values $2, 2$; the chain reads $\sqrt{5} \geq 2 \geq 2 \geq 2$.

Deleting row 3 leaves $\left(\begin{smallmatrix} 2 & 0 \\ 0 & 1 \end{smallmatrix}\right)$, with singular values $2, 1$; the chain reads $\sqrt{5} \geq 2 \geq 2 \geq 1$.

All three satisfy $\sigma_1(\mathbf{A}) \geq \sigma_1(\mathbf{B}) \geq \sigma_2(\mathbf{A}) \geq \sigma_2(\mathbf{B})$, as Theorem 16.9.8 requires.

16.9.7.3 C. Going deeper

Exercise C1: Rank cannot drop suddenly.

Let $\mathbf{A} \in M_{m\times n}(F)$ have rank $r \geq 1$.

(a) Prove that every $\mathbf{B} \in M_{m\times n}(F)$ with $\|\mathbf{A}-\mathbf{B}\|_2 < \sigma_r(\mathbf{A})$ has $\operatorname{rank}\mathbf{B} \geq r$.

(b) Deduce that for every $\mathbf{A}$ there is an $\varepsilon > 0$ such that every $\mathbf{B}$ within ε of $\mathbf{A}$ in the spectral norm has $\operatorname{rank}\mathbf{B} \geq \operatorname{rank}\mathbf{A}$.

(c) Show that the reverse inequality can fail however small ε is: give matrices $\mathbf{A}$ and $\mathbf{B}$ with $\|\mathbf{A}-\mathbf{B}\|_2$ as small as we like and $\operatorname{rank}\mathbf{B} > \operatorname{rank}\mathbf{A}$.

Hint: for (a), argue by contradiction with Theorem 16.9.6.

Solution.

(a) Suppose $\operatorname{rank}\mathbf{B} \leq r-1$. By Theorem 16.9.6 with $k = r-1$,

$$\|\mathbf{A}-\mathbf{B}\|_2 \;\geq\; \sigma_r(\mathbf{A}),$$

contradicting the hypothesis. Hence $\operatorname{rank}\mathbf{B} \geq r$.

(b) If $\mathbf{A} = 0$ any $\varepsilon > 0$ works, since then $r = 0$ and every $\mathbf{B}$ has rank at least 0. Otherwise take $\varepsilon = \sigma_r(\mathbf{A})$, which is > 0 because $\mathbf{A}$ has exactly $r = \operatorname{rank}\mathbf{A}$ non-zero singular values (Theorem 12.8.3). Then (a) applies.

(c) Take $\mathbf{A} = \operatorname{diag}(1, 0)$, of rank 1, and $\mathbf{B} = \operatorname{diag}(1, \delta)$ with $\delta > 0$. Then $\mathbf{A} - \mathbf{B} = \operatorname{diag}(0, -\delta)$, so $\|\mathbf{A} - \mathbf{B}\|_2 = \delta$, as small as we like, while $\operatorname{rank}\mathbf{B} = 2 > 1 = \operatorname{rank}\mathbf{A}$. Rank can jump **up** under an arbitrarily small perturbation, and never jumps down under a small one: that asymmetry is exactly (a), and it is why numerical rank is defined by a threshold on the singular values rather than by exact vanishing.

Exercise C2: The dilation, and a second proof of the perturbation bound.

Let $\mathbf{A}, \mathbf{E} \in M_{m\times n}(F)$ and let $\mathcal{H}(\cdot)$ be the Hermitian dilation of Proposition 16.9.3.

(a) Prove that $\mathcal{H}(\mathbf{A} + \mathbf{E}) = \mathcal{H}(\mathbf{A}) + \mathcal{H}(\mathbf{E})$ and that $\mathcal{H}(\mathbf{E})$ is Hermitian.

(b) Prove that $\|\mathcal{H}(\mathbf{E})\|_2 = \|\mathbf{E}\|_2$.

(c) Hence give a second proof of Corollary 16.9.5 for $1 \le i \le p$, using Corollary 16.3.6, and say in one sentence why this route explains the absence of hypotheses on $\mathbf{E}$.

Hint: for (b), use Proposition 16.9.3 and Theorem 15.3.3 (c).

Solution.

(a) Both claims are immediate from the block form: $\mathcal{H}$ is built entrywise from $\mathbf{A}$ and $\mathbf{A}^*$, and both $\mathbf{A} \mapsto \mathbf{A}$ and $\mathbf{A} \mapsto \mathbf{A}^*$ are additive, so

$$\mathcal{H}(\mathbf{A} + \mathbf{E}) = \begin{pmatrix} \mathbf{0} & \mathbf{A} + \mathbf{E} \\ \mathbf{A}^* + \mathbf{E}^* & \mathbf{0} \end{pmatrix} = \mathcal{H}(\mathbf{A}) + \mathcal{H}(\mathbf{E}).$$

That $\mathcal{H}(\mathbf{E})$ is Hermitian was proved in Proposition 16.9.3, which places no hypothesis on its argument.

(b) Write $\mathbf{M} = \mathcal{H}(\mathbf{E})$, which is Hermitian by (a). Then $\mathbf{M}^*\mathbf{M} = \mathbf{M}^2$, whose eigenvalues are the squares of those of $\mathbf{M}$ (apply Corollary 11.4.3 to $\mathbf{M}$ and square the diagonal). By Proposition 16.9.3 the eigenvalues of $\mathbf{M}$ are $\pm\sigma_i(\mathbf{E})$ for $i \le p$ together with zeros, so the eigenvalues of $\mathbf{M}^*\mathbf{M}$ are the numbers $\sigma_i(\mathbf{E})^2$, each twice, together with zeros. The largest is $\sigma_1(\mathbf{E})^2$, so $\sigma_1(\mathbf{M}) = \sigma_1(\mathbf{E})$ by Definition 12.8.1, and Theorem 15.3.3 (c) turns this into $\|\mathcal{H}(\mathbf{E})\|_2 = \|\mathbf{E}\|_2$.

(c) Let $1 \le i \le p$. By Proposition 16.9.3 the largest p eigenvalues of $\mathcal{H}(\mathbf{A})$ are $\sigma_1(\mathbf{A}) \ge \cdots \ge \sigma_p(\mathbf{A})$, all of the remaining ones being ≤ 0; so $\lambda_i(\mathcal{H}(\mathbf{A})) = \sigma_i(\mathbf{A})$, and likewise $\lambda_i(\mathcal{H}(\mathbf{A} + \mathbf{E})) = \sigma_i(\mathbf{A} + \mathbf{E})$. By (a), $\mathcal{H}(\mathbf{A} + \mathbf{E}) = \mathcal{H}(\mathbf{A}) + \mathcal{H}(\mathbf{E})$ with $\mathcal{H}(\mathbf{A})$ and $\mathcal{H}(\mathbf{E})$ both Hermitian, so Corollary 16.3.6 applies and gives

$$|\sigma_i(\mathbf{A} + \mathbf{E}) - \sigma_i(\mathbf{A})| = |\lambda_i(\mathcal{H}(\mathbf{A} + \mathbf{E})) - \lambda_i(\mathcal{H}(\mathbf{A}))| \le \|\mathcal{H}(\mathbf{E})\|_2 = \|\mathbf{E}\|_2.$$

The route explains the missing hypotheses: Corollary 16.3.6 demands that the perturbation be Hermitian, and $\mathcal{H}(\mathbf{E})$ **is** Hermitian for every $\mathbf{E}$ whatsoever. Passing to the dilation manufactures the hypothesis instead of assuming it.

16.10 Inertia, Again and Additively

Chapter 13 attached three numbers to a real symmetric matrix — how many positive, how many negative, how many zero entries appear on the diagonal after a congruence — and proved that the three do not depend on which congruence was used. The proof there was elementary and self-contained: an orthogonal basis for the form, two subspaces, a dimension count. This section proves the same theorem a second time, from the min–max description of the eigenvalues, and then shows what the second proof buys that the first could not: the three numbers become **additive across a Schur complement**.

Throughout, $F = \mathbb{R}$ or $F = \mathbb{C}$, and every matrix whose eigenvalues or inertia are named is Hermitian — real symmetric when $F = \mathbb{R}$. Its eigenvalues are real and are indexed decreasingly, $\lambda_1(\mathbf{A}) \geq \cdots \geq \lambda_n(\mathbf{A})$, as everywhere in this chapter. **Congruence** means the operation $\mathbf{A} \mapsto \mathbf{P}^*\mathbf{A}\mathbf{P}$ with $\mathbf{P}$ invertible, which sends Hermitian matrices to Hermitian matrices; over $\mathbb{R}$ the star is the plain transpose and this is exactly the relation $\mathbf{A} \simeq \mathbf{B}$ of Definition 13.2.1, and Chapter 12 already used the complex version in Proposition 12.1.2.

16.10.1 A symbol for the triple

Chapter 13 §05 named the three counts and proved them well defined, and Definition 13.5.1 records the words: the triple (n_+, n_-, n_0) is the **inertia** and the pair (n_+, n_-) the **signature**. What it did not do is give the triple a symbol, because it never needed to write an equation between two triples. This section writes several, so the symbol is worth the line it costs.

Definition 16.10.1 — The Inertia Triple

Let $\mathbf{A} \in M_n(F)$ be Hermitian, with eigenvalues $\lambda_1(\mathbf{A}) \geq \cdots \geq \lambda_n(\mathbf{A})$ listed **with multiplicity**. Write $n_+(\mathbf{A})$, $n_-(\mathbf{A})$ and $n_0(\mathbf{A})$ for the numbers of indices i with $\lambda_i(\mathbf{A}) > 0$, with $\lambda_i(\mathbf{A}) < 0$ and with $\lambda_i(\mathbf{A}) = 0$, and set

$$\operatorname{In}(\mathbf{A}) := \big(n_+(\mathbf{A}),\ n_-(\mathbf{A}),\ n_0(\mathbf{A})\big) \in \mathbb{N}^3.$$

Triples are added **entrywise**.

Clause by clause. Every eigenvalue is counted, so $n_+ + n_- + n_0 = n$ always. The counts are *with multiplicity*: $\operatorname{In}(\mathbf{I}_n) = (n, 0, 0)$, not $(1, 0, 0)$. And $n_0(\mathbf{A}) = \dim \operatorname{nul}(\mathbf{A})$, because a Hermitian matrix is unitarily diagonalizable (Corollary 11.4.3, or Corollary 11.5.2 when $F = \mathbb{R}$), so the eigenspace for 0 has dimension equal to the multiplicity of 0 in the list; equivalently $n_+ + n_- = \operatorname{rank} \mathbf{A}$.

For $F = \mathbb{R}$ this is not a new object. Theorem 13.5.3 says precisely that the numbers of positive, negative and zero *eigenvalues* of a real symmetric $\mathbf{A}$ are the numbers of positive, negative and zero *diagonal entries* after any congruence to diagonal form — that is, the inertia of Definition 13.5.1. So $\operatorname{In}(\mathbf{A})$ is the old triple, freshly abbreviated.

A few values, and the dictionary with definiteness. $\operatorname{In}(\mathbf{0}_n) = (0, 0, n)$, and $\operatorname{In}(\operatorname{diag}(1, -1)) = (1, 1, 0)$. By Theorem 12.1.4, $\mathbf{A} \succeq 0$ exactly when every eigenvalue is ≥ 0, that is when $n_-(\mathbf{A}) = 0$; by Theorem 12.1.5, $\mathbf{A} \succ 0$ exactly when $\operatorname{In}(\mathbf{A}) = (n, 0, 0)$. Definiteness is the extreme case of inertia, and everything below degenerates to a known statement about definiteness when the

triple is extreme.

16.10.2 Sylvester's law, proved again

The description of n_+ that this chapter can supply is not a count of diagonal entries at all. It is a maximum over subspaces, and it mentions no basis, no diagonalization and no matrix.

Theorem 16.10.1 — Sylvester's Law of Inertia, Second Proof

Let $\mathbf{A} \in M_n(F)$ be Hermitian. Call a subspace $W \leq F^n$ **$\mathbf{A}$-positive** if $\langle \mathbf{Ax}, \mathbf{x} \rangle > 0$ for every $\mathbf{x} \in W$ with $\mathbf{x} \neq \mathbf{0}$. Then:

(a) $n_+(\mathbf{A}) = \max\{\dim W : W \text{ is } \mathbf{A}\text{-positive}\}$, and the maximum is attained at the span of an orthonormal family of eigenvectors for the positive eigenvalues of $\mathbf{A}$;

(b) for every invertible $\mathbf{P} \in M_n(F)$, the matrix $\mathbf{P}^*\mathbf{AP}$ is Hermitian and

$$\mathrm{In}(\mathbf{P}^*\mathbf{AP}) = \mathrm{In}(\mathbf{A}).$$

Over $\mathbb{R}$, part (b) is Sylvester's Law of Inertia, Theorem 13.5.1.

Idea. For (a), read Theorem 16.2.3 through a sign. Its max–min form says $\lambda_k(\mathbf{A})$ is the largest value that $R_{\mathbf{A}}$ can be *guaranteed* to exceed on a k-dimensional subspace; and "W is $\mathbf{A}$-positive" says exactly that $R_{\mathbf{A}}$ is guaranteed to be positive on W. So $\mathbf{A}$-positive subspaces of dimension k exist precisely when $\lambda_k(\mathbf{A}) > 0$, which is precisely when $k \leq n_+$. For (b), the right-hand side of (a) is defined from the quadratic form alone, and a congruence is a change of variables inside that form: $\mathbf{x} \mapsto \mathbf{Px}$ matches up the two families of positive subspaces, dimension for dimension.

Proof. Throughout, note that $\langle \mathbf{Ax}, \mathbf{x} \rangle = \mathbf{x}^*\mathbf{Ax}$ is real for Hermitian $\mathbf{A}$ (Proposition 10.6.7 (a), or directly: $\overline{\mathbf{x}^*\mathbf{Ax}} = \mathbf{x}^*\mathbf{A}^*\mathbf{x} = \mathbf{x}^*\mathbf{Ax}$), and that for $\mathbf{x} \neq \mathbf{0}$ the sign of $\langle \mathbf{Ax}, \mathbf{x} \rangle$ is the sign of the Rayleigh quotient $R_{\mathbf{A}}(\mathbf{x}) = \langle \mathbf{Ax}, \mathbf{x} \rangle / \langle \mathbf{x}, \mathbf{x} \rangle$ of Definition 16.1.1, since $\langle \mathbf{x}, \mathbf{x} \rangle = \|\mathbf{x}\|^2 > 0$. So W is $\mathbf{A}$-positive if and only if $R_{\mathbf{A}}(\mathbf{x}) > 0$ for every $\mathbf{x} \in W \setminus \{\mathbf{0}\}$.

(a), the lower bound. Put $k = n_+(\mathbf{A})$. If $k = 0$ the zero subspace is $\mathbf{A}$-positive and there is nothing to prove, so assume $k \geq 1$. By the spectral theorem (Corollary 11.4.3, or Corollary 11.5.2 when $F = \mathbb{R}$) there is an orthonormal basis $\mathbf{q}_1, \ldots, \mathbf{q}_n$ of F^n with $\mathbf{Aq}_i = \lambda_i(\mathbf{A})\mathbf{q}_i$, the eigenvalues in decreasing order. Put $W_0 = \mathrm{span}(\mathbf{q}_1, \ldots, \mathbf{q}_k)$, of dimension k. For $\mathbf{0} \neq \mathbf{x} = \sum_{i \leq k} c_i \mathbf{q}_i$, expanding by orthonormality,

$$\langle \mathbf{Ax}, \mathbf{x} \rangle = \sum_{i=1}^{k} \lambda_i(\mathbf{A}) |c_i|^2 \;\geq\; \lambda_k(\mathbf{A}) \sum_{i=1}^{k} |c_i|^2 = \lambda_k(\mathbf{A}) \|\mathbf{x}\|^2 > 0,$$

because $\lambda_i(\mathbf{A}) \geq \lambda_k(\mathbf{A})$ for $i \leq k$ and $\lambda_k(\mathbf{A}) > 0$, the latter since $k = n_+(\mathbf{A})$ counts the positive eigenvalues of a decreasing list. So W_0 is $\mathbf{A}$-positive of dimension $n_+(\mathbf{A})$.

(a), the upper bound. Let W be $\mathbf{A}$-positive with $d = \dim W \geq 1$. The unit sphere $S_W = \{\mathbf{x} \in W : \|\mathbf{x}\| = 1\}$ is a closed bounded subset of F^n, hence compact by fact (A3) of Chapter 15's introduction, and it is non-empty because $d \geq 1$. The function $\mathbf{x} \mapsto R_{\mathbf{A}}(\mathbf{x})$ is continuous on it, so by the extreme value theorem — fact (A4) of Chapter

15's introduction — it attains a minimum $m = R_{\mathbf{A}}(\mathbf{x}_0)$ there, and $m > 0$ because $\mathbf{x}_0 \in W$ is non-zero. By homogeneity of $R_{\mathbf{A}}$, the same m is the minimum over all non-zero $\mathbf{x} \in W$. Now W is one competitor in the max–min form of Theorem 16.2.3, so

$$\lambda_d(\mathbf{A}) = \max_{\dim W' = d} \min_{\mathbf{0} \neq \mathbf{x} \in W'} R_{\mathbf{A}}(\mathbf{x}) \;\geq\; m \;>\; 0.$$

A decreasing list with $\lambda_d > 0$ has at least d positive entries, so $d \leq n_+(\mathbf{A})$. Together with the lower bound this proves (a).

(b). Put $\mathbf{B} = \mathbf{P}^*\mathbf{A}\mathbf{P}$. Then $\mathbf{B}^* = \mathbf{P}^*\mathbf{A}^*\mathbf{P} = \mathbf{B}$, so $\mathbf{B}$ is Hermitian. For every $\mathbf{x} \in F^n$,

$$\langle \mathbf{B}\mathbf{x}, \mathbf{x} \rangle = \mathbf{x}^*\mathbf{P}^*\mathbf{A}\mathbf{P}\mathbf{x} = (\mathbf{P}\mathbf{x})^*\mathbf{A}(\mathbf{P}\mathbf{x}) = \langle \mathbf{A}(\mathbf{P}\mathbf{x}), \mathbf{P}\mathbf{x} \rangle.$$

Since $\mathbf{P}$ is invertible, $\mathbf{x} \mapsto \mathbf{P}\mathbf{x}$ is an isomorphism of F^n; its restriction to a subspace W is an isomorphism $W \to \mathbf{P}W$, which carries a basis to a basis (Theorem 3.5.2), so $\dim \mathbf{P}W = \dim W$. And $W \mapsto \mathbf{P}W$ is a bijection on subspaces, with inverse $W' \mapsto \mathbf{P}^{-1}W'$. Moreover W is $\mathbf{B}$-positive if and only if $\mathbf{P}W$ is $\mathbf{A}$-positive: the non-zero vectors of $\mathbf{P}W$ are exactly the vectors $\mathbf{P}\mathbf{x}$ with $\mathbf{0} \neq \mathbf{x} \in W$, and the display says the two quadratic forms agree at matched vectors. Hence the two sets of dimensions appearing in (a) coincide, and (a) gives $n_+(\mathbf{B}) = n_+(\mathbf{A})$.

Applying this to $-\mathbf{A}$, whose eigenvalues are the negatives of those of $\mathbf{A}$ and whose congruence by $\mathbf{P}$ is $-\mathbf{B}$, gives $n_-(\mathbf{B}) = n_+(-\mathbf{B}) = n_+(-\mathbf{A}) = n_-(\mathbf{A})$. Finally $n_0 = n - n_+ - n_-$ for both. This proves the theorem.

■

What each proof gives. Over $\mathbb{R}$ the two theorems say the same thing, since a congruence is exactly a change of basis for the underlying form (Theorem 13.2.1). They are not interchangeable.

Chapter 13's proof uses only the existence of an orthogonal basis for the form, the invariance of rank under congruence and the dimension formula. It mentions no inner product, no eigenvalue and no limit — in Chapter 13 the eigenvalues enter only afterwards, in Theorem 13.5.3 — and it is the proof to give for a symmetric bilinear form on an abstract real vector space, where no inner product has been chosen and the words "Hermitian matrix" have no meaning until one is.

The proof above costs the spectral theorem and one appeal to compactness. In exchange it gives three things. First, a **description of n_+ with no basis in it at all** — a maximum over subspaces — together with an explicit optimal subspace, which is what Exercise (C1: An intrinsic description of n_+) asked the reader to establish by hand from an orthogonal basis; here it falls out of the min–max, with the eigenvalues attached. Second, it works **over** $\mathbb{C}$, for Hermitian matrices and the congruence $\mathbf{A} \mapsto \mathbf{P}^*\mathbf{A}\mathbf{P}$, which Theorem 13.5.1 does not cover. Third, it keeps the eigenvalues in view, so the perturbation theory of Section 3 applies to the inertia directly; that is the next theorem. Haynsworth's theorem at the end of the section leans on the second gain: for complex Hermitian matrices, only this proof supplies the law of inertia it needs.

The companions of part (a) are worth stating, because one of them is a trap.

Corollary 16.10.2 — What Each Count Is a Maximum Of

Let $\mathbf{A} \in M_n(F)$ be Hermitian.

(a) $n_-(\mathbf{A}) = \max\{\dim W : \langle \mathbf{Ax}, \mathbf{x}\rangle < 0 \text{ for every } \mathbf{0} \neq \mathbf{x} \in W\}$;
(b) $n_+(\mathbf{A}) + n_0(\mathbf{A}) = \max\{\dim W : \langle \mathbf{Ax}, \mathbf{x}\rangle \geq 0 \text{ for every } \mathbf{x} \in W\}$, and symmetrically $n_-(\mathbf{A}) + n_0(\mathbf{A})$ is the largest dimension of a subspace on which $\langle \mathbf{Ax}, \mathbf{x}\rangle \leq 0$;
(c) $n_0(\mathbf{A}) = \dim \operatorname{nul}(\mathbf{A}) = n - n_+(\mathbf{A}) - n_-(\mathbf{A})$.

Idea. Each claim has a witness and a competitor, as in Courant–Fischer. The witness is the span of the eigenvectors with the right sign; any competing subspace that is too large must meet the span of the eigenvectors of the wrong sign, and on that intersection the form has the wrong sign. For (c), no maximum is involved at all — the kernel is read off the eigenvalues.

Proof.

(a) Apply Theorem 16.10.1 (a) to $-\mathbf{A}$: its eigenvalues are the negatives of those of $\mathbf{A}$, so $n_+(-\mathbf{A}) = n_-(\mathbf{A})$, and a subspace is $(-\mathbf{A})$-positive exactly when $\langle \mathbf{Ax}, \mathbf{x}\rangle < 0$ on its non-zero vectors.

(b) Fix, as in the previous proof, an orthonormal eigenbasis $\mathbf{q}_1, \dots, \mathbf{q}_n$ of $\mathbf{A}$ with $\mathbf{Aq}_i = \lambda_i(\mathbf{A})\mathbf{q}_i$ (Corollary 11.4.3). Let $t = n_+(\mathbf{A}) + n_0(\mathbf{A})$, so that $\lambda_i(\mathbf{A}) \geq 0$ exactly for $i \leq t$. On $W_1 = \operatorname{span}(\mathbf{q}_1, \dots, \mathbf{q}_t)$ the same expansion gives $\langle \mathbf{Ax}, \mathbf{x}\rangle = \sum_{i \leq t} \lambda_i(\mathbf{A})|c_i|^2 \geq 0$, so the maximum is at least t. Conversely let W satisfy $\langle \mathbf{Ax}, \mathbf{x}\rangle \geq 0$ throughout and suppose $\dim W > t$. Put $W_2 = \operatorname{span}(\mathbf{q}_{t+1}, \dots, \mathbf{q}_n)$, of dimension $n - t = n_-(\mathbf{A})$, on whose non-zero vectors $\langle \mathbf{Ax}, \mathbf{x}\rangle = \sum_{i > t} \lambda_i(\mathbf{A})|c_i|^2 < 0$, every $\lambda_i(\mathbf{A})$ with $i > t$ being negative. Since $\dim W + \dim W_2 > t + (n - t) = n$, Lemma 16.2.1 produces $\mathbf{0} \neq \mathbf{x} \in W \cap W_2$, for which $\langle \mathbf{Ax}, \mathbf{x}\rangle$ is both ≥ 0 and < 0. This is impossible, so $\dim W \leq t$. The statement with $\leq$ follows by applying this one to $-\mathbf{A}$.

(c) The first equality was recorded after Definition 16.10.1, and the second is $n_+ + n_- + n_0 = n$.

■

Warning. n_0 **is not the largest dimension of a subspace on which the form vanishes.** Parts (a) and (b) describe n_-, n_+ and their sums with n_0 as maxima over subspaces; n_0 itself has no such description, and guessing one is the standard error here. Take $\mathbf{A} = \operatorname{diag}(1, -1)$, so $\operatorname{In}(\mathbf{A}) = (1, 1, 0)$ and $n_0(\mathbf{A}) = 0$. On the line $W = \operatorname{span}\big((1, 1)\big)$,

$$\langle \mathbf{Ax}, \mathbf{x}\rangle = x_1^2 - x_2^2 = 0 \qquad \text{for every } \mathbf{x} \in W,$$

so a subspace of dimension 1 carries the identically zero form while $n_0(\mathbf{A}) = 0$. What n_0 *is* is $\dim \operatorname{nul}(\mathbf{A})$, by (c) — a kernel, not a maximum. The largest dimension of a subspace on which the form vanishes identically is a different invariant. For a real symmetric **invertible** $\mathbf{A}$ it is the Witt index of Chapter 13 §07, which that section defines only for non-degenerate forms and bounds by $n/2$. For a singular $\mathbf{A}$ the bound fails — for $\mathbf{A} = 0$ the whole space qualifies — and in general the answer is $n_0 + \min(n_+, n_-)$, which Exercise (C1: How large can a subspace be on which the form vanishes?) computes.

Quick check. A Hermitian $\mathbf{A} \in M_5(F)$ has $\operatorname{In}(\mathbf{A}) = (2, 2, 1)$. What is the largest dimension of a subspace on which $\langle \mathbf{Ax}, \mathbf{x}\rangle > 0$ for all non-zero $\mathbf{x}$, and the largest on which $\langle \mathbf{Ax}, \mathbf{x}\rangle \geq 0$ for all $\mathbf{x}$?

Solution. 2 and 3. The first is $n_+(\mathbf{A}) = 2$ by Theorem 16.10.1 (a); the second is $n_+(\mathbf{A}) + n_0(\mathbf{A}) = 2+1 = 3$ by Corollary 16.10.2 (b). The kernel direction may be added to a positive subspace without breaking ≥ 0, but it does break > 0 — which is the whole difference between the two numbers.

16.10.3 Inertia under a perturbation of small rank

A congruence leaves the inertia alone and does nothing else: it can move the eigenvalues anywhere compatible with their signs. Chapter 13 §05's warning displayed the pair

$$\mathbf{A} = \operatorname{diag}(1,-1), \qquad \mathbf{P}^{\top}\mathbf{A}\mathbf{P} = \operatorname{diag}(4,-9) \quad (\mathbf{P} = \operatorname{diag}(2,3)),$$

where λ_1 rose from 1 to 4 and λ_2 fell from -1 to -9. There is no interlacing here: $\lambda_1(\mathbf{A}) \geq \lambda_1(\mathbf{P}^{\top}\mathbf{A}\mathbf{P})$ already fails. A congruence *is* a perturbation, $\mathbf{P}^{*}\mathbf{A}\mathbf{P} = \mathbf{A} + \mathbf{E}$ with $\mathbf{E} = \mathbf{P}^{*}\mathbf{A}\mathbf{P} - \mathbf{A}$, but $\mathbf{E}$ can have full rank, and then the rank bound of Section 3 says nothing. When the perturbation has small rank, it does.

Theorem 16.10.3 — Inertia Moves by at Most the Rank

Let $\mathbf{A}, \mathbf{E} \in M_n(F)$ be Hermitian with $\operatorname{rank}\mathbf{E} \leq r$. Then

$$|n_+(\mathbf{A}+\mathbf{E}) - n_+(\mathbf{A})| \leq r, \qquad |n_-(\mathbf{A}+\mathbf{E}) - n_-(\mathbf{A})| \leq r,$$

and $|n_0(\mathbf{A}+\mathbf{E}) - n_0(\mathbf{A})| \leq r$ as well.

Idea. Corollary 16.3.8 says that adding a matrix of rank r shifts each eigenvalue by at most r places in the ordered list. A count of positive eigenvalues is a count of places, so it too can move by at most r.

Proof. Put $s = n_+(\mathbf{A}+\mathbf{E})$. If $s \leq r$ then certainly $n_+(\mathbf{A}) \geq 0 \geq s - r$. Otherwise $i := s - r$ satisfies $1 \leq i$ and $i + r = s \leq n$, so Corollary 16.3.8 applies with this i and gives

$$\lambda_s(\mathbf{A}+\mathbf{E}) = \lambda_{i+r}(\mathbf{A}+\mathbf{E}) \;\leq\; \lambda_i(\mathbf{A}) = \lambda_{s-r}(\mathbf{A}).$$

Since $s = n_+(\mathbf{A}+\mathbf{E})$ we have $\lambda_s(\mathbf{A}+\mathbf{E}) > 0$, hence $\lambda_{s-r}(\mathbf{A}) > 0$, hence $n_+(\mathbf{A}) \geq s - r$. In either case

$$n_+(\mathbf{A}+\mathbf{E}) - n_+(\mathbf{A}) \leq r.$$

For the opposite inequality, write $\mathbf{A} = (\mathbf{A}+\mathbf{E}) + (-\mathbf{E})$, where $-\mathbf{E}$ is Hermitian with $\operatorname{rank}(-\mathbf{E}) = \operatorname{rank}\mathbf{E} \leq r$, and apply what was just proved with $\mathbf{A}+\mathbf{E}$ in the role of $\mathbf{A}$: $n_+(\mathbf{A}) - n_+(\mathbf{A}+\mathbf{E}) \leq r$. The two together give the first claim.

The second claim is the first applied to the Hermitian pair $-\mathbf{A}, -\mathbf{E}$, using $n_-(\mathbf{M}) = n_+(-\mathbf{M})$. For the third, adding the first two would only give $2r$; the sharp bound comes from kernels instead. By Corollary 16.10.2 (c), $n_0(\mathbf{M}) = \dim\operatorname{nul}(\mathbf{M})$ for every Hermitian $\mathbf{M}$. A vector killed by both $\mathbf{A}$ and $\mathbf{E}$ is killed by $\mathbf{A}+\mathbf{E}$, so $\operatorname{nul}(\mathbf{A}) \cap \operatorname{nul}(\mathbf{E}) \subseteq \operatorname{nul}(\mathbf{A}+\mathbf{E})$; and $\dim\operatorname{nul}(\mathbf{E}) = n - \operatorname{rank}\mathbf{E} \geq n - r$ by Theorem 3.3.1. The sharper form of Lemma 16.2.1 then gives

$$n_0(\mathbf{A}+\mathbf{E}) \;\geq\; \dim\bigl(\operatorname{nul}(\mathbf{A}) \cap \operatorname{nul}(\mathbf{E})\bigr) \;\geq\; n_0(\mathbf{A}) + (n-r) - n \;=\; n_0(\mathbf{A}) - r.$$

Applied to $\mathbf{A} = (\mathbf{A}+\mathbf{E}) + (-\mathbf{E})$ the same argument gives $n_0(\mathbf{A}) \geq n_0(\mathbf{A}+\mathbf{E}) - r$, and

the two together are the claim. The bound is attained: $\mathbf{A} = \mathbf{I}_r \oplus 0$ and $\mathbf{E} = -\mathbf{I}_r \oplus 0$ give $n_0(\mathbf{A}) = n - r$ and $n_0(\mathbf{A} + \mathbf{E}) = n$. This proves the theorem.

■

Example. (A rank-one perturbation, three ways)

Let $\mathbf{A} = \operatorname{diag}(3, -1, -2)$ and $\mathbf{v} = (1, 1, 0)$, and let $\mathbf{E}_t = t\,\mathbf{v}\mathbf{v}^{\top}$, which has rank 1 for $t \neq 0$. Find $\operatorname{In}(\mathbf{A} + \mathbf{E}_t)$ for $t = 2$, $t = \frac{3}{2}$ and $t = -5$, and check Theorem 16.10.3.

Solution. $\operatorname{In}(\mathbf{A}) = (1, 2, 0)$, read off the diagonal. Since $\mathbf{v}$ has third entry 0,

$$\mathbf{A} + \mathbf{E}_t = \begin{pmatrix} 3+t & t & 0 \\ t & t-1 & 0 \\ 0 & 0 & -2 \end{pmatrix} = \begin{pmatrix} 3+t & t \\ t & t-1 \end{pmatrix} \oplus (-2),$$

and the eigenvalue list of a block diagonal matrix is the two lists together (its characteristic polynomial is the product of the two, by Theorem 6.8.4). The entry -2 contributes one negative eigenvalue for every t. The 2×2 block has

$$\det = (3+t)(t-1) - t^2 = 2t - 3, \qquad \operatorname{tr} = 2t + 2,$$

and since the determinant of a real symmetric 2×2 matrix is the product of its two real eigenvalues and the trace is their sum, the eigenvalues both have the sign of the trace when the determinant is positive, have opposite signs when it is negative, and are 0 and tr when it is zero.

- $t = 2$: $\det = 1 > 0$, $\operatorname{tr} = 6 > 0$, so the block contributes $(2, 0, 0)$ and $\operatorname{In}(\mathbf{A} + \mathbf{E}_2) = (2, 1, 0)$.
- $t = \frac{3}{2}$: $\det = 0$, $\operatorname{tr} = 5$, so the block contributes $(1, 0, 1)$ and $\operatorname{In}(\mathbf{A} + \mathbf{E}_{3/2}) = (1, 1, 1)$.
- $t = -5$: $\det = -13 < 0$, so the block contributes $(1, 1, 0)$ and $\operatorname{In}(\mathbf{A} + \mathbf{E}_{-5}) = (1, 2, 0)$, unchanged.

Against $\operatorname{In}(\mathbf{A}) = (1, 2, 0)$: at $t = 2$ one negative direction has become positive, so n_+ and n_- each move by $1 = r$ and the bound of Theorem 16.10.3 is attained; at $t = \frac{3}{2}$, exactly on the way between, the direction passes through 0, so n_- and n_0 each move by 1. No rank-one perturbation of this $\mathbf{A}$ can reach $(3, 0, 0)$, which would need n_+ to move by 2.

16.10.4 Additivity across a Schur complement

Chapter 7 built the Schur complement out of block elimination and proved two things about it: $\det \mathbf{M} = \det \mathbf{A} \cdot \det(\mathbf{M}/\mathbf{A})$ (Theorem 7.3.2) and $\operatorname{rank} \mathbf{M} = k + \operatorname{rank}(\mathbf{M}/\mathbf{A})$ (Theorem 7.3.3). Chapter 12 then used the same elimination on Hermitian matrices — in §01, observing that it is the block **LDU** factorization written as a congruence, and in §06, to prove Theorem 12.6.1 — and each time read off a statement about positive definiteness only. Haynsworth's theorem is what that congruence is worth in general: the rank does not merely add, the *signs* add.

Theorem 16.10.4 — Haynsworth's Inertia Additivity Formula

Let $1 \leq k \leq n-1$ and let

$$\mathbf{M} = \begin{pmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{B}^* & \mathbf{D} \end{pmatrix} \in M_n(F)$$

be Hermitian, with $\mathbf{A} \in M_k(F)$ **invertible**, $\mathbf{B} \in M_{k\times(n-k)}(F)$ and $\mathbf{D} \in M_{n-k}(F)$. Then $\mathbf{A}$ and the Schur complement $\mathbf{M}/\mathbf{A} = \mathbf{D} - \mathbf{B}^*\mathbf{A}^{-1}\mathbf{B}$ (Definition 7.3.1) are Hermitian, and

$$\operatorname{In}(\mathbf{M}) = \operatorname{In}(\mathbf{A}) + \operatorname{In}(\mathbf{M}/\mathbf{A}).$$

Idea. Block elimination factors $\mathbf{M}$ as $Ł\,(\mathbf{A} \oplus \mathbf{M}/\mathbf{A})\,\mathbf{U}$ with Ł lower and $\mathbf{U}$ upper unit block triangular (Theorem 7.3.1). For a **Hermitian** $\mathbf{M}$ with $\mathbf{A}$ Hermitian, the two outer factors are conjugate transposes of each other, so the factorization is a congruence and not merely a factorization. Theorem 16.10.1 (b) then says the inertia of $\mathbf{M}$ is the inertia of $\mathbf{A} \oplus \mathbf{M}/\mathbf{A}$, and the inertia of a block diagonal matrix is the sum of the inertias of its blocks, because its characteristic polynomial is the product.

Proof. Since $\mathbf{M}^* = \mathbf{M}$, comparing blocks gives $\mathbf{A}^* = \mathbf{A}$ and $\mathbf{D}^* = \mathbf{D}$. As $\mathbf{A}$ is Hermitian and invertible, $(\mathbf{A}^{-1})^* = (\mathbf{A}^*)^{-1} = \mathbf{A}^{-1}$, so $\mathbf{A}^{-1}$ is Hermitian and

$$(\mathbf{M}/\mathbf{A})^* = \mathbf{D}^* - \mathbf{B}^*(\mathbf{A}^{-1})^*\mathbf{B} = \mathbf{D} - \mathbf{B}^*\mathbf{A}^{-1}\mathbf{B} = \mathbf{M}/\mathbf{A}.$$

Step 1: the elimination is a congruence. By Theorem 7.3.1 (a), applied with $\mathbf{C} = \mathbf{B}^*$,

$$\mathbf{M} = Ł\,\big(\mathbf{A} \oplus (\mathbf{M}/\mathbf{A})\big)\,\mathbf{U}, \qquad Ł = \begin{pmatrix} \mathbf{I}_k & \mathbf{0} \\ \mathbf{B}^*\mathbf{A}^{-1} & \mathbf{I}_{n-k} \end{pmatrix}, \quad \mathbf{U} = \begin{pmatrix} \mathbf{I}_k & \mathbf{A}^{-1}\mathbf{B} \\ \mathbf{0} & \mathbf{I}_{n-k} \end{pmatrix}.$$

Now $\mathbf{U}^*$ has blocks $\mathbf{I}_k, \mathbf{0}$ on top and $(\mathbf{A}^{-1}\mathbf{B})^* = \mathbf{B}^*\mathbf{A}^{-1}$, $\mathbf{I}_{n-k}$ below, using that $\mathbf{A}^{-1}$ is Hermitian; that is, $\mathbf{U}^* = Ł$. So

$$\mathbf{M} = \mathbf{U}^*\big(\mathbf{A} \oplus (\mathbf{M}/\mathbf{A})\big)\mathbf{U}.$$

The matrix $\mathbf{U}$ is invertible, with inverse $\mathbf{P} \coloneqq \left(\begin{smallmatrix} \mathbf{I}_k & -\mathbf{A}^{-1}\mathbf{B} \\ \mathbf{0} & \mathbf{I}_{n-k} \end{smallmatrix}\right)$, as multiplying out confirms. Multiplying the display by $\mathbf{P}^*$ on the left and $\mathbf{P}$ on the right, and using $\mathbf{P}^*\mathbf{U}^* = (\mathbf{U}\mathbf{P})^* = \mathbf{I}_n$,

$$\mathbf{P}^*\mathbf{M}\mathbf{P} = \mathbf{A} \oplus (\mathbf{M}/\mathbf{A}). \tag{16.10.1}$$

Step 2: apply the law of inertia. $\mathbf{P}$ is invertible, so Theorem 16.10.1 (b) gives

$$\operatorname{In}(\mathbf{M}) = \operatorname{In}(\mathbf{P}^*\mathbf{M}\mathbf{P}) = \operatorname{In}\big(\mathbf{A} \oplus (\mathbf{M}/\mathbf{A})\big).$$

Step 3: inertia is additive over a block diagonal sum. Let $\mathbf{X} \in M_k(F)$ and $\mathbf{Y} \in M_{n-k}(F)$ be Hermitian. The matrix $x\mathbf{I}_n - (\mathbf{X} \oplus \mathbf{Y})$ is block diagonal with blocks $x\mathbf{I}_k - \mathbf{X}$ and $x\mathbf{I}_{n-k} - \mathbf{Y}$, so by Theorem 6.8.4 its determinant is $\det(x\mathbf{I}_k - \mathbf{X})\det(x\mathbf{I}_{n-k} - \mathbf{Y})$; that is, $p_{\mathbf{X}\oplus\mathbf{Y}} = p_{\mathbf{X}}\,p_{\mathbf{Y}}$. The eigenvalue list of a Hermitian matrix with multiplicity is the list of roots of its characteristic polynomial with multiplicity, so the list for $\mathbf{X} \oplus \mathbf{Y}$ is the

two lists concatenated. Counting positive, negative and zero entries gives $\mathrm{In}(\mathbf{X} \oplus \mathbf{Y}) = \mathrm{In}(\mathbf{X}) + \mathrm{In}(\mathbf{Y})$.

Applying Step 3 with $\mathbf{X} = \mathbf{A}$ and $\mathbf{Y} = \mathbf{M}/\mathbf{A}$ to the conclusion of Step 2 proves the theorem.

■

Three remarks. First, Eq. 16.10.1 is the cleanest illustration in the book of what a Schur complement *is*: the block elimination of Chapter 7, performed with the same matrix on both sides, is a congruence, and $\mathbf{M}/\mathbf{A}$ is simply what the congruence leaves in the lower corner. For Hermitian $\mathbf{M}$, Chapter 7's determinant and rank formulas are both shadows of this one identity. Second, taking ranks in Eq. 16.10.1 recovers Theorem 7.3.3 for Hermitian $\mathbf{M}$, since $n_+ + n_- = \text{rank}$; Haynsworth refines the rank formula by splitting each rank into its two signs. Third, the theorem needs $\mathbf{A}$ invertible and nothing else — no definiteness anywhere, which is what separates it from Chapter 12 §06's test.

Example. (The Chapter 13 example, through a Schur complement)

Find $\mathrm{In}(\mathbf{M})$ for

$$\mathbf{M} = \begin{pmatrix} 1 & 1 & 2 \\ 1 & 2 & 3 \\ 2 & 3 & 1 \end{pmatrix},$$

the matrix of Example (A signature by symmetric elimination), using Theorem 16.10.4 with the leading 2×2 block.

Solution. Take $\mathbf{A} = \left(\begin{smallmatrix} 1 & 1 \\ 1 & 2 \end{smallmatrix}\right)$, $\mathbf{B} = (2,3)^{\top}$ and $\mathbf{D} = (1)$. Then $\det \mathbf{A} = 1 \neq 0$, so $\mathbf{A}$ is invertible with $\mathbf{A}^{-1} = \left(\begin{smallmatrix} 2 & -1 \\ -1 & 1 \end{smallmatrix}\right)$. Its leading principal minors are 1 and 1, both positive, so $\mathbf{A} \succ 0$ by Theorem 12.1.5 and $\mathrm{In}(\mathbf{A}) = (2,0,0)$.

For the Schur complement, $\mathbf{B}^{\top}\mathbf{A}^{-1} = (2,3)\left(\begin{smallmatrix} 2 & -1 \\ -1 & 1 \end{smallmatrix}\right) = (1,1)$, so $\mathbf{B}^{\top}\mathbf{A}^{-1}\mathbf{B} = (1,1) \cdot (2,3) = 5$ and

$$\mathbf{M}/\mathbf{A} = 1 - 5 = -4, \qquad \mathrm{In}(\mathbf{M}/\mathbf{A}) = (0,1,0).$$

Hence $\mathrm{In}(\mathbf{M}) = (2,0,0) + (0,1,0) = (2,1,0)$.

Two checks. The congruence of Eq. 16.10.1 is given by $\mathbf{A}^{-1}\mathbf{B} = (1,1)^{\top}$, hence

$$\mathbf{P} = \begin{pmatrix} 1 & 0 & -1 \\ 0 & 1 & -1 \\ 0 & 0 & 1 \end{pmatrix}, \qquad \mathbf{P}^{\top}\mathbf{M}\mathbf{P} = \begin{pmatrix} 1 & 1 & 0 \\ 1 & 2 & 0 \\ 0 & 0 & -4 \end{pmatrix},$$

which is $\mathbf{A} \oplus (-4)$ as the theorem says; and Example (A signature by symmetric elimination) reached $\mathrm{diag}(1,1,-4)$ by paired row and column operations, finding the same -4. The Schur complement of the leading block *is* the last pivot of the symmetric elimination. The eigenvalues were never needed: they are the roots of $x^3 - 4x^2 - 9x + 4$, which Example (A signature by symmetric elimination) already noted are irrational.

Example. (A 4×4 inertia in two lines)

Find $\mathrm{In}(\mathbf{N})$ for

$$\mathbf{N} = \begin{pmatrix} 1 & 0 & 1 & 2 \\ 0 & 1 & 1 & -1 \\ 1 & 1 & 1 & 0 \\ 2 & -1 & 0 & 3 \end{pmatrix}.$$

Solution. The leading 2×2 block is $\mathbf{A} = \mathbf{I}_2$, which is invertible with $\mathrm{In}(\mathbf{A}) = (2, 0, 0)$ and $\mathbf{A}^{-1} = \mathbf{I}_2$. With

$$\mathbf{B} = \begin{pmatrix} 1 & 2 \\ 1 & -1 \end{pmatrix}, \qquad \mathbf{D} = \begin{pmatrix} 1 & 0 \\ 0 & 3 \end{pmatrix},$$

the Schur complement needs no inversion at all:

$$\mathbf{N}/\mathbf{A} = \mathbf{D} - \mathbf{B}^{\top}\mathbf{B} = \begin{pmatrix} 1 & 0 \\ 0 & 3 \end{pmatrix} - \begin{pmatrix} 2 & 1 \\ 1 & 5 \end{pmatrix} = \begin{pmatrix} -1 & -1 \\ -1 & -2 \end{pmatrix}.$$

This 2×2 matrix has determinant $2-1 = 1 > 0$ and trace $-3 < 0$, so both its eigenvalues are negative and $\mathrm{In}(\mathbf{N}/\mathbf{A}) = (0, 2, 0)$. By Theorem 16.10.4,

$$\mathrm{In}(\mathbf{N}) = (2, 0, 0) + (0, 2, 0) = (2, 2, 0).$$

In particular $\mathbf{N}$ is invertible and indefinite. The characteristic polynomial of $\mathbf{N}$ is $x^4 - 6x^3 + 5x^2 + 8x + 1$, which has no rational root; the four eigenvalues were never computed, and the signature came from one 2×2 determinant and one trace.

Warning. **$\mathbf{A}$ must be invertible, and the off-diagonal block is not a spectator.** Take $\mathbf{M} = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$, with $k = 1$. Neither diagonal block is invertible, so no Schur complement exists for this partition and Theorem 16.10.4 does not apply — and its conclusion would be false if one tried to read the blocks directly: $\mathrm{In}(\mathbf{M}) = (1, 1, 0)$, since the eigenvalues are ± 1, while the two diagonal blocks contribute $(0, 0, 1) + (0, 0, 1) = (0, 0, 2)$. Even when $\mathbf{A}$ *is* invertible, the diagonal blocks alone decide nothing: for $\mathbf{M}_b = \left(\begin{smallmatrix} 1 & b \\ b & 1 \end{smallmatrix}\right)$ with b real, the Schur complement is $1 - b^2$, so $\mathrm{In}(\mathbf{M}_b)$ is $(2, 0, 0)$, $(1, 0, 1)$ or $(1, 1, 0)$ according as $|b| < 1$, $= 1$ or > 1. All the information is in the coupling.

The positive definite case of Haynsworth is a theorem Chapter 12 proved by hand, and it is now one line.

Corollary 16.10.5 — Block Definiteness, a Second Proof

Let $1 \le k \le n - 1$ and let $\mathbf{M} = \left(\begin{smallmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{B}^* & \mathbf{D} \end{smallmatrix}\right) \in M_n(F)$ be Hermitian with $\mathbf{A} \in M_k(F)$ and $\mathbf{A} \succ 0$. Then

$$\mathbf{M} \succ 0 \iff \mathbf{M}/\mathbf{A} \succ 0, \qquad \mathbf{M} \succeq 0 \iff \mathbf{M}/\mathbf{A} \succeq 0.$$

Proof. $\mathbf{A} \succ 0$ is invertible (Theorem 12.1.5) with $\mathrm{In}(\mathbf{A}) = (k, 0, 0)$, so Theorem 16.10.4 gives

$$\mathrm{In}(\mathbf{M}) = (k, 0, 0) + \mathrm{In}(\mathbf{M}/\mathbf{A}).$$

Comparing entries, $n_+(\mathbf{M}) = k + n_+(\mathbf{M}/\mathbf{A})$ and $n_-(\mathbf{M}) = n_-(\mathbf{M}/\mathbf{A})$, while $\mathbf{M}/\mathbf{A} \in M_{n-k}(F)$.

Now $\mathbf{M} \succ 0$ means $n_+(\mathbf{M}) = n$ (Theorem 12.1.5), that is $n_+(\mathbf{M}/\mathbf{A}) = n - k$, that is

$\mathbf{M}/\mathbf{A} \succ 0$. And $\mathbf{M} \succeq 0$ means $n_-(\mathbf{M}) = 0$ (Theorem 12.1.4), that is $n_-(\mathbf{M}/\mathbf{A}) = 0$, that is $\mathbf{M}/\mathbf{A} \succeq 0$. This proves the corollary.

■

This is Theorem 12.6.1 (b). Chapter 12 §06 proved it with the very same congruence, and then read positivity directly off the split quadratic form $\mathbf{y}_1^*\mathbf{A}\mathbf{y}_1 + \mathbf{y}_2^*(\mathbf{M}/\mathbf{A})\mathbf{y}_2$, with no eigenvalue in sight. The two proofs share their first step and differ in the second: Chapter 12's is shorter and needs nothing beyond Proposition 12.1.2, while the one above reads the verdict off a count, and so shows the definite case as the extreme instance of an equality that holds for every Hermitian $\mathbf{M}$ with $\mathbf{A}$ invertible, definite or not.

16.10.5 Exercises

16.10.5.1 A. Check your understanding

Exercise A1.

(a) Define $\mathrm{In}(\mathbf{A})$ for a Hermitian $\mathbf{A}$, and say what $n_+ + n_-$ equals.

(b) State the subspace description of $n_+(\mathbf{A})$ and name the subspace that attains it.

(c) Determine whether the following is correct, and justify: "$n_0(\mathbf{A})$ is the largest dimension of a subspace on which $\langle \mathbf{A}\mathbf{x}, \mathbf{x}\rangle$ vanishes identically."

(d) State Theorem 16.10.4, with all hypotheses.

(e) A congruence preserves the inertia of a Hermitian matrix. Does it preserve the eigenvalues, the trace, or the rank? Justify each answer.

Solution.

(a) $\mathrm{In}(\mathbf{A}) = (n_+, n_-, n_0)$, the numbers of positive, negative and zero eigenvalues of $\mathbf{A}$ counted with multiplicity (Definition 16.10.1). Their sum is n, and $n_+ + n_- = \operatorname{rank}\mathbf{A}$, since $n_0 = \dim\operatorname{nul}(\mathbf{A})$ by Corollary 16.10.2 (c).

(b) $n_+(\mathbf{A})$ is the largest dimension of a subspace W with $\langle \mathbf{A}\mathbf{x}, \mathbf{x}\rangle > 0$ for every non-zero $\mathbf{x} \in W$ (Theorem 16.10.1 (a)), attained at the span of orthonormal eigenvectors for the positive eigenvalues, that is at $\operatorname{span}(\mathbf{q}_1, \dots, \mathbf{q}_{n_+})$ in an eigenbasis ordered decreasingly.

(c) Incorrect. For $\mathbf{A} = \operatorname{diag}(1, -1)$ we have $n_0(\mathbf{A}) = 0$, yet $\langle \mathbf{A}\mathbf{x}, \mathbf{x}\rangle = x_1^2 - x_2^2$ vanishes identically on the line spanned by $(1, 1)$. The correct description is $n_0(\mathbf{A}) = \dim\operatorname{nul}(\mathbf{A})$.

(d) If $\mathbf{M} = \left(\begin{smallmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{B}^* & \mathbf{D} \end{smallmatrix}\right) \in M_n(F)$ is Hermitian with $\mathbf{A} \in M_k(F)$ invertible and $1 \le k \le n-1$, then $\mathrm{In}(\mathbf{M}) = \mathrm{In}(\mathbf{A}) + \mathrm{In}(\mathbf{M}/\mathbf{A})$, where $\mathbf{M}/\mathbf{A} = \mathbf{D} - \mathbf{B}^*\mathbf{A}^{-1}\mathbf{B}$.

(e) Rank: yes, since $\operatorname{rank} = n_+ + n_-$ is determined by the inertia (and independently, congruence by an invertible matrix preserves rank by Theorem 2.5.9). Eigenvalues: no — $\operatorname{diag}(1, -1)$ and $\operatorname{diag}(4, -9)$ are congruent by $\mathbf{P} = \operatorname{diag}(2, 3)$. Trace: no, by the same pair, whose traces are 0 and -5.

16.10.5.2 B. Practice

Exercise B1: Two inertias by Schur complement.

Find the inertia of each of the following, using Theorem 16.10.4 with the leading 2×2 block, and compute no eigenvalues.

(a) $\mathbf{M} = \begin{pmatrix} 2 & 1 & 1 \\ 1 & 1 & 0 \\ 1 & 0 & -1 \end{pmatrix}$.

(b) $\mathbf{N} = \begin{pmatrix} 1 & 0 & 1 & 1 \\ 0 & -1 & 1 & 0 \\ 1 & 1 & 2 & 0 \\ 1 & 0 & 0 & 1 \end{pmatrix}$.

Solution.

(a) $\mathbf{A} = \left(\begin{smallmatrix} 2 & 1 \\ 1 & 1 \end{smallmatrix}\right)$ has leading principal minors 2 and 1, both positive, so $\mathbf{A} \succ 0$ (Theorem 12.1.5) and $\operatorname{In}(\mathbf{A}) = (2, 0, 0)$; also $\mathbf{A}^{-1} = \left(\begin{smallmatrix} 1 & -1 \\ -1 & 2 \end{smallmatrix}\right)$. With $\mathbf{B} = (1, 0)^{\top}$ and $\mathbf{D} = (-1)$,

$$\mathbf{B}^{\top}\mathbf{A}^{-1}\mathbf{B} = (1, 0)\begin{pmatrix} 1 & -1 \\ -1 & 2 \end{pmatrix}\begin{pmatrix} 1 \\ 0 \end{pmatrix} = 1,$$

so $\mathbf{M}/\mathbf{A} = -1 - 1 = -2$ and $\operatorname{In}(\mathbf{M}/\mathbf{A}) = (0, 1, 0)$. Hence $\operatorname{In}(\mathbf{M}) = (2, 1, 0)$. (Consistency check: $\det \mathbf{M} = \det \mathbf{A} \cdot (\mathbf{M}/\mathbf{A}) = 1 \cdot (-2) = -2$ by Theorem 7.3.2, and a 3×3 matrix with inertia $(2, 1, 0)$ has negative determinant.)

(b) $\mathbf{A} = \operatorname{diag}(1, -1)$ is invertible with $\mathbf{A}^{-1} = \mathbf{A}$ and $\operatorname{In}(\mathbf{A}) = (1, 1, 0)$. With

$$\mathbf{B} = \begin{pmatrix} 1 & 1 \\ 1 & 0 \end{pmatrix}, \qquad \mathbf{D} = \begin{pmatrix} 2 & 0 \\ 0 & 1 \end{pmatrix},$$

we get $\mathbf{A}^{-1}\mathbf{B} = \left(\begin{smallmatrix} 1 & 1 \\ -1 & 0 \end{smallmatrix}\right)$ and

$$\mathbf{B}^{\top}\mathbf{A}^{-1}\mathbf{B} = \begin{pmatrix} 1 & 1 \\ 1 & 0 \end{pmatrix}\begin{pmatrix} 1 & 1 \\ -1 & 0 \end{pmatrix} = \begin{pmatrix} 0 & 1 \\ 1 & 1 \end{pmatrix},$$

so

$$\mathbf{N}/\mathbf{A} = \begin{pmatrix} 2 & 0 \\ 0 & 1 \end{pmatrix} - \begin{pmatrix} 0 & 1 \\ 1 & 1 \end{pmatrix} = \begin{pmatrix} 2 & -1 \\ -1 & 0 \end{pmatrix},$$

whose determinant is $-1 < 0$, so its two eigenvalues have opposite signs and $\operatorname{In}(\mathbf{N}/\mathbf{A}) = (1, 1, 0)$. Hence $\operatorname{In}(\mathbf{N}) = (1, 1, 0) + (1, 1, 0) = (2, 2, 0)$.

Exercise B2: How much can a rank-two perturbation do?.

Let $\mathbf{A} \in M_6(\mathbb{R})$ be symmetric with $\operatorname{In}(\mathbf{A}) = (4, 1, 1)$, and let $\mathbf{E}$ be symmetric with $\operatorname{rank} \mathbf{E} = 2$.

(a) Which values of $n_+(\mathbf{A} + \mathbf{E})$ does Theorem 16.10.3 allow?

(b) Show that the two extreme values are both achieved, for suitable $\mathbf{A}$ and $\mathbf{E}$.

(c) Can $\mathbf{A} + \mathbf{E}$ be negative definite? Justify.

Solution.

(a) By Theorem 16.10.3 with $r = 2$, $|n_+(\mathbf{A}+\mathbf{E}) - 4| \le 2$, and $n_+ \le 6$ always, so $n_+(\mathbf{A}+\mathbf{E}) \in \{2,3,4,5,6\}$.

(b) Take $\mathbf{A} = \operatorname{diag}(1,1,1,1,-1,0)$, which has inertia $(4,1,1)$. With $\mathbf{E} = \operatorname{diag}(0,0,0,0,2,1)$, of rank 2, we get $\mathbf{A}+\mathbf{E} = \mathbf{I}_6$, so $n_+ = 6$. With $\mathbf{E} = \operatorname{diag}(-2,-2,0,0,0,0)$, of rank 2, we get $\mathbf{A}+\mathbf{E} = \operatorname{diag}(-1,-1,1,1,-1,0)$, so $n_+ = 2$.

(c) No. Negative definiteness would mean $n_+(\mathbf{A}+\mathbf{E}) = 0$, and $|0-4| = 4 > 2$ contradicts Theorem 16.10.3.

Exercise B3: A bordered matrix.

Let $\mathbf{D} \in M_n(\mathbb{R})$ be symmetric and invertible, let $\mathbf{b} \in \mathbb{R}^n$ and $c \in \mathbb{R}$, and put $\mathbf{M} = \left(\begin{smallmatrix} \mathbf{D} & \mathbf{b} \\ \mathbf{b}^{\top} & c \end{smallmatrix}\right)$.

(a) Express $\operatorname{In}(\mathbf{M})$ in terms of $\operatorname{In}(\mathbf{D})$ and the scalar $s = c - \mathbf{b}^{\top}\mathbf{D}^{-1}\mathbf{b}$.

(b) Take $\mathbf{D} = \operatorname{diag}(1,-1)$ and $\mathbf{b} = (1,1)$. Compute $\operatorname{In}(\mathbf{M})$ for $c = 0$, $c = 1$ and $c = -1$.

(c) For which c is $\mathbf{M}$ singular?

Solution.

(a) By Theorem 16.10.4 with $\mathbf{A} = \mathbf{D}$, and $\mathbf{M}/\mathbf{D} = s$ a 1×1 matrix,

$$\operatorname{In}(\mathbf{M}) = \operatorname{In}(\mathbf{D}) + \begin{cases} (1,0,0) & s > 0, \\ (0,1,0) & s < 0, \\ (0,0,1) & s = 0. \end{cases}$$

(b) Here $\mathbf{D}^{-1} = \operatorname{diag}(1,-1) = \mathbf{D}$, so $\mathbf{b}^{\top}\mathbf{D}^{-1}\mathbf{b} = 1 - 1 = 0$ and $s = c$. Also $\operatorname{In}(\mathbf{D}) = (1,1,0)$. Hence $\operatorname{In}(\mathbf{M})$ is $(1,1,1)$ for $c = 0$, $(2,1,0)$ for $c = 1$, and $(1,2,0)$ for $c = -1$. The case $c = 0$ recovers Exercise (C3: Inertia of a block matrix) (c), which found the same triple by exhibiting the congruence directly.

(c) $\mathbf{M}$ is singular exactly when $n_0(\mathbf{M}) \ge 1$, which by (a) happens exactly when $s = 0$, since $\mathbf{D}$ is invertible and so contributes $n_0(\mathbf{D}) = 0$. Here that is $c = 0$.

16.10.5.3 C. Going deeper

Exercise C1: How large can a subspace be on which the form vanishes?.

Let $\mathbf{A} \in M_n(F)$ be Hermitian with $\operatorname{In}(\mathbf{A}) = (n_+, n_-, n_0)$. Call a subspace $W \le F^n$ **totally isotropic** for $\mathbf{A}$ if $\langle \mathbf{A}\mathbf{x}, \mathbf{x}\rangle = 0$ for every $\mathbf{x} \in W$; for real symmetric $\mathbf{A}$ this is the notion of Chapter 13 §07, in the form that section derives from polarization.

(a) Prove that every totally isotropic W satisfies $\dim W \le n_0 + \min(n_+, n_-)$.

(b) Construct a totally isotropic subspace of dimension exactly $n_0 + \min(n_+, n_-)$.

(c) Deduce that the largest dimension of a totally isotropic subspace equals n_0 if and only if $\mathbf{A}$ is positive semidefinite or negative semidefinite.

Hint: for (a), a totally isotropic subspace satisfies both inequalities of Corollary 16.10.2 (b). For (b), pair up a positive eigenvector with a negative one.

Solution.

(a) A totally isotropic W satisfies $\langle \mathbf{Ax}, \mathbf{x}\rangle \geq 0$ throughout and also $\langle \mathbf{Ax}, \mathbf{x}\rangle \leq 0$ throughout. By Corollary 16.10.2 (b), the first gives $\dim W \leq n_+ + n_0$ and the second $\dim W \leq n_- + n_0$. Hence $\dim W \leq n_0 + \min(n_+, n_-)$.

(b) Fix an orthonormal eigenbasis $\mathbf{q}_1, \ldots, \mathbf{q}_n$ with $\mathbf{Aq}_i = \lambda_i \mathbf{q}_i$ and $\lambda_1 \geq \cdots \geq \lambda_n$ (Corollary 11.4.3, or Corollary 11.5.2 when $F = \mathbb{R}$), so that $\lambda_i > 0$ for $i \leq n_+$, $\lambda_i = 0$ for $n_+ < i \leq n_+ + n_0$, and $\lambda_i < 0$ for $i > n_+ + n_0$. Put $t = \min(n_+, n_-)$ and, for $1 \leq j \leq t$, let $j' = n + 1 - j$. Then $j \leq n_+$ and $j' \geq n + 1 - n_- > n_+ + n_0$, so $\lambda_j > 0 > \lambda_{j'}$ and the indices $1, \ldots, t,\ 1', \ldots, t'$ are $2t$ distinct indices, none of them in the zero block. Put

$$\mathbf{x}_j = \frac{\mathbf{q}_j}{\sqrt{\lambda_j}} + \frac{\mathbf{q}_{j'}}{\sqrt{-\lambda_{j'}}} \qquad (1 \leq j \leq t),$$

and let W be spanned by $\mathbf{x}_1, \ldots, \mathbf{x}_t$ together with the n_0 vectors $\mathbf{q}_i$ with $\lambda_i = 0$. These $t + n_0$ vectors are independent, since they are non-zero combinations of pairwise disjoint sets of vectors from a basis.
For $\mathbf{x} \in W$ write $\mathbf{x} = \sum_j c_j \mathbf{x}_j + \mathbf{z}$ with $\mathbf{Az} = \mathbf{0}$. Then $\mathbf{Ax} = \sum_j c_j \mathbf{Ax}_j$ with $\mathbf{Ax}_j = \sqrt{\lambda_j}\,\mathbf{q}_j - \sqrt{-\lambda_{j'}}\,\mathbf{q}_{j'}$, and

$$\langle \mathbf{Ax}, \mathbf{x}\rangle = \mathbf{x}^* \mathbf{Ax} = \sum_{j,k} \overline{c_k}\, c_j\, \mathbf{x}_k^* \mathbf{Ax}_j + \sum_j c_j\, \mathbf{z}^* \mathbf{Ax}_j.$$

Each $\mathbf{z}^*\mathbf{Ax}_j = 0$, because $\mathbf{z}$ lies in the span of eigenvectors orthogonal to $\mathbf{q}_j$ and $\mathbf{q}_{j'}$. For $k \neq j$, $\mathbf{x}_k^*\mathbf{Ax}_j = 0$, because $\mathbf{x}_k$ and $\mathbf{Ax}_j$ are combinations of disjoint sets of orthonormal vectors. And

$$\mathbf{x}_j^*\mathbf{Ax}_j = \frac{\sqrt{\lambda_j}}{\sqrt{\lambda_j}} - \frac{\sqrt{-\lambda_{j'}}}{\sqrt{-\lambda_{j'}}} = 1 - 1 = 0.$$

Hence $\langle \mathbf{Ax}, \mathbf{x}\rangle = 0$ for every $\mathbf{x} \in W$, and W is totally isotropic of dimension $n_0 + \min(n_+, n_-)$.

(c) By (a) and (b) the largest totally isotropic dimension is $n_0 + \min(n_+, n_-)$, which equals n_0 exactly when $\min(n_+, n_-) = 0$, that is when $n_- = 0$ or $n_+ = 0$, that is when $\mathbf{A} \succeq 0$ or $-\mathbf{A} \succeq 0$ (Theorem 12.1.4).

Exercise C2: The inertia of a Hermitian dilation.

Let $\mathbf{A} \in M_{m\times n}(F)$ have rank r, and let $\mathcal{H}(\mathbf{A}) = \left(\begin{smallmatrix} \mathbf{0} & \mathbf{A} \\ \mathbf{A}^* & \mathbf{0} \end{smallmatrix}\right) \in M_{m+n}(F)$ be the Hermitian dilation of Proposition 16.9.3.

(a) Prove that $\mathrm{In}(\mathcal{H}(\mathbf{A})) = (r,\ r,\ m + n - 2r)$.

(b) Deduce a formula for $\operatorname{rank} \mathbf{A}$ in terms of the inertia of $\mathcal{H}(\mathbf{A})$, and check that it gives $\operatorname{rank} \mathbf{0} = 0$.

(c) Verify (a) for $\mathbf{A} = \left(\begin{smallmatrix} 1 & 0 & 2 \\ 0 & 1 & 1 \end{smallmatrix}\right)$.

Solution.

(a) By Proposition 16.9.3 the eigenvalue list of $\mathcal{H}(\mathbf{A})$ with multiplicity consists of $\pm\sigma_i(\mathbf{A})$ for $1 \le i \le p = \min(m,n)$, together with $m+n-2p$ zeros. Exactly r of the $\sigma_i(\mathbf{A})$ are non-zero (Theorem 12.8.3), so the positive entries are the r numbers $\sigma_1, \dots, \sigma_r$ and the negative entries are their negatives, giving $n_+ = n_- = r$. The rest are zero: $(m+n) - 2r$ of them. Hence $\operatorname{In}(\mathcal{H}(\mathbf{A})) = (r, r, m+n-2r)$.

(b) $\operatorname{rank}\mathbf{A} = n_+(\mathcal{H}(\mathbf{A})) = \frac{1}{2}\big(\operatorname{rank}\mathcal{H}(\mathbf{A})\big)$, using $n_+ + n_- = \operatorname{rank}$. For $\mathbf{A} = \mathbf{0}$ the dilation is the zero matrix of size $m+n$, whose inertia is $(0, 0, m+n)$, so the formula returns 0.

(c) Here $m = 2$, $n = 3$ and $\operatorname{rank}\mathbf{A} = 2$, since the first two columns are $\mathbf{e}_1, \mathbf{e}_2$. Also

$$\mathbf{A}\mathbf{A}^{\top} = \begin{pmatrix} 5 & 2 \\ 2 & 2 \end{pmatrix},$$

of trace 7 and determinant 6, hence eigenvalues 6 and 1; so $\sigma_1(\mathbf{A}) = \sqrt{6}$ and $\sigma_2(\mathbf{A}) = 1$. By Proposition 16.9.3 the eigenvalues of the 5×5 matrix $\mathcal{H}(\mathbf{A})$ are $\pm\sqrt{6}, \pm 1$ and one 0, so $\operatorname{In}(\mathcal{H}(\mathbf{A})) = (2, 2, 1)$, which is $(r, r, m+n-2r) = (2, 2, 5-4)$.

Exercise C3: Inertia from the leading principal minors.

Let $\mathbf{M} \in M_n(F)$ be Hermitian and suppose that every leading principal submatrix $\mathbf{M}_k \in M_k(F)$ (rows and columns $1, \dots, k$) is **invertible**, for $k = 1, \dots, n$. Write $d_k = \det \mathbf{M}_k$ and $d_0 = 1$.

(a) Prove that for $2 \le k \le n$ the Schur complement $\mathbf{M}_k/\mathbf{M}_{k-1}$ is the scalar d_k/d_{k-1}.

(b) Deduce that $\operatorname{In}(\mathbf{M}) = (n_+, n_-, 0)$, where n_- is the number of indices $k \in \{1, \dots, n\}$ with $d_k/d_{k-1} < 0$ — that is, the number of **sign changes** in the sequence $d_0, d_1, \dots, d_n$.

(c) Apply this to the matrix $\mathbf{M}$ of Example (The Chapter 13 example, through a Schur complement) and compare.

Hint: for (b), induct on k using Theorem 16.10.4.

Solution.

(a) Write $\mathbf{M}_k = \begin{pmatrix} \mathbf{M}_{k-1} & \mathbf{b} \\ \mathbf{b}^* & c \end{pmatrix}$. Since $\mathbf{M}_{k-1}$ is invertible, $\mathbf{M}_k/\mathbf{M}_{k-1}$ is defined and is a 1×1 matrix, and Theorem 7.3.2 (a) gives $d_k = \det \mathbf{M}_k = \det \mathbf{M}_{k-1} \cdot (\mathbf{M}_k/\mathbf{M}_{k-1}) = d_{k-1}(\mathbf{M}_k/\mathbf{M}_{k-1})$. As $d_{k-1} \neq 0$, dividing gives $\mathbf{M}_k/\mathbf{M}_{k-1} = d_k/d_{k-1}$.

(b) Induct on k. For $k = 1$, $\mathbf{M}_1 = (d_1)$ is a non-zero real scalar (real because $\mathbf{M}$ is Hermitian), and $\operatorname{In}(\mathbf{M}_1)$ is $(1,0,0)$ or $(0,1,0)$ according to the sign of $d_1/d_0 = d_1$. For the step, $\mathbf{M}_{k-1}$ is invertible, so Theorem 16.10.4 applies to $\mathbf{M}_k$ with $\mathbf{A} = \mathbf{M}_{k-1}$:

$$\operatorname{In}(\mathbf{M}_k) = \operatorname{In}(\mathbf{M}_{k-1}) + \operatorname{In}(d_k/d_{k-1}),$$

and the last term is $(1,0,0)$ or $(0,1,0)$ according to the sign of the ratio, which is non-zero. Summing from $k = 1$ to n,

$$\operatorname{In}(\mathbf{M}) = \operatorname{In}(\mathbf{M}_n) = \big(\#\{k : d_k/d_{k-1} > 0\},\ \#\{k : d_k/d_{k-1} < 0\},\ 0\big),$$

and $d_k/d_{k-1} < 0$ says exactly that d_{k-1} and d_k have opposite signs. (Taking

$n_- = 0$ here recovers the leading-minor criterion of Theorem 12.1.5: all $d_k > 0$ if and only if $\mathbf{M} \succ 0$.)

(c) For $\mathbf{M} = \left(\begin{smallmatrix} 1 & 1 & 2 \\ 1 & 2 & 3 \\ 2 & 3 & 1 \end{smallmatrix}\right)$ the leading minors are $d_1 = 1$, $d_2 = 2 - 1 = 1$ and $d_3 = -4$, all non-zero, so (b) applies. The sequence $d_0, d_1, d_2, d_3 = 1, 1, 1, -4$ has exactly one sign change, at the last step. Hence $n_- = 1$, $n_+ = 2$ and $\mathrm{In}(\mathbf{M}) = (2, 1, 0)$, agreeing with Example (The Chapter 13 example, through a Schur complement) and with Example (A signature by symmetric elimination).

16.11 Which Functions Respect the Order

Chapter 12 §05 ended on two facts that sit awkwardly together. If $\mathbf{A} \succeq \mathbf{B} \succeq 0$, then $\mathbf{A}^{1/2} \succeq \mathbf{B}^{1/2}$ (Proposition 12.5.4); but $\mathbf{A}^2 \succeq \mathbf{B}^2$ can fail (Example (Squaring does not preserve the Loewner order)). For numbers, both $t \mapsto t^{1/2}$ and $t \mapsto t^2$ are increasing on $[0, \infty)$, and both preserve inequalities. This section names the property that separates them and proves it for every function the book can reach. It then compares that property with what §02's min–max theorem already gives for *every* increasing function, and states without proof the classification that settles the question. Since this is the last section of the chapter, it ends by summing up the chapter's moves and listing the promises the chapter has paid.

Throughout, $F = \mathbb{R}$ or $F = \mathbb{C}$, and every matrix whose eigenvalues are indexed is Hermitian, with eigenvalues $\lambda_1(\mathbf{A}) \geq \cdots \geq \lambda_n(\mathbf{A})$ indexed decreasingly and repeated according to multiplicity. The letter I denotes an **interval** of real numbers (open, closed or half-open, bounded or not). It is plain italic, and it is not the bold identity matrix $\mathbf{I}$. A function $f\colon I \to \mathbb{R}$ is **increasing** when $s \leq t$ implies $f(s) \leq f(t)$; strictness is not required. Every result below holds for either choice of F, with the same proof. No analysis is used anywhere in this section except in the last part, which states a theorem without proving it.

16.11.1 Functions of a Hermitian matrix

Chapter 11 §08 already applies a function to a matrix, and nothing needs rebuilding. Let $\mathbf{A} \in M_n(F)$ be Hermitian. The operator $\mathbf{x} \mapsto \mathbf{A}\mathbf{x}$ on F^n has an orthonormal basis of eigenvectors (Corollary 11.4.3, Corollary 11.5.2), so it has a spectral resolution

$$\mathbf{A} = \mu_1 \mathbf{P}_1 + \cdots + \mu_k \mathbf{P}_k$$

with $\mu_1, \ldots, \mu_k$ the **distinct** eigenvalues and $\mathbf{P}_j$ the orthogonal projection onto the eigenspace of μ_j (Definition 11.8.1, Theorem 11.8.1). For any function f defined on $\mathrm{spec}(\mathbf{A})$, Definition 11.8.2 sets

$$f(\mathbf{A}) \coloneqq f(\mu_1)\mathbf{P}_1 + \cdots + f(\mu_k)\mathbf{P}_k.$$

In this section f is always defined on an interval I containing $\mathrm{spec}(\mathbf{A})$, and $f(\mathbf{A})$ is formed from the restriction of f to the spectrum: the values of f off the spectrum play no part. Four facts from Theorem 11.8.3 are used constantly.

- **Polynomials give the expected answer** (part (a)): $t \mapsto \alpha + \beta t$ gives $\alpha\mathbf{I} + \beta\mathbf{A}$, and $t \mapsto t^2$ gives $\mathbf{A}^2$.
- **Sums and products go through** (part (b)): $(f + g)(\mathbf{A}) = f(\mathbf{A}) + g(\mathbf{A})$, $(cf)(\mathbf{A}) = c\, f(\mathbf{A})$ and $(fg)(\mathbf{A}) = f(\mathbf{A})g(\mathbf{A})$.

- **Real-valued f gives a Hermitian $f(\mathbf{A})$** (part (c)). This is what lets $f(\mathbf{A})$ be compared with anything in the Loewner order.
- **The eigenvectors do not change** (part (d)): $f(\mathbf{A})$ has the same orthonormal eigenbasis as $\mathbf{A}$.

Two instances have names already. If $0 \notin \operatorname{spec}(\mathbf{A})$, then $t \mapsto 1/t$ gives $\mathbf{A}^{-1}$, as Chapter 11 §08 records right after Definition 11.8.2. If $\mathbf{A} \succeq 0$, then $t \mapsto t^{1/2}$ gives the positive square root $\mathbf{A}^{1/2}$ of Theorem 12.2.1, which Chapter 12 §02 constructed in exactly this way.

16.11.2 Operator monotone and operator convex functions

Chapter 12 §05 introduced the Loewner order $\mathbf{A} \succeq \mathbf{B}$, meaning $\mathbf{A} - \mathbf{B} \succeq 0$ (Definition 12.5.1). With the functional calculus available, the natural question is which functions f carry $\mathbf{A} \succeq \mathbf{B}$ to $f(\mathbf{A}) \succeq f(\mathbf{B})$.

The obvious guess is "the increasing ones", since that is the answer for numbers. It is wrong. The function $t \mapsto t^2$ is increasing on $[0, \infty)$, and Example (Squaring does not preserve the Loewner order) gives Hermitian 2×2 matrices $\mathbf{A} \succeq \mathbf{B} \succeq 0$ with $\mathbf{A}^2 \not\succeq \mathbf{B}^2$. So the property we want is stronger than being increasing, and it needs its own name.

A function is operator monotone when applying it to Hermitian matrices never breaks the Loewner order, at every size at once.

Definition 16.11.1 — Operator Monotone and Operator Convex Functions

Let $I \subseteq \mathbb{R}$ be an interval and let $f : I \to \mathbb{R}$.

(a) f is **operator monotone on I** if, **for every size** $n \geq 1$ and every pair of Hermitian matrices $\mathbf{A}, \mathbf{B} \in M_n(F)$ whose spectra lie in I,

$$\mathbf{A} \succeq \mathbf{B} \quad \Longrightarrow \quad f(\mathbf{A}) \succeq f(\mathbf{B}).$$

(b) f is **operator convex on I** if, **for every size** $n \geq 1$, every pair of Hermitian matrices $\mathbf{A}, \mathbf{B} \in M_n(F)$ whose spectra lie in I, and every $\theta \in [0, 1]$,

$$f\big(\theta \mathbf{A} + (1-\theta)\mathbf{B}\big) \preceq \theta f(\mathbf{A}) + (1-\theta) f(\mathbf{B}).$$

It is **operator concave on I** if $-f$ is operator convex on I.

Here $f(\mathbf{A})$ is the matrix of Definition 11.8.2.

In words: the first condition takes any two Hermitian matrices of the same size with spectra inside the domain of f. If the first dominates the second, applying f must preserve that. The second condition is the matrix version of "the chord lies above the graph". Both are infinitely many conditions, one for each size n. A function that passes the test for 2×2 matrices has not yet passed it for 3×3 ones. The clause "for every n" is why the notion is hard, and also why it is interesting.

Everything in the definition makes sense. Since $\operatorname{spec}(\mathbf{A}) \subseteq I$, the matrix $f(\mathbf{A})$ is defined, and it is Hermitian because f is real-valued (Theorem 11.8.3 (c)). So $f(\mathbf{A}) \succeq f(\mathbf{B})$ is a statement about two Hermitian matrices, as Definition 12.5.1 requires. In (b) one more thing needs checking: the spectrum of $\mathbf{C} = \theta\mathbf{A} + (1-\theta)\mathbf{B}$ must lie in I, or $f(\mathbf{C})$ would not be defined. The matrix $\mathbf{C}$ is Hermitian. Let $\mathbf{x}$ be a unit eigenvector of $\mathbf{C}$ for the eigenvalue μ. Then

$$\mu = \langle \mathbf{C}\mathbf{x}, \mathbf{x}\rangle = \theta\langle \mathbf{A}\mathbf{x}, \mathbf{x}\rangle + (1-\theta)\langle \mathbf{B}\mathbf{x}, \mathbf{x}\rangle.$$

By Lemma 12.5.2, $\langle \mathbf{A}\mathbf{x}, \mathbf{x}\rangle$ lies in $[\lambda_n(\mathbf{A}), \lambda_1(\mathbf{A})]$. That interval is contained in I, because its endpoints are eigenvalues of $\mathbf{A}$ and I is an interval. Likewise $\langle \mathbf{B}\mathbf{x}, \mathbf{x}\rangle \in I$. So μ is a convex combination of two points of the interval I, and it therefore lies in I.

The smallest size already says something, and the proof is three lines.

Proposition 16.11.1 — Operator Monotone Functions Are Increasing

If f is operator monotone on I, then f is increasing on I.

Proof. Let $s \le t$ in I, and take $n = 1$, $\mathbf{A} = (t)$, $\mathbf{B} = (s)$. These are Hermitian, their spectra $\{t\}$ and $\{s\}$ lie in I, and $\mathbf{A} - \mathbf{B} = (t-s) \succeq 0$. Hence $f(\mathbf{A}) \succeq f(\mathbf{B})$, and since $f(\mathbf{A}) = (f(t))$ and $f(\mathbf{B}) = (f(s))$, this says $f(t) - f(s) \ge 0$. This shows that f is increasing. ∎

The converse is false, and the failure is the reason this section exists.

Warning. **Increasing is not enough.** "Increasing" is exactly the case $n = 1$ of the definition, and sizes $n \ge 2$ are where all the new content lies. The function $t \mapsto t^2$ is increasing on $[0, \infty)$ and is **not** operator monotone there. The 2×2 matrices $\mathbf{A} = \left(\begin{smallmatrix} 2 & 1 \\ 1 & 1 \end{smallmatrix}\right)$ and $\mathbf{B} = \left(\begin{smallmatrix} 1 & 1 \\ 1 & 1 \end{smallmatrix}\right)$ of Example (Squaring does not preserve the Loewner order) satisfy $\mathbf{A} \succeq \mathbf{B} \succeq 0$, yet $\mathbf{A}^2 - \mathbf{B}^2$ has negative determinant. Chapter 12 §05 traced the failure to non-commutativity: the number proof factors $a^2 - b^2$ as $(a-b)(a+b)$, and for matrices that factorization needs $\mathbf{AB} = \mathbf{BA}$.

Quick check. Is $t \mapsto t^3$ operator monotone on $\mathbb{R}$ when only $n = 1$ is tested? What does the answer tell you about $n = 2$?

Solution. For $n = 1$ the condition says only that f is increasing, as the proof of Proposition 16.11.1 shows, and $t \mapsto t^3$ is increasing on $\mathbb{R}$. So it passes at $n = 1$. That tells us nothing about $n = 2$, where the test is genuinely new. In fact $t \mapsto t^3$ fails at $n = 2$ (exercise C3).

16.11.3 The examples we can prove

Four families are within reach, and the first is the simplest. It includes a degenerate case, the constant functions, which respect every order because they flatten everything to one matrix.

Proposition 16.11.2 — Increasing Affine Functions

Let $\alpha, \beta \in \mathbb{R}$ with $\beta \geq 0$. Then $f(t) = \alpha + \beta t$ is operator monotone on $\mathbb{R}$. Moreover, every affine function $t \mapsto \alpha + \beta t$, with β of either sign, is both operator convex and operator concave on $\mathbb{R}$.

Proof. By Theorem 11.8.3 (a), $f(\mathbf{A}) = \alpha\mathbf{I} + \beta\mathbf{A}$ for every Hermitian $\mathbf{A}$. Let $\mathbf{A} \succeq \mathbf{B}$ be Hermitian of the same size. Then $f(\mathbf{A}) - f(\mathbf{B}) = \beta(\mathbf{A} - \mathbf{B})$, and for every $\mathbf{x}$,

$$\langle \beta(\mathbf{A} - \mathbf{B})\mathbf{x}, \mathbf{x}\rangle = \beta\langle (\mathbf{A} - \mathbf{B})\mathbf{x}, \mathbf{x}\rangle \;\geq\; 0,$$

a product of two non-negative numbers. Hence $f(\mathbf{A}) \succeq f(\mathbf{B})$. For the second statement, with $\mathbf{C} = \theta\mathbf{A} + (1-\theta)\mathbf{B}$,

$$\begin{aligned} f(\mathbf{C}) &= \alpha\mathbf{I} + \beta\theta\mathbf{A} + \beta(1-\theta)\mathbf{B} \\ &= \theta(\alpha\mathbf{I} + \beta\mathbf{A}) + (1-\theta)(\alpha\mathbf{I} + \beta\mathbf{B}) = \theta f(\mathbf{A}) + (1-\theta) f(\mathbf{B}), \end{aligned}$$

so the inequality in Definition 16.11.1 (b) holds with equality, for f and for $-f$ alike. ∎

The second example is the one that behaves like the square root: $t \mapsto -1/t$. For numbers, $a \geq b > 0$ gives $-1/a \geq -1/b$ because one may divide by the product ab. For matrices that division is unavailable, since $\mathbf{A}$ and $\mathbf{B}$ need not commute. Chapter 12 §05 already found the way round.

Proposition 16.11.3 — The Negative Reciprocal Is Operator Monotone

The function $t \mapsto -1/t$ is operator monotone on $(0, \infty)$. Explicitly: if $\mathbf{A}, \mathbf{B} \in M_n(F)$ are Hermitian with $\mathbf{A} \succeq \mathbf{B} \succ 0$, then $\mathbf{A} \succ 0$ and

$$-\mathbf{A}^{-1} \;\succeq\; -\mathbf{B}^{-1}, \qquad \text{that is,} \qquad \mathbf{B}^{-1} \succeq \mathbf{A}^{-1}.$$

Idea. A congruence removes the non-commutativity. Conjugating by $\mathbf{B}^{-1/2}$ turns $\mathbf{B}$ into $\mathbf{I}$ and $\mathbf{A}$ into $\mathbf{C} = \mathbf{B}^{-1/2}\mathbf{A}\mathbf{B}^{-1/2} \succeq \mathbf{I}$. Now one of the two matrices is the identity, which commutes with everything, so the argument for numbers applies to the eigenvalues of $\mathbf{C}$: they are all ≥ 1, so those of $\mathbf{C}^{-1}$ are all ≤ 1. Undoing the congruence carries $\mathbf{I} \succeq \mathbf{C}^{-1}$ back to $\mathbf{B}^{-1} \succeq \mathbf{A}^{-1}$. That is exactly the proof of Theorem 12.5.3 (d), so the proposition is that clause read as a statement about the function $t \mapsto -1/t$.

Proof. Let $\mathbf{A} \succeq \mathbf{B}$ be Hermitian with spectra in $(0, \infty)$. By Theorem 12.1.5 (b), a Hermitian matrix whose eigenvalues are all positive is positive definite, so $\mathbf{B} \succ 0$. By Theorem 12.5.3 (d), $\mathbf{A} \succ 0$ and $\mathbf{B}^{-1} \succeq \mathbf{A}^{-1}$. Put $f(t) = -1/t$. By Definition 11.8.2 and the instance $t \mapsto 1/t$ recalled above, $f(\mathbf{A}) = -\mathbf{A}^{-1}$ and $f(\mathbf{B}) = -\mathbf{B}^{-1}$. Hence

$$f(\mathbf{A}) - f(\mathbf{B}) = \mathbf{B}^{-1} - \mathbf{A}^{-1} \;\succeq\; 0,$$

which is the assertion. The size n was arbitrary, so f is operator monotone on $(0,\infty)$.

■

Two things make the whitening work, and they are worth separating. First, once one of the two matrices is $\mathbf{I}$, the comparison $\mathbf{C} \succeq \mathbf{I}$ can be settled eigenvalue by eigenvalue, because $\mathbf{I}$ commutes with everything. Second, inversion gets along with congruence: $(\mathbf{S}^*\mathbf{M}\mathbf{S})^{-1} = \mathbf{S}^{-1}\mathbf{M}^{-1}(\mathbf{S}^{-1})^*$ is again a congruence, and that is what carries the conclusion back from $\mathbf{C}$ to $\mathbf{A}$. For a general f there is no such identity, since $f(\mathbf{S}^*\mathbf{M}\mathbf{S})$ is usually not a congruence of $f(\mathbf{M})$, so the argument does not simply transfer to other functions.

To build more examples out of these, one needs to know which ways of combining functions preserve the property.

Proposition 16.11.4 — Combining Operator Monotone Functions

Let f and g be operator monotone on I.

(a) For every $c \geq 0$ and every $\alpha \in \mathbb{R}$, the functions $f+g$ and $\alpha + cf$ are operator monotone on I.

(b) For every $s \in \mathbb{R}$, the translate $t \mapsto f(t+s)$ is operator monotone on the interval $I - s = \{t - s : t \in I\}$.

Proof.

(a) Let $\mathbf{A} \succeq \mathbf{B}$ be Hermitian of the same size with spectra in I. By Theorem 11.8.3 (b), $(f+g)(\mathbf{A}) - (f+g)(\mathbf{B}) = \big(f(\mathbf{A}) - f(\mathbf{B})\big) + \big(g(\mathbf{A}) - g(\mathbf{B})\big)$. Both brackets are $\succeq 0$ by hypothesis, and for every $\mathbf{x}$ the quadratic form of the sum is the sum of the two non-negative quadratic forms. So the sum is $\succeq 0$ by Definition 12.1.1. Likewise, using (b) and (a) of the same theorem, $(\alpha+cf)(\mathbf{A}) - (\alpha+cf)(\mathbf{B}) = c\big(f(\mathbf{A}) - f(\mathbf{B})\big)$, whose quadratic form is $c \geq 0$ times a non-negative one.

(b) Let $g(t) = f(t+s)$ on $I - s$, and let $\mathbf{A}$ be Hermitian with spectrum in $I - s$, with spectral resolution $\mathbf{A} = \sum_j \mu_j \mathbf{P}_j$. By Theorem 11.8.1 (c) and (d),

$$\mathbf{A} + s\mathbf{I} = \sum_j (\mu_j + s)\mathbf{P}_j,$$

and the numbers $\mu_j + s$ are distinct. The $\mathbf{P}_j$ are non-zero self-adjoint idempotents with $\mathbf{P}_i\mathbf{P}_j = \mathbf{0}$ for $i \neq j$ and $\sum_j \mathbf{P}_j = \mathbf{I}$ (Theorem 11.8.1 (b), (c)). So by Theorem 11.8.2 this is the spectral resolution of $\mathbf{A} + s\mathbf{I}$, whose spectrum $\{\mu_j + s\}$ lies in I. By Definition 11.8.2, applied to each side,

$$f(\mathbf{A} + s\mathbf{I}) = \sum_j f(\mu_j + s)\mathbf{P}_j = g(\mathbf{A}).$$

Now if $\mathbf{A} \succeq \mathbf{B}$ with spectra in $I - s$, then $(\mathbf{A}+s\mathbf{I}) - (\mathbf{B}+s\mathbf{I}) = \mathbf{A} - \mathbf{B} \succeq 0$, and both shifted matrices have spectra in I. Hence $g(\mathbf{A}) = f(\mathbf{A} + s\mathbf{I}) \succeq f(\mathbf{B} + s\mathbf{I}) = g(\mathbf{B})$.

■

Combining the last two propositions produces a whole one-parameter family. It will reappear

in the final part of the section as the building block of every operator monotone function.

Corollary 16.11.5 — Shifted Reciprocals

For every $s \geq 0$, the function $t \mapsto -1/(t+s)$ is operator monotone on $(0, \infty)$. For every $s > 0$, so is

$$t \longmapsto \frac{t}{t+s} = 1 - \frac{s}{t+s}.$$

Proof. By Proposition 16.11.3 and Proposition 16.11.4 (b), $t \mapsto -1/(t+s)$ is operator monotone on $(0, \infty) - s = (-s, \infty)$. Every Hermitian matrix with spectrum in $(0, \infty)$ has spectrum in $(-s, \infty)$, so it is in particular operator monotone on $(0, \infty)$. For the second function, $t/(t+s) = 1 + s \cdot \big(-1/(t+s)\big)$ with $s > 0$, so Proposition 16.11.4 (a) applies.

■

The fourth example is the one that started the section, and it is already proved. By Proposition 12.5.4, $\mathbf{A} \succeq \mathbf{B} \succeq 0$ implies $\mathbf{A}^{1/2} \succeq \mathbf{B}^{1/2}$. A Hermitian matrix has spectrum in $[0, \infty)$ exactly when it is $\succeq 0$ (Theorem 12.1.4 (b)), and $\mathbf{A}^{1/2}$ is $f(\mathbf{A})$ for $f(t) = t^{1/2}$. So Chapter 12 §05's proposition says precisely that $t \mapsto t^{1/2}$ **is operator monotone on** $[0, \infty)$. It is not re-proved here. Its proof was a different kind of argument, an eigenvector of $\mathbf{A}^{1/2} - \mathbf{B}^{1/2}$ pushed to a contradiction, and it too never needs $\mathbf{A}$ and $\mathbf{B}$ to commute.

A non-example by minimal change. The function $t \mapsto t = t^1$ is operator monotone on $[0, \infty)$ by Proposition 16.11.2. Raise the exponent from 1 to 2. The function is still increasing, still a polynomial, and still satisfies the case $n = 1$. What fails is the clause "for every n", already at $n = 2$, with the witness of Example (Squaring does not preserve the Loewner order). Lowering the exponent from 1 to $\frac{1}{2}$ instead keeps the property. Among the powers, then, the dividing line lies somewhere around the exponent 1. Chapter 12 §05 said where it lies exactly, and the last part of this section returns to that.

Why "for every n". Each size imposes its own condition, and the conditions differ. At $n = 1$, $t \mapsto t^2$ passes on $[0, \infty)$ and at $n = 2$ it fails. A definition at one fixed size would admit functions that break at the next size, and it would not say what the functional calculus does to matrices in general. Requiring every size at once makes the class small enough to classify completely, which is what Loewner's theorem at the end of this section does. The name comes from the same place as the name of the order: both are Loewner's.

16.11.4 Eigenvalues move monotonically for every increasing function

Operator monotonicity is a strong requirement, and a weaker one comes for free. §02 proved that the whole ordered list of eigenvalues respects the Loewner order: by Corollary 16.2.4, $\mathbf{A} \succeq \mathbf{B}$ implies $\lambda_i(\mathbf{A}) \geq \lambda_i(\mathbf{B})$ for **every** i. That paid the debt Chapter 12 §05 recorded after Theorem 12.5.3, and it holds with no hypothesis on commuting. Composing with an increasing f keeps it, once one knows what f does to the ordered list of eigenvalues.

Lemma 16.11.6 — The Eigenvalue List of an Increasing Function

Let $\mathbf{A} \in M_n(F)$ be Hermitian with $\operatorname{spec}(\mathbf{A}) \subseteq I$, and let $f\colon I \to \mathbb{R}$ be increasing. Then $f(\mathbf{A})$ is Hermitian and

$$\lambda_i\big(f(\mathbf{A})\big) = f\big(\lambda_i(\mathbf{A})\big) \qquad (i = 1, \dots, n).$$

Proof. The matrix $f(\mathbf{A})$ is Hermitian by Theorem 11.8.3 (c). By Corollary 11.4.3 (over $\mathbb{C}$) or Corollary 11.5.2 (over $\mathbb{R}$), there is an orthonormal basis $(\mathbf{q}_1, \dots, \mathbf{q}_n)$ of F^n with $\mathbf{A}\mathbf{q}_i = \lambda_i(\mathbf{A})\mathbf{q}_i$. Let $\mathbf{A} = \sum_j \mu_j \mathbf{P}_j$ be the spectral resolution, and fix i. Exactly one of the distinct eigenvalues equals $\lambda_i(\mathbf{A})$; call it μ_{j_0}. Then $\mathbf{q}_i$ lies in the eigenspace of μ_{j_0}, which is the image of $\mathbf{P}_{j_0}$, so $\mathbf{P}_{j_0}\mathbf{q}_i = \mathbf{q}_i$. For $j \neq j_0$, the eigenspace of μ_{j_0} is orthogonal to that of μ_j (Theorem 11.8.1 (a)), so $\mathbf{P}_j\mathbf{q}_i = \mathbf{0}$. By Definition 11.8.2,

$$f(\mathbf{A})\mathbf{q}_i = \sum_j f(\mu_j)\mathbf{P}_j\mathbf{q}_i = f(\mu_{j_0})\mathbf{q}_i = f\big(\lambda_i(\mathbf{A})\big)\mathbf{q}_i.$$

Thus $(\mathbf{q}_1, \dots, \mathbf{q}_n)$ is an orthonormal basis of eigenvectors of $f(\mathbf{A})$, and $f(\lambda_1(\mathbf{A})), \dots, f(\lambda_n(\mathbf{A}))$ is its list of eigenvalues with multiplicity. Since $\lambda_1(\mathbf{A}) \geq \cdots \geq \lambda_n(\mathbf{A})$ and f is increasing, this list is already in decreasing order. A decreasing list of all the eigenvalues with multiplicity is the list $\lambda_1(f(\mathbf{A})) \geq \cdots \geq \lambda_n(f(\mathbf{A}))$, so the two agree term by term.

■

The lemma needs f increasing only for the order of the list. For a general f, the numbers $f(\lambda_i(\mathbf{A}))$ are still the eigenvalues of $f(\mathbf{A})$, but they may have to be re-sorted. Two lines now give the eigenvalue-level statement.

Proposition 16.11.7 — Every Increasing Function Is Monotone on Eigenvalues

Let $f\colon I \to \mathbb{R}$ be increasing, and let $\mathbf{A}, \mathbf{B} \in M_n(F)$ be Hermitian with spectra in I and $\mathbf{A} \succeq \mathbf{B}$. Then

$$\lambda_i\big(f(\mathbf{A})\big) \;\geq\; \lambda_i\big(f(\mathbf{B})\big) \qquad \text{for every } i = 1, \dots, n.$$

Proof. By Corollary 16.2.4, $\lambda_i(\mathbf{A}) \geq \lambda_i(\mathbf{B})$ for every i. Since f is increasing, $f(\lambda_i(\mathbf{A})) \geq f(\lambda_i(\mathbf{B}))$. By Lemma 16.11.6, applied to $\mathbf{A}$ and to $\mathbf{B}$, the two sides are $\lambda_i(f(\mathbf{A}))$ and $\lambda_i(f(\mathbf{B}))$.

■

So the squaring map, which is not operator monotone, is nevertheless monotone on eigenvalues. The Chapter 12 witness shows both at once.

Example. (The Squares Are Not Ordered, but Their Eigenvalues Are)

Let $\mathbf{A} = \left(\begin{smallmatrix} 2 & 1 \\ 1 & 1 \end{smallmatrix}\right)$ and $\mathbf{B} = \left(\begin{smallmatrix} 1 & 1 \\ 1 & 1 \end{smallmatrix}\right)$, the pair of Example (Squaring does not preserve the Loewner order), for which $\mathbf{A} \succeq \mathbf{B} \succeq 0$ and $\mathbf{A}^2 \not\succeq \mathbf{B}^2$. Compute the eigenvalues of $\mathbf{A}^2$ and $\mathbf{B}^2$ and compare them index by index.

Solution. From Example (Squaring does not preserve the Loewner order), $\mathbf{A}^2 = \left(\begin{smallmatrix} 5 & 3 \\ 3 & 2 \end{smallmatrix}\right)$ and $\mathbf{B}^2 = \left(\begin{smallmatrix} 2 & 2 \\ 2 & 2 \end{smallmatrix}\right)$. The first has trace 7 and determinant $10 - 9 = 1$, so its eigenvalues are the roots of $x^2 - 7x + 1$:

$$\lambda_1(\mathbf{A}^2) = \frac{7 + 3\sqrt{5}}{2} \approx 6.854, \qquad \lambda_2(\mathbf{A}^2) = \frac{7 - 3\sqrt{5}}{2} \approx 0.146.$$

The second has trace 4 and determinant 0, so $\lambda_1(\mathbf{B}^2) = 4$ and $\lambda_2(\mathbf{B}^2) = 0$. Index by index: $\frac{7+3\sqrt{5}}{2} \geq 4$ because $3\sqrt{5} \geq 1$, and $\frac{7-3\sqrt{5}}{2} \geq 0$ because $49 \geq 45$. So $\lambda_i(\mathbf{A}^2) \geq \lambda_i(\mathbf{B}^2)$ for $i = 1, 2$, as Proposition 16.11.7 predicts for the increasing function $t \mapsto t^2$ on $[0, \infty)$. Nevertheless $\mathbf{A}^2 - \mathbf{B}^2$ is not $\succeq 0$.

So for every increasing f, the eigenvalues of $f(\mathbf{A})$ dominate those of $f(\mathbf{B})$ one index at a time. What operator monotonicity adds is that the *matrices* are ordered, and the example shows that this is strictly more.

Warning. **Eigenvalues in order do not make matrices in order.** It is tempting to read Proposition 16.11.7 as "almost" operator monotonicity. It is not, because $\lambda_i(\mathbf{M}) \geq \lambda_i(\mathbf{N})$ for every i does **not** imply $\mathbf{M} \succeq \mathbf{N}$. Take $\mathbf{M} = \operatorname{diag}(1, 0)$ and $\mathbf{N} = \operatorname{diag}(0, 1)$: they have the same eigenvalues $1 \geq 0$, yet $\mathbf{M} - \mathbf{N} = \operatorname{diag}(1, -1)$ is indefinite. The Loewner order sees the eigenvectors as well as the eigenvalues, and the eigenvalue list forgets them.

16.11.5 Operator convexity, and where the two notions part

Operator convexity is the second notion of Definition 16.11.1, and one might expect it to behave like operator monotonicity. It does not: the function that fails to be operator monotone turns out to be operator convex.

Proposition 16.11.8 — The Square Is Operator Convex

The function $t \mapsto t^2$ is operator convex on $\mathbb{R}$. Explicitly: for Hermitian $\mathbf{A}, \mathbf{B} \in M_n(F)$ and $\theta \in [0, 1]$,

$$\theta\mathbf{A}^2 + (1-\theta)\mathbf{B}^2 - \big(\theta\mathbf{A} + (1-\theta)\mathbf{B}\big)^2 = \theta(1-\theta)(\mathbf{A} - \mathbf{B})^2 \succeq 0.$$

Idea. For numbers, $\theta a^2 + (1-\theta)b^2 - (\theta a + (1-\theta)b)^2 = \theta(1-\theta)(a-b)^2$, which is a variance. The matrix version of the expansion produces $\mathbf{AB} + \mathbf{BA}$ where the number version has $2ab$, and that is exactly the cross term of $(\mathbf{A} - \mathbf{B})^2 = \mathbf{A}^2 - \mathbf{AB} - \mathbf{BA} + \mathbf{B}^2$. So this time non-commutativity cancels itself out and costs nothing. The square of a Hermitian matrix is $\succeq 0$, which finishes the proof.

Proof. By Theorem 11.8.3 (a), the function $t \mapsto t^2$ sends a Hermitian matrix to its square, so the displayed identity is what Definition 16.11.1 (b) requires. Expanding, and

keeping the order of every product,

$$\big(\theta\mathbf{A}+(1-\theta)\mathbf{B}\big)^2 = \theta^2\mathbf{A}^2+\theta(1-\theta)(\mathbf{AB}+\mathbf{BA}) + (1-\theta)^2\mathbf{B}^2.$$

Subtracting this from $\theta\mathbf{A}^2+(1-\theta)\mathbf{B}^2$, and using $\theta-\theta^2=\theta(1-\theta)=(1-\theta)-(1-\theta)^2$,

$$\theta\mathbf{A}^2+(1-\theta)\mathbf{B}^2-\big(\theta\mathbf{A}+(1-\theta)\mathbf{B}\big)^2 = \theta(1-\theta)\big(\mathbf{A}^2-\mathbf{AB}-\mathbf{BA}+\mathbf{B}^2\big) = \theta(1-\theta)(\mathbf{A}-\mathbf{B})^2.$$

The matrix $\mathbf{D}=\mathbf{A}-\mathbf{B}$ is Hermitian, so $\mathbf{D}^2=\mathbf{D}^*\mathbf{D}\succeq 0$ by Theorem 12.1.4 (c). Since $\theta(1-\theta)\geq 0$, the quadratic form of $\theta(1-\theta)\mathbf{D}^2$ is non-negative, which proves the inequality.

■

The contrast is now complete, and it runs both ways.

- $t\mapsto t^2$ is **operator convex but not operator monotone** on $[0,\infty)$: Proposition 16.11.8 and Example (Squaring does not preserve the Loewner order).
- $t\mapsto -1/t$ is **operator monotone but not operator convex** on $(0,\infty)$: Proposition 16.11.3, and at $n=1$ the scalar function $-1/t$ is not even convex, since with $a=1$, $b=3$ and $\theta=\frac{1}{2}$ the value at the midpoint is $-\frac{1}{2}$, above the chord's $-\frac{2}{3}$.

So neither notion implies the other. Each implies its scalar version (increasing, convex) by taking $n=1$, and they strengthen those versions in different directions. Exercise C2 adds that $t\mapsto 1/t$ is operator convex on $(0,\infty)$, so $-1/t$ is operator monotone *and* operator concave there.

16.11.6 What is not proved here

The question the section opened with has a complete answer, and this chapter does not prove it. Here is the statement, so that the reader knows what the answer looks like and which of the facts above are pieces of it.

Theorem 16.11.9 — Loewner's Theorem, Statement

Let $f\colon(0,\infty)\to\mathbb{R}$. The following are equivalent.

(i) f is operator monotone on $(0,\infty)$.

(ii) There are $\alpha\in\mathbb{R}$, $\beta\geq 0$ and a positive measure ν on $[0,\infty)$ with $\int_{[0,\infty)}\frac{\mathrm{d}\nu(s)}{1+s^2}<\infty$, such that for every $t>0$

$$f(t)=\alpha+\beta t + \int_{[0,\infty)}\Big(\frac{s}{1+s^2}-\frac{1}{t+s}\Big)\,\mathrm{d}\nu(s).$$

(iii) f is the restriction to $(0,\infty)$ of a function that is analytic on $\mathbb{C}\setminus(-\infty,0]$ and sends every point of the upper half-plane $\{z:\operatorname{Im}z>0\}$ to a point with non-negative imaginary part.

We do not prove this theorem here. Its proof needs complex analysis and some measure theory, which lie outside Chapter 15's list (A1)–(A6); Chapter 20 proves it. Nothing in this chapter depends on it.

Read (ii) against what was proved above. The functions it superposes are $t \mapsto -1/(t+s)$ for $s \geq 0$, the translates of $-1/t$ that Corollary 16.11.5 showed to be operator monotone. The constants $s/(1+s^2)$ do not depend on t and are there only to make the integral converge. The term $\alpha + \beta t$ is Proposition 16.11.2. So the theorem says that **the examples of this section are, in a precise sense, all the examples there are**: every operator monotone function on $(0,\infty)$ is an increasing affine function plus a non-negative superposition of shifted reciprocals. The easy direction, (ii) $\Rightarrow$ (i), is essentially Proposition 16.11.4 applied to an integral rather than a finite sum. What this book lacks is the analysis that carries the Loewner order through an integral, which is not on the list (A1)–(A6) in Chapter 15's introduction. The hard direction, (i) $\Rightarrow$ (ii), is the classification itself.

Condition (iii) answers the opening question in one line. For z in the upper half-plane, $z^{1/2}$ (the branch that is positive on $(0,\infty)$) halves the argument of z, so its argument stays between 0 and $\pi/2$ and $z^{1/2}$ stays in the upper half-plane. The square doubles the argument, which can pass π. **The square root keeps the upper half-plane, and the square folds it over.**

> *Quick check.* Find a point z of the upper half-plane whose square has negative imaginary part.

> *Solution.* Take $z = -1 + i$, with $\operatorname{Im} z = 1 > 0$. Then $z^2 = 1 - 2i + i^2 = -2i$, with imaginary part $-2 < 0$. So $z \mapsto z^2$ fails condition (iii) of Theorem 16.11.9, consistently with Example (Squaring does not preserve the Loewner order).

The same test settles the powers $t \mapsto t^p$. For $0 < p < 1$, the function z^p multiplies the argument by p and keeps the upper half-plane, and indeed for $t > 0$ (a standard integral, not proved here)

$$t^p = \frac{\sin p\pi}{\pi} \int_0^\infty s^{p-1} \, \frac{t}{t+s} \, \mathrm{d}s,$$

a positive superposition of the functions $t/(t+s)$ of Corollary 16.11.5. For $p > 1$, the argument of z^p passes π for some z in the upper half-plane, and the test fails. This is the dividing line at exponent 1 that Chapter 12 §05 announced. Both halves, that t^p is operator monotone on $(0,\infty)$ for every $p \in (0,1)$ and that it is not for any $p > 1$, are proved in Chapter 20, with Loewner's theorem. What is proved so far is the case $p = \frac{1}{2}$ (Proposition 12.5.4) and, by applying it repeatedly, the cases $p = 1/2^k$ (exercise C1).

16.11.7 Summary and transfer

The chapter began with a list of eigenvalues that the book had been able to *order* since Chapter 12 without being able to *describe*. It ends with each eigenvalue described as an optimization, and with a set of comparison theorems that follow from that description. Five moves did the work, and each transfers beyond this chapter.

- **The dimension count.** Two subspaces of an n-dimensional space whose dimensions add to more than n share a non-zero vector. This one line drives Courant–Fischer (Theorem 16.2.3) and Weyl's inequalities (§03) directly, and through Courant–Fischer everything after them. *Transfer:* whenever an extremal problem over vectors has to be compared with a fixed subspace, count dimensions before computing anything.

- **Min–max.** Describe a quantity as a minimum over subspaces of a maximum over vectors, and prove it with two inequalities of different characters: one exhibits a witness subspace and computes, and the other takes an arbitrary subspace and intersects it with a span of eigenvectors. Applying the result to $-\mathbf{A}$ gives the dual form for free. *Transfer:* a description that names no eigenvector is what makes two different matrices comparable. The same shape describes singular values (§09) and inertia (§10).
- **Compress and interlace.** Restricting a Hermitian form to a subspace gives a smaller Hermitian matrix whose eigenvalues are trapped by the original's: compressing to a k-dimensional subspace puts λ_i of the piece between λ_i and λ_{i+n-k} of the whole, which are consecutive when $k = n - 1$. Deleting a row and column (§04), compressing to an orthonormal frame (§06) and deleting a row or a column of a rectangular matrix (§09) are all this move; adding a rank-one term (§05) reaches the same interlaced picture by a different route, the Loewner order together with Weyl's rank bound. *Transfer:* to bound the spectrum of a piece, look for the whole of which it is a compression.
- **Perturb in order.** Compare $\lambda_i(\mathbf{A}+\mathbf{E})$ with $\lambda_i(\mathbf{A})$ index by index, never "each eigenvalue with its nearest neighbor". For Hermitian perturbations the Lipschitz constant is 1 in the spectral norm, independent of n, of the gaps and of the eigenvectors (§03). For singular values it needs no hypothesis on $\mathbf{E}$ at all (§09). *Transfer:* where the Jordan block of Chapter 15 §07 showed that eigenvalues of general matrices can move like $\varepsilon^{1/k}$, the Hermitian and singular-value problems are perfectly conditioned. Reduce a question to one of them whenever possible.
- **Majorize.** When the right comparison is between *sums* of the largest entries rather than individual ones, compare partial sums of decreasing rearrangements. The diagonal of a Hermitian matrix is majorized by its spectrum, and by the Schur–Horn theorem majorization describes the possible diagonals *exactly* (§08); and the Ky Fan and Lidskii sums (§§06–07) are of the same type. *Transfer:* a family of partial-sum inequalities indexed by k, together with equality of the totals, is a majorization in disguise, and writing it as one lets the whole family be used at once.

Two supporting moves recur under these five: **apply the result to $-\mathbf{A}$**, which turns every max–min into a min–max and every top-k statement into a bottom-k one, and **reduce singular values to eigenvalues**, through $\mathbf{A}^*\mathbf{A}$ or the Hermitian dilation. This section also reused a move from Chapter 12 §05, **whiten, then compare**: use a congruence to make one of the two matrices $\mathbf{I}$. It works for $t \mapsto -1/t$ because inversion turns a congruence into a congruence, and not for a general f.

The chapter also paid a series of promises made in earlier chapters, some of them long ago.

The promise	Made in	Paid by
The maximization route to eigenvalues "returns in Chapter 16, where the Rayleigh quotient and the Courant–Fischer theorem describe every eigenvalue of a self-adjoint operator by optimization"	Chapter 11 §02	§01 (The Rayleigh quotient) and §02 (The min–max theorem), Theorem 16.2.3

The promise	Made in	Paid by
"Chapter 16 characterizes the eigenvalues of a Hermitian matrix as maxima and minima of $\langle \mathbf{Ax}, \mathbf{x} \rangle$ — at which point the test becomes the theory"	Chapter 12 §12	§01 and §02, Theorem 16.2.3
$\mathbf{A} \succeq \mathbf{B}$ gives $\lambda_i(\mathbf{A}) \geq \lambda_i(\mathbf{B})$ for **every** i, not only $i = 1$ and $i = n$ as in Theorem 12.5.3 (b)	Chapter 12 §05	§02, Corollary 16.2.4
"The eigenvalues of a Hermitian matrix move by at most $\|\mathbf{E}\|_2$ under a Hermitian perturbation"	Chapter 15 §07	§03 (How far eigenvalues move), Weyl's perturbation bound
Lemma 12.10.2 is "the extreme case of a family of statements about sums of the largest eigenvalues"	Chapter 12 §10	§06 (Subspaces and Sums of Eigenvalues), Ky Fan's theorem, of which it is a special case
The second half of the approximation theorem, in the spectral norm	Chapter 12 §10 and Chapter 15 §08	§09 (The same theory for singular values), Eckart–Young in the spectral norm
Interlacing of the zeros of consecutive orthogonal polynomials, "Chapter 16's business"	Chapter 10 §10	§04 (Deleting a row and a column): strict interlacing, through the bordered-matrix criterion
The operator monotone functions named in Chapter 12 §05	Chapter 12 §05	§11: definition and first examples; t^s, $\log t$ and Loewner's theorem remain Chapter 20's, as that section said

Four earlier theorems also received second proofs from the variational side, each of which shows something the first proof did not. The positivity of principal submatrices of a positive semidefinite matrix now follows from interlacing (§04, Deleting a row and a column). Hadamard's inequality Theorem 12.6.4 follows from AM–GM after a diagonal scaling, with Schur's theorem supplying the equal totals (§08, The diagonal and the spectrum). Sylvester's law of inertia Theorem 13.5.1 is now a statement about the dimensions of subspaces, with no basis in it (§10, Inertia, again and additively). And the block test Theorem 12.6.1 is now a consequence of inertia additivity (§10).

Some things the chapter did not do. Bounds for the eigenvalues of non-Hermitian matrices under perturbation, beginning with Bauer–Fike, are Chapter 19's. Chapter 20 has Loewner's theorem with the powers t^p, Schur-concave functions, the strongest form of Lidskii's inequality, and Eckart–Young in every unitarily invariant norm. The variational principle itself, though, is now a tool the book can use without comment: an eigenvalue of a Hermitian matrix is a min–max, and comparison theorems follow from that.

16.11.8 Exercises

16.11.8.1 A. Check your understanding

Exercise A1.

(a) Define "f is operator monotone on I", and say what the clause "for every n" ranges over.

(b) Explain why an operator monotone function is increasing, and name an increasing function that is not operator monotone.

(c) Decide whether the following is correct, and justify your answer: if $f\colon I \to \mathbb{R}$ is increasing and $\mathbf{A} \succeq \mathbf{B}$ are Hermitian with spectra in I, then $\lambda_i(f(\mathbf{A})) \geq \lambda_i(f(\mathbf{B}))$ for every i.

(d) Decide whether the following is correct, and justify your answer: if $\mathbf{A}, \mathbf{B}$ are Hermitian of the same size and $\lambda_i(\mathbf{A}) \geq \lambda_i(\mathbf{B})$ for every i, then $\mathbf{A} \succeq \mathbf{B}$.

(e) Which of $t \mapsto t^2$ and $t \mapsto -1/t$ is operator monotone on $(0, \infty)$, and which is operator convex there?

(f) What does this section prove about Loewner's theorem?

Solution.

(a) For every $n \geq 1$ and all Hermitian $\mathbf{A}, \mathbf{B} \in M_n(F)$ with spectra in I, $\mathbf{A} \succeq \mathbf{B}$ implies $f(\mathbf{A}) \succeq f(\mathbf{B})$, where $f(\mathbf{A})$ is formed by Definition 11.8.2 (Definition 16.11.1 (a)). The clause ranges over all matrix sizes: the implication must hold for 1×1, 2×2, 3×3, ... matrices simultaneously.

(b) Taking $n = 1$ gives $f(t) \geq f(s)$ whenever $t \geq s$ in I (Proposition 16.11.1). The function $t \mapsto t^2$ on $[0, \infty)$ is increasing and is not operator monotone (Example (Squaring does not preserve the Loewner order)).

(c) Correct. This is Proposition 16.11.7: Corollary 16.2.4 orders the eigenvalues of $\mathbf{A}$ and $\mathbf{B}$ index by index, f preserves each inequality, and Lemma 16.11.6 identifies $f(\lambda_i(\mathbf{A}))$ with $\lambda_i(f(\mathbf{A}))$.

(d) Incorrect. $\operatorname{diag}(1, 0)$ and $\operatorname{diag}(0, 1)$ have the same eigenvalues, but their difference $\operatorname{diag}(1, -1)$ is indefinite, so neither dominates the other.

(e) $t \mapsto -1/t$ is operator monotone on $(0, \infty)$ (Proposition 16.11.3) and is not operator convex, since already the scalar function is not convex: at 1, 3 and their midpoint 2, $-\frac{1}{2} > \frac{1}{2}(-1 - \frac{1}{3}) = -\frac{2}{3}$. $t \mapsto t^2$ is operator convex (Proposition 16.11.8) and not operator monotone on $(0, \infty)$. The witness of Example (Squaring does not preserve the Loewner order) has 0 in the spectrum of $\mathbf{B}$, but the pair $\mathbf{A} = \left(\begin{smallmatrix} 3 & 1 \\ 1 & 1 \end{smallmatrix}\right) \succeq \mathbf{B} = \left(\begin{smallmatrix} 2 & 1 \\ 1 & 1 \end{smallmatrix}\right) \succ 0$ works: $\mathbf{A}^2 - \mathbf{B}^2 = \left(\begin{smallmatrix} 5 & 1 \\ 1 & 0 \end{smallmatrix}\right)$ has determinant -1.

(f) Only the statement (Theorem 16.11.9) and the fact that its building blocks $t \mapsto -1/(t+s)$ are operator monotone (Corollary 16.11.5). The theorem itself is proved in Chapter 20.

16.11.8.2 B. Practice

Exercise B1: Which are operator monotone?.

Determine which of the following functions are operator monotone on the interval given.

Justify your answer.

(i) $f(t) = 5 + 4t$ on $\mathbb{R}$.

(ii) $f(t) = 3 - 2t$ on $\mathbb{R}$.

(iii) $f(t) = 2 - \dfrac{3}{t+1}$ on $(0, \infty)$.

(iv) $f(t) = \dfrac{t}{t+2}$ on $(0, \infty)$.

(v) $f(t) = t^2$ on $[0, \infty)$.

Solution.

(i) Operator monotone, by Proposition 16.11.2 with $\beta = 4 \geq 0$.

(ii) Not operator monotone. It is not increasing, since $f(1) = 1 < 3 = f(0)$, so it fails at $n = 1$ with $\mathbf{A} = (1) \succeq \mathbf{B} = (0)$; compare Proposition 16.11.1.

(iii) Operator monotone. By Corollary 16.11.5 with $s = 1$, $t \mapsto -1/(t+1)$ is operator monotone on $(0, \infty)$, and $f = 2 + 3 \cdot \big(-1/(t+1)\big)$ with $3 \geq 0$, so Proposition 16.11.4 (a) applies.

(iv) Operator monotone, by Corollary 16.11.5 with $s = 2 > 0$.

(v) Not operator monotone: Example (Squaring does not preserve the Loewner order) gives $\mathbf{A} \succeq \mathbf{B} \succeq 0$, with spectra $\{(3 \pm \sqrt{5})/2\}$ and $\{0, 2\}$ in $[0, \infty)$, and $\mathbf{A}^2 \not\succeq \mathbf{B}^2$.

Exercise B2: One pair, three functions.

Let

$$\mathbf{A} = \begin{pmatrix} 3 & 1 \\ 1 & 1 \end{pmatrix}, \qquad \mathbf{B} = \begin{pmatrix} 2 & 1 \\ 1 & 1 \end{pmatrix}.$$

(a) Show that $\mathbf{A} \succeq \mathbf{B} \succ 0$.

(b) Compute $\mathbf{A}^{-1}$ and $\mathbf{B}^{-1}$, and verify directly that $\mathbf{B}^{-1} \succeq \mathbf{A}^{-1}$, as Proposition 16.11.3 predicts.

(c) Show that $\mathbf{A}^2 \not\succeq \mathbf{B}^2$ by exhibiting a vector $\mathbf{x}$ with $\mathbf{x}^\top (\mathbf{A}^2 - \mathbf{B}^2)\mathbf{x} < 0$.

(d) Compute the eigenvalues of $\mathbf{A}^2$ and $\mathbf{B}^2$, and verify that $\lambda_i(\mathbf{A}^2) \geq \lambda_i(\mathbf{B}^2)$ for $i = 1, 2$. Hence explain which result of this section (c) and (d) illustrate together.

Solution.

(a) $\mathbf{A} - \mathbf{B} = \operatorname{diag}(1, 0)$, a diagonal matrix with non-negative entries, so $\mathbf{A} - \mathbf{B} \succeq 0$ and $\mathbf{A} \succeq \mathbf{B}$. The leading principal minors of $\mathbf{B}$ are 2 and $2 - 1 = 1$, both positive, so $\mathbf{B} \succ 0$ by Sylvester's criterion (Theorem 12.1.5 (d)).

(b) $\det \mathbf{A} = 2$ and $\det \mathbf{B} = 1$, so

$$\mathbf{A}^{-1} = \frac{1}{2}\begin{pmatrix} 1 & -1 \\ -1 & 3 \end{pmatrix}, \qquad \mathbf{B}^{-1} = \begin{pmatrix} 1 & -1 \\ -1 & 2 \end{pmatrix}, \qquad \mathbf{B}^{-1} - \mathbf{A}^{-1} = \frac{1}{2}\begin{pmatrix} 1 & -1 \\ -1 & 1 \end{pmatrix}.$$

For every $\mathbf{x} \in \mathbb{R}^2$, $\mathbf{x}^\top (\mathbf{B}^{-1} - \mathbf{A}^{-1})\mathbf{x} = \frac{1}{2}(x_1 - x_2)^2 \geq 0$, so $\mathbf{B}^{-1} \succeq \mathbf{A}^{-1}$.

(c) $\mathbf{A}^2 = \left(\begin{smallmatrix} 10 & 4 \\ 4 & 2 \end{smallmatrix}\right)$ and $\mathbf{B}^2 = \left(\begin{smallmatrix} 5 & 3 \\ 3 & 2 \end{smallmatrix}\right)$, so $\mathbf{A}^2 - \mathbf{B}^2 = \left(\begin{smallmatrix} 5 & 1 \\ 1 & 0 \end{smallmatrix}\right)$, with determinant $-1 < 0$. With $\mathbf{x} = (1, -3)$,

$$\mathbf{x}^\top (\mathbf{A}^2 - \mathbf{B}^2)\mathbf{x} = 5 + 2 \cdot (1)(-3) + 0 = -1 < 0.$$

(d) $\mathbf{A}^2$ has trace 12 and determinant $(\det \mathbf{A})^2 = 4$, so its eigenvalues are $6 \pm \sqrt{32} = 6 \pm 4\sqrt{2}$, approximately 11.657 and 0.343. $\mathbf{B}^2$ has trace 7 and determinant 1, so its eigenvalues are $(7 \pm 3\sqrt{5})/2$, approximately 6.854 and 0.146. For $i = 1$, $12 + 8\sqrt{2} \geq 7 + 3\sqrt{5}$ because $8\sqrt{2} > 3\sqrt{5}$. For $i = 2$, $12 - 8\sqrt{2} \geq 7 - 3\sqrt{5}$ is $5 + 3\sqrt{5} \geq 8\sqrt{2}$. Both sides are positive, and squaring gives $70 + 30\sqrt{5} \geq 128$, that is $\sqrt{5} \geq \frac{29}{15}$, which holds because $5 \geq \frac{841}{225}$. Hence (c) and (d) together illustrate Proposition 16.11.7 and the warning after it: the increasing function $t \mapsto t^2$ orders the eigenvalues but not the matrices.

Exercise B3: The convexity identity in numbers.

With $\mathbf{A}$ and $\mathbf{B}$ as in B2 and $\theta = \frac{1}{2}$, compute

$$\mathbf{M} = \tfrac{1}{2}\mathbf{A}^2 + \tfrac{1}{2}\mathbf{B}^2 - \left(\tfrac{1}{2}\mathbf{A} + \tfrac{1}{2}\mathbf{B}\right)^2$$

directly, confirm that $\mathbf{M} = \frac{1}{4}(\mathbf{A} - \mathbf{B})^2$, and hence conclude that $\left(\frac{1}{2}(\mathbf{A} + \mathbf{B})\right)^2 \preceq \frac{1}{2}(\mathbf{A}^2 + \mathbf{B}^2)$.

Solution. From B2, $\frac{1}{2}\mathbf{A}^2 + \frac{1}{2}\mathbf{B}^2 = \frac{1}{2}\left(\begin{smallmatrix} 15 & 7 \\ 7 & 4 \end{smallmatrix}\right) = \left(\begin{smallmatrix} 15/2 & 7/2 \\ 7/2 & 2 \end{smallmatrix}\right)$. Next $\frac{1}{2}(\mathbf{A} + \mathbf{B}) = \left(\begin{smallmatrix} 5/2 & 1 \\ 1 & 1 \end{smallmatrix}\right)$, whose square is

$$\begin{pmatrix} \frac{25}{4} + 1 & \frac{5}{2} + 1 \\ \frac{5}{2} + 1 & 1 + 1 \end{pmatrix} = \begin{pmatrix} \frac{29}{4} & \frac{7}{2} \\ \frac{7}{2} & 2 \end{pmatrix}.$$

Hence $\mathbf{M} = \left(\begin{smallmatrix} 15/2 - 29/4 & 0 \\ 0 & 0 \end{smallmatrix}\right) = \operatorname{diag}(\frac{1}{4}, 0)$. On the other side, $\mathbf{A} - \mathbf{B} = \operatorname{diag}(1, 0)$, so $\frac{1}{4}(\mathbf{A} - \mathbf{B})^2 = \operatorname{diag}(\frac{1}{4}, 0) = \mathbf{M}$, as Proposition 16.11.8 says with $\theta(1 - \theta) = \frac{1}{4}$. Since $\operatorname{diag}(\frac{1}{4}, 0)$ is diagonal with non-negative entries, $\mathbf{M} \succeq 0$, which is the displayed inequality.

16.11.8.3 C. Going deeper

Exercise C1: Iterated square roots.

(a) Let $\mathbf{A} \succeq \mathbf{B} \succeq 0$. Prove that $\mathbf{A}^{1/4} \succeq \mathbf{B}^{1/4}$, where $\mathbf{A}^{1/4}$ is $f(\mathbf{A})$ for $f(t) = t^{1/4}$ on $[0, \infty)$.

(b) Deduce that $t \mapsto t^{1/2^k}$ is operator monotone on $[0, \infty)$ for every integer $k \geq 0$.

(c) Explain why the argument of (b) cannot reach $t \mapsto t^{3/4}$, and say where the operator monotonicity of t^p for every $p \in (0, 1)$ is proved.

Hint for (a): the positive square root is unique.

Solution.

(a) Let $g(t) = t^{1/4}$ on $[0, \infty)$. Since $\mathbf{A} \succeq 0$, its spectrum lies in $[0, \infty)$ (Theorem 12.1.4 (b)), and $g(\mathbf{A}) = \sum_j \mu_j^{1/4} \mathbf{P}_j$ is Hermitian with non-negative eigenvalues by Theorem 11.8.3 (c) and (d), so $g(\mathbf{A}) \succeq 0$. By Theorem 11.8.3 (b), $g(\mathbf{A})^2 = (g^2)(\mathbf{A})$, and $g^2(t) = t^{1/2}$, so $g(\mathbf{A})^2 = \mathbf{A}^{1/2}$. By the uniqueness in Theorem 12.1.4 (d), applied to $\mathbf{A}^{1/2} \succeq 0$, $g(\mathbf{A})$ is the positive square root of $\mathbf{A}^{1/2}$: $\mathbf{A}^{1/4} = (\mathbf{A}^{1/2})^{1/2}$. The same holds for $\mathbf{B}$. Now Proposition 12.5.4 applied to $\mathbf{A} \succeq \mathbf{B} \succeq 0$ gives $\mathbf{A}^{1/2} \succeq \mathbf{B}^{1/2}$, and $\mathbf{B}^{1/2} \succeq 0$ by Theorem 12.2.1. Applying Proposition 12.5.4

again, to $\mathbf{A}^{1/2} \succeq \mathbf{B}^{1/2} \succeq 0$, gives $(\mathbf{A}^{1/2})^{1/2} \succeq (\mathbf{B}^{1/2})^{1/2}$, that is $\mathbf{A}^{1/4} \succeq \mathbf{B}^{1/4}$.

(b) Induction on k. For $k = 0$ the function is $t \mapsto t$, operator monotone by Proposition 16.11.2. Suppose $\mathbf{A}^{1/2^k} \succeq \mathbf{B}^{1/2^k}$ whenever $\mathbf{A} \succeq \mathbf{B} \succeq 0$. The argument of (a), with $t^{1/2^{k+1}}$ in place of $t^{1/4}$ and $t^{1/2^k}$ in place of $t^{1/2}$, shows that $\mathbf{A}^{1/2^{k+1}} = (\mathbf{A}^{1/2^k})^{1/2}$, and similarly for $\mathbf{B}$. Both $\mathbf{A}^{1/2^k}$ and $\mathbf{B}^{1/2^k}$ are $\succeq 0$, so Proposition 12.5.4 applied to $\mathbf{A}^{1/2^k} \succeq \mathbf{B}^{1/2^k} \succeq 0$ gives $\mathbf{A}^{1/2^{k+1}} \succeq \mathbf{B}^{1/2^{k+1}}$.

(c) Each step of (b) takes a square root, which halves the exponent. Starting from 1, the exponents reached are exactly $1, \frac{1}{2}, \frac{1}{4}, \ldots$, and $\frac{3}{4}$ is not among them. The operator monotonicity of t^p for every $p \in (0,1)$ needs a new idea, an integral representation of the kind in Theorem 16.11.9, and it is proved in Chapter 20.

Exercise C2: The reciprocal is operator convex.

(a) Let $\mathbf{G} \in M_n(F)$ with $\mathbf{G} \succ 0$. Prove that the $2n \times 2n$ matrix $\begin{pmatrix} \mathbf{G} & \mathbf{I}_n \\ \mathbf{I}_n & \mathbf{G}^{-1} \end{pmatrix}$ is Hermitian and $\succeq 0$.

(b) Let $\mathbf{A}, \mathbf{B} \succ 0$ be of the same size and $\theta \in [0,1]$. Prove that

$$\big(\theta\mathbf{A} + (1-\theta)\mathbf{B}\big)^{-1} \preceq \theta\mathbf{A}^{-1} + (1-\theta)\mathbf{B}^{-1},$$

that is, $t \mapsto 1/t$ is operator convex on $(0, \infty)$.

(c) Deduce that $t \mapsto -1/t$ is both operator monotone and operator concave on $(0, \infty)$.

Hint: Schur complements.

Solution.

(a) $\mathbf{G}$ is Hermitian, and so is $\mathbf{G}^{-1}$, since $(\mathbf{G}^{-1})^* = (\mathbf{G}^*)^{-1} = \mathbf{G}^{-1}$. The off-diagonal blocks are $\mathbf{I}_n$ and $\mathbf{I}_n^* = \mathbf{I}_n$, so the block matrix $\mathbf{M}_\mathbf{G}$ is Hermitian. Its corner $\mathbf{G}$ is $\succ 0$, and its Schur complement is

$$\mathbf{M}_\mathbf{G}/\mathbf{G} = \mathbf{G}^{-1} - \mathbf{I}_n^* \mathbf{G}^{-1} \mathbf{I}_n = \mathbf{0} \succeq 0.$$

By Theorem 12.6.1 (b), $\mathbf{M}_\mathbf{G} \succeq 0$.

(b) Put $\mathbf{C} = \theta\mathbf{A} + (1-\theta)\mathbf{B}$. For $\mathbf{x} \neq \mathbf{0}$, $\langle \mathbf{C}\mathbf{x}, \mathbf{x}\rangle = \theta\langle \mathbf{A}\mathbf{x}, \mathbf{x}\rangle + (1-\theta)\langle \mathbf{B}\mathbf{x}, \mathbf{x}\rangle$. Both inner products are > 0, and θ and $1-\theta$ are ≥ 0 and not both zero, so the sum is > 0. Thus $\mathbf{C} \succ 0$. By (a), $\mathbf{M}_\mathbf{A} \succeq 0$ and $\mathbf{M}_\mathbf{B} \succeq 0$, so for every $\mathbf{y} \in F^{2n}$ the quadratic form of

$$\theta\mathbf{M}_\mathbf{A} + (1-\theta)\mathbf{M}_\mathbf{B} = \begin{pmatrix} \mathbf{C} & \mathbf{I}_n \\ \mathbf{I}_n & \theta\mathbf{A}^{-1} + (1-\theta)\mathbf{B}^{-1} \end{pmatrix}$$

is $\theta\langle \mathbf{M}_\mathbf{A}\mathbf{y}, \mathbf{y}\rangle + (1-\theta)\langle \mathbf{M}_\mathbf{B}\mathbf{y}, \mathbf{y}\rangle \geq 0$, and this block matrix is $\succeq 0$. Its corner $\mathbf{C}$ is $\succ 0$, so Theorem 12.6.1 (b) gives

$$\theta\mathbf{A}^{-1} + (1-\theta)\mathbf{B}^{-1} - \mathbf{C}^{-1} \succeq 0,$$

which is the claim. Since $t \mapsto 1/t$ sends a positive definite matrix to its inverse (Definition 11.8.2), and a Hermitian matrix has spectrum in $(0,\infty)$ exactly when it is $\succ 0$ (Theorem 12.1.5 (b)), this is Definition 16.11.1 (b) for $f(t) = 1/t$.

(c) Operator monotone by Proposition 16.11.3. Operator concave by definition, because its negative $t \mapsto 1/t$ is operator convex by (b).

Exercise C3: The cube needs its own witness.

(a) With $\mathbf{A}$ and $\mathbf{B}$ as in B2, show that $\mathbf{A}^3 \not\succeq \mathbf{B}^3$. Conclude that $t \mapsto t^3$ is not operator monotone on $[0, \infty)$.

(b) One might hope to deduce (a) from the failure of $t \mapsto t^2$. Suppose $t \mapsto t^3$ were operator monotone on $[0, \infty)$. Applying it and $t \mapsto t^{1/2}$ (Proposition 12.5.4) to both sides of $\mathbf{A} \succeq \mathbf{B} \succeq 0$, repeatedly and in any order, yields inequalities $\mathbf{A}^q \succeq \mathbf{B}^q$ for certain exponents q. Show that every such q has the form $3^j/2^k$ with integers $j, k \geq 0$, and that 2 never has this form. Explain why this means (a) needed a witness of its own.

Solution.

(a) From B2, $\mathbf{A} \succeq \mathbf{B} \succeq 0$, with spectra in $(0, \infty)$. Multiplying the squares of B2 once more,

$$\mathbf{A}^3 = \begin{pmatrix} 34 & 14 \\ 14 & 6 \end{pmatrix}, \qquad \mathbf{B}^3 = \begin{pmatrix} 13 & 8 \\ 8 & 5 \end{pmatrix}, \qquad \mathbf{A}^3 - \mathbf{B}^3 = \begin{pmatrix} 21 & 6 \\ 6 & 1 \end{pmatrix}.$$

The determinant is $21 - 36 = -15 < 0$, so the difference is indefinite. Explicitly, with $\mathbf{x} = (1, -5)$,

$$\mathbf{x}^\top (\mathbf{A}^3 - \mathbf{B}^3)\mathbf{x} = 21 + 2 \cdot 6 \cdot (-5) + 25 = -14 < 0.$$

By Theorem 11.8.3 (a), $t \mapsto t^3$ sends $\mathbf{A}$ to $\mathbf{A}^3$, so it is not operator monotone on $[0, \infty)$.

(b) Start from $\mathbf{A} = \mathbf{A}^{3^0/2^0}$. Taking the square root of $\mathbf{A}^q$ gives $\mathbf{A}^{q/2}$, and cubing it gives $\mathbf{A}^{3q}$, by Theorem 11.8.3 (b) and the uniqueness of the positive square root, as in C1 (a); likewise for $\mathbf{B}$. If $q = 3^j/2^k$, the results are $3^j/2^{k+1}$ and $3^{j+1}/2^k$, of the same form. By induction on the number of steps, every exponent reached has the form $3^j/2^k$. If $2 = 3^j/2^k$, then $3^j = 2^{k+1}$, and the left side is odd while the right side is even, since $k + 1 \geq 1$. So no exponent reached equals 2. The hypothetical operator monotonicity of the cube therefore cannot be converted, by these means, into that of the square. The failure of the square does not formally imply the failure of the cube, and (a) had to find a pair of matrices of its own.

Chapter 17

Convexity

Three chapters in a row have met convexity and moved on. Chapter 15 §01 drew the unit balls of three norms and remarked that each is convex, because the triangle inequality forces $\|t\mathbf{u} + (1-t)\mathbf{v}\| \leq 1$ whenever $\|\mathbf{u}\|, \|\mathbf{v}\| \leq 1$ (Definition 15.1.2). Chapter 12 §01 set as an exercise that the positive semidefinite matrices are closed under sums and non-negative multiples (Exercise (C2: The cone of positive matrices)). Chapter 16 §06 proved that the sum of the k largest eigenvalues is subadditive, and so a convex function of the matrix (Corollary 16.6.5), and said that this was only to be expected of a maximum of linear functions. And Chapter 16 §08 showed, again in an exercise, that the possible diagonals of the Hermitian matrices with a given spectrum contain the segment between any two of their points (Exercise (C3: The possible diagonals form a convex set)). Each time, convexity was checked on the spot and not studied. One debt is older still: Chapter 15's plan listed **dual norms**, and Chapter 15 never defined one.

This chapter studies convexity for its own sake. A set is convex when it contains the segment between any two of its points, and the theory built on that single condition has two faces. One face is **combinatorial**. Every point of a convex hull in dimension n is an average of at most $n+1$ of the original points, and from that count follow the theorems of Radon and Helly on how convex sets intersect. The other face is **geometric**, and it carries most of the weight. A point outside a closed convex set can be separated from it by a hyperplane, and the hyperplane comes from the nearest point of the set, generalizing the orthogonal projection of Chapter 10. From separation come the rest: a convex set described by the half-spaces that contain it, the dual norm as the support function of the unit ball, Farkas's lemma and the duality of linear programming, the minimax theorem for matrix games, and the fact that a compact convex set is the hull of its extreme points. The chapter ends with convex functions, which is where the Ky Fan observation of Chapter 16 belongs.

The field is $\mathbb{R}$ throughout. Convexity asks for weights t with $0 \leq t \leq 1$, and "between 0 and 1" needs an order on the scalars, which $\mathbb{C}$ does not have. A complex space is treated as a real one when it is needed, by allowing only real scalars: the Hermitian $n \times n$ matrices, for instance, form a real vector space and not a complex one, and that is how positive semidefinite matrices and eigenvalue functions enter. Spaces are finite-dimensional, and each section says whether a result needs only the vector space, a norm, or an inner product. Most of the chapter works in $\mathbb{R}^n$ with the standard inner product.

17.0.1 The analysis this chapter imports

The list is Chapter 15's, facts (A1)–(A6) of that chapter's introduction, cited by the same name at the point of use: "by the extreme value theorem, fact (A4) of Chapter 15's introduction". This chapter needs chiefly two of them. **(A3)**, the compactness of closed bounded sets, and **(A4)**, the extreme value theorem, are what make a nearest point, a maximum over a hull, or an extreme point exist rather than merely be approached. §02 uses (A3) to prove that the hull of a compact set is compact, and the separation and extreme-point theorems of §§03 and 08 rest on both. **(A1)**, completeness, gives the suprema that define gauges and support functions. For the second-derivative test of convexity in §10, the one-variable case uses **(A6)**, the mean value theorem, and the several-variable case uses the symmetry and Taylor assumptions that Chapter 13 §06 recorded for its own second-derivative test. §11 builds the logarithm from the exponential of Chapter 9 §09 (that section's facts (A1)–(A3)) and needs **(A5)**, the intermediate value theorem, to show every positive number has one.

The words **closed** and **open** are defined in §01, in the sequential form in which Chapter 15's introduction defines continuity, and a closedness argument uses nothing but that definition and the elementary algebra of limits. A section that needs any analytic fact outside Chapter 15's list says so where it uses it.

17.0.2 What you need

- **Chapter 1** — independence and dimension, used to count points: Definition 1.4.1, Theorem 1.6.3, Theorem 1.3.1, Theorem 1.6.5, and the dimension formula Theorem 1.7.3. Zorn's lemma (Theorem 1.8.1) is mentioned once, to mark where the infinite-dimensional Hahn–Banach theorem would begin.
- **Chapter 3** — cosets, which are the affine subspaces of this chapter: Definition 3.9.2, Lemma 3.9.3; and Theorem 3.3.1.
- **Chapter 4** — linear functionals and hyperplanes, the raw material of every separation argument: Definition 4.1.1, Theorem 4.1.1, Definition 4.5.2, Theorem 4.5.3, Proposition 4.6.4.
- **Chapter 9 §09** — the exponential of a number, with that section's imported facts (A1)–(A3), from which §11 builds the logarithm and real powers: Theorem 9.9.4.
- **Chapter 10** — the inner product and the orthogonal projection, which §03 generalizes from subspaces to closed convex sets: Definition 10.1.1, Theorem 10.1.5, Theorem 10.3.2, Definition 10.3.2, Theorem 10.3.3, Theorem 10.3.5.
- **Chapter 12** — positivity: Definition 12.1.1, Theorem 12.1.4, Definition 12.5.1.
- **Chapter 13 §06** — the Hessian and the second-derivative test, Definition 13.6.2 and Theorem 13.6.4, with that section's Taylor assumption.
- **Chapter 15** — norms, their unit balls and their equivalence, compactness, and the operator norm: Definition 15.1.1, Definition 15.1.2, Proposition 15.1.2, Lemma 15.1.1, Theorem 15.2.2, Corollary 15.2.3, Corollary 15.2.5, Definition 15.3.2, Theorem 15.3.3.
- **Chapter 16** — the places where convexity was met: Theorem 16.6.2 and Corollary 16.6.5, Definition 16.8.1 and Theorem 16.8.5, Lemma 16.8.6, Definition 16.11.1 and Proposition 16.11.8.

17.0.3 Roadmap

- **Convex sets and hulls.** The definition, the first examples (half-spaces, the balls of every norm, the standard simplex, the positive semidefinite matrices, the vectors majorized by a fixed vector), the operations that preserve convexity, and the convex hull as the set of all convex combinations. Affine hulls, which are Chapter 3's cosets. Closed and open sets.
- **Carathéodory's theorem.** In dimension n, every point of a hull is a convex combination of at most $n+1$ of the points, and no fewer will do in general. Hence the hull of a compact set is compact. Radon's theorem, and Helly's theorem on intersections.
- **Separating hyperplanes.** The nearest point of a closed convex set, characterized by an obtuse-angle condition that becomes Chapter 10's orthogonality when the set is a subspace. Strict separation of a point from a closed convex set, supporting hyperplanes, and the finite-dimensional Hahn–Banach theorem. Why two disjoint closed convex sets need not be strictly separated.
- **Gauges, support functions, dual norms.** Every bounded, closed, symmetric convex set that contains a ball around $\mathbf{0}$ is the unit ball of a norm, which is the converse of Chapter 15's convexity remark. The support function, the polar set, and the dual norm, with the proof that the dual of the dual norm is the original norm. This supplies the dual norms that Chapter 15 left out.
- **Cones and Farkas's lemma.** Convex cones and their duals; a finitely generated cone is closed, which is the subtle step; the alternative theorem of Farkas; and a closed cone with a non-closed linear image, showing why finite generation matters.
- **Linear programming.** Weak and strong duality from Farkas's lemma, complementary slackness, and a worked problem solved together with its dual. This answers the remark in Chapter 2 §07 that flows with capacities are a problem about inequalities.
- **The minimax theorem.** Matrix games, mixed strategies over the simplex, and von Neumann's theorem, contrasted with the Courant–Fischer min–max of Chapter 16, whose proof is a dimension count rather than convexity.
- **Extreme points.** A compact convex set is the convex hull of its extreme points (Minkowski's theorem). The extreme points of the unit balls of the three norms, of the density matrices, and of the doubly stochastic matrices; for the last, Birkhoff's theorem that the permutation matrices are all of them is stated and left to Chapter 18. A compact convex set whose extreme points do not form a closed set.
- **Polytopes.** Hulls of finitely many points against bounded intersections of finitely many half-spaces, and the Minkowski–Weyl theorem that they are the same sets. Vertices as the basic feasible points of linear programming.
- **Convex functions.** The epigraph, Jensen's inequality, the second-derivative test, and continuity. A pointwise supremum of affine functions is convex, which accounts for Chapter 16's Ky Fan sums.
- **Three classical inequalities.** The logarithm and real powers, built from Chapter 9's exponential; the weighted arithmetic–geometric mean inequality as Jensen's inequality for $-\log$; Young's and Hölder's inequalities; Minkowski's inequality, so that every $\|\cdot\|_p$ is a norm on F^n; and the dual of every p-norm, which completes §04. The chapter's summary closes this section.

17.0.4 Named moves

- **Count, then drop a point.** Too many points in too few dimensions are dependent, affinely or linearly. Move the weights along the dependence until one of them reaches

zero, and drop that point without leaving the hull. Carathéodory's theorem, its version for cones, and Radon's theorem are all this move.

- **Nearest point, then the normal direction.** To separate a point from a closed convex set, take the nearest point of the set and use the vector from it to the outside point as the normal of the hyperplane. The separation theorems are the geometry of this one projection.
- **Dualize.** A closed convex set is determined by the half-spaces containing it, and a closed convex cone by its dual cone. Every statement about the one side has a statement about the other: Farkas's lemma is that move made into a theorem, and linear-programming duality is Farkas applied to one combined system.
- **A supremum of linear functions is convex.** Support functions, dual norms, the largest eigenvalue and the Ky Fan sums are all suprema of linear functions, and each inherits its convexity from that alone.
- **Lift, then eliminate.** To see what a set looks like from fewer coordinates, eliminate one variable at a time: Fourier–Motzkin elimination pairs each upper bound with each lower bound, and is what proves the Minkowski–Weyl theorem of §09.
- **Compactness turns a supremum into a maximum.** Chapter 15's move, used again: once a hull or a set of weights is known to be compact, a maximum or a nearest point is attained at a point that can be named and fed back into the argument.

17.1 Convex Sets and Hulls

Convexity has turned up in this book four times without being asked for: in the unit balls of Chapter 15, the positive semidefinite matrices of Chapter 12, and the Ky Fan sums and the possible diagonals of Chapter 16 (the chapter introduction lists the places). Each time the property was checked by hand and set aside. This section gives it a name, finds the smallest convex set containing a given set, and fixes the words **closed** and **open** that the rest of the chapter needs.

The field is $\mathbb{R}$, throughout the chapter. The definition below asks for a scalar t with $0 \le t \le 1$, which needs an order on the scalars; $\mathbb{C}$ has none. A complex space is treated as a real one by allowing only real scalars. That is how the Hermitian matrices enter below: they form a vector space over $\mathbb{R}$, and not over $\mathbb{C}$, since $i\mathbf{A}$ is not Hermitian when $\mathbf{A} \neq \mathbf{0}$ is. Unless a statement says otherwise, V is a real vector space; where a result needs a finite dimension, a norm or an inner product, it says so.

17.1.1 Segments, and sets that contain them

Chapter 15 §01 checked the convexity of a unit ball with one line: if $\|\mathbf{u}\|, \|\mathbf{v}\| \le 1$ and $0 \le t \le 1$, then $\|t\mathbf{u}+(1-t)\mathbf{v}\| \le 1$. The expression $t\mathbf{x}+(1-t)\mathbf{y}$, with t running over $[0,1]$, keeps recurring, so it deserves a name, and so does the property of containing all of it.

Picture it first. At $t = 1$ the expression is $\mathbf{x}$, at $t = 0$ it is $\mathbf{y}$, and at $t = \frac{1}{2}$ it is the midpoint. Writing it as $\mathbf{y}+t(\mathbf{x}-\mathbf{y})$ shows the rest: we start at $\mathbf{y}$ and travel the fraction t of the way to $\mathbf{x}$. As t runs over $[0,1]$, the point runs along the straight **segment** from $\mathbf{y}$ to $\mathbf{x}$, and nowhere else.

A convex set is one that contains the whole straight segment between any two of its points.

Definition 17.1.1 — Convex Set

Let V be a vector space **over** $\mathbb{R}$. A subset $C \subseteq V$ is **convex** if, **for all** $\mathbf{x}, \mathbf{y} \in C$ and **every** real t with $0 \le t \le 1$,

$$t\mathbf{x} + (1-t)\mathbf{y} \in C.$$

The set $\{t\mathbf{x} + (1-t)\mathbf{y} : 0 \le t \le 1\}$ is the **segment** joining $\mathbf{x}$ and $\mathbf{y}$, written $[\mathbf{x}, \mathbf{y}]$.

In words: pick any two points of C, possibly equal; the segment joining them must lie inside C. The quantifier "for all $\mathbf{x}, \mathbf{y}$" is what makes this a property of the set rather than of a pair; one segment escaping C is enough to make it non-convex. The restriction $0 \le t \le 1$ is the other half of the content, and the end of this subsection shows what happens without it. There is nothing to check for well-definedness: a subset either has the property or it does not.

Example. (The first convex sets)

Check each of the following against Definition 17.1.1.

(a) The empty set, and a single point $\{\mathbf{p}\}$.

(b) A subspace U of V, and a coset $\mathbf{p} + U$ of it (Definition 3.9.2).

(c) A **closed half-space** $\{\mathbf{x} \in V : \varphi(\mathbf{x}) \le c\}$, where φ is a non-zero linear functional on V (Definition 4.1.1) and $c \in \mathbb{R}$.

(d) A closed ball $\{\mathbf{x} \in V : \|\mathbf{x} - \mathbf{p}\| \le r\}$ of any norm on V, with center $\mathbf{p}$ and radius $r \ge 0$.

(e) The set of positive semidefinite matrices (Definition 12.1.1) in the real vector space of $n \times n$ Hermitian matrices.

Solution.

(a) The empty set has no two points, so the condition holds vacuously; for $\{\mathbf{p}\}$, $t\mathbf{p} + (1-t)\mathbf{p} = \mathbf{p}$. These degenerate cases matter because an intersection of convex sets, which we meet shortly, is often empty or a single point, and the statements below must allow for both.

(b) Let $\mathbf{x} = \mathbf{p} + \mathbf{u}$ and $\mathbf{y} = \mathbf{p} + \mathbf{w}$ with $\mathbf{u}, \mathbf{w} \in U$. Then

$$t\mathbf{x} + (1-t)\mathbf{y} = \mathbf{p} + \big(t\mathbf{u} + (1-t)\mathbf{w}\big),$$

and $t\mathbf{u} + (1-t)\mathbf{w} \in U$ because a subspace is closed under linear combinations. Taking $\mathbf{p} = \mathbf{0}$ gives the subspace itself. Here the restriction on t was not used at all; we return to this below.

(c) Let $\varphi(\mathbf{x}) \le c$ and $\varphi(\mathbf{y}) \le c$. By linearity,

$$\varphi\big(t\mathbf{x} + (1-t)\mathbf{y}\big) = t\varphi(\mathbf{x}) + (1-t)\varphi(\mathbf{y}) \le tc + (1-t)c = c,$$

where the inequality multiplies the first hypothesis by t and the second by $1-t$. Multiplying an inequality by a number preserves it only when the number is ≥ 0, so both $t \ge 0$ and $1-t \ge 0$ were used. In $\mathbb{R}^n$ every linear functional is $\mathbf{x} \mapsto \mathbf{a}^{\top}\mathbf{x}$ for some $\mathbf{a}$ (Theorem 4.1.1), so the closed half-spaces of $\mathbb{R}^n$ are the sets $\{\mathbf{x} : \mathbf{a}^{\top}\mathbf{x} \le c\}$ with $\mathbf{a} \neq \mathbf{0}$. The same computation shows that the **open half-space** $\{\mathbf{x} : \varphi(\mathbf{x}) < c\}$ is convex, and that the **affine hyperplane** $\{\mathbf{x} : \varphi(\mathbf{x}) = c\}$ is convex.

(d) Let $\|\mathbf{x}-\mathbf{p}\| \le r$ and $\|\mathbf{y}-\mathbf{p}\| \le r$. Since $t\mathbf{x}+(1-t)\mathbf{y}-\mathbf{p} = t(\mathbf{x}-\mathbf{p})+(1-t)(\mathbf{y}-\mathbf{p})$, (N3) and (N2) of Definition 15.1.1 give

$$\|t\mathbf{x} + (1-t)\mathbf{y} - \mathbf{p}\| \le t\|\mathbf{x}-\mathbf{p}\| + (1-t)\|\mathbf{y}-\mathbf{p}\| \le r,$$

where homogeneity used $|t| = t$ and $|1-t| = 1-t$. With $\mathbf{p} = \mathbf{0}$ and $r = 1$ this is the closed unit ball of Definition 15.1.2, and the computation is the one Chapter 15 §01 made there.

(e) The Hermitian matrices form a real vector space: a real linear combination of Hermitian matrices is Hermitian. Let $\mathbf{A} \succeq 0$ and $\mathbf{B} \succeq 0$. Then $t\mathbf{A} + (1-t)\mathbf{B}$ is Hermitian, and for every $\mathbf{x} \in \mathbb{C}^n$,

$$\langle (t\mathbf{A} + (1-t)\mathbf{B})\mathbf{x}, \mathbf{x}\rangle = t\langle \mathbf{A}\mathbf{x}, \mathbf{x}\rangle + (1-t)\langle \mathbf{B}\mathbf{x}, \mathbf{x}\rangle \ge 0,$$

since both inner products on the right are ≥ 0 by (P2) and both coefficients are ≥ 0. So (P1) and (P2) hold, and $t\mathbf{A} + (1-t)\mathbf{B} \succeq 0$. The same computation with any $s, t \ge 0$ in place of t and $1-t$ shows $s\mathbf{A} + t\mathbf{B} \succeq 0$, so the positive semidefinite matrices form a convex cone, in the sense of §05. (This is what Exercise (C2: The cone of positive matrices) (a) asks.)

The standard example of a convex set in coordinates gets its own name, because the rest of this section keeps returning to it.

Definition 17.1.2 — Standard Simplex

For $n \ge 1$, the **standard simplex** in $\mathbb{R}^n$ is

$$\Delta_n := \Big\{ \mathbf{t} = (t_1, \dots, t_n) \in \mathbb{R}^n : t_i \ge 0 \text{ for every } i, \quad t_1 + \cdots + t_n = 1 \Big\}.$$

$\Delta_1 = \{1\}$ is a point, Δ_2 is the segment from $(1,0)$ to $(0,1)$, and Δ_3 is the triangle with corners $\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3$. It is convex: it is the intersection of the n closed half-spaces $\{t_i \ge 0\}$ with the affine hyperplane $\{t_1 + \cdots + t_n = 1\}$, and each of these is convex by Example (The first convex sets) (c). (That an intersection of convex sets is convex is the first item of Proposition 17.1.1 below; it is also immediate here, because a point that lies in each set lies in their intersection.) An element of Δ_n is a list of n **weights**: non-negative, and adding up to 1.

convex not convex: the dashed segment leaves the set

A non-example by minimal change. Keep the closed unit ball B_2 of $\mathbb{R}^2$ but take only its edge, the unit circle $\{\mathbf{x} : \|\mathbf{x}\|_2 = 1\}$. Much survives: the circle is symmetric under $\mathbf{x} \mapsto -\mathbf{x}$, bounded, and as round as the disc. But the clause "for all $\mathbf{x}, \mathbf{y}$" fails at $\mathbf{x} = \mathbf{e}_1$, $\mathbf{y} = -\mathbf{e}_1$, $t = \frac{1}{2}$: the midpoint is $\mathbf{0}$, and $\|\mathbf{0}\|_2 = 0 \ne 1$. What was lost is exactly the inequality ≤ 1 that absorbed the triangle inequality in Example (The first convex sets) (d); with an equality there is nothing to absorb it.

Why this definition. Two variations are worth trying.

- *Let t range over all of $\mathbb{R}$.* Then C must contain the whole **line** through any two of its points. The subspaces and cosets of Example (The first convex sets) meet this demand, which is why (b) never used $0 \le t \le 1$; the half-spaces and balls do not. Exercise (C3: Sets that contain lines) shows that, apart from $\emptyset$, the sets meeting it are exactly the cosets.
- *Ask only for $t = \frac{1}{2}$.* A set containing the midpoint of any two of its points is **midpoint convex**, which is genuinely weaker: $\mathbb{Q}^2$ is midpoint convex, yet it misses $\frac{1}{\sqrt{2}}\mathbf{e}_1 \in [\mathbf{0}, \mathbf{e}_1]$. Exercise (C1: Midpoint convexity) shows that the gap disappears for closed sets, defined at the end of this section.

The name is the everyday word: a convex lens has no dents.

Warning. **A union of convex sets need not be convex.** The two coordinate axes in $\mathbb{R}^2$ are subspaces, hence convex, but their union contains $\mathbf{e}_1$ and $\mathbf{e}_2$ and not their midpoint $(\frac{1}{2}, \frac{1}{2})$, which lies on neither axis. Even two points fail: $\{\mathbf{0}\} \cup \{\mathbf{e}_1\}$ is a union of two convex sets and misses $\frac{1}{2}\mathbf{e}_1$. The operation that does respect convexity is intersection (Proposition 17.1.1), and the convex replacement for a union is the hull of the union, defined below.

Quick check. Is $\{(x, y) \in \mathbb{R}^2 : y \ge |x|\}$ convex? Is $\{(x, y) \in \mathbb{R}^2 : y \le |x|\}$ convex?

Solution. The first is convex. It is the set where both $y - x \ge 0$ and $y + x \ge 0$, an intersection of two closed half-spaces, and a point on a segment between two points of both half-spaces lies in both by Example (The first convex sets) (c). The second is not: $(1, 1)$ and $(-1, 1)$ belong to it, since $1 \le 1$, but their midpoint $(0, 1)$ does not, since $1 \le 0$ is false. The two sets differ only in the direction of the inequality, and the direction decides everything; a convex function such as $|x|$ has a convex region **above** its graph (§10).

Here is a payoff. Chapter 16 §08 met a set of vectors that it could describe exactly, but whose convexity it proved only in an exercise. Everything needed to prove it is now in place.

Example. (The vectors majorized by a fixed vector)

Let $\boldsymbol{\lambda} \in \mathbb{R}^n$. Prove that the set $\{\mathbf{d} \in \mathbb{R}^n : \mathbf{d} \prec \boldsymbol{\lambda}\}$ of vectors majorized by $\boldsymbol{\lambda}$ (Definition 16.8.1) is convex, and deduce that the diagonals of the Hermitian matrices with spectrum $\boldsymbol{\lambda}$ form a convex set.

Solution. For $\mathbf{x} \in \mathbb{R}^n$ and $1 \le k \le n$, write $s_k(\mathbf{x}) = x_1^{\downarrow} + \cdots + x_k^{\downarrow}$, the sum of the k largest entries.

Step 1: any k entries add up to at most $s_k(\mathbf{x})$. List the entries x_i at a set I of k positions decreasingly as $v_1 \ge \cdots \ge v_k$. Since $\mathbf{x}$ has j entries $v_1, \dots, v_j \ge v_j$, we get $x_j^{\downarrow} \ge v_j$ for each j. Summing gives $\sum_{i \in I} x_i \le s_k(\mathbf{x})$, with equality when I holds the positions of the k largest entries.

Step 2: s_k respects averages. Let $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$ and $0 \le t \le 1$, and let I hold the positions of the k largest entries of $\mathbf{z} = t\mathbf{x} + (1 - t)\mathbf{y}$. By Step 1, used once with equality and twice as an inequality,

$$s_k(\mathbf{z}) = t \sum_{i \in I} x_i + (1 - t) \sum_{i \in I} y_i \le t\, s_k(\mathbf{x}) + (1 - t)\, s_k(\mathbf{y}),$$

where the inequality again needs $t \geq 0$ and $1 - t \geq 0$.

Step 3: convexity. Let $\mathbf{d} \prec \boldsymbol{\lambda}$ and $\mathbf{d}' \prec \boldsymbol{\lambda}$, and put $\mathbf{z} = t\mathbf{d} + (1-t)\mathbf{d}'$. For $k \leq n-1$, Step 2 and (M1) for both vectors give $s_k(\mathbf{z}) \leq t\, s_k(\boldsymbol{\lambda}) + (1-t)\, s_k(\boldsymbol{\lambda}) = s_k(\boldsymbol{\lambda})$. The total of $\mathbf{z}$ is $t\sum_i \lambda_i + (1-t)\sum_i \lambda_i = \sum_i \lambda_i$ by (M2) for both. So $\mathbf{z} \prec \boldsymbol{\lambda}$, and the set is convex.

For the deduction, the Schur–Horn Theorem (Theorem 16.8.5) says that the diagonals of the Hermitian matrices with eigenvalues $\boldsymbol{\lambda}$ are **exactly** the vectors $\mathbf{d} \prec \boldsymbol{\lambda}$. So the set of those diagonals is the set just shown to be convex.

This is the statement of Exercise (C3: The possible diagonals form a convex set), now with a proof in the text, and Step 2 is a first glimpse of §10's convex functions: s_k satisfies $s_k(t\mathbf{x} + (1-t)\mathbf{y}) \leq t\, s_k(\mathbf{x}) + (1-t)\, s_k(\mathbf{y})$ because it is a maximum of linear functions.

17.1.2 Operations that preserve convexity

Checking the definition directly is rarely the fastest route. Most convex sets are built from simpler ones by a few operations, and the following proposition lists those that preserve convexity. It needs one construction. For subsets $A, B \subseteq V$ and a real c, the **Minkowski sum** and the **scalar multiple** are

$$A + B \coloneqq \{\mathbf{a} + \mathbf{b} : \mathbf{a} \in A,\ \mathbf{b} \in B\}, \qquad cA \coloneqq \{c\mathbf{a} : \mathbf{a} \in A\}.$$

A **translate** $\mathbf{p} + A$ is the Minkowski sum $\{\mathbf{p}\} + A$; a coset (Definition 3.9.2) is a translate of a subspace.

Proposition 17.1.1 — Operations Preserving Convexity

Let V and W be real vector spaces.

(a) The intersection of **any** family of convex subsets of V is convex.

(b) If $T\colon V \to W$ is linear, $C \subseteq V$ is convex and $D \subseteq W$ is convex, then the image $T(C)$ and the preimage $T^{-1}(D) = \{\mathbf{v} \in V : T\mathbf{v} \in D\}$ are convex.

(c) If $A, B \subseteq V$ are convex and $c \in \mathbb{R}$, then $A + B$, cA and every translate $\mathbf{p} + A$ are convex.

Idea. Rewrite the point of the segment so that convexity of the given sets applies: linearity moves the weights through T, and a Minkowski sum regroups term by term.

Proof. Throughout, let $0 \leq t \leq 1$.

(a) Let (C_α) be a family of convex sets and $\mathbf{x}, \mathbf{y} \in \bigcap_\alpha C_\alpha$. For each α, both points lie in C_α, so $t\mathbf{x} + (1-t)\mathbf{y} \in C_\alpha$ by convexity of C_α. Hence the point lies in every C_α, that is, in the intersection. (The intersection of the empty family is V by convention, and V is convex.)

(b) Let $T\mathbf{x}, T\mathbf{y} \in T(C)$ with $\mathbf{x}, \mathbf{y} \in C$. By linearity, $tT\mathbf{x} + (1-t)T\mathbf{y} = T\big(t\mathbf{x} + (1-t)\mathbf{y}\big)$, and $t\mathbf{x} + (1-t)\mathbf{y} \in C$ by convexity; so the point lies in $T(C)$. For the preimage, let $T\mathbf{x}, T\mathbf{y} \in D$. Then $T\big(t\mathbf{x} + (1-t)\mathbf{y}\big) = tT\mathbf{x} + (1-t)T\mathbf{y} \in D$ by convexity of D, so $t\mathbf{x} + (1-t)\mathbf{y} \in T^{-1}(D)$.

(c) Let $\mathbf{a}+\mathbf{b}$ and $\mathbf{a}'+\mathbf{b}'$ lie in $A+B$. Rearranging,

$$t(\mathbf{a}+\mathbf{b})+(1-t)(\mathbf{a}'+\mathbf{b}')=\big(t\mathbf{a}+(1-t)\mathbf{a}'\big)+\big(t\mathbf{b}+(1-t)\mathbf{b}'\big),$$

and the two brackets lie in A and in B by convexity. So the point lies in $A+B$. The scalar multiple cA is the image of A under the linear map $\mathbf{v}\mapsto c\mathbf{v}$, and is convex by (b). A translate $\mathbf{p}+A=\{\mathbf{p}\}+A$ is convex because a single point is convex (Example (The first convex sets) (a)). This proves the proposition.

■

The proposition turns many checks into one line. The solution set of a system of linear inequalities,

$$\{\mathbf{x}\in\mathbb{R}^n:\mathbf{A}\mathbf{x}\le\mathbf{b}\}=\bigcap_{i=1}^{m}\{\mathbf{x}:\mathbf{a}_i^{\top}\mathbf{x}\le b_i\},$$

where $\mathbf{a}_i^{\top}$ is the i-th row of $\mathbf{A}\in M_{m\times n}(\mathbb{R})$ and $\mathbf{A}\mathbf{x}\le\mathbf{b}$ means $\le$ in every entry, is an intersection of closed half-spaces (a zero row gives $\mathbb{R}^n$ or $\emptyset$), hence convex by (a). This is the kind of set that the closing remark of Chapter 2 §07 points to, where non-negativity and capacities are added to a flow problem, and §06 of this chapter optimizes over it. The set of **density matrices** $\{\mathbf{A}:\mathbf{A}\succeq 0,\ \operatorname{tr}\mathbf{A}=1\}$ is convex for the same reason: it is the intersection of the positive semidefinite set of Example (The first convex sets) (e) with the preimage of $\{1\}$ under the linear map tr.

17.1.3 Convex combinations and the convex hull

A convex set contains the segment between any two of its points. Apply that twice: it contains $\mathbf{x}_1$, $\mathbf{x}_2$ and hence every point of $[\mathbf{x}_1,\mathbf{x}_2]$, and then every point on a segment from such a point to $\mathbf{x}_3$. The points reached are the averages of $\mathbf{x}_1,\mathbf{x}_2,\mathbf{x}_3$ with non-negative weights, and the pattern deserves a name.

Definition 17.1.3 — Convex Combination

Let V be a real vector space and $\mathbf{x}_1,\dots,\mathbf{x}_k\in V$, with $k\ge 1$. A **convex combination** of $\mathbf{x}_1,\dots,\mathbf{x}_k$ is a vector

$$t_1\mathbf{x}_1+t_2\mathbf{x}_2+\cdots+t_k\mathbf{x}_k\qquad\text{with }(t_1,\dots,t_k)\in\Delta_k,$$

that is, with **every** $t_i\ge 0$ and $t_1+\cdots+t_k=1$.

It is a linear combination with two restrictions on the coefficients, and each restriction has a job. Dropping "$t_i\ge 0$" gives the affine combinations of the next subsection; dropping "sum to 1" as well gives all linear combinations, and the span. A convex combination of two points is a point of the segment joining them, with $(t,1-t)$ as the weights. The weights may be read as masses placed at the points, and the combination is then their center of mass. The case $k=1$ is included and is $1\cdot\mathbf{x}_1=\mathbf{x}_1$.

Lemma 17.1.2 — Convex Sets Contain Their Convex Combinations

Let C be a convex subset of a real vector space. Then every convex combination of points of C lies in C.

Idea. Peel off the last point. A convex combination of k points is a combination of two points, one of which is a convex combination of the first $k-1$ points, rescaled so that its weights again add up to 1. Induction on k does the rest; the only care needed is not to divide by zero while rescaling.

Proof. We use induction on the number k of points. For $k = 1$, the combination is $\mathbf{x}_1 \in C$. Let $k \geq 2$, suppose the statement holds for $k-1$ points, and let $\mathbf{x} = \sum_{i=1}^{k} t_i \mathbf{x}_i$ with $\mathbf{x}_i \in C$ and $(t_1, \dots, t_k) \in \Delta_k$.

Case 1: $t_k = 1$. Then the other weights are non-negative and add up to 0, so all of them are 0, and $\mathbf{x} = \mathbf{x}_k \in C$.

Case 2: $t_k < 1$. Put $s = 1 - t_k > 0$ and $\mathbf{y} = \sum_{i=1}^{k-1} (t_i/s)\mathbf{x}_i$. The division is legal because $s \neq 0$. The coefficients t_i/s are ≥ 0 and add up to $(1-t_k)/s = 1$, so $\mathbf{y}$ is a convex combination of $k-1$ points of C, and $\mathbf{y} \in C$ by the inductive hypothesis. Then

$$\mathbf{x} = s\mathbf{y} + t_k \mathbf{x}_k = (1 - t_k)\mathbf{y} + t_k \mathbf{x}_k,$$

which lies in C by Definition 17.1.1, applied to the points $\mathbf{x}_k$ and $\mathbf{y}$ of C with $t = t_k \in [0, 1]$. This completes the induction.

■

A set that is not convex can be enlarged to one that is. We want the most economical enlargement: nothing added that convexity does not force.

The convex hull of a set is the smallest convex set containing it.

Definition 17.1.4 — Convex Hull

Let S be a subset of a real vector space V. The **convex hull** of S is the intersection of **all** convex subsets of V that contain S:

$$\operatorname{conv} S := \bigcap \{C \subseteq V : C \text{ is convex and } S \subseteq C\}.$$

The family being intersected is never empty, because V itself is convex and contains S. By Proposition 17.1.1 (a), $\operatorname{conv} S$ is convex; it contains S, since each set in the family does; and it lies inside every convex set containing S, since it is the intersection of all of them. So "smallest" in the slogan is literal: $\operatorname{conv} S$ is a convex set containing S and contained in every other one. In particular, $\operatorname{conv} C = C$ **exactly when** C is convex. This description from outside is clean but gives no way to decide whether a given point lies in the hull. The next theorem gives the description from inside.

Theorem 17.1.3 — The Hull Is the Set of Convex Combinations

Let S be a subset of a real vector space V. Then $\operatorname{conv} S$ is the set of all convex

combinations of points of S:

$$\operatorname{conv} S = \Big\{ \sum_{i=1}^{k} t_i \mathbf{x}_i : k \geq 1,\ \mathbf{x}_1, \dots, \mathbf{x}_k \in S,\ (t_1, \dots, t_k) \in \Delta_k \Big\}.$$

Idea. Call the right-hand side D. One inclusion is Lemma 17.1.2 applied to the convex set $\operatorname{conv} S$. For the other, $\operatorname{conv} S$ is the smallest convex set containing S, so it suffices to show that D is **some** convex set containing S. An average of two averages is again an average, of the combined list.

Proof. Let D denote the right-hand side.

($\supseteq$) The set $\operatorname{conv} S$ is convex and contains S. By Lemma 17.1.2 it contains every convex combination of its own points, in particular of points of S. Hence $D \subseteq \operatorname{conv} S$.

($\subseteq$) Each $\mathbf{x} \in S$ is the convex combination $1 \cdot \mathbf{x}$, so $S \subseteq D$. To see that D is convex, let $\mathbf{x} = \sum_{i=1}^{k} a_i \mathbf{x}_i$ and $\mathbf{y} = \sum_{j=1}^{l} b_j \mathbf{y}_j$ be points of D, with all $\mathbf{x}_i, \mathbf{y}_j \in S$, and let $0 \leq t \leq 1$. Then

$$t\mathbf{x} + (1-t)\mathbf{y} = \sum_{i=1}^{k} (t a_i) \mathbf{x}_i + \sum_{j=1}^{l} \big((1-t) b_j\big) \mathbf{y}_j,$$

a combination of the $k+l$ points $\mathbf{x}_1, \dots, \mathbf{x}_k, \mathbf{y}_1, \dots, \mathbf{y}_l$ of S, with coefficients $t a_i \geq 0$ and $(1-t) b_j \geq 0$ adding up to $t \cdot 1 + (1-t) \cdot 1 = 1$. So $t\mathbf{x} + (1-t)\mathbf{y} \in D$, and D is convex. Since $\operatorname{conv} S$ is contained in every convex set containing S, we get $\operatorname{conv} S \subseteq D$.

This proves $\operatorname{conv} S = D$.

■

A combination needs a point, so $\operatorname{conv} \emptyset = \emptyset$; and, padding with zero weights and merging repeated points, $\operatorname{conv}\{\mathbf{x}_1, \dots, \mathbf{x}_m\}$ is the set of all $\sum_i t_i \mathbf{x}_i$ with $\mathbf{t} \in \Delta_m$; since $\sum_i t_i \mathbf{e}_i = (t_1, \dots, t_n)$, **the standard simplex is the hull of the standard basis**.

The theorem does not say how many points a combination needs. Every k is allowed, and for an infinite S nothing in it bounds k. That question is the business of §02.

Example. (Deciding membership in a triangle)

Let $\mathbf{p}_1 = (1, 0)$, $\mathbf{p}_2 = (3, 1)$, $\mathbf{p}_3 = (0, 2)$ in $\mathbb{R}^2$. Decide whether $\mathbf{x} = (\frac{5}{4}, \frac{3}{4})$ and $\mathbf{y} = (2, 2)$ lie in $\operatorname{conv}\{\mathbf{p}_1, \mathbf{p}_2, \mathbf{p}_3\}$.

Solution. By Theorem 17.1.3 and the remark after it, a point $\mathbf{z}$ lies in the hull exactly when $\mathbf{z} = t_1\mathbf{p}_1 + t_2\mathbf{p}_2 + t_3\mathbf{p}_3$ for some $\mathbf{t} \in \Delta_3$. The two coordinates and the condition $t_1 + t_2 + t_3 = 1$ give three linear equations in t_1, t_2, t_3, with coefficient matrix

$$\mathbf{M} = \begin{pmatrix} 1 & 3 & 0 \\ 0 & 1 & 2 \\ 1 & 1 & 1 \end{pmatrix}, \qquad \det \mathbf{M} = 5 \neq 0.$$

So each $\mathbf{z}$ has exactly one solution $\mathbf{t}$, and $\mathbf{z}$ is in the hull if and only if that solution has no negative entry.

For $\mathbf{x}$, the solution is $\mathbf{t} = (\frac{1}{2}, \frac{1}{4}, \frac{1}{4})$. Check: $\frac{1}{2}(1,0) + \frac{1}{4}(3,1) + \frac{1}{4}(0,2) = (\frac{1}{2} + \frac{3}{4}, \frac{1}{4} + \frac{1}{2}) = (\frac{5}{4}, \frac{3}{4})$, and the weights add up to 1. All three are ≥ 0, so $\mathbf{x}$ lies in the hull.

For $\mathbf{y}$, the solution is $\mathbf{t} = (-\frac{2}{5}, \frac{4}{5}, \frac{3}{5})$. Check: $-\frac{2}{5}(1,0) + \frac{4}{5}(3,1) + \frac{3}{5}(0,2) = (-\frac{2}{5} + \frac{12}{5}, \frac{4}{5} + \frac{6}{5}) = (2,2)$, and $-\frac{2}{5} + \frac{4}{5} + \frac{3}{5} = 1$. The only solution has $t_1 < 0$, so **no** convex combination equals $\mathbf{y}$, and $\mathbf{y} \notin \operatorname{conv}\{\mathbf{p}_1, \mathbf{p}_2, \mathbf{p}_3\}$. The negative weight even says where $\mathbf{y}$ is: on the far side of the line through $\mathbf{p}_2$ and $\mathbf{p}_3$ from $\mathbf{p}_1$.

Quick check. Is $(\frac{1}{2}, \frac{1}{2}, \frac{1}{2})$ in the convex hull of $\mathbf{0},\ \mathbf{e}_1 + \mathbf{e}_2,\ \mathbf{e}_2 + \mathbf{e}_3,\ \mathbf{e}_1 + \mathbf{e}_3$ in $\mathbb{R}^3$?

Solution. Yes. Give each of the four points weight $\frac{1}{4}$: the weights are ≥ 0 and add up to 1, and

$$\tfrac{1}{4}\big(\mathbf{0} + (\mathbf{e}_1 + \mathbf{e}_2) + (\mathbf{e}_2 + \mathbf{e}_3) + (\mathbf{e}_1 + \mathbf{e}_3)\big) = \tfrac{1}{4}(2,2,2) = (\tfrac{1}{2}, \tfrac{1}{2}, \tfrac{1}{2}).$$

By Theorem 17.1.3, the point lies in the hull. One convex combination is a complete certificate of membership; proving **non**-membership, as for $\mathbf{y}$ above, needs an argument about all combinations at once.

17.1.4 Affine combinations and the affine hull

Dropping the sign condition from a convex combination gives the other natural kind of average. It describes the flat pieces of V: lines, planes, and their analogues, not necessarily through $\mathbf{0}$. Chapter 3 §09 already has these objects, as cosets $\mathbf{p} + U$ of subspaces, and the point of this subsection is to connect them with combinations.

Definition 17.1.5 — Affine Combination, Affine Hull

Let V be a real vector space.

(a) An **affine combination** of $\mathbf{x}_1, \dots, \mathbf{x}_k \in V$, $k \geq 1$, is a vector $\sum_{i=1}^{k} t_i \mathbf{x}_i$ with real t_i satisfying $t_1 + \cdots + t_k = 1$. No sign condition is imposed.

(b) An **affine subspace** of V is a coset $\mathbf{p} + U$ of a subspace U (Definition 3.9.2). Its **dimension** is $\dim U$.

(c) The **affine hull** of $S \subseteq V$, written $\operatorname{aff} S$, is the set of all affine combinations of points of S.

The dimension in (b) is well defined, because the coset determines its subspace: $U = \{\mathbf{a} - \mathbf{b} : \mathbf{a}, \mathbf{b} \in \mathbf{p} + U\}$. Indeed each such difference is $(\mathbf{p} + \mathbf{u}) - (\mathbf{p} + \mathbf{w}) = \mathbf{u} - \mathbf{w} \in U$, and each $\mathbf{u} \in U$ is the difference $(\mathbf{p} + \mathbf{u}) - \mathbf{p}$. So a line in $\mathbb{R}^3$ not through $\mathbf{0}$ is an affine subspace of dimension 1, and a single point $\{\mathbf{p}\} = \mathbf{p} + \{\mathbf{0}\}$ is one of dimension 0.

Proposition 17.1.4 — The Affine Hull Is a Coset

Let S be a **non-empty** subset of a real vector space V, let $\mathbf{x}_0 \in S$, and put $U = \operatorname{span}\{\mathbf{x} - \mathbf{x}_0 : \mathbf{x} \in S\}$. Then

$$\operatorname{aff} S = \mathbf{x}_0 + U,$$

and $\operatorname{aff} S$ is contained in every affine subspace of V that contains S. In particular U does not depend on the choice of $\mathbf{x}_0 \in S$.

Idea. Since the weights add up to 1, an affine combination is $\mathbf{x}_0$ plus a linear combination of the differences $\mathbf{x}_i - \mathbf{x}_0$; that identity, read in both directions, gives the equality, and minimality follows because an affine subspace through $\mathbf{x}_0$ is $\mathbf{x}_0$ plus a subspace.

Proof. ($\subseteq$) Let $\mathbf{x} = \sum_i t_i \mathbf{x}_i$ with $\mathbf{x}_i \in S$ and $\sum_i t_i = 1$. Since the t_i add up to 1, $\mathbf{x}_0 = \sum_i t_i \mathbf{x}_0$, and therefore

$$\mathbf{x} = \mathbf{x}_0 + \sum_i t_i(\mathbf{x}_i - \mathbf{x}_0) \in \mathbf{x}_0 + U.$$

($\supseteq$) An element of $\mathbf{x}_0 + U$ is $\mathbf{x}_0 + \sum_j c_j(\mathbf{y}_j - \mathbf{x}_0)$ for some $\mathbf{y}_j \in S$ and real c_j, by Definition 1.3.2. It equals

$$\Big(1 - \sum_j c_j\Big)\mathbf{x}_0 + \sum_j c_j \mathbf{y}_j,$$

a combination of points of S whose coefficients add up to 1, hence an affine combination.

Now let $\mathbf{p} + W$ be an affine subspace containing S. Since $\mathbf{x}_0 \in \mathbf{p} + W$, Lemma 3.9.3 (b) gives $\mathbf{p} + W = \mathbf{x}_0 + W$. Each $\mathbf{x} \in S$ also lies in $\mathbf{x}_0 + W$, so $\mathbf{x} - \mathbf{x}_0 \in W$. Thus W is a subspace containing every $\mathbf{x} - \mathbf{x}_0$, and $U \subseteq W$ by Theorem 1.3.1. Hence $\operatorname{aff} S = \mathbf{x}_0 + U \subseteq \mathbf{x}_0 + W$. Finally, U is the subspace determined by the coset $\operatorname{aff} S$, by the remark after Definition 17.1.5, and that coset does not mention $\mathbf{x}_0$. This proves the proposition. ∎

So the affine hull is to affine subspaces what the span is to subspaces, and what the convex hull is to convex sets: the smallest one containing S. It also gives every convex set a dimension. The **dimension** of a non-empty convex set C is $\dim \operatorname{aff} C$. A segment in $\mathbb{R}^3$ has dimension 1 and a triangle dimension 2. For Δ_n, take $\mathbf{x}_0 = \mathbf{e}_1$ in Proposition 17.1.4: each $\mathbf{t} - \mathbf{e}_1$ has coordinates adding up to 0, so U lies in the kernel H of $\mathbf{t} \mapsto t_1 + \cdots + t_n$, which has dimension $n - 1$ by Theorem 3.3.1 (the map is onto $\mathbb{R}$); and U contains the $n-1$ vectors $\mathbf{e}_i - \mathbf{e}_1$ ($i \geq 2$), independent because the i-th coordinate of $\sum_{j \geq 2} c_j(\mathbf{e}_j - \mathbf{e}_1)$ is c_i, so $U = H$ by Theorem 1.6.8. Hence Δ_n has dimension $n - 1$, and it is flat inside $\mathbb{R}^n$: no ball of positive radius fits inside it.

17.1.5 Closed and open sets

The later sections take limits: §03 needs a nearest point of a convex set to exist, and §02 needs the hull of a compact set to be compact. Chapter 15 §02 used the right notion in passing, inside Corollary 15.2.5; here it is given a name, together with its partner.

Throughout this subsection, V is a **finite-dimensional** real vector space with a norm $\|\cdot\|$. By Example (Inner products, weights, and a function space) (a), an inner product space is a special case, with the induced norm. A sequence $(\mathbf{x}_k)$ **converges** to $\mathbf{x}$, written $\mathbf{x}_k \to \mathbf{x}$, if $\|\mathbf{x}_k - \mathbf{x}\| \to 0$. By Corollary 15.2.3 (a), whether $\mathbf{x}_k \to \mathbf{x}$ does not depend on which norm is used, so neither does anything defined from it below.

A closed set keeps the limits of its sequences. An open set is one that every sequence converging to one of its points must eventually enter.

Definition 17.1.6 — Closed Set, Open Set

Let V be a finite-dimensional real vector space with a norm, and let $K, U \subseteq V$.

(a) K is **closed** if, **whenever** $(\mathbf{x}_k)$ is a sequence of points **of** K with $\mathbf{x}_k \to \mathbf{x}$ for some $\mathbf{x} \in V$, the limit $\mathbf{x}$ lies in K.

(b) U is **open** if, **whenever** $\mathbf{x}_k \to \mathbf{x}$ with $\mathbf{x} \in U$, there is an index N such that $\mathbf{x}_k \in U$ for **every** $k \geq N$.

By Corollary 15.2.3 (a), both properties are the same for every norm on V. Closedness in (a) is the notion used in Corollary 15.2.5.

In words: (a) demands that no convergent sequence inside K has its limit outside, and (b) that every sequence converging to a point of U is eventually inside U. This is the sequential form, matching the way Chapter 15's introduction defines continuity; it is the form taken as the definition, and Proposition 17.1.6 (a) gives the equivalent ball form, which §03 and §10 use.

Continuity will be needed for linear maps, and in finite dimension it costs nothing.

Lemma 17.1.5 — Linear Maps Are Lipschitz

Let V and W be finite-dimensional real vector spaces with norms, and let $T\colon V \to W$ be linear. There is a constant $M \geq 0$ such that

$$\|T\mathbf{x} - T\mathbf{y}\| \leq M\|\mathbf{x} - \mathbf{y}\| \qquad \text{for all } \mathbf{x}, \mathbf{y} \in V.$$

In particular $\mathbf{x}_k \to \mathbf{x}$ implies $T\mathbf{x}_k \to T\mathbf{x}$; and every linear functional $\varphi\colon V \to \mathbb{R}$, with $|\cdot|$ as the norm on $\mathbb{R}$, is continuous.

Idea. In a basis, $\|T\mathbf{x}\|$ is at most a constant times the 1-norm of the coordinates of $\mathbf{x}$, and norm equivalence trades that norm for the given one.

Proof. If $V = \{\mathbf{0}\}$, then $T = 0$ and $M = 0$ works. Otherwise let $(\mathbf{v}_1, \dots, \mathbf{v}_n)$ be a basis of V, and write $\mathbf{x} = \sum_i x_i \mathbf{v}_i$. The function $N(\mathbf{x}) = \sum_i |x_i|$ is a norm on V: it is the 1-norm of the coordinate vector (Example (The 1-, 2- and ∞-norms on F^n)), and the coordinate map is linear (Theorem 1.5.2) and injective, so (N1), (N2) and (N3) transfer. By Theorem 15.2.2 there is $c > 0$ with $N(\mathbf{x}) \leq c\|\mathbf{x}\|$ for every $\mathbf{x}$. By (N3) and (N2) of Definition 15.1.1 in W,

$$\|T\mathbf{x}\| = \Big\|\sum_i x_i T\mathbf{v}_i\Big\| \leq \sum_i |x_i|\,\|T\mathbf{v}_i\| \leq \Big(\max_i \|T\mathbf{v}_i\|\Big) N(\mathbf{x}) \leq M\|\mathbf{x}\|,$$

with $M = c \max_i \|T\mathbf{v}_i\|$. Applying this to $\mathbf{x} - \mathbf{y}$ and using $T\mathbf{x} - T\mathbf{y} = T(\mathbf{x} - \mathbf{y})$ gives the inequality. If $\|\mathbf{x}_k - \mathbf{x}\| \to 0$, then $\|T\mathbf{x}_k - T\mathbf{x}\| \leq M\|\mathbf{x}_k - \mathbf{x}\| \to 0$. The statement about φ is the case $W = \mathbb{R}$.

■

This is Step 1 of Lemma 15.3.1, with a basis of V in place of the standard basis of F^n.

Proposition 17.1.6 — Closed and Open Sets: First Facts

Let V be a finite-dimensional real vector space with a norm.

(a) A subset $U \subseteq V$ is open **if and only if** for every $\mathbf{x} \in U$ there is a real $r > 0$ with $\{\mathbf{y} \in V : \|\mathbf{y} - \mathbf{x}\| < r\} \subseteq U$.

(b) The intersection of any family of closed sets is closed, and the union of finitely many closed sets is closed.

(c) For a linear functional φ on V and $c \in \mathbb{R}$, the sets $\{\varphi \le c\}$, $\{\varphi \ge c\}$ and $\{\varphi = c\}$ are closed. Every closed ball $\{\mathbf{x} : \|\mathbf{x} - \mathbf{p}\| \le r\}$ is closed, and every subspace and every coset of a subspace is closed.

Idea. Each part unwinds the definitions. For the converse in (a), radii $1/k$ build a sequence breaking openness; for unions in (b), some set catches infinitely many terms.

Proof.

(a) ($\Leftarrow$) Let $\mathbf{x}_k \to \mathbf{x} \in U$, and take r as in the hypothesis. Since $\|\mathbf{x}_k - \mathbf{x}\| \to 0$, there is N with $\|\mathbf{x}_k - \mathbf{x}\| < r$ for $k \ge N$, and then $\mathbf{x}_k \in U$.
($\Rightarrow$) Suppose some $\mathbf{x} \in U$ has no such r. Then for each $k \ge 1$ the radius $r = 1/k$ fails, so there is $\mathbf{x}_k \notin U$ with $\|\mathbf{x}_k - \mathbf{x}\| < 1/k$. Hence $\mathbf{x}_k \to \mathbf{x} \in U$ while no $\mathbf{x}_k$ lies in U, and U is not open.

(b) Let (K_α) be closed, and $\mathbf{x}_k \to \mathbf{x}$ with every $\mathbf{x}_k \in \bigcap_\alpha K_\alpha$. For each α, the sequence lies in K_α, so $\mathbf{x} \in K_\alpha$. Hence $\mathbf{x}$ lies in the intersection. For a union $K_1 \cup \cdots \cup K_m$: if $\mathbf{x}_k \to \mathbf{x}$ with every $\mathbf{x}_k$ in the union, then some K_i contains $\mathbf{x}_k$ for infinitely many k, because there are only m sets. Those terms form a subsequence of points of K_i converging to $\mathbf{x}$, so $\mathbf{x} \in K_i$ by closedness of K_i.

(c) Let $\varphi(\mathbf{x}_k) \le c$ for every k, and $\mathbf{x}_k \to \mathbf{x}$. By Lemma 17.1.5, $\varphi(\mathbf{x}_k) \to \varphi(\mathbf{x})$, and a non-strict inequality survives a limit, so $\varphi(\mathbf{x}) \le c$. The same argument handles $\ge$, and $\{\varphi = c\}$ is the intersection of the two, closed by (b). For the ball, let $\|\mathbf{x}_k - \mathbf{p}\| \le r$ and $\mathbf{x}_k \to \mathbf{x}$. By Lemma 15.1.1, $\big|\|\mathbf{x}_k - \mathbf{p}\| - \|\mathbf{x} - \mathbf{p}\|\big| \le \|\mathbf{x}_k - \mathbf{x}\| \to 0$, so $\|\mathbf{x} - \mathbf{p}\|$ is the limit of numbers $\le r$, and is $\le r$.

Finally let U be a subspace, with basis $(\mathbf{u}_1, \dots, \mathbf{u}_m)$. By Theorem 1.6.5 extend it to a basis $(\mathbf{u}_1, \dots, \mathbf{u}_m, \mathbf{v}_{m+1}, \dots, \mathbf{v}_n)$ of V, and let φ_j, for $m < j \le n$, send a vector to its coefficient on $\mathbf{v}_j$; each φ_j is linear by Theorem 1.5.2. A vector lies in U exactly when these coefficients all vanish, since the basis expansion is unique (Theorem 1.5.1). So $U = \bigcap_{j>m} \{\varphi_j = 0\}$, which is closed by the previous paragraph and (b); when $m = n$, $U = V$, which is closed because every limit lies in V. A coset $\mathbf{p} + U$ is closed because $\mathbf{x}_k \to \mathbf{x}$ with $\mathbf{x}_k \in \mathbf{p} + U$ gives $\mathbf{x}_k - \mathbf{p} \to \mathbf{x} - \mathbf{p}$ with $\mathbf{x}_k - \mathbf{p} \in U$, hence $\mathbf{x} - \mathbf{p} \in U$. This proves the proposition. ∎

By (b) and (c), the solution set $\{\mathbf{x} : \mathbf{A}\mathbf{x} \le \mathbf{b}\}$ of a system of linear inequalities is closed as well as convex, and so is Δ_n. An open ball $\{\mathbf{x} : \|\mathbf{x} - \mathbf{p}\| < r\}$ is open by (a): for $\mathbf{x}$ in it, the radius $r - \|\mathbf{x} - \mathbf{p}\| > 0$ works, by the triangle inequality.

Warning. **"Closed" is not the opposite of "open", and it is not "closed under an operation".** The interval $[0, 1) \subseteq \mathbb{R}$ is neither: $1 - 1/k$ stays inside and converges

to $1 \notin [0,1)$, and $-1/k$ converges to $0 \in [0,1)$ without ever entering it. At the other extreme, $\emptyset$ and V are both closed and open. And $\mathbb{Q}^2$ is closed under addition and midpoints, yet not a closed subset of $\mathbb{R}^2$: by fact (A1) of Chapter 15's introduction, $\sqrt{2}$ is a limit of rationals q_k, and $(q_k, 0) \to (\sqrt{2}, 0)$.

Quick check. Is the open half-plane $\{(x,y) \in \mathbb{R}^2 : x > 0\}$ closed? Is Δ_n open in $\mathbb{R}^n$?

Solution. Neither. The points $(1/k, 0)$ lie in the half-plane and converge to $(0,0)$, which does not, so the half-plane is not closed. For Δ_n, take $\mathbf{x} = \mathbf{e}_1 \in \Delta_n$ and $\mathbf{x}_k = (1+1/k)\mathbf{e}_1 \to \mathbf{e}_1$; no $\mathbf{x}_k$ lies in Δ_n, because its coordinates add up to $1+1/k \neq 1$. So Δ_n is not open, which is the flatness of the simplex seen through sequences. (It is closed, by (b) and (c) of Proposition 17.1.6.)

With convex sets, hulls and closed sets in hand, the question left open by Theorem 17.1.3 can be asked precisely: how many points does a convex combination need? The answer, in §02, depends only on the dimension, and it is what makes the hull of a compact set compact.

17.1.6 Exercises

17.1.6.1 A. Check your understanding

Exercise A1.

(a) State Definition 17.1.1 and Definition 17.1.3.

(b) True or false: the union of two convex sets is convex. Justify your answer.

(c) True or false: the intersection of two convex sets is convex. Justify your answer.

(d) Explain why the sphere $\{\mathbf{x} \in \mathbb{R}^3 : \|\mathbf{x}\|_2 = 1\}$ is **not** convex, naming the clause that fails.

(e) Describe $\operatorname{conv} S$ and $\operatorname{aff} S$ for $S = \{\mathbf{e}_1, \mathbf{e}_2\} \subseteq \mathbb{R}^2$.

(f) Give a subset of $\mathbb{R}$ that is neither open nor closed, and one that is both.

Solution.

(a) A subset C of a real vector space is convex if $t\mathbf{x} + (1-t)\mathbf{y} \in C$ for all $\mathbf{x}, \mathbf{y} \in C$ and every $t \in [0,1]$. A convex combination of $\mathbf{x}_1, \dots, \mathbf{x}_k$ is $\sum_i t_i \mathbf{x}_i$ with every $t_i \geq 0$ and $\sum_i t_i = 1$.

(b) False. The two coordinate axes of $\mathbb{R}^2$ are convex, and their union contains $\mathbf{e}_1, \mathbf{e}_2$ but not $\frac{1}{2}(\mathbf{e}_1 + \mathbf{e}_2)$.

(c) True, by Proposition 17.1.1 (a): a point of a segment between two points of both sets lies in each set, by convexity of each.

(d) The clause "for all $\mathbf{x}, \mathbf{y} \in C$" fails for $\mathbf{x} = \mathbf{e}_1$, $\mathbf{y} = -\mathbf{e}_1$, $t = \frac{1}{2}$: both points lie on the sphere, and the midpoint $\mathbf{0}$ does not.

(e) By Theorem 17.1.3, $\operatorname{conv} S = \{t\mathbf{e}_1 + (1-t)\mathbf{e}_2 : 0 \leq t \leq 1\}$, the segment from $\mathbf{e}_1$ to $\mathbf{e}_2$, which is Δ_2. By Definition 17.1.5, $\operatorname{aff} S = \{t\mathbf{e}_1 + (1-t)\mathbf{e}_2 : t \in \mathbb{R}\}$, the whole line $x_1 + x_2 = 1$.

(f) $[0,1)$ is neither (see the warning above). $\mathbb{R}$ is both: every limit of real numbers

lies in $\mathbb{R}$, so it is closed, and every sequence lies in $\mathbb{R}$, so it is open; the same holds for $\emptyset$ vacuously.

17.1.6.2 B. Practice

Exercise B1: Determine which are convex.

Determine which of the following sets are convex. Justify your answer.

(a) $\{(x, y) \in \mathbb{R}^2 : y \geq x^2\}$.
(b) $\{(x, y) \in \mathbb{R}^2 : xy \geq 1\}$.
(c) $\{\mathbf{A} \in M_2(\mathbb{R}) : \mathbf{A}^\top = \mathbf{A},\ \det \mathbf{A} \geq 0\}$.
(d) $\{\mathbf{x} \in \mathbb{R}^3 : x_1 + 2x_2 - x_3 = 4\}$.

Solution. Throughout, let $0 \leq t \leq 1$.

(a) Convex. Let $y \geq x^2$ and $y' \geq x'^2$, and put $x_t = tx + (1-t)x'$. Expanding,

$$tx^2 + (1-t)x'^2 - x_t^2 = t(1-t)(x - x')^2 \geq 0,$$

so $ty + (1-t)y' \geq tx^2 + (1-t)x'^2 \geq x_t^2$.

(b) Not convex. The points $(1, 1)$ and $(-1, -1)$ satisfy $xy = 1$, but their midpoint $(0, 0)$ has $xy = 0 < 1$.

(c) Not convex. $\mathbf{A} = \operatorname{diag}(1, 0)$ and $\mathbf{B} = \operatorname{diag}(0, -1)$ are symmetric with $\det \mathbf{A} = \det \mathbf{B} = 0$, but $\frac{1}{2}(\mathbf{A} + \mathbf{B}) = \operatorname{diag}(\frac{1}{2}, -\frac{1}{2})$ has determinant $-\frac{1}{4} < 0$.

(d) Convex. It is the affine hyperplane $\{\varphi = 4\}$ for the linear functional $\varphi(\mathbf{x}) = x_1 + 2x_2 - x_3$, convex by Example (The first convex sets) (c). It is also a coset of $\ker \varphi$, convex by Example (The first convex sets) (b).

Exercise B2: Membership in a hull.

Let $\mathbf{p}_1 = (0, 0)$, $\mathbf{p}_2 = (4, 1)$, $\mathbf{p}_3 = (1, 3)$ in $\mathbb{R}^2$. Decide whether $(2, 2)$ and $(3, 3)$ lie in $\operatorname{conv}\{\mathbf{p}_1, \mathbf{p}_2, \mathbf{p}_3\}$. Justify your answer.

Solution. As in Example (Deciding membership in a triangle), $\mathbf{z}$ lies in the hull exactly when the system $t_1\mathbf{p}_1 + t_2\mathbf{p}_2 + t_3\mathbf{p}_3 = \mathbf{z}$, $t_1 + t_2 + t_3 = 1$ has a solution with every $t_i \geq 0$. Its coefficient matrix

$$\begin{pmatrix} 0 & 4 & 1 \\ 0 & 1 & 3 \\ 1 & 1 & 1 \end{pmatrix}$$

has determinant $11 \neq 0$ (expand along the first column: $1 \cdot (4 \cdot 3 - 1 \cdot 1) = 11$), so the solution is unique.

For $\mathbf{z} = (2, 2)$: $\mathbf{t} = (\frac{1}{11}, \frac{4}{11}, \frac{6}{11})$. Check: $\frac{4}{11}(4, 1) + \frac{6}{11}(1, 3) = (\frac{16+6}{11}, \frac{4+18}{11}) = (2, 2)$, and $\frac{1+4+6}{11} = 1$. All weights are ≥ 0, so $(2, 2)$ is in the hull.

For $\mathbf{z} = (3, 3)$: $\mathbf{t} = (-\frac{4}{11}, \frac{6}{11}, \frac{9}{11})$. Check: $\frac{6}{11}(4, 1) + \frac{9}{11}(1, 3) = (\frac{24+9}{11}, \frac{6+27}{11}) = (3, 3)$, and $\frac{-4+6+9}{11} = 1$. The unique solution has $t_1 < 0$, so no convex combination equals $(3, 3)$, and it is not in the hull.

17.1.6.3 C. Going deeper

Exercise C1: Midpoint convexity.

Let V be a finite-dimensional real vector space with a norm, and let $C \subseteq V$ be **midpoint convex**: $\frac{1}{2}(\mathbf{x}+\mathbf{y}) \in C$ whenever $\mathbf{x}, \mathbf{y} \in C$.

(a) Prove by induction on m that $t\mathbf{x}+(1-t)\mathbf{y} \in C$ for all $\mathbf{x}, \mathbf{y} \in C$ and every **dyadic** $t = j/2^m$ with $0 \le j \le 2^m$.

(b) Prove that if C is also closed, then C is convex.

(c) Give a midpoint convex subset of $\mathbb{R}$ that is not convex, and say which hypothesis of (b) it violates.

Hint for (b): approximate t by $\lfloor 2^m t \rfloor / 2^m$ (the floor exists and $2^{-m} \to 0$ by the completeness of $\mathbb{R}$, fact (A1) of Chapter 15's introduction).

Solution.

(a) For $m = 0$, $t \in \{0, 1\}$ and the point is $\mathbf{y}$ or $\mathbf{x}$. Suppose the claim holds for m, and let $t = j/2^{m+1}$. If j is even, $t = (j/2)/2^m$ and the inductive hypothesis applies. If j is odd, then $t = \frac{1}{2}(t_- + t_+)$ with $t_\pm = (j \pm 1)/2^{m+1} = \frac{(j\pm1)/2}{2^m}$, which are dyadic of level m and lie in $[0, 1]$. By the inductive hypothesis $\mathbf{z}_\pm = t_\pm \mathbf{x} + (1 - t_\pm)\mathbf{y} \in C$, and

$$\tfrac{1}{2}(\mathbf{z}_- + \mathbf{z}_+) = \tfrac{1}{2}(t_- + t_+)\mathbf{x} + \big(1 - \tfrac{1}{2}(t_- + t_+)\big)\mathbf{y} = t\mathbf{x} + (1-t)\mathbf{y},$$

which lies in C by midpoint convexity.

(b) Let $\mathbf{x}, \mathbf{y} \in C$ and $t \in [0, 1]$. Put $t_m = \lfloor 2^m t \rfloor / 2^m$, a dyadic number in $[0, 1]$ with $0 \le t - t_m < 2^{-m}$ (the floor exists and $2^{-m} \to 0$ by the completeness of $\mathbb{R}$, fact (A1) of Chapter 15's introduction). By (a), $\mathbf{z}_m = t_m \mathbf{x} + (1 - t_m)\mathbf{y} \in C$. Then

$$\|\mathbf{z}_m - \big(t\mathbf{x} + (1-t)\mathbf{y}\big)\| = |t_m - t| \, \|\mathbf{x} - \mathbf{y}\| < 2^{-m}\|\mathbf{x} - \mathbf{y}\| \to 0,$$

so $\mathbf{z}_m \to t\mathbf{x} + (1-t)\mathbf{y}$, and closedness of C puts the limit in C. Hence C is convex.

(c) $\mathbb{Q} \subseteq \mathbb{R}$. The midpoint of two rationals is rational, but $0, 1 \in \mathbb{Q}$ while $t \cdot 1 + (1-t) \cdot 0 = t \notin \mathbb{Q}$ for $t = 1/\sqrt{2}$. The set is not closed: the rationals $\lfloor 10^k / \sqrt{2} \rfloor / 10^k$ converge to $1/\sqrt{2}$ (the floor exists and $10^{-k} \to 0$ by the completeness of $\mathbb{R}$, fact (A1) of Chapter 15's introduction).

Exercise C3: Sets that contain lines.

Let V be a real vector space and $A \subseteq V$ a **non-empty** set containing $t\mathbf{x} + (1-t)\mathbf{y}$ for all $\mathbf{x}, \mathbf{y} \in A$ and **every** real t.

(a) Fix $\mathbf{a} \in A$ and put $U = \{\mathbf{x} - \mathbf{a} : \mathbf{x} \in A\}$. Prove that U is a subspace of V, so that $A = \mathbf{a} + U$ is an affine subspace.

(b) Hence prove that a non-empty $S \subseteq V$ is an affine subspace if and only if $S = \operatorname{aff} S$.

Hint for (a): for closure under addition, use a midpoint and then a scaling.

Solution.

(a) $\mathbf{0} = \mathbf{a}-\mathbf{a} \in U$. *Scalars:* let $\mathbf{u} = \mathbf{x}-\mathbf{a} \in U$ and $c \in \mathbb{R}$. The point $c\mathbf{x}+(1-c)\mathbf{a}$ lies in A by hypothesis, and it equals $\mathbf{a}+c\mathbf{u}$; so $c\mathbf{u} \in U$. *Sums:* let $\mathbf{u} = \mathbf{x}-\mathbf{a}$ and $\mathbf{w} = \mathbf{y}-\mathbf{a}$ with $\mathbf{x}, \mathbf{y} \in A$. The midpoint $\mathbf{m} = \frac{1}{2}\mathbf{x} + \frac{1}{2}\mathbf{y} \in A$, so $\frac{1}{2}(\mathbf{u}+\mathbf{w}) = \mathbf{m} - \mathbf{a} \in U$, and by the scalar step with $c = 2$, $\mathbf{u}+\mathbf{w} \in U$. By Theorem 1.2.1, U is a subspace, and $A = \mathbf{a} + U$ by the definition of U.

(b) ($\Leftarrow$) If $S = \operatorname{aff} S$, then S is a coset by Proposition 17.1.4. ($\Rightarrow$) If $S = \mathbf{p} + W$ is an affine subspace, then $\operatorname{aff} S \subseteq S$ by the minimality clause of Proposition 17.1.4, and $S \subseteq \operatorname{aff} S$ because each $\mathbf{x} \in S$ is the affine combination $1 \cdot \mathbf{x}$. So $S = \operatorname{aff} S$.

17.2 Carathéodory's Theorem

By Theorem 17.1.3, the convex hull of a set S consists of the convex combinations of points of S, with any number of points allowed. For a hundred points in the plane, that description permits a single point of the hull to be an average of all hundred at once. A picture says that this is wasteful: the hundred points spread out into a polygon, the polygon can be cut into triangles with corners among the points, and every point of the polygon lies in one of those triangles, so three points always suffice. This section proves the general statement. In a space of dimension n, every point of a convex hull is a convex combination of at most $n+1$ points of the set, and the bound cannot be lowered. Two consequences follow. The hull of a compact set is compact, which §08 uses. And from the same counting argument come Radon's theorem and Helly's theorem, which describe how convex sets in $\mathbb{R}^n$ can intersect.

As in §01, all spaces are real. Carathéodory's theorem needs a **finite dimension** and nothing else; the compactness corollary needs, in addition, a norm, and any norm will do.

17.2.1 When there are too many points

The proof we want has a simple plan. If a point is written as a convex combination of **too many** points, find a way to shift the weights so that the point stays where it is while one weight falls to zero. That point can then be dropped. Two things are needed: a precise meaning of "too many", and a way to shift the weights without moving the point.

Both come from one observation. If $\sum_i \lambda_i \mathbf{x}_i = \mathbf{0}$ and $\sum_i \lambda_i = 0$, then for every real s,

$$\sum_i (t_i - s\lambda_i)\mathbf{x}_i = \sum_i t_i \mathbf{x}_i \quad \text{and} \quad \sum_i (t_i - s\lambda_i) = \sum_i t_i.$$

So the weights $t_i - s\lambda_i$ describe the same point, and they still add up to 1. A relation of this shape is what we need a word for.

A list of points is affinely dependent when some combination with coefficients adding to zero, not all of them zero, cancels out.

Definition 17.2.1 — Affine Independence

Let V be a real vector space and let $(\mathbf{x}_0, \mathbf{x}_1, \ldots, \mathbf{x}_m)$ be a list in V, $m \geq 0$. The list is

affinely independent if, **for all** real $\lambda_0, \dots, \lambda_m$,

$$\sum_{i=0}^{m} \lambda_i \mathbf{x}_i = \mathbf{0} \quad \text{and} \quad \sum_{i=0}^{m} \lambda_i = 0 \quad \Longrightarrow \quad \lambda_0 = \lambda_1 = \cdots = \lambda_m = 0.$$

It is **affinely dependent** otherwise. A relation $\sum_i \lambda_i \mathbf{x}_i = \mathbf{0}$ with $\sum_i \lambda_i = 0$ and the λ_i **not all zero** is an **affine dependence**.

In words: this is linear independence (Definition 1.4.1) with one extra hypothesis, that the coefficients add up to zero. The extra hypothesis makes the condition easier to satisfy, and it makes the notion blind to the choice of origin. Translating every point by $\mathbf{p}$ changes $\sum_i \lambda_i \mathbf{x}_i$ by $\big(\sum_i \lambda_i\big)\mathbf{p} = \mathbf{0}$, so a translated list is affinely dependent exactly when the original is.

Some small cases:

- A single point $(\mathbf{x}_0)$ is always affinely independent: $\lambda_0 = 0$ is forced by the sum condition alone.
- Two points $(\mathbf{x}_0, \mathbf{x}_1)$ are affinely dependent exactly when they are equal: the condition forces $\lambda_1 = -\lambda_0$, and then $\lambda_0(\mathbf{x}_0 - \mathbf{x}_1) = \mathbf{0}$ has a solution $\lambda_0 \neq 0$ if and only if $\mathbf{x}_0 = \mathbf{x}_1$.
- Three collinear points are affinely dependent: $(0,0), (1,1), (2,2)$ satisfy $1 \cdot (0,0) - 2 \cdot (1,1) + 1 \cdot (2,2) = \mathbf{0}$, with $1 - 2 + 1 = 0$.

A non-example by minimal change. The list $(\mathbf{0}, \mathbf{e}_1, \mathbf{e}_2)$ in $\mathbb{R}^2$ is affinely independent: the $\mathbf{e}_1$- and $\mathbf{e}_2$-coordinates of $\lambda_0\mathbf{0} + \lambda_1\mathbf{e}_1 + \lambda_2\mathbf{e}_2 = \mathbf{0}$ give $\lambda_1 = \lambda_2 = 0$, and then the sum condition gives $\lambda_0 = 0$. Move the third point to $2\mathbf{e}_1$. The list $(\mathbf{0}, \mathbf{e}_1, 2\mathbf{e}_1)$ still spans the same line as $(\mathbf{0}, \mathbf{e}_1)$, but now $1 \cdot \mathbf{0} - 2\mathbf{e}_1 + 1 \cdot (2\mathbf{e}_1) = \mathbf{0}$ with $1 - 2 + 1 = 0$: the three points have fallen onto one line, and the implication in the definition fails.

Warning. **Affine independence is not linear independence.** The list $(\mathbf{0}, \mathbf{e}_1, \mathbf{e}_2)$ in $\mathbb{R}^2$ is linearly dependent, since it contains $\mathbf{0}$, yet it was just shown to be affinely independent. A triangle is an affinely independent list of three points in a two-dimensional space, which linear independence would never allow. That is why the bound in this section is $n + 1$, and not n. The implication does run one way: a linearly independent list is affinely independent, since an affine dependence is in particular a linear relation with coefficients not all zero.

The next lemma converts affine dependence into linear dependence of differences, which is what allows a dimension count.

Lemma 17.2.1 — Affine Dependence by Differences

Let V be a real vector space and $\mathbf{x}_0, \dots, \mathbf{x}_m \in V$.

(a) The list $(\mathbf{x}_0, \dots, \mathbf{x}_m)$ is affinely independent **if and only if** the list $(\mathbf{x}_1 - \mathbf{x}_0, \dots, \mathbf{x}_m - \mathbf{x}_0)$ is linearly independent.

(b) If $\dim V = n$, every affinely independent list in V has at most $n + 1$ entries. Equivalently, every list of $n + 2$ or more points of V is affinely dependent.

Idea. The sum condition determines λ_0 from the other coefficients, and eliminating it turns an affine relation among the points into a linear relation among the differences, and back.

Proof.

(a) Suppose $\sum_{i=0}^{m} \lambda_i \mathbf{x}_i = \mathbf{0}$ and $\sum_{i=0}^{m} \lambda_i = 0$. Then $\lambda_0 = -\sum_{i\geq 1} \lambda_i$, and substituting,

$$\sum_{i=1}^{m} \lambda_i(\mathbf{x}_i - \mathbf{x}_0) = \sum_{i=0}^{m} \lambda_i \mathbf{x}_i = \mathbf{0}.$$

Conversely, if $\sum_{i=1}^{m} \lambda_i(\mathbf{x}_i - \mathbf{x}_0) = \mathbf{0}$, then setting $\lambda_0 = -\sum_{i\geq 1} \lambda_i$ gives an affine relation $\sum_{i=0}^{m} \lambda_i \mathbf{x}_i = \mathbf{0}$ with $\sum_{i=0}^{m} \lambda_i = 0$. These two passages are inverse to each other, and $(\lambda_0, \dots, \lambda_m)$ is not all zero exactly when $(\lambda_1, \dots, \lambda_m)$ is not all zero, because λ_0 is determined by the others. So affine dependences of the points correspond to linear relations, not all zero, among the differences, and one exists exactly when the other does.

(b) If $(\mathbf{x}_0, \dots, \mathbf{x}_m)$ is affinely independent, then by (a) the m differences $\mathbf{x}_i - \mathbf{x}_0$ are linearly independent, so $m \leq n$ by Theorem 1.6.3 (a). The list has $m + 1 \leq n + 1$ entries.

■

17.2.2 The theorem

Now the plan can be carried out. The statement is sharper than the count: the points can be taken affinely independent, and the count is a consequence.

Theorem 17.2.2 — Carathéodory's Theorem

Let V be a real vector space with $\dim V = n$, and let $S \subseteq V$. Every point of $\operatorname{conv} S$ is a convex combination of an **affinely independent** list of points of S. In particular, every point of $\operatorname{conv} S$ is a convex combination of **at most** $n + 1$ points of S.

Idea. **Count, then drop a point.** Write $\mathbf{x}$ with as few points as possible, so that every weight is positive. If the points were affinely dependent, the weights $t_i - s\lambda_i$ would describe the same $\mathbf{x}$ for every s. Start at $s = 0$ and increase s. The weights with $\lambda_i > 0$ decrease, and there is at least one of these, because the λ_i add up to zero without all being zero. Stop at the first moment a weight reaches 0: all the weights are still ≥ 0, and one point has become unnecessary. That contradicts minimality.

Proof. Let $\mathbf{x} \in \operatorname{conv} S$. By Theorem 17.1.3, $\mathbf{x}$ is a convex combination of finitely many points of S. Among all ways of writing it so, choose one,

$$\mathbf{x} = \sum_{i=0}^{m} t_i \mathbf{x}_i, \qquad \mathbf{x}_i \in S, \quad (t_0, \dots, t_m) \in \Delta_{m+1},$$

with the number $m + 1$ of points as small as possible. Then every $t_i > 0$: a zero weight could be deleted, and the remaining weights would still be non-negative and add up to 1, giving a shorter expression.

Suppose, for a contradiction, that $(\mathbf{x}_0, \dots, \mathbf{x}_m)$ is affinely dependent, and let $\sum_i \lambda_i \mathbf{x}_i = \mathbf{0}$,

$\sum_i \lambda_i = 0$ be an affine dependence. The λ_i are not all zero and add up to 0, so at least one of them is positive. Put

$$s = \min\Big\{ \frac{t_i}{\lambda_i} : \lambda_i > 0 \Big\},$$

a minimum over a non-empty finite set, and let j be an index where it is attained; $s > 0$ since each $t_i > 0$. Define $t'_i = t_i - s\lambda_i$. Then:

- $t'_i \geq 0$ for every i. If $\lambda_i \leq 0$, then $t'_i \geq t_i > 0$, since $s > 0$. If $\lambda_i > 0$, then $s \leq t_i/\lambda_i$ by the choice of s, so $s\lambda_i \leq t_i$.
- $t'_j = t_j - (t_j/\lambda_j)\lambda_j = 0$.
- $\sum_i t'_i = \sum_i t_i - s\sum_i \lambda_i = 1$ and $\sum_i t'_i \mathbf{x}_i = \sum_i t_i \mathbf{x}_i - s\sum_i \lambda_i \mathbf{x}_i = \mathbf{x}$.

So $\mathbf{x}$ is a convex combination of the m points $\mathbf{x}_i$, $i \neq j$, contradicting the minimality of $m+1$. Hence $(\mathbf{x}_0, \dots, \mathbf{x}_m)$ is affinely independent. By Lemma 17.2.1 (b) it has at most $n+1$ entries. This proves the theorem.

■

In the plane, then, every point of the hull of any set S lies in a triangle whose corners are points of S, possibly a degenerate one (a segment or a single point). In $\mathbb{R}^3$ it lies in a tetrahedron with corners in S. The proof is constructive: given any convex combination, it says how to shorten it, one point at a time.

Example. (Dropping a point in the plane)

In $\mathbb{R}^2$ let $\mathbf{x}_0 = (0,0)$, $\mathbf{x}_1 = (3,0)$, $\mathbf{x}_2 = (0,3)$, $\mathbf{x}_3 = (2,2)$, and let $\mathbf{x} = \frac{1}{4}(\mathbf{x}_0 + \mathbf{x}_1 + \mathbf{x}_2 + \mathbf{x}_3) = (\frac{5}{4}, \frac{5}{4})$. Write $\mathbf{x}$ as a convex combination of three of these points by the method of the proof.

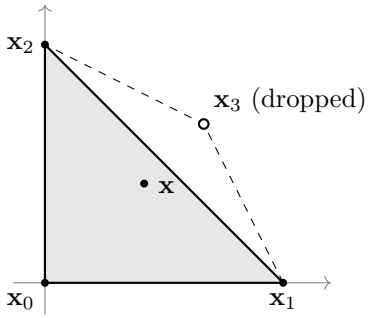
Solution. Four points in $\mathbb{R}^2$ are affinely dependent by Lemma 17.2.1 (b). To find a dependence, solve $\sum_i \lambda_i \mathbf{x}_i = \mathbf{0}$ and $\sum_i \lambda_i = 0$: the two coordinate equations read $3\lambda_1 + 2\lambda_3 = 0$ and $3\lambda_2 + 2\lambda_3 = 0$. Taking $\lambda_3 = 3$ gives $\lambda_1 = \lambda_2 = -2$, and then $\lambda_0 = -(\lambda_1+\lambda_2+\lambda_3) = 1$. Check: $1\cdot(0,0) - 2(3,0) - 2(0,3) + 3(2,2) = (-6+6, -6+6) = \mathbf{0}$, and $1 - 2 - 2 + 3 = 0$.

The positive coefficients are $\lambda_0 = 1$ and $\lambda_3 = 3$, with ratios $t_0/\lambda_0 = \frac{1}{4}$ and $t_3/\lambda_3 = \frac{1}{12}$. So $s = \frac{1}{12}$, attained at $j = 3$, and the new weights are

$$\mathbf{t}' = \big(\tfrac{1}{4} - \tfrac{1}{12},\ \tfrac{1}{4} + \tfrac{2}{12},\ \tfrac{1}{4} + \tfrac{2}{12},\ \tfrac{1}{4} - \tfrac{3}{12}\big) = \big(\tfrac{1}{6},\ \tfrac{5}{12},\ \tfrac{5}{12},\ 0\big).$$

Check: $\frac{5}{12}(3,0) + \frac{5}{12}(0,3) = (\frac{5}{4}, \frac{5}{4}) = \mathbf{x}$, and $\frac{2}{12} + \frac{5}{12} + \frac{5}{12} = 1$. So $\mathbf{x} = \frac{1}{6}\mathbf{x}_0 + \frac{5}{12}\mathbf{x}_1 + \frac{5}{12}\mathbf{x}_2$ lies in the triangle with corners $\mathbf{x}_0, \mathbf{x}_1, \mathbf{x}_2$, and $\mathbf{x}_3$ has been dropped.

The minimum matters. Using the other positive coefficient, $s = \frac{1}{4}$, would make the weight of $\mathbf{x}_3$ equal to $\frac{1}{4} - \frac{3}{4} = -\frac{1}{2} < 0$: the point would still be described correctly, but not as a convex combination.



$\mathbf{x}$ is an average of all four points,
and already lies in the shaded triangle of three

The bound $n+1$ cannot be improved, and the standard simplex shows it.

Example. (The bound is attained)

In $\mathbb{R}^n$, let $S = \{\mathbf{0}, \mathbf{e}_1, \dots, \mathbf{e}_n\}$ and let $\mathbf{c} = \frac{1}{n+1}(\mathbf{0} + \mathbf{e}_1 + \cdots + \mathbf{e}_n) = \frac{1}{n+1}\mathbf{1}$. Show that $\mathbf{c} \in \operatorname{conv} S$ is not a convex combination of any n points of S.

Solution. The point $\mathbf{c}$ is a convex combination of the $n+1$ points of S, each with weight $\frac{1}{n+1}$. A convex combination of n of the points leaves one out. If it leaves out $\mathbf{e}_j$, the combination is $t_0\mathbf{0} + \sum_{i \neq j} t_i \mathbf{e}_i$, whose j-th coordinate is 0, while $c_j = \frac{1}{n+1} \neq 0$. If it leaves out $\mathbf{0}$, the combination is $\sum_i t_i \mathbf{e}_i = (t_1, \dots, t_n)$, whose coordinates add up to 1, while those of $\mathbf{c}$ add up to $\frac{n}{n+1} \neq 1$. Either way it is not $\mathbf{c}$.

The bound can be far from attained for a particular set, however, and it is worth seeing one.

Example. (Two points suffice for a circle)

Let $S = \{\mathbf{x} \in \mathbb{R}^2 : \|\mathbf{x}\|_2 = 1\}$ be the unit circle. Show that $\operatorname{conv} S$ is the closed unit disc B_2, and that every point of B_2 is a convex combination of **two** points of S.

Solution. B_2 is convex (Example (The first convex sets) (d)) and contains S, so $\operatorname{conv} S \subseteq B_2$ by Definition 17.1.4. Conversely, let $(a, b) \in B_2$, so $a^2 + b^2 \leq 1$, and put $c = \sqrt{1 - a^2}$, which is real since $|a| \leq 1$. The points (a, c) and $(a, -c)$ lie on S, and $|b| \leq c$ because $b^2 \leq 1 - a^2$. With $t = \frac{c+b}{2c}$ when $c > 0$,

$$t(a, c) + (1 - t)(a, -c) = \big(a,\ (2t - 1)c\big) = (a, b),$$

and $0 \leq t \leq 1$ because $-c \leq b \leq c$. When $c = 0$, we have $a = \pm 1$ and $b = 0$, and (a, b) is itself a point of S. So every point of the disc lies on a vertical chord of the circle, and $B_2 \subseteq \operatorname{conv} S$ by Theorem 17.1.3.

Quick check. A point of $\mathbb{R}^3$ is given as a convex combination of seven points of a set S. What is the smallest number of points of S that Theorem 17.2.2 guarantees will suffice? Can one always manage with three?

Solution. Four, since $n+1 = 4$ for $n = 3$. Three do not always suffice: by Example (The

bound is attained) with $n = 3$, the point $\frac{1}{4}(1, 1, 1)$ is a convex combination of $\mathbf{0}, \mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3$ and of no three of them.

Remark. The only place the proof used $\dim V = n$ was the final count, through Lemma 17.2.1 (b), and all that count needs is a space containing the differences of the points. If S lies in an affine subspace of dimension d, then $n + 1$ can be replaced by $d + 1$; Exercise (C1: Carathéodory in the affine hull) carries this out. A set of points on a line in $\mathbb{R}^{100}$ needs only two at a time.

17.2.3 The hull of a compact set

The first use of the theorem is a statement about limits. Recall from Corollary 15.2.5 that a subset K of a finite-dimensional real space with a norm is **compact** if every sequence in K has a subsequence converging to a point **of** K. Compactness is what lets later sections take a maximum, or a nearest point, over a hull, and it is not obvious that a hull keeps it. A convex combination may use arbitrarily many points, so a sequence of combinations could use more and more of them, and there would be no single compact set of parameters from which to extract a convergent subsequence. Carathéodory's bound removes that possibility: every point of the hull is described by exactly $n + 1$ points of K and $n + 1$ weights.

Corollary 17.2.3 — The Hull of a Compact Set Is Compact

Let V be a finite-dimensional real vector space with a norm, and let $K \subseteq V$ be compact.

(a) $\operatorname{conv} K$ is compact.

(b) If K is non-empty, then every linear functional φ on V attains a maximum on $\operatorname{conv} K$, and

$$\max_{\mathbf{x} \in \operatorname{conv} K} \varphi(\mathbf{x}) = \max_{\mathbf{x} \in K} \varphi(\mathbf{x}).$$

Idea. For (a), write each term of a sequence in $\operatorname{conv} K$ as a combination of exactly $n + 1$ points of K, using Theorem 17.2.2 and padding with zero weights. That turns one sequence into $n + 2$ sequences: one of weight vectors in Δ_{n+1}, and $n + 1$ of points of K. Extract a convergent subsequence from each in turn, a subsequence of the previous one each time, and pass to the limit in the combination. For (b), a linear functional cannot do better on an average than on the best of the points averaged.

Proof. Let $n = \dim V$.

(a) If $K = \emptyset$, then $\operatorname{conv} K = \emptyset$, which is compact vacuously. Otherwise let $(\mathbf{y}_k)$ be a sequence in $\operatorname{conv} K$. By Theorem 17.2.2, each $\mathbf{y}_k$ is a convex combination of at most $n + 1$ points of K; repeating one of those points with weight 0 if necessary, we may write

$$\mathbf{y}_k = \sum_{i=0}^{n} t_{k,i}\, \mathbf{x}_{k,i}, \qquad \mathbf{x}_{k,i} \in K, \quad \mathbf{t}_k = (t_{k,0}, \dots, t_{k,n}) \in \Delta_{n+1}.$$

Step 1: the weights. Δ_{n+1} is closed in $\mathbb{R}^{n+1}$ by Proposition 17.1.6 (b), (c), and bounded, since each coordinate of a point of it lies in $[0, 1]$. By **the compactness**

of closed bounded sets in $\mathbb{R}^{n+1}$, fact (A3) of Chapter 15's introduction, some subsequence of $(\mathbf{t}_k)$ converges to a point $\mathbf{t} = (t_0, \dots, t_n) \in \Delta_{n+1}$. In particular $t_{k,i} \to t_i$ along it for each i, since $|t_{k,i} - t_i| \le \|\mathbf{t}_k - \mathbf{t}\|_2$.
Step 2: the points. Along that subsequence, the sequence $(\mathbf{x}_{k,0})$ lies in K, so by compactness of K a further subsequence has $\mathbf{x}_{k,0} \to \mathbf{x}_0 \in K$. Along it, a further subsequence has $\mathbf{x}_{k,1} \to \mathbf{x}_1 \in K$, and so on through $i = n$. A subsequence of a convergent sequence converges to the same limit, so along the final subsequence, which we index by k again, $\mathbf{t}_k \to \mathbf{t}$ and $\mathbf{x}_{k,i} \to \mathbf{x}_i$ for every i.
Step 3: the limit. Put $\mathbf{y} = \sum_{i=0}^{n} t_i \mathbf{x}_i$, which lies in $\operatorname{conv} K$ by Theorem 17.1.3. By (N3) and (N2) of Definition 15.1.1, along the final subsequence,

$$\begin{aligned} \|\mathbf{y}_k - \mathbf{y}\| &\le \sum_{i=0}^{n} \|t_{k,i}\mathbf{x}_{k,i} - t_i\mathbf{x}_i\| \\ &\le \sum_{i=0}^{n} \Big(|t_{k,i} - t_i| \, \|\mathbf{x}_{k,i}\| + t_i \|\mathbf{x}_{k,i} - \mathbf{x}_i\| \Big), \end{aligned}$$

where the second line writes $t_{k,i}\mathbf{x}_{k,i} - t_i\mathbf{x}_i = (t_{k,i} - t_i)\mathbf{x}_{k,i} + t_i(\mathbf{x}_{k,i} - \mathbf{x}_i)$. Each $\|\mathbf{x}_{k,i}\| \le \|\mathbf{x}_i\| + \|\mathbf{x}_{k,i} - \mathbf{x}_i\|$ is bounded, since the last term tends to 0. So every term on the right tends to 0, and $\mathbf{y}_k \to \mathbf{y} \in \operatorname{conv} K$ along the subsequence. Hence $\operatorname{conv} K$ is compact.

(b) By Lemma 17.1.5, φ is continuous. By **the extreme value theorem, fact (A4) of Chapter 15's introduction**, applied to φ on the non-empty compact set K, there is $\mathbf{x}^* \in K$ with $\varphi(\mathbf{x}) \le M = \varphi(\mathbf{x}^*)$ for every $\mathbf{x} \in K$. Now let $\mathbf{y} = \sum_i t_i \mathbf{x}_i$ be any point of $\operatorname{conv} K$, with $\mathbf{x}_i \in K$ and $\mathbf{t} \in \Delta_m$ (Theorem 17.1.3). By linearity, and since every $t_i \ge 0$,

$$\varphi(\mathbf{y}) = \sum_i t_i \varphi(\mathbf{x}_i) \le \sum_i t_i M = M.$$

So M bounds φ on $\operatorname{conv} K$, and it is attained there, at $\mathbf{x}^* \in K \subseteq \operatorname{conv} K$. This proves the corollary.

■

For instance, $\varphi(x, y) = x + 2y$ takes the values $0, 3, 6$ at the corners $(0,0), (3,0), (0,3)$ of the triangle in Example (Dropping a point in the plane); as in the proof of (b), at a point $\sum_i t_i \mathbf{x}_i$ of the triangle it takes the average $3t_1 + 6t_2 \le 6$ of these values, so its maximum over the triangle is 6, attained at $(0,3)$. At the interior point $\mathbf{x} = (\frac{5}{4}, \frac{5}{4})$ it takes $\frac{15}{4} = \frac{1}{6} \cdot 0 + \frac{5}{12} \cdot 3 + \frac{5}{12} \cdot 6$, an average of the corner values and so no larger than the largest.

To maximize a linear functional over the hull of finitely many points it is enough to evaluate it at those points (Exercise (B3: Linear functionals on a polygon)). §08 extends this to every compact convex set, and §09 shows that a bounded feasible region of §06 is such a hull.

Warning. **The hull of a closed set need not be closed.** In $\mathbb{R}^2$, let $S = \{(0,1)\} \cup \{(x, 0) : x \in \mathbb{R}\}$, a point together with a line. S is closed, by Proposition 17.1.6 (b), (c). Its hull is

$$\operatorname{conv} S = \{(x, y) : 0 \le y < 1\} \cup \{(0,1)\}.$$

Indeed a convex combination of points of S with total weight y on $(0,1)$ has second coordinate y, and when $y < 1$ any first coordinate x is reached, as $y(0,1) + (1-y)\big(x/(1-y), 0\big) = (x, y)$; when $y = 1$ all the weight is on $(0,1)$. The points $(1, 1 - 1/k)$ lie in $\operatorname{conv} S$

and converge to $(1, 1)$, which does not. So compactness in Corollary 17.2.3 cannot be weakened to closedness: here S is closed but unbounded, and the hull loses the line $y = 1$, except for the one point that belongs to S.

17.2.4 Radon's theorem and Helly's theorem

The dimension count behind Carathéodory's theorem says something about intersections of convex sets as well. Its first form is a statement about $n + 2$ points.

Theorem 17.2.4 — Radon's Theorem

Let V be a real vector space with $\dim V = n$, and let $\mathbf{x}_1, \dots, \mathbf{x}_m \in V$ with $m \geq n + 2$. Then the index set $\{1, \dots, m\}$ can be split into two **disjoint** non-empty sets I and J with

$$\operatorname{conv}\{\mathbf{x}_i : i \in I\} \cap \operatorname{conv}\{\mathbf{x}_j : j \in J\} \neq \emptyset.$$

Idea. Take an affine dependence and separate its positive coefficients from the rest. Moving the negative terms across the equation gives an equation between a positive combination of some points and a positive combination of the others, with the **same total weight** on each side, because the coefficients add up to zero. Divide by that total, and each side becomes a convex combination.

Proof. By Lemma 17.2.1 (b), the list $(\mathbf{x}_1, \dots, \mathbf{x}_m)$ is affinely dependent: there are $\lambda_1, \dots, \lambda_m$, not all zero, with $\sum_i \lambda_i \mathbf{x}_i = \mathbf{0}$ and $\sum_i \lambda_i = 0$. Let $I = \{i : \lambda_i > 0\}$ and $J = \{j : \lambda_j \leq 0\}$, which are disjoint with union $\{1, \dots, m\}$. Since the λ_i add up to 0 and are not all zero, some λ_i is positive and some is negative, so neither I nor J is empty. Put $\sigma = \sum_{i \in I} \lambda_i > 0$; then $\sum_{j \in J} (-\lambda_j) = \sigma$ as well, since the total is 0. Moving the terms indexed by J across and dividing by σ,

$$\mathbf{y} := \sum_{i \in I} \frac{\lambda_i}{\sigma} \mathbf{x}_i = \sum_{j \in J} \frac{-\lambda_j}{\sigma} \mathbf{x}_j.$$

On the left the coefficients are positive and add up to 1; on the right they are ≥ 0 and add up to 1. So $\mathbf{y}$ lies in both hulls, by Theorem 17.1.3. This proves the theorem.

■

A partition as in the theorem is a **Radon partition**. In the plane, four points in general position (no three on a line) either have one inside the triangle of the other three, or they form a quadrilateral whose two diagonals cross; Exercise (B2: Radon partitions in the plane) finds the partition in each case. The count $n + 2$ cannot be lowered: the $n + 1$ points $\mathbf{0}, \mathbf{e}_1, \dots, \mathbf{e}_n$ have no Radon partition (Exercise (C3: The counts are sharp)).

Helly's theorem turns the counting around. Instead of asking how many points a hull needs, it asks how many sets of a family must be checked to know that all of them have a common point. Checking pairs is not enough, since three lines in the plane can meet pairwise in three different points; checking triples in the plane is.

Theorem 17.2.5 — Helly's Theorem

Let V be a real vector space with $\dim V = n$, and let $C_1, \dots, C_m$ be convex subsets of V, with $m \geq n+1$. If **every** $n+1$ of the sets have a point in common, then all m of them have a point in common.

Idea. Induction on the number of sets. Given $m \geq n+2$ sets, the inductive hypothesis provides, for each i, a point $\mathbf{x}_i$ lying in every set **except possibly** C_i. That is $m \geq n+2$ points, so Radon's theorem splits them into two groups whose hulls meet at some $\mathbf{y}$. Any one set C_k misses at most one point, $\mathbf{x}_k$, and that point lies in only one of the two groups; the other group lies entirely in C_k, and so does its hull, which contains $\mathbf{y}$.

Proof. We use induction on m. For $m = n+1$, the hypothesis applied to all m sets is the conclusion. Let $m \geq n+2$, and suppose the theorem holds for families of $m-1$ convex sets. For each $i = 1, \dots, m$, the family $\{C_k : k \neq i\}$ has $m-1 \geq n+1$ members, and every $n+1$ of them have a common point by hypothesis. By the inductive hypothesis, there is a point $\mathbf{x}_i$ with

$$\mathbf{x}_i \in C_k \quad \text{for every } k \neq i.$$

Since $m \geq n+2$, Theorem 17.2.4 splits $\{1, \dots, m\}$ into disjoint non-empty sets I, J and gives a point $\mathbf{y} \in \operatorname{conv}\{\mathbf{x}_i : i \in I\} \cap \operatorname{conv}\{\mathbf{x}_j : j \in J\}$.

Fix $k \in \{1, \dots, m\}$. If $k \in I$, then $k \notin J$, so every $\mathbf{x}_j$ with $j \in J$ lies in C_k. Since C_k is convex, Lemma 17.1.2 puts every convex combination of these points in C_k, so $\operatorname{conv}\{\mathbf{x}_j : j \in J\} \subseteq C_k$ by Theorem 17.1.3, and in particular $\mathbf{y} \in C_k$. If $k \in J$, the same argument with I in place of J gives $\mathbf{y} \in C_k$. Hence $\mathbf{y}$ lies in every C_k. This completes the induction.

■

Example. (Helly's proof run on four half-planes)

In $\mathbb{R}^2$, let

$$C_1 = \{y \geq 0\}, \qquad C_2 = \{x \geq 0\},$$
$$C_3 = \{x + y \leq 2\}, \quad C_4 = \{x - y \leq 1\}.$$

Find points $\mathbf{x}_i$ in all the sets except C_i, and follow the proof of Theorem 17.2.5 to a common point of all four.

Solution. Here $n = 2$ and $m = 4 = n+2$, so the proof applies Radon's theorem (Theorem 17.2.4) to four points. The following points lie in every set except their own, as substitution into the four inequalities shows:

$$\mathbf{x}_1 = (0, -1), \quad \mathbf{x}_2 = (-1, 0), \quad \mathbf{x}_3 = (2, 2), \quad \mathbf{x}_4 = (2, 0).$$

For instance, $\mathbf{x}_1$ has $x = 0 \geq 0$, $x + y = -1 \leq 2$, $x - y = 1 \leq 1$, and $y = -1 < 0$ violates C_1. And $\mathbf{x}_4$ has $y = 0$, $x = 2$, $x + y = 2$, and $x - y = 2 > 1$ violates C_4.

An affine dependence: the equations $\sum_i \lambda_i \mathbf{x}_i = \mathbf{0}$, $\sum_i \lambda_i = 0$ are satisfied by $\boldsymbol{\lambda} = (-6, 4, -3, 5)$. Check: the first coordinates give $-4-6+10 = 0$, the second $6-6+0 = 0$,

and $-6+4-3+5=0$. The positive coefficients are at $I=\{2,4\}$, with $\sigma=9$, so

$$\mathbf{y}=\tfrac{4}{9}\mathbf{x}_2+\tfrac{5}{9}\mathbf{x}_4=\left(\tfrac{-4+10}{9},0\right)=\left(\tfrac{2}{3},0\right),$$

and from the other side $\frac{6}{9}\mathbf{x}_1+\frac{3}{9}\mathbf{x}_3=\left(\frac{6}{9},\frac{-6+6}{9}\right)=(\frac{2}{3},0)$, as it must be. Finally $\mathbf{y}=(\frac{2}{3},0)$ satisfies $y=0\geq 0$, $x=\frac{2}{3}\geq 0$, $x+y=\frac{2}{3}\leq 2$ and $x-y=\frac{2}{3}\leq 1$: it lies in all four half-planes. The proof explains why, without any checking: C_2 and C_4 contain $\mathbf{x}_1$ and $\mathbf{x}_3$, hence the segment between them, which contains $\mathbf{y}$; and C_1 and C_3 contain $\mathbf{x}_2$ and $\mathbf{x}_4$, hence the other segment through $\mathbf{y}$.

Remark. Helly's theorem is about **finite** families, and the finiteness cannot simply be dropped. The closed half-lines $[k,\infty)\subseteq\mathbb{R}$, for $k=1,2,3,\ldots$, are convex, and any finitely many of them meet (at their largest k), but no real number lies in all of them. For compact convex sets the infinite version does hold; Exercise (C2: Helly's theorem for a sequence of compact sets) proves it for a sequence of sets.

With these results the chapter has its combinatorial foundation. §03 turns to geometry: a point outside a closed convex set can be separated from it by a hyperplane.

17.2.5 Exercises

17.2.5.1 A. Check your understanding

Exercise A1.

(a) State Theorem 17.2.2.

(b) True or false: every point in the convex hull of ten points of $\mathbb{R}^2$ is a convex combination of three of them. Justify your answer.

(c) True or false: the convex hull of a closed subset of $\mathbb{R}^2$ is closed. Justify your answer.

(d) True or false: any four points of $\mathbb{R}^3$ have a Radon partition. Justify your answer.

(e) Is the list $(\mathbf{e}_1,\mathbf{e}_2,\mathbf{e}_3)$ in $\mathbb{R}^3$ affinely independent? Is $(\mathbf{e}_1,\mathbf{e}_2,\mathbf{e}_1+\mathbf{e}_2-\mathbf{e}_3,\mathbf{e}_3)$?

(f) Which facts from Chapter 15's list of imported analysis does Corollary 17.2.3 use, and where?

Solution.

(a) If $\dim V=n$ and $S\subseteq V$, every point of $\operatorname{conv}S$ is a convex combination of an affinely independent list of points of S, and so of at most $n+1$ points of S.

(b) True, by Theorem 17.2.2 with $n=2$: at most three are needed, and if fewer are used, a point can be added with weight 0.

(c) False. The warning in this section gives $S=\{(0,1)\}\cup\{(x,0):x\in\mathbb{R}\}$, closed, with $(1,1)$ a limit of points of $\operatorname{conv}S$ not in $\operatorname{conv}S$.

(d) False. Radon's theorem (Theorem 17.2.4) needs $n+2=5$ points in $\mathbb{R}^3$, and four can fail. The points $\mathbf{0},\mathbf{e}_1,\mathbf{e}_2,\mathbf{e}_3$ are affinely independent, since $\mathbf{e}_1,\mathbf{e}_2,\mathbf{e}_3$ are linearly independent (Lemma 17.2.1 (a)). A point common to the hulls of two disjoint groups of them would give two convex combinations with equal value, and subtracting them gives a relation with coefficients adding up to 0 and not all zero,

which is an affine dependence. So there is no Radon partition; Exercise (C3: The counts are sharp) carries this out for $n+1$ affinely independent points in general.

(e) Yes: it is linearly independent, and a linearly independent list is affinely independent. The second list is affinely dependent: $\mathbf{e}_1+\mathbf{e}_2-(\mathbf{e}_1+\mathbf{e}_2-\mathbf{e}_3)-\mathbf{e}_3=\mathbf{0}$ with coefficients $1,1,-1,-1$, which add up to 0.

(f) (A3), the compactness of closed bounded sets, for the weights in part (a); and (A4), the extreme value theorem, for the maximum over K in part (b). Part (a) also uses the hypothesis that K is compact, once for each of the $n+1$ points.

17.2.5.2 B. Practice

Exercise B1: Shortening a combination.

In $\mathbb{R}^2$, let $\mathbf{x}_1=(0,0)$, $\mathbf{x}_2=(4,0)$, $\mathbf{x}_3=(4,4)$, $\mathbf{x}_4=(0,4)$, and

$$\mathbf{x}=\tfrac{1}{10}\mathbf{x}_1+\tfrac{2}{10}\mathbf{x}_2+\tfrac{3}{10}\mathbf{x}_3+\tfrac{4}{10}\mathbf{x}_4.$$

(a) Compute $\mathbf{x}$, and find an affine dependence among $\mathbf{x}_1,\dots,\mathbf{x}_4$.

(b) Use the method of Theorem 17.2.2 to write $\mathbf{x}$ as a convex combination of three of the points.

(c) Apply the method with the dependence multiplied by -1. Which point is dropped now? Hence $\mathbf{x}$ lies in two different triangles with corners among the $\mathbf{x}_i$.

Solution.

(a) $\mathbf{x}=\frac{2}{10}(4,0)+\frac{3}{10}(4,4)+\frac{4}{10}(0,4)=(\frac{8+12}{10},\frac{12+16}{10})=(2,\frac{14}{5})$. The corners of a square satisfy $\mathbf{x}_1-\mathbf{x}_2+\mathbf{x}_3-\mathbf{x}_4=(0-4+4-0,0-0+4-4)=\mathbf{0}$, with $1-1+1-1=0$. So $\boldsymbol{\lambda}=(1,-1,1,-1)$.

(b) The positive coefficients are at $\mathbf{x}_1$ and $\mathbf{x}_3$, with ratios $\frac{1/10}{1}=\frac{1}{10}$ and $\frac{3/10}{1}=\frac{3}{10}$. So $s=\frac{1}{10}$, attained at $\mathbf{x}_1$, and the new weights are $\mathbf{t}-s\boldsymbol{\lambda}=(0,\frac{3}{10},\frac{2}{10},\frac{5}{10})$. Check: $\frac{3}{10}(4,0)+\frac{2}{10}(4,4)+\frac{5}{10}(0,4)=(\frac{12+8}{10},\frac{8+20}{10})=(2,\frac{14}{5})$, and the weights add up to 1. So $\mathbf{x}\in\operatorname{conv}\{\mathbf{x}_2,\mathbf{x}_3,\mathbf{x}_4\}$.

(c) With $-\boldsymbol{\lambda}=(-1,1,-1,1)$, the positive coefficients are at $\mathbf{x}_2$ and $\mathbf{x}_4$, with ratios $\frac{2}{10}$ and $\frac{4}{10}$. So $s=\frac{2}{10}$, attained at $\mathbf{x}_2$, and the weights become $\mathbf{t}+s\boldsymbol{\lambda}=(\frac{3}{10},0,\frac{5}{10},\frac{2}{10})$. Check: $\frac{5}{10}(4,4)+\frac{2}{10}(0,4)=(2,\frac{20+8}{10})=(2,\frac{14}{5})$. Now $\mathbf{x}_2$ is dropped, and $\mathbf{x}\in\operatorname{conv}\{\mathbf{x}_1,\mathbf{x}_3,\mathbf{x}_4\}$. The two answers are consistent: the triangle with corners $\mathbf{x}_2,\mathbf{x}_3,\mathbf{x}_4$ is the part of the square where $x+y\geq 4$, the triangle with corners $\mathbf{x}_1,\mathbf{x}_3,\mathbf{x}_4$ is the part where $y\geq x$, and $(2,\frac{14}{5})$ satisfies both. The shorter combination produced by Carathéodory's theorem is not unique; it depends on the dependence used and on its sign.

Exercise B2: Radon partitions in the plane.

Find a Radon partition, and a point common to the two hulls, for each list of four points in $\mathbb{R}^2$. Justify your answer.

(a) $(0,0),(4,0),(0,4),(1,1)$.

(b) $(0,0),(3,1),(1,3),(4,4)$.

Solution. Label the points $\mathbf{x}_1, \dots, \mathbf{x}_4$ in the order given, and follow the proof of Theorem 17.2.4.

(a) The equations $\sum_i \lambda_i \mathbf{x}_i = \mathbf{0}$, $\sum_i \lambda_i = 0$ read $4\lambda_2 + \lambda_4 = 0$, $4\lambda_3 + \lambda_4 = 0$, $\lambda_1 + \lambda_2 + \lambda_3 + \lambda_4 = 0$. Taking $\lambda_4 = 4$ gives $\lambda_2 = \lambda_3 = -1$ and $\lambda_1 = -2$. So $I = \{4\}$, $J = \{1, 2, 3\}$, $\sigma = 4$, and

$$\mathbf{y} = \mathbf{x}_4 = (1, 1) = \tfrac{2}{4}(0, 0) + \tfrac{1}{4}(4, 0) + \tfrac{1}{4}(0, 4).$$

The fourth point lies inside the triangle of the other three.

(b) The equations read $3\lambda_2 + \lambda_3 + 4\lambda_4 = 0$, $\lambda_2 + 3\lambda_3 + 4\lambda_4 = 0$, and $\sum_i \lambda_i = 0$. Subtracting the first two gives $\lambda_2 = \lambda_3$, and then $4\lambda_2 + 4\lambda_4 = 0$, so $\lambda_4 = -\lambda_2$ and $\lambda_1 = -\lambda_2 - \lambda_3 - \lambda_4 = -\lambda_2$. Taking $\lambda_2 = -1$ gives $\boldsymbol{\lambda} = (1, -1, -1, 1)$. So $I = \{1, 4\}$, $J = \{2, 3\}$, $\sigma = 2$, and

$$\mathbf{y} = \tfrac{1}{2}(0, 0) + \tfrac{1}{2}(4, 4) = (2, 2) = \tfrac{1}{2}(3, 1) + \tfrac{1}{2}(1, 3).$$

The two diagonals of the quadrilateral cross at $(2, 2)$.

Exercise B3: Linear functionals on a polygon.

Let V be a finite-dimensional real vector space with a norm, and $\mathbf{x}_1, \dots, \mathbf{x}_m \in V$.

(a) Prove that $\{\mathbf{x}_1, \dots, \mathbf{x}_m\}$ is compact, and deduce that $P = \operatorname{conv}\{\mathbf{x}_1, \dots, \mathbf{x}_m\}$ is compact.

(b) Prove that every linear functional φ on V attains its maximum over P at one of the points $\mathbf{x}_i$.

(c) Find the maximum and the minimum of $\varphi(x, y) = 2x - y$ over the triangle $\operatorname{conv}\{(1, 0), (3, 1), (0, 2)\}$ of Example (Deciding membership in a triangle).

Solution.

(a) Let $(\mathbf{y}_k)$ be a sequence in the finite set. Some $\mathbf{x}_i$ occurs as $\mathbf{y}_k$ for infinitely many k, since there are only m candidates, and those terms form a constant subsequence, which converges to $\mathbf{x}_i$, a point of the set. So the set is compact, and P is compact by Corollary 17.2.3 (a).

(b) By Corollary 17.2.3 (b), the maximum of φ over P equals its maximum over $\{\mathbf{x}_1, \dots, \mathbf{x}_m\}$, which is $\max_i \varphi(\mathbf{x}_i)$, attained at an $\mathbf{x}_i$ with the largest value.

(c) The values at the corners are $\varphi(1, 0) = 2$, $\varphi(3, 1) = 5$, $\varphi(0, 2) = -2$. By (b), the maximum over the triangle is 5, at $(3, 1)$. Applying (b) to $-\varphi$, the minimum is -2, at $(0, 2)$.

17.2.5.3 C. Going deeper

Exercise C1: Carathéodory in the affine hull.

Let V be a real vector space, $S \subseteq V$ non-empty, and suppose $\operatorname{aff} S$ has dimension d (Definition 17.1.5).

(a) Prove that every affinely independent list of points of S has at most $d + 1$ entries.

(b) Hence prove that every point of $\operatorname{conv} S$ is a convex combination of at most $d+1$ points of S.

(c) Let $S = \{(t,t,t) : 0 \le t \le 1\} \cup \{(2,2,2)\} \subseteq \mathbb{R}^3$. What bound does Theorem 17.2.2 give, and what bound does (b) give?

Solution.

(a) By Proposition 17.1.4, $\operatorname{aff} S = \mathbf{x}_0 + U$ with $\dim U = d$. If $(\mathbf{y}_0, \dots, \mathbf{y}_m)$ is an affinely independent list in S, then each $\mathbf{y}_i$ lies in $\mathbf{x}_0 + U$, so each difference $\mathbf{y}_i - \mathbf{y}_0 = (\mathbf{y}_i - \mathbf{x}_0) - (\mathbf{y}_0 - \mathbf{x}_0)$ lies in U. By Lemma 17.2.1 (a) the m differences are linearly independent, and they lie in the d-dimensional space U, so $m \le d$ by Theorem 1.6.3 (a).

(b) By Theorem 17.2.2, each point of $\operatorname{conv} S$ is a convex combination of an affinely independent list of points of S, which has at most $d+1$ entries by (a).

(c) Here $n = 3$, so Theorem 17.2.2 gives 4. All of S lies on the line $\operatorname{span}(\mathbf{1})$, and S contains two distinct points, so $\operatorname{aff} S$ is that line and $d = 1$; (b) gives 2. Indeed $\operatorname{conv} S$ is the segment from $\mathbf{0}$ to $(2,2,2)$, and each of its points is a convex combination of the two endpoints.

Exercise C2: Helly's theorem for a sequence of compact sets.

Let V be a real vector space of dimension n with a norm, and let $C_1, C_2, C_3, \dots$ be a sequence of **compact** convex subsets of V such that every $n+1$ of them have a common point.

(a) Prove that a compact set K is closed.

(b) Prove that for each $m \ge 1$ there is a point $\mathbf{y}_m \in C_1 \cap \cdots \cap C_m$.

(c) Prove that $\bigcap_{k \ge 1} C_k \neq \emptyset$.

(d) Explain where the argument fails for the closed half-lines $[k, \infty)$ of the remark after Theorem 17.2.5.

Hint for (c): all the $\mathbf{y}_m$ lie in C_1.

Solution.

(a) Let $\mathbf{x}_k \to \mathbf{x}$ with $\mathbf{x}_k \in K$. By compactness, a subsequence converges to some $\mathbf{x}' \in K$. It also converges to $\mathbf{x}$, as a subsequence of a convergent sequence, and a limit is unique: $\|\mathbf{x} - \mathbf{x}'\| \le \|\mathbf{x} - \mathbf{x}_{k_j}\| + \|\mathbf{x}_{k_j} - \mathbf{x}'\| \to 0$, so $\mathbf{x} = \mathbf{x}'$ by (N1). Hence $\mathbf{x} \in K$.

(b) For $m \le n$, the sets $C_1, \dots, C_m$, together with $C_{m+1}, \dots, C_{n+1}$, are $n+1$ of the sets, and a common point of all of them lies in $C_1 \cap \cdots \cap C_m$. For $m \ge n+1$, Theorem 17.2.5 applies to the convex sets $C_1, \dots, C_m$.

(c) Every $\mathbf{y}_m$ lies in the compact set C_1, so a subsequence $\mathbf{y}_{m_j}$ converges to some $\mathbf{y}$. Fix k. For $m_j \ge k$, $\mathbf{y}_{m_j} \in C_k$, and C_k is closed by (a); the terms with $m_j \ge k$ form a sequence in C_k converging to $\mathbf{y}$, so $\mathbf{y} \in C_k$. As k was arbitrary, $\mathbf{y} \in \bigcap_k C_k$.

(d) Steps (a) and (b) survive for $C_k = [k, \infty)$ with $n = 1$: the sets are closed, and $\mathbf{y}_m = m$ lies in the first m of them. Step (c) fails, because $C_1 = [1, \infty)$ is not compact: the sequence $\mathbf{y}_m = m$ has no convergent subsequence, and the points

escape to infinity instead of accumulating at a common point.

Exercise C3: The counts are sharp.

Let V be a real vector space of dimension n, and let $(\mathbf{x}_0, \dots, \mathbf{x}_n)$ be affinely independent.

(a) Prove that each point of $\operatorname{conv}\{\mathbf{x}_0, \dots, \mathbf{x}_n\}$ has **exactly one** expression $\sum_i t_i \mathbf{x}_i$ with $\mathbf{t} \in \Delta_{n+1}$.

(b) Deduce that $\frac{1}{n+1}\sum_i \mathbf{x}_i$ is not a convex combination of any n of the points. (This recovers Example (The bound is attained).)

(c) Prove that $\mathbf{x}_0, \dots, \mathbf{x}_n$ have **no** Radon partition, so that $n+2$ in Theorem 17.2.4 cannot be lowered.

Solution.

(a) If $\sum_i t_i \mathbf{x}_i = \sum_i t'_i \mathbf{x}_i$ with $\mathbf{t}, \mathbf{t}' \in \Delta_{n+1}$, then $\sum_i (t_i - t'_i)\mathbf{x}_i = \mathbf{0}$ and $\sum_i (t_i - t'_i) = 1 - 1 = 0$. By affine independence every $t_i - t'_i = 0$.

(b) The point has the expression with all weights $\frac{1}{n+1}$. A convex combination of n of the points is an expression of the form in (a) with the omitted point given weight 0. By the uniqueness in (a), it would have to coincide with the all-$\frac{1}{n+1}$ expression, which has no zero weight.

(c) Suppose I, J are disjoint, non-empty, and $\sum_{i\in I} a_i \mathbf{x}_i = \sum_{j\in J} b_j \mathbf{x}_j$ with non-negative weights, each family adding up to 1. Then $\sum_{i\in I} a_i \mathbf{x}_i - \sum_{j\in J} b_j \mathbf{x}_j = \mathbf{0}$ is a relation among the $\mathbf{x}_i$ whose coefficients add up to $1 - 1 = 0$; an index lying in neither set gets coefficient 0, and no index lies in both, since $I \cap J = \emptyset$. By affine independence, all these coefficients are 0, so every $a_i = 0$, contradicting $\sum_{i\in I} a_i = 1$. Hence no Radon partition exists.

17.3 Separating Hyperplanes

Sections 01 and 02 looked at a convex set from the inside: which combinations of its points it contains, and how few points a combination needs. This section looks at it from the outside. A point that is not in a closed convex set can be cut off from it by a hyperplane, a set can be touched at its edge by a hyperplane that leaves the whole set on one side, and two disjoint convex sets can be pulled apart by one. All three facts come from a single construction, the point of the set nearest to a given point, and that construction is Chapter 10's orthogonal projection with the subspace replaced by a convex set.

Throughout, V is a finite-dimensional real inner product space, with inner product $\langle \cdot, \cdot \rangle$ (Definition 10.1.1), induced norm $\|\cdot\|$ (Definition 10.1.3), and $n = \dim V$. A sequence **converges**, $\mathbf{x}_k \to \mathbf{x}$, when $\|\mathbf{x}_k - \mathbf{x}\| \to 0$; **closed** means closed in the sense of Definition 17.1.6, so that a closed set contains the limit of every convergent sequence of its points. A set is **compact** if every sequence in it has a subsequence converging to a point of the set; this is the word of Corollary 15.2.5, which says that every closed bounded subset of V is compact. The field is $\mathbb{R}$ because the whole section is about inequalities.

17.3.1 The nearest point of a closed convex set

Chapter 10 answered a question about subspaces: given $\mathbf{v}$ and a finite-dimensional subspace U, which vector of U is closest to $\mathbf{v}$? Theorem 10.3.5 said there is exactly one, the orthogonal projection $P_U\mathbf{v}$, and that $\mathbf{v} - P_U\mathbf{v}$ is perpendicular to U. Now replace U by a set with less structure, such as a disc, a box or a half-plane, and ask the same question. Two small experiments in $\mathbb{R}^2$ show which hypotheses the answer needs.

- The **open** disc $\{\mathbf{y} : \|\mathbf{y}\| < 1\}$ and the point $\mathbf{x} = (2, 0)$. The points $(1 - 1/k, 0)$ of the disc come closer and closer to $\mathbf{x}$, but the distance 1 is never reached, since the only candidate $(1, 0)$ is missing. There is no nearest point. The set is convex but not closed.
- The **circle** $\{\mathbf{y} : \|\mathbf{y}\| = 1\}$ and the point $\mathbf{x} = \mathbf{0}$. Every point of the circle is at distance 1, so every point is a nearest point. The set is closed but not convex.

So we ask for both properties, and then everything works.

Theorem 17.3.1 — Nearest Point Theorem

Let C be a **non-empty, closed, convex** subset of V, and let $\mathbf{x} \in V$.

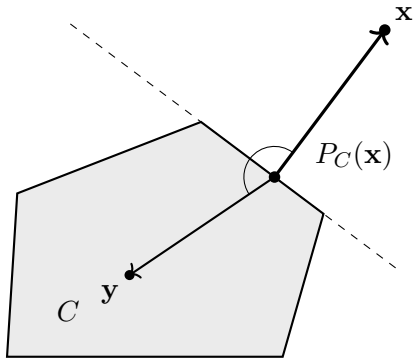
(a) There is **exactly one** point $\mathbf{p} \in C$ with $\|\mathbf{x} - \mathbf{p}\| \le \|\mathbf{x} - \mathbf{y}\|$ for every $\mathbf{y} \in C$.

(b) A point $\mathbf{p} \in C$ is this nearest point **if and only if**

$$\langle \mathbf{x} - \mathbf{p}, \mathbf{y} - \mathbf{p} \rangle \le 0 \qquad \text{for every } \mathbf{y} \in C. \tag{17.3.1}$$

The nearest point is written $P_C(\mathbf{x})$, and the map $P_C \colon V \to C$ is the **projection onto** C. The number $d(\mathbf{x}, C) = \|\mathbf{x} - P_C(\mathbf{x})\|$ is the **distance** from $\mathbf{x}$ to C.

Idea. Three jobs, three tools. ① Existence: a nearest point is a minimum of the continuous function $\mathbf{y} \mapsto \|\mathbf{x} - \mathbf{y}\|$, and a minimum exists on a compact set; C itself may be unbounded, so cut it down to the part of C within a fixed distance of $\mathbf{x}$. ② The inequality Eq. 17.3.1 is the first-order condition: slide from $\mathbf{p}$ a little way towards another point $\mathbf{y}$ of C, which convexity allows, and ask that the distance not decrease. ③ Read backwards, the inequality says that the angle at $\mathbf{p}$ between $\mathbf{x} - \mathbf{p}$ and $\mathbf{y} - \mathbf{p}$ is at least a right angle, and expanding $\|\mathbf{x} - \mathbf{y}\|^2$ then gives $\|\mathbf{x} - \mathbf{y}\|^2 \ge \|\mathbf{x} - \mathbf{p}\|^2 + \|\mathbf{y} - \mathbf{p}\|^2$. That inequality proves both that $\mathbf{p}$ is nearest and that nothing else is.



the angle at $P_C(\mathbf{x})$ between $\mathbf{x} - P_C(\mathbf{x})$ and $\mathbf{y} - P_C(\mathbf{x})$ is obtuse;
the dashed line through $P_C(\mathbf{x})$ is perpendicular to $\mathbf{x} - P_C(\mathbf{x})$

Proof. Existence. Since $C \neq \emptyset$, pick $\mathbf{y}_0 \in C$ and put $R = \|\mathbf{x} - \mathbf{y}_0\|$. Let

$$K = \{\mathbf{y} \in C : \|\mathbf{x} - \mathbf{y}\| \leq R\}.$$

Then $\mathbf{y}_0 \in K$, and K is bounded, since $\|\mathbf{y}\| \leq \|\mathbf{x}\| + \|\mathbf{y} - \mathbf{x}\| \leq \|\mathbf{x}\| + R$ for $\mathbf{y} \in K$ by Corollary 10.1.6. It is closed: if $\mathbf{y}_k \in K$ and $\mathbf{y}_k \to \mathbf{y}$, then $\mathbf{y} \in C$ because C is closed, and

$$\|\mathbf{x} - \mathbf{y}\| \leq \|\mathbf{x} - \mathbf{y}_k\| + \|\mathbf{y}_k - \mathbf{y}\| \leq R + \|\mathbf{y}_k - \mathbf{y}\|$$

for every k; the right-hand side tends to R, and a non-strict inequality survives a limit, so $\|\mathbf{x} - \mathbf{y}\| \leq R$. By Corollary 15.2.5, the form in which Chapter 15 carried **the compactness of closed bounded sets, fact (A3) of Chapter 15's introduction**, over to every finite-dimensional space, K is compact. The function $f(\mathbf{y}) = \|\mathbf{x} - \mathbf{y}\|$ is continuous, since $|f(\mathbf{y}) - f(\mathbf{y}')| \leq \|\mathbf{y} - \mathbf{y}'\|$ by Lemma 15.1.1. By **the extreme value theorem, fact (A4) of Chapter 15's introduction**, f attains a minimum on K at some $\mathbf{p} \in K$. Every $\mathbf{y} \in C \setminus K$ has $f(\mathbf{y}) > R \geq f(\mathbf{p})$. So $\|\mathbf{x} - \mathbf{p}\| \leq \|\mathbf{x} - \mathbf{y}\|$ for every $\mathbf{y} \in C$.

(b), ($\Rightarrow$). Let $\mathbf{p}$ be a nearest point and let $\mathbf{y} \in C$. For $0 < t \leq 1$, the point $\mathbf{p} + t(\mathbf{y} - \mathbf{p}) = (1 - t)\mathbf{p} + t\mathbf{y}$ lies in C by Definition 17.1.1. Hence, expanding with Theorem 10.1.2 (c) over $\mathbb{R}$,

$$\|\mathbf{x} - \mathbf{p}\|^2 \leq \|(\mathbf{x} - \mathbf{p}) - t(\mathbf{y} - \mathbf{p})\|^2 = \|\mathbf{x} - \mathbf{p}\|^2 - 2t\langle \mathbf{x} - \mathbf{p}, \mathbf{y} - \mathbf{p}\rangle + t^2\|\mathbf{y} - \mathbf{p}\|^2.$$

Cancel $\|\mathbf{x} - \mathbf{p}\|^2$ and divide by $2t > 0$: $\langle \mathbf{x} - \mathbf{p}, \mathbf{y} - \mathbf{p}\rangle \leq \frac{t}{2}\|\mathbf{y} - \mathbf{p}\|^2$. This holds for every $t = 1/k$, and letting $k \to \infty$ gives Eq. 17.3.1.

(b), ($\Leftarrow$)*, and uniqueness.* Let $\mathbf{p} \in C$ satisfy Eq. 17.3.1, and let $\mathbf{y} \in C$. The same expansion with $t = 1$ gives

$$\begin{aligned} \|\mathbf{x} - \mathbf{y}\|^2 &= \|\mathbf{x} - \mathbf{p}\|^2 - 2\langle \mathbf{x} - \mathbf{p}, \mathbf{y} - \mathbf{p}\rangle + \|\mathbf{y} - \mathbf{p}\|^2 \\ &\geq \|\mathbf{x} - \mathbf{p}\|^2 + \|\mathbf{y} - \mathbf{p}\|^2. \end{aligned} \qquad (*)$$

So $\|\mathbf{x} - \mathbf{y}\| \geq \|\mathbf{x} - \mathbf{p}\|$, and $\mathbf{p}$ is a nearest point. Finally, the nearest point $\mathbf{p}$ found in the existence step satisfies Eq. 17.3.1 by ($\Rightarrow$), so ($*$) applies to it; for $\mathbf{y} \in C$ with $\mathbf{y} \neq \mathbf{p}$ it gives $\|\mathbf{x} - \mathbf{y}\|^2 \geq \|\mathbf{x} - \mathbf{p}\|^2 + \|\mathbf{y} - \mathbf{p}\|^2 > \|\mathbf{x} - \mathbf{p}\|^2$, and $\mathbf{y}$ is not a nearest point. This proves the theorem.

■

The inequality ($*$) is Pythagoras with the equality relaxed to an inequality. That is exactly the relation with Chapter 10, and it deserves to be said precisely.

This theorem generalizes Theorem 10.3.5. Let $C = U$ be a subspace of V. It is convex, and closed by Proposition 17.1.6 (c). For $\mathbf{p} \in U$, the vector $\mathbf{y} - \mathbf{p}$ runs over **all** of U as $\mathbf{y}$ does, and with each $\mathbf{u} \in U$ it also takes the value $-\mathbf{u}$. So Eq. 17.3.1 says $\langle \mathbf{x} - \mathbf{p}, \mathbf{u}\rangle \leq 0$ and $-\langle \mathbf{x} - \mathbf{p}, \mathbf{u}\rangle \leq 0$, that is,

$$\langle \mathbf{x} - \mathbf{p}, \mathbf{u}\rangle = 0 \qquad \text{for every } \mathbf{u} \in U.$$

For a subspace the variational inequality becomes an equality, the statement $\mathbf{x} - \mathbf{p} \in U^{\perp}$. Then $\mathbf{x} = \mathbf{p} + (\mathbf{x} - \mathbf{p})$ is the splitting of Theorem 10.3.2 (a), so $P_C(\mathbf{x}) = P_U\mathbf{x}$ by Definition 10.3.2, and ($*$) becomes the equation of Theorem 10.1.3 used in the proof of Theorem 10.3.5. The projection onto a closed convex set is the orthogonal projection with "perpendicular" weakened to "at an obtuse angle".

Example. (Three projections)

Find $P_C(\mathbf{x})$ in each case, and check Eq. 17.3.1.

(a) C is the closed unit ball $\{\mathbf{y} : \|\mathbf{y}\| \le 1\}$ of V, and $\|\mathbf{x}\| > 1$.

(b) C is the box $[0,1]^3 = \{\mathbf{y} \in \mathbb{R}^3 : 0 \le y_i \le 1 \text{ for each } i\}$ with the dot product, and $\mathbf{x} = (3, -1, 2)$.

(c) C is the half-space $\{\mathbf{y} : \langle \mathbf{a}, \mathbf{y} \rangle \le c\}$, where $\mathbf{a} \neq \mathbf{0}$, and $\langle \mathbf{a}, \mathbf{x} \rangle > c$.

Solution.

(a) $P_C(\mathbf{x}) = \mathbf{x}/\|\mathbf{x}\|$. With $\mathbf{p} = \mathbf{x}/\|\mathbf{x}\|$ we have $\|\mathbf{p}\| = 1$ and $\mathbf{x} - \mathbf{p} = (\|\mathbf{x}\| - 1)\mathbf{p}$, so for $\mathbf{y} \in C$

$$\langle \mathbf{x} - \mathbf{p}, \mathbf{y} - \mathbf{p} \rangle = (\|\mathbf{x}\| - 1)\big(\langle \mathbf{p}, \mathbf{y} \rangle - 1\big) \le 0,$$

because $\|\mathbf{x}\| - 1 > 0$ and $\langle \mathbf{p}, \mathbf{y} \rangle \le \|\mathbf{p}\|\|\mathbf{y}\| \le 1$ by Theorem 10.1.5. By Theorem 17.3.1 (b), $\mathbf{p}$ is the nearest point, and $d(\mathbf{x}, C) = \|\mathbf{x}\| - 1$.

(b) Clamp each coordinate into $[0,1]$: $\mathbf{p} = (1, 0, 1)$. Then $\mathbf{x} - \mathbf{p} = (2, -1, 1)$ and, for $\mathbf{y} \in C$,

$$\langle \mathbf{x} - \mathbf{p}, \mathbf{y} - \mathbf{p} \rangle = 2(y_1 - 1) - y_2 + (y_3 - 1) \le 0,$$

since $y_1 \le 1$, $y_2 \ge 0$ and $y_3 \le 1$. So $P_C(\mathbf{x}) = (1, 0, 1)$ and $d(\mathbf{x}, C) = \sqrt{4 + 1 + 1} = \sqrt{6}$. The vector $\mathbf{a} = \mathbf{x} - \mathbf{p} = (2, -1, 1)$ also cuts $\mathbf{x}$ off: $\langle \mathbf{a}, \mathbf{x} \rangle = 9$ and $\|\mathbf{a}\|^2 = 6$, so $c = \langle \mathbf{a}, \mathbf{x} \rangle - \frac{1}{2}\|\mathbf{a}\|^2 = 6$, and the plane $2y_1 - y_2 + y_3 = 6$ strictly separates C from $\mathbf{x}$, since its left side is at most $2 + 0 + 1 = 3$ on C and equals 9 at $\mathbf{x}$. Theorem 17.3.2 below turns this recipe into a theorem.

(c) Put $\lambda = (\langle \mathbf{a}, \mathbf{x} \rangle - c)/\|\mathbf{a}\|^2$, which is positive, and $\mathbf{p} = \mathbf{x} - \lambda\mathbf{a}$. Then $\langle \mathbf{a}, \mathbf{p} \rangle = \langle \mathbf{a}, \mathbf{x} \rangle - \lambda\|\mathbf{a}\|^2 = c$, so $\mathbf{p} \in C$, and for $\mathbf{y} \in C$

$$\langle \mathbf{x} - \mathbf{p}, \mathbf{y} - \mathbf{p} \rangle = \lambda\big(\langle \mathbf{a}, \mathbf{y} \rangle - c\big) \le 0.$$

So $P_C(\mathbf{x}) = \mathbf{x} - \lambda\mathbf{a}$: drop the perpendicular to the boundary hyperplane, as Chapter 10 would have done. The distance is $\lambda\|\mathbf{a}\| = (\langle \mathbf{a}, \mathbf{x} \rangle - c)/\|\mathbf{a}\|$.

Two degenerate cases fix the scale. If $C = \{\mathbf{c}\}$ is a single point, then $P_C(\mathbf{x}) = \mathbf{c}$ for every $\mathbf{x}$, and Eq. 17.3.1 holds because $\mathbf{y} - \mathbf{p} = \mathbf{0}$. If $C = V$, then P_C is the identity. In every case $P_C(\mathbf{x}) = \mathbf{x}$ exactly when $\mathbf{x} \in C$.

Quick check. Where did the proof of Theorem 17.3.1 use that C is closed, and where that it is convex? Match each use with one of the two failing experiments before the theorem.

Solution. Closedness was used in the existence step, to make K closed and hence compact; the open disc fails there, since the minimizing candidates converge to a point outside it. Convexity was used in ($\Rightarrow$), to know that $(1 - t)\mathbf{p} + t\mathbf{y} \in C$, and uniqueness rests on that step. The circle fails there: with $\mathbf{x} = \mathbf{0}$, $\mathbf{p} = \mathbf{e}_1$ and $\mathbf{y} = -\mathbf{e}_1$, $\langle \mathbf{x} - \mathbf{p}, \mathbf{y} - \mathbf{p} \rangle = 2 > 0$.

Warning. **The proof needs an inner product, and uniqueness can fail without one.** In $\mathbb{R}^2$ with $\|\cdot\|_\infty$, let C be the x_1-axis, which is closed and convex, and $\mathbf{x} = (0, 1)$. Then $\|\mathbf{x} - (t, 0)\|_\infty = \max(|t|, 1) = 1$ for every $t \in [-1, 1]$, so there is a whole segment of nearest points. Existence survives, since its proof used only (N3) and compactness.

Uniqueness does not, because it came from the expansion of $\|\mathbf{x}-\mathbf{y}\|^2$, which is available only for induced norms.

17.3.2 Hyperplanes and half-spaces

A hyperplane in the sense of Chapter 4 passes through $\mathbf{0}$: it is a subspace of codimension 1 (Definition 4.5.2). To separate sets we need translates of hyperplanes, and Chapter 4 §06 called a coset $\mathbf{p}+H$ of a hyperplane H (Definition 3.9.2) an **affine hyperplane**. In an inner product space these have a concrete form. By Theorem 4.5.3, $H = \ker\varphi$ for a non-zero $\varphi \in V^*$; by Theorem 10.5.1, $\varphi = \langle\cdot, \mathbf{a}\rangle$ for a non-zero $\mathbf{a} \in V$. Hence

$$\mathbf{p}+H = \{\mathbf{y} \in V : \langle \mathbf{a}, \mathbf{y}\rangle = c\}, \qquad c = \langle \mathbf{a}, \mathbf{p}\rangle,$$

and conversely every such set with $\mathbf{a} \neq \mathbf{0}$ is an affine hyperplane, with $\mathbf{a}$ as a **normal vector**. It cuts V into the two **closed half-spaces** $\{\langle \mathbf{a}, \cdot\rangle \le c\}$ and $\{\langle \mathbf{a}, \cdot\rangle \ge c\}$. Both are convex, because $\langle \mathbf{a}, \cdot\rangle$ is linear, and closed by Proposition 17.1.6 (c).

Definition 17.3.1 — Separation by a Hyperplane

Let $A, B \subseteq V$ be non-empty. A **non-zero** vector $\mathbf{a} \in V$ and a number $c \in \mathbb{R}$ **separate** A and B if

$$\langle \mathbf{a}, \mathbf{x}\rangle \le c \le \langle \mathbf{a}, \mathbf{y}\rangle \qquad \text{for all } \mathbf{x} \in A \text{ and all } \mathbf{y} \in B.$$

They **strictly separate** A and B if in addition there is a real $\varepsilon > 0$ with $\langle \mathbf{a}, \mathbf{x}\rangle \le c-\varepsilon$ and $\langle \mathbf{a}, \mathbf{y}\rangle \ge c+\varepsilon$ for all $\mathbf{x} \in A$, $\mathbf{y} \in B$.

In words: A lies in one closed half-space of $\{\langle \mathbf{a}, \cdot\rangle = c\}$ and B in the other, and strict separation puts a slab of width $2\varepsilon/\|\mathbf{a}\|$ between them. Replacing $(\mathbf{a}, c)$ by $(-\mathbf{a}, -c)$ swaps the roles of A and B. With $\mathbf{a} = \mathbf{0}$ and $c = 0$ any two sets would be "separated".

17.3.3 Cutting off a point

The first consequence of Theorem 17.3.1 is the one the chapter uses most. If $\mathbf{x}$ is not in C, the vector from $P_C(\mathbf{x})$ to $\mathbf{x}$ is a normal vector for a hyperplane that cuts $\mathbf{x}$ off.

Theorem 17.3.2 — Separating a Point from a Closed Convex Set

Let $C \subseteq V$ be non-empty, closed and convex, and let $\mathbf{x} \notin C$. Put $\mathbf{a} = \mathbf{x} - P_C(\mathbf{x})$. Then $\mathbf{a} \neq \mathbf{0}$ and

$$\langle \mathbf{a}, \mathbf{y}\rangle \le \langle \mathbf{a}, \mathbf{x}\rangle - \|\mathbf{a}\|^2 \qquad \text{for every } \mathbf{y} \in C.$$

In particular $\mathbf{a}$ and $c = \langle \mathbf{a}, \mathbf{x}\rangle - \tfrac{1}{2}\|\mathbf{a}\|^2$ strictly separate C and $\{\mathbf{x}\}$.

Proof. Write $\mathbf{p} = P_C(\mathbf{x})$. Since $\mathbf{p} \in C$ and $\mathbf{x} \notin C$, $\mathbf{a} = \mathbf{x} - \mathbf{p} \neq \mathbf{0}$. For $\mathbf{y} \in C$, Eq. 17.3.1 gives $\langle \mathbf{a}, \mathbf{y} - \mathbf{p}\rangle \le 0$, hence

$$\langle \mathbf{a}, \mathbf{y}\rangle \le \langle \mathbf{a}, \mathbf{p}\rangle = \langle \mathbf{a}, \mathbf{x}\rangle - \langle \mathbf{a}, \mathbf{x}-\mathbf{p}\rangle = \langle \mathbf{a}, \mathbf{x}\rangle - \|\mathbf{a}\|^2.$$

With $\varepsilon = \tfrac{1}{2}\|\mathbf{a}\|^2 > 0$ this reads $\langle \mathbf{a}, \mathbf{y}\rangle \le c - \varepsilon$, while $\langle \mathbf{a}, \mathbf{x}\rangle = c + \varepsilon$. This proves the

theorem.

■

In the picture after Theorem 17.3.1, the hyperplane of the theorem is the line parallel to the dashed one, halfway between $P_C(\mathbf{x})$ and $\mathbf{x}$.

The theorem turns into a description of a closed convex set from the outside. Sections 01 and 02 built convex sets up from points; this builds them down from half-spaces.

Corollary 17.3.3 — A Closed Convex Set Is an Intersection of Half-Spaces

Every non-empty closed convex subset C of V is the intersection of all the closed half-spaces $\{\mathbf{y} : \langle \mathbf{a}, \mathbf{y} \rangle \le c\}$, with $\mathbf{a} \neq \mathbf{0}$, that contain C.

Proof. Each of these half-spaces contains C, so C lies in their intersection. Conversely, let $\mathbf{x} \notin C$. By Theorem 17.3.2, with $\mathbf{a} = \mathbf{x} - P_C(\mathbf{x}) \neq \mathbf{0}$, the half-space $\{\mathbf{y} : \langle \mathbf{a}, \mathbf{y} \rangle \le \langle \mathbf{a}, \mathbf{x} \rangle - \|\mathbf{a}\|^2\}$ contains C but not $\mathbf{x}$. So $\mathbf{x}$ is not in the intersection. (If $C = V$, the family of half-spaces is empty and its intersection is V by convention.)

■

The corollary has a converse that is immediate: an intersection of closed half-spaces is closed and convex, because each half-space is and both properties pass to intersections. So the closed convex sets are **exactly** the intersections of closed half-spaces. §04 turns this into a formula, the support function, and §09 studies the case of finitely many half-spaces.

17.3.4 Supporting hyperplanes

A point on the edge of C cannot be cut off, because it belongs to C. The best one can hope for is a hyperplane through the point with all of C on one side, touching C without cutting it. To say "on the edge" we need two more words.

Definition 17.3.2 — Interior Point, Closure, Boundary Point

Let $S \subseteq V$. A point $\mathbf{x} \in V$ is an **interior point** of S if there is a real $r > 0$ such that **every** $\mathbf{y}$ with $\|\mathbf{y} - \mathbf{x}\| < r$ lies in S; the set of interior points is written $\operatorname{int}(S)$. The **closure** $\overline{S}$ of S is the set of limits of all convergent sequences of points of S. A **boundary point** of S is a point of $\overline{S}$ that is not an interior point of S.

Constant sequences show $S \subseteq \overline{S}$, and by Definition 17.1.6, S is closed exactly when $\overline{S} = S$. By Theorem 15.2.2 neither notion depends on the norm used: a ball of radius r for one norm contains a ball of positive radius for any other. For the closed unit disc of $\mathbb{R}^2$, the interior points are those with $\|\mathbf{x}\| < 1$, and the boundary points form the unit circle. A segment in $\mathbb{R}^2$ has no interior points at all, so every one of its points is a boundary point; that is the case the next lemma isolates.

Lemma 17.3.4 — A Convex Set Is Solid or Flat

Let $V \neq \{\mathbf{0}\}$ and let $C \subseteq V$ be non-empty and convex. Then **either** C has an interior point, **or** C lies in an affine hyperplane: there are $\mathbf{a} \neq \mathbf{0}$ and $c \in \mathbb{R}$ with $\langle \mathbf{a}, \mathbf{y} \rangle = c$ for every $\mathbf{y} \in C$.

Idea. Fix $\mathbf{c}_0 \in C$ and look at the directions $\mathbf{y} - \mathbf{c}_0$ available inside C. If they span a proper subspace, a normal vector to that subspace is the $\mathbf{a}$ we want. If they span V, then C contains $n+1$ points in general position, hence the solid simplex they span, and the center of a solid simplex is an interior point because its barycentric coordinates change only a little when the point moves a little.

Proof. Fix $\mathbf{c}_0 \in C$ and let $W = \operatorname{span}\{\mathbf{y} - \mathbf{c}_0 : \mathbf{y} \in C\}$.

Case 1: $W \neq V$. Then $\dim W < n$, so $\dim W^{\perp} = n - \dim W \geq 1$ by Theorem 10.3.2 (c), and there is $\mathbf{a} \neq \mathbf{0}$ in $W^{\perp}$. For $\mathbf{y} \in C$, $\langle \mathbf{a}, \mathbf{y} - \mathbf{c}_0 \rangle = 0$, that is, $\langle \mathbf{a}, \mathbf{y} \rangle = \langle \mathbf{a}, \mathbf{c}_0 \rangle$. Take $c = \langle \mathbf{a}, \mathbf{c}_0 \rangle$.

Case 2: $W = V$. Choose a linearly independent list $(\mathbf{y}_1 - \mathbf{c}_0, \dots, \mathbf{y}_m - \mathbf{c}_0)$ with every $\mathbf{y}_i \in C$ and m as large as possible; $m \leq n$ by Theorem 1.6.3. Every vector $\mathbf{y} - \mathbf{c}_0$ with $\mathbf{y} \in C$ lies in the span of this list, since otherwise Lemma 1.5.3 would lengthen it. So the span contains every generator of W, hence equals V, and the list is a basis; thus $m = n$. Let $\varphi_i(\mathbf{v})$ be the i-th coordinate of $\mathbf{v}$ in this basis, a linear functional by Theorem 1.5.2, and write $\varphi_i = \langle \cdot, \mathbf{w}_i \rangle$ by Theorem 10.5.1. Put $\mu_i(\mathbf{v}) = \varphi_i(\mathbf{v} - \mathbf{c}_0)$. Then for every $\mathbf{v} \in V$,

$$\mathbf{v} = \Big(1 - \sum_{i=1}^{n} \mu_i(\mathbf{v})\Big)\mathbf{c}_0 + \sum_{i=1}^{n} \mu_i(\mathbf{v})\, \mathbf{y}_i,$$

and when $\mu_i(\mathbf{v}) \geq 0$ for every i and $\sum_i \mu_i(\mathbf{v}) \leq 1$, this is a convex combination of points of C, hence a point of C: by Theorem 17.1.3 it lies in $\operatorname{conv} C$, and $\operatorname{conv} C = C$ by Definition 17.1.4, since C is itself a convex set containing C.

Let $\mathbf{z} = \mathbf{c}_0 + \frac{1}{n+1}\sum_i (\mathbf{y}_i - \mathbf{c}_0)$, so that $\mu_i(\mathbf{z}) = \frac{1}{n+1}$ for every i. Each $\mathbf{w}_i \neq \mathbf{0}$, because $\varphi_i(\mathbf{y}_i - \mathbf{c}_0) = 1$; put $L = \max_i \|\mathbf{w}_i\| > 0$ and $r = 1/\big(n(n+1)L\big)$. If $\|\mathbf{v} - \mathbf{z}\| < r$, then by Theorem 10.1.5

$$|\mu_i(\mathbf{v}) - \mu_i(\mathbf{z})| = |\langle \mathbf{v} - \mathbf{z}, \mathbf{w}_i \rangle| \leq L\|\mathbf{v} - \mathbf{z}\| < \frac{1}{n(n+1)},$$

so $\mu_i(\mathbf{v}) > \frac{1}{n+1} - \frac{1}{n(n+1)} \geq 0$ and $\sum_i \mu_i(\mathbf{v}) < \frac{n}{n+1} + \frac{1}{n+1} = 1$. Hence $\mathbf{v} \in C$, and $\mathbf{z}$ is an interior point of C.

■

The second ingredient says that from an interior point one can see the whole closure.

Lemma 17.3.5 — Closure and Interior of a Convex Set

Let $C \subseteq V$ be convex.

(a) $\overline{C}$ is closed and convex.

(b) If $\mathbf{z} \in \operatorname{int}(C)$, $\mathbf{w} \in \overline{C}$ and $0 < t \leq 1$, then $(1-t)\mathbf{w} + t\mathbf{z} \in \operatorname{int}(C)$.

Idea. Part (a) pushes limits through: a limit of limits is a limit, and a convex combination of limits is the limit of convex combinations. For (b), picture a small ball around $\mathbf{z}$ inside C, and the cone from $\mathbf{w}$ over it. The cone contains a smaller ball around $(1-t)\mathbf{w} + t\mathbf{z}$; since $\mathbf{w}$ is only a limit, replace it by a nearby point $\mathbf{w}'$ of C, which shrinks the ball by half.

Proof.

(a) Let $\mathbf{x}_k \in \overline{C}$ with $\mathbf{x}_k \to \mathbf{x}$. Each $\mathbf{x}_k$ is a limit of points of C, so there is $\mathbf{c}_k \in C$ with $\|\mathbf{c}_k - \mathbf{x}_k\| < 1/k$. Then $\|\mathbf{c}_k - \mathbf{x}\| \leq 1/k + \|\mathbf{x}_k - \mathbf{x}\| \to 0$, so $\mathbf{x} \in \overline{C}$. For convexity, let $\mathbf{x} = \lim \mathbf{c}_k$ and $\mathbf{y} = \lim \mathbf{d}_k$ with $\mathbf{c}_k, \mathbf{d}_k \in C$, and $0 \leq s \leq 1$. The points $s\mathbf{c}_k + (1-s)\mathbf{d}_k$ lie in C and converge to $s\mathbf{x} + (1-s)\mathbf{y}$, by Corollary 10.1.6, so that point lies in $\overline{C}$.

(b) Take $\rho > 0$ with every point within distance ρ of $\mathbf{z}$ in C, and put $\mathbf{p} = (1-t)\mathbf{w} + t\mathbf{z}$. If $t = 1$ then $\mathbf{p} = \mathbf{z}$ and there is nothing to prove, so let $t < 1$. Choose $\mathbf{w}' \in C$ with $(1-t)\|\mathbf{w} - \mathbf{w}'\| < t\rho/2$, possible because $\mathbf{w}$ is a limit of points of C. Let $\|\mathbf{q} - \mathbf{p}\| < t\rho/2$, and put $\mathbf{z}' = \big(\mathbf{q} - (1-t)\mathbf{w}'\big)/t$, so that $\mathbf{q} = (1-t)\mathbf{w}' + t\mathbf{z}'$. Since $\mathbf{p} = (1-t)\mathbf{w} + t\mathbf{z}$,

$$\mathbf{z}' - \mathbf{z} = \frac{(\mathbf{q} - \mathbf{p}) + (1-t)(\mathbf{w} - \mathbf{w}')}{t}, \qquad \|\mathbf{z}' - \mathbf{z}\| < \frac{t\rho/2 + t\rho/2}{t} = \rho.$$

Hence $\mathbf{z}' \in C$, and $\mathbf{q} \in C$ by Definition 17.1.1. So every point within $t\rho/2$ of $\mathbf{p}$ lies in C, and $\mathbf{p} \in \operatorname{int}(C)$.

■

Now the theorem. It asks only that $\mathbf{x}_0$ not be an interior point, which covers the boundary points of C and also the points outside $\overline{C}$.

Theorem 17.3.6 — Supporting Hyperplane Theorem

Let $V \neq \{\mathbf{0}\}$, let $C \subseteq V$ be convex, and let $\mathbf{x}_0 \in V$ be a point that is **not** an interior point of C. Then there is a **non-zero** $\mathbf{a} \in V$ with

$$\langle \mathbf{a}, \mathbf{y} \rangle \leq \langle \mathbf{a}, \mathbf{x}_0 \rangle \qquad \text{for every } \mathbf{y} \in C.$$

If moreover $\mathbf{x}_0 \in C$, the affine hyperplane $\{\mathbf{y} : \langle \mathbf{a}, \mathbf{y} \rangle = \langle \mathbf{a}, \mathbf{x}_0 \rangle\}$ passes through $\mathbf{x}_0$ and has C in one of its closed half-spaces; it is called a **supporting hyperplane** of C at $\mathbf{x}_0$.

Idea. Approach $\mathbf{x}_0$ from outside $\overline{C}$ and cut off each approximating point with Theorem 17.3.2. The normal vectors, scaled to length 1, live on the compact unit sphere, so a subsequence converges, and in the limit the strict inequalities become the non-strict one we want. The only thing that could go wrong is that there are no points outside $\overline{C}$ near $\mathbf{x}_0$. Lemma 17.3.4 and Lemma 17.3.5 rule that out: if C is flat, its own hyperplane serves; if C is solid, pushing $\mathbf{x}_0$ directly away from an interior point leaves $\overline{C}$ at once.

Proof. If $C = \emptyset$, any non-zero $\mathbf{a}$ works, and one exists because $V \neq \{\mathbf{0}\}$. So let $C \neq \emptyset$.

Case 1: C has no interior point. By Lemma 17.3.4 there are $\mathbf{a} \neq \mathbf{0}$ and c with $\langle \mathbf{a}, \mathbf{y} \rangle = c$ for all $\mathbf{y} \in C$. If $\langle \mathbf{a}, \mathbf{x}_0 \rangle \geq c$, then $\mathbf{a}$ works. Otherwise $-\mathbf{a}$ works, since $\langle -\mathbf{a}, \mathbf{y} \rangle = -c < -\langle \mathbf{a}, \mathbf{x}_0 \rangle$.

Case 2: C has an interior point $\mathbf{z}$. For $k \geq 1$ let $\mathbf{x}_k = \mathbf{x}_0 + \frac{1}{k}(\mathbf{x}_0 - \mathbf{z})$. We claim $\mathbf{x}_k \notin \overline{C}$. Indeed, with $t = \frac{1}{k+1}$,

$$(1-t)\mathbf{x}_k + t\mathbf{z} = \tfrac{k}{k+1}\mathbf{x}_0 + \tfrac{1}{k+1}(\mathbf{x}_0 - \mathbf{z}) + \tfrac{1}{k+1}\mathbf{z} = \mathbf{x}_0,$$

so if $\mathbf{x}_k$ were in $\overline{C}$, then $\mathbf{x}_0$ would be an interior point of C by Lemma 17.3.5 (b), contrary to the hypothesis. By Lemma 17.3.5 (a), $\overline{C}$ is non-empty, closed and convex, so Theorem 17.3.2, applied to $\overline{C}$ and $\mathbf{x}_k$, gives $\mathbf{b}_k \neq \mathbf{0}$ with $\langle \mathbf{b}_k, \mathbf{y} \rangle \leq \langle \mathbf{b}_k, \mathbf{x}_k \rangle$ for all $\mathbf{y} \in \overline{C}$, in particular for all $\mathbf{y} \in C$. Put $\mathbf{a}_k = \mathbf{b}_k / \|\mathbf{b}_k\|$, a unit vector satisfying the same inequality.

The unit sphere of V is compact by Corollary 15.2.5, which rests on **fact (A3) of Chapter 15's introduction**. So a subsequence $(\mathbf{a}_{k_j})$ converges to some $\mathbf{a}$ with $\|\mathbf{a}\| = 1$; in particular $\mathbf{a} \neq \mathbf{0}$. Fix $\mathbf{y} \in C$. Then $\langle \mathbf{a}_{k_j}, \mathbf{y} - \mathbf{x}_{k_j} \rangle \leq 0$ for every j, and $\mathbf{x}_k \to \mathbf{x}_0$ because $\|\mathbf{x}_k - \mathbf{x}_0\| = \|\mathbf{x}_0 - \mathbf{z}\|/k$. By Theorem 10.1.5,

$$\begin{aligned} \big|\langle \mathbf{a}_{k_j}, \mathbf{y} - \mathbf{x}_{k_j} \rangle - \langle \mathbf{a}, \mathbf{y} - \mathbf{x}_0 \rangle\big| &\leq \big|\langle \mathbf{a}_{k_j} - \mathbf{a}, \mathbf{y} - \mathbf{x}_{k_j} \rangle\big| + \big|\langle \mathbf{a}, \mathbf{x}_0 - \mathbf{x}_{k_j} \rangle\big| \\ &\leq \|\mathbf{a}_{k_j} - \mathbf{a}\|\big(\|\mathbf{y} - \mathbf{x}_0\| + \|\mathbf{x}_0 - \mathbf{z}\|\big) + \|\mathbf{x}_0 - \mathbf{x}_{k_j}\|, \end{aligned}$$

which tends to 0. A non-strict inequality survives the limit, so $\langle \mathbf{a}, \mathbf{y} - \mathbf{x}_0 \rangle \leq 0$. This proves the theorem.

■

A supporting hyperplane need not be unique. At the corner $(1, 1)$ of the square $[-1, 1]^2$, every $\mathbf{a} = (a_1, a_2)$ with $a_1, a_2 \geq 0$, not both zero, works, since $a_1 y_1 + a_2 y_2 \leq a_1 + a_2$ on the square. At a point of the unit circle, the boundary of the disc, only the positive multiples of the point itself work. Corners admit many supporting hyperplanes and smooth points one; §08 builds its induction on dimension on these hyperplanes, and §04 uses them to prove that a norm is recovered from its dual.

17.3.5 Separating two convex sets

To separate two sets, separate one point from one set: the point $\mathbf{0}$ from the set of differences.

Theorem 17.3.7 — Separating Hyperplane Theorem

Let $C_1, C_2 \subseteq V$ be **non-empty, disjoint** and convex.

(a) If C_1 is **compact** and C_2 is **closed**, then C_1 and C_2 are strictly separated: there are $\mathbf{a} \neq \mathbf{0}$ and c with $\langle \mathbf{a}, \mathbf{x} \rangle < c < \langle \mathbf{a}, \mathbf{y} \rangle$ for all $\mathbf{x} \in C_1$, $\mathbf{y} \in C_2$, and indeed with a margin $\varepsilon > 0$ as in Definition 17.3.1.

(b) In general, C_1 and C_2 are separated: there are $\mathbf{a} \neq \mathbf{0}$ and c with $\langle \mathbf{a}, \mathbf{x} \rangle \leq c \leq \langle \mathbf{a}, \mathbf{y} \rangle$ for all $\mathbf{x} \in C_1$, $\mathbf{y} \in C_2$.

Idea. The difference set $D = \{\mathbf{y} - \mathbf{x} : \mathbf{x} \in C_1, \mathbf{y} \in C_2\}$ is convex and misses $\mathbf{0}$, and a normal $\mathbf{a}$ with D on its positive side separates C_1 from C_2. For (a), compactness of C_1 makes D closed, and Theorem 17.3.2 cuts $\mathbf{0}$ off; for (b), $\mathbf{0}$ is not an interior point of D, and Theorem 17.3.6 applies.

Proof. Let $D = \{\mathbf{y} - \mathbf{x} : \mathbf{x} \in C_1, \mathbf{y} \in C_2\}$. It is convex: for $0 \leq t \leq 1$,

$$t(\mathbf{y} - \mathbf{x}) + (1 - t)(\mathbf{y}' - \mathbf{x}') = \big(t\mathbf{y} + (1 - t)\mathbf{y}'\big) - \big(t\mathbf{x} + (1 - t)\mathbf{x}'\big),$$

a difference of a point of C_2 and a point of C_1. And $\mathbf{0} \notin D$, since $C_1 \cap C_2 = \emptyset$.

(a) We show D is closed. Let $\mathbf{y}_k - \mathbf{x}_k \to \mathbf{d}$ with $\mathbf{x}_k \in C_1$, $\mathbf{y}_k \in C_2$. Since C_1 is compact, a subsequence $\mathbf{x}_{k_j}$ converges to some $\mathbf{x} \in C_1$. Then $\mathbf{y}_{k_j} = (\mathbf{y}_{k_j} - \mathbf{x}_{k_j}) + \mathbf{x}_{k_j} \to \mathbf{d} + \mathbf{x}$, since a subsequence of a convergent sequence has the same limit, part of the elementary algebra of limits that Chapter 15's introduction imports; so $\mathbf{d} + \mathbf{x} \in C_2$ because C_2 is closed, and $\mathbf{d} = (\mathbf{d} + \mathbf{x}) - \mathbf{x} \in D$. Now Theorem 17.3.2, applied to D and the point $\mathbf{0} \notin D$, gives $\mathbf{b} \neq \mathbf{0}$ with $\langle \mathbf{b}, \mathbf{d} \rangle \leq -\|\mathbf{b}\|^2$ for all $\mathbf{d} \in D$. With $\mathbf{a} = -\mathbf{b}$ this says

$$\langle \mathbf{a}, \mathbf{x} \rangle + \|\mathbf{a}\|^2 \leq \langle \mathbf{a}, \mathbf{y} \rangle \qquad \text{for all } \mathbf{x} \in C_1,\ \mathbf{y} \in C_2.$$

Fix $\mathbf{y} \in C_2$. The numbers $\langle \mathbf{a}, \mathbf{x} \rangle$, $\mathbf{x} \in C_1$, are bounded above by $\langle \mathbf{a}, \mathbf{y} \rangle - \|\mathbf{a}\|^2$, so by **the completeness of $\mathbb{R}$, fact (A1) of Chapter 15's introduction**, they have a least upper bound s, and $s + \|\mathbf{a}\|^2 \leq \langle \mathbf{a}, \mathbf{y} \rangle$ for every $\mathbf{y} \in C_2$. Take $\varepsilon = \frac{1}{2}\|\mathbf{a}\|^2$ and $c = s + \varepsilon$. Then $\langle \mathbf{a}, \mathbf{x} \rangle \leq s = c - \varepsilon$ and $\langle \mathbf{a}, \mathbf{y} \rangle \geq c + \varepsilon$.

(b) If $V = \{\mathbf{0}\}$, two non-empty subsets both contain $\mathbf{0}$ and cannot be disjoint, so $V \neq \{\mathbf{0}\}$. The point $\mathbf{0}$ is not in D, so it is not an interior point of D. By Theorem 17.3.6 there is $\mathbf{b} \neq \mathbf{0}$ with $\langle \mathbf{b}, \mathbf{d} \rangle \leq \langle \mathbf{b}, \mathbf{0} \rangle = 0$ for all $\mathbf{d} \in D$. With $\mathbf{a} = -\mathbf{b}$, this says $\langle \mathbf{a}, \mathbf{x} \rangle \leq \langle \mathbf{a}, \mathbf{y} \rangle$ for all $\mathbf{x} \in C_1$, $\mathbf{y} \in C_2$. As in (a), the least upper bound c of the numbers $\langle \mathbf{a}, \mathbf{x} \rangle$, $\mathbf{x} \in C_1$, exists by (A1) and satisfies $\langle \mathbf{a}, \mathbf{x} \rangle \leq c \leq \langle \mathbf{a}, \mathbf{y} \rangle$. This proves the theorem.

■

17.3.6 Where strict separation fails

Part (a) asked one of the two sets to be compact. That hypothesis cannot be weakened to "closed", and the standard witness is a hyperbola and its asymptote.

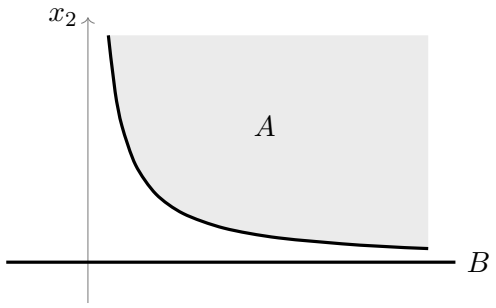
Example. (A hyperbola and its asymptote)

In $\mathbb{R}^2$ with the dot product, let

$$A = \{\mathbf{x} : x_1 > 0,\ x_2 > 0,\ x_1 x_2 \geq 1\}, \qquad B = \{\mathbf{x} : x_2 = 0\}.$$

Show that A and B are non-empty, disjoint, closed and convex, that the x_1-axis is the

only hyperplane separating them, and that they are **not** strictly separated.



A and B are closed, convex and disjoint,
but the gap between them shrinks to zero

Solution. Non-empty and disjoint. $(1,1) \in A$ and $\mathbf{0} \in B$; every point of A has $x_2 > 0$, and every point of B has $x_2 = 0$.

B is closed and convex. It is a subspace, so it is convex, and closed by Proposition 17.1.6 (c).

A is convex. Let $\mathbf{x}, \mathbf{z} \in A$ and $0 \le t \le 1$, and let $\mathbf{w} = t\mathbf{x} + (1-t)\mathbf{z}$. Its coordinates are positive. Expanding,

$$w_1 w_2 = t^2 x_1 x_2 + (1-t)^2 z_1 z_2 + t(1-t)(x_1 z_2 + x_2 z_1).$$

By $\left(\sqrt{x_1 z_2} - \sqrt{x_2 z_1}\right)^2 \ge 0$, we get $x_1 z_2 + x_2 z_1 \ge 2\sqrt{x_1 x_2 z_1 z_2} \ge 2$, using $x_1 x_2 \ge 1$ and $z_1 z_2 \ge 1$. Hence $w_1 w_2 \ge t^2 + (1-t)^2 + 2t(1-t) = 1$, and $\mathbf{w} \in A$.

A is closed. If $\mathbf{x}_k \to \mathbf{x}$ with $\mathbf{x}_k \in A$, then the coordinates converge, so $x_1, x_2 \ge 0$, and $x_{k,1} x_{k,2} \to x_1 x_2$ by the algebra of limits, so $x_1 x_2 \ge 1$. A product that is at least 1 has no zero factor, so $x_1, x_2 > 0$, and $\mathbf{x} \in A$.

The only separating hyperplane. Let $\mathbf{a} \neq \mathbf{0}$ and c separate A and B, in either order. On B, $\langle \mathbf{a}, (t,0) \rangle = a_1 t$ for all real t, and these values lie on one side of c; that forces $a_1 = 0$. So $a_2 \neq 0$, and after replacing $(\mathbf{a}, c)$ by $(-\mathbf{a}, -c)$ we may take $a_2 > 0$. On B the value is 0. On A the values are $a_2 x_2$, and since $(1/s, s) \in A$ for every $s > 0$, they fill the interval $(0, \infty)$. These are unbounded above, so A is on the side $\ge c$ and B on the side $\le c$: $0 \le c \le a_2 s$ for every $s > 0$, which forces $c = 0$. The hyperplane $\{a_2 x_2 = 0\}$ is the x_1-axis, and it separates, since $a_2 x_2 > 0$ on A and $= 0$ on B.

No strict separation. Strict separation would need the only separating hyperplane to miss both sets, and B **is** that hyperplane.

The points $(t, 1/t) \in A$ and $(t, 0) \in B$ are $1/t$ apart, and Exercise (C2: Strict separation and distance) shows that this vanishing distance is exactly what rules out strict separation.

Warning. **Disjoint closed convex sets need not be strictly separated.** The hyperbola region and its asymptote above are the example to remember: both closed, both convex, disjoint, and every hyperplane that separates them contains one of them. "Disjoint" gives only the weak separation of Theorem 17.3.7 (b). Strict separation needs more, such as compactness of one set in (a).

17.3.7 Extending linear functionals

Separation has an analytic twin. Instead of a set and a point, take a linear functional defined on a subspace and bounded there by a convex function; can it be extended to the whole space without breaking the bound? The bounds allowed are the following.

Definition 17.3.3 — Sublinear Functional

Let V be a real vector space. A function $p\colon V \to \mathbb{R}$ is **sublinear** if, for **all** $\mathbf{x}, \mathbf{y} \in V$ and **all** real $t \geq 0$,

$$p(\mathbf{x}+\mathbf{y}) \leq p(\mathbf{x}) + p(\mathbf{y}) \qquad \text{and} \qquad p(t\mathbf{x}) = t\,p(\mathbf{x}).$$

Every norm is sublinear: (N3) is the first condition, and (N2) with $t \geq 0$ the second. Every linear functional is sublinear, with equality in the first condition. So is $p(\mathbf{x}) = \max(x_1, x_2)$ on $\mathbb{R}^2$, which is neither a norm nor linear: $p(-\mathbf{e}_1) = 0$. Taking $t = 0$ gives $p(\mathbf{0}) = 0$. A non-example by minimal change is $p(\mathbf{x}) = \|\mathbf{x}\|^2$: the first condition fails at $\mathbf{x} = \mathbf{y} \neq \mathbf{0}$ (it would give $4\|\mathbf{x}\|^2 \leq 2\|\mathbf{x}\|^2$), and so does the second, since $p(t\mathbf{x}) = t^2 p(\mathbf{x})$.

It turns out that sublinearity is exactly what makes one-step extensions possible.

Theorem 17.3.8 — Hahn–Banach Theorem, Finite-Dimensional

Let V be a **finite-dimensional** real vector space, let p be a sublinear functional on V, let U be a subspace of V, and let $f \in U^*$ satisfy $f(\mathbf{u}) \leq p(\mathbf{u})$ for every $\mathbf{u} \in U$. Then there is $F \in V^*$ with

$$F(\mathbf{u}) = f(\mathbf{u}) \text{ for every } \mathbf{u} \in U \qquad \text{and} \qquad F(\mathbf{v}) \leq p(\mathbf{v}) \text{ for every } \mathbf{v} \in V.$$

Idea. Add one dimension at a time. On $U + \operatorname{span}(\mathbf{v})$, a linear extension is fixed by one number $c = F(\mathbf{v})$. The requirement $F \leq p$ at the vectors $\mathbf{u} + t\mathbf{v}$ with $t > 0$ gives upper bounds on c, and at those with $t < 0$ it gives lower bounds. Sublinearity of p, together with linearity of f, is exactly what makes every lower bound at most every upper bound, so some c fits. Then induct on $\dim V - \dim U$. No inner product is needed.

Proof. We induct on $k = \dim V - \dim U$. If $k = 0$, then $U = V$ and $F = f$ works.

Let $k \geq 1$ and assume the theorem whenever the difference of dimensions is $k-1$. Pick $\mathbf{v} \in V \setminus U$ and let $W = U + \operatorname{span}(\mathbf{v})$. Each $\mathbf{w} \in W$ can be written as $\mathbf{u} + t\mathbf{v}$ with $\mathbf{u} \in U$ and $t \in \mathbb{R}$, and only in one way: if $\mathbf{u} + t\mathbf{v} = \mathbf{u}' + t'\mathbf{v}$ with $t \neq t'$, then $\mathbf{v} = (\mathbf{u}' - \mathbf{u})/(t - t') \in U$, which is false; so $t = t'$ and $\mathbf{u} = \mathbf{u}'$. Appending $\mathbf{v}$ to a basis of U gives a basis of W by Lemma 1.5.3, so $\dim V - \dim W = k - 1$. For $c \in \mathbb{R}$, the formula $g(\mathbf{u} + t\mathbf{v}) = f(\mathbf{u}) + tc$ therefore defines a linear functional on W that extends f.

For $\mathbf{u}, \mathbf{u}' \in U$, linearity of f, the hypothesis, and sublinearity of p give

$$f(\mathbf{u}) + f(\mathbf{u}') = f(\mathbf{u}+\mathbf{u}') \leq p(\mathbf{u}+\mathbf{u}') \leq p(\mathbf{u}-\mathbf{v}) + p(\mathbf{u}'+\mathbf{v}),$$

that is, $f(\mathbf{u}) - p(\mathbf{u}-\mathbf{v}) \leq p(\mathbf{u}'+\mathbf{v}) - f(\mathbf{u}')$. So every number in $L = \{f(\mathbf{u}) - p(\mathbf{u}-\mathbf{v}) : \mathbf{u} \in U\}$ is at most every number in $R = \{p(\mathbf{u}'+\mathbf{v}) - f(\mathbf{u}') : \mathbf{u}' \in U\}$. By **fact (A1) of Chapter 15's introduction**, the non-empty set L, bounded above by any element

of R, has a least upper bound c, and $c \le r$ for every $r \in R$. With this c, we check $g(\mathbf{u}+t\mathbf{v}) \le p(\mathbf{u}+t\mathbf{v})$ in three cases.

- $t = 0$: this is the hypothesis $f(\mathbf{u}) \le p(\mathbf{u})$.
- $t > 0$: $c \le p(\mathbf{u}/t + \mathbf{v}) - f(\mathbf{u}/t)$, the element of R at $\mathbf{u}' = \mathbf{u}/t$. Multiply by t and use $p(t\,\cdot) = t\,p(\cdot)$: $tc \le p(\mathbf{u}+t\mathbf{v}) - f(\mathbf{u})$.
- $t = -s < 0$: $c \ge f(\mathbf{u}/s) - p(\mathbf{u}/s - \mathbf{v})$, since this is an element of L. Multiply by s: $sc \ge f(\mathbf{u}) - p(\mathbf{u} - s\mathbf{v})$, that is, $f(\mathbf{u}) - sc \le p(\mathbf{u}+t\mathbf{v})$.

So $g \le p$ on W. By the induction hypothesis applied to W and g, there is $F \in V^*$ extending g, hence f, with $F \le p$ on V. This proves the theorem.

■

Beyond finite dimension. The induction above stops after $\dim V - \dim U$ steps. In an infinite-dimensional space there is no last step, and the one-step extension has to be combined with Zorn's lemma (Theorem 1.8.1), exactly as Chapter 1 §08 combined "append one vector" with Zorn's lemma to prove Theorem 1.8.3. The resulting theorem, the Hahn–Banach theorem of functional analysis, is outside the scope of this book, and nothing here depends on it.

The special case that matters most is a norm.

Corollary 17.3.9 — Norm-Preserving Extension

Let V be a finite-dimensional real vector space with a norm $\|\cdot\|$, let U be a subspace, and let $f \in U^*$ satisfy $|f(\mathbf{u})| \le \|\mathbf{u}\|$ for every $\mathbf{u} \in U$. Then there is $F \in V^*$ extending f with $|F(\mathbf{v})| \le \|\mathbf{v}\|$ for every $\mathbf{v} \in V$.

Proof. A norm is sublinear, so Theorem 17.3.8 with $p = \|\cdot\|$ gives F extending f with $F(\mathbf{v}) \le \|\mathbf{v}\|$ for all $\mathbf{v}$. Applying this to $-\mathbf{v}$ gives $-F(\mathbf{v}) = F(-\mathbf{v}) \le \|-\mathbf{v}\| = \|\mathbf{v}\|$ by (N2). Hence $|F(\mathbf{v})| \le \|\mathbf{v}\|$.

■

In particular, for any $\mathbf{x} \neq \mathbf{0}$, taking $U = \operatorname{span}(\mathbf{x})$ and $f(t\mathbf{x}) = t\|\mathbf{x}\|$ produces a functional F with $F(\mathbf{x}) = \|\mathbf{x}\|$ and $|F| \le \|\cdot\|$ everywhere: a linear functional that "sees" the full length of $\mathbf{x}$ without ever exceeding the norm. §04 meets this functional again, as the vector at which a dual norm is attained.

Example. (Many extensions)

On $\mathbb{R}^2$ with $\|\cdot\|_\infty$, let $U = \operatorname{span}\big((1,1)\big)$ and $f\big(s(1,1)\big) = s$. Find every F as in Corollary 17.3.9, and compare with the interval produced by the proof of Theorem 17.3.8 for $\mathbf{v} = \mathbf{e}_1$.

Solution. First, $|f(s(1,1))| = |s| = \|s(1,1)\|_\infty$, so the hypothesis holds. An extension has $F(\mathbf{e}_1) = c$ for some c, and then $F(\mathbf{e}_2) = F\big((1,1)\big) - c = 1 - c$, so $F(\mathbf{x}) = cx_1 + (1-c)x_2$.

If $0 \le c \le 1$, then $|F(\mathbf{x})| \le c|x_1| + (1-c)|x_2| \le \|\mathbf{x}\|_\infty$. If $c > 1$, then $\mathbf{x} = (1,-1)$ gives $F(\mathbf{x}) = 2c - 1 > 1 = \|\mathbf{x}\|_\infty$. If $c < 0$, then $\mathbf{x} = (-1,1)$ gives $F(\mathbf{x}) = 1 - 2c > 1$. So the extensions are exactly $F(\mathbf{x}) = cx_1 + (1-c)x_2$ with $c \in [0,1]$: infinitely many.

In the proof, with $p = \|\cdot\|_\infty$, $\mathbf{u} = s(1,1)$ and $\mathbf{v} = \mathbf{e}_1$, the elements of L are $s - \max(|s-1|, |s|)$, which is 0 for $s \geq \frac{1}{2}$ and $2s - 1 < 0$ for $s < \frac{1}{2}$; so $\sup L = 0$. The elements of R are $\max(|s+1|, |s|) - s$, which is 1 for $s \geq -\frac{1}{2}$ and $-2s > 1$ for $s < -\frac{1}{2}$; so $\inf R = 1$. Every c between $\sup L$ and $\inf R$ works, and that is the interval $[0, 1]$ found directly. The proof picked its left end.

The corners of the square B_∞ are why the extension is not unique: U meets the unit sphere at the corner $(1, 1)$, and every supporting line of the square at that corner gives an extension.

17.3.8 Exercises

17.3.8.1 A. Check your understanding

Exercise A1.

(a) State the characterization Eq. 17.3.1 of the nearest point, and say what it becomes when C is a subspace.

(b) Which two facts of Chapter 15's introduction does the existence of $P_C(\mathbf{x})$ use, and to which set are they applied?

(c) Determine whether the following statement is correct, and justify your answer: every non-empty closed subset of $\mathbb{R}^2$ has a unique point nearest to $\mathbf{0}$.

(d) Determine whether the following statement is correct, and justify your answer: two disjoint non-empty closed convex subsets of $\mathbb{R}^2$ can always be strictly separated.

Solution.

(a) A point $\mathbf{p} \in C$ is $P_C(\mathbf{x})$ exactly when $\langle \mathbf{x} - \mathbf{p}, \mathbf{y} - \mathbf{p} \rangle \leq 0$ for every $\mathbf{y} \in C$ (Theorem 17.3.1 (b)). For a subspace U it becomes the equality $\langle \mathbf{x} - \mathbf{p}, \mathbf{u} \rangle = 0$ for every $\mathbf{u} \in U$, so $P_C(\mathbf{x}) = P_U \mathbf{x}$ and Theorem 10.3.5 is recovered.

(b) The compactness of closed bounded sets (A3), through Corollary 15.2.5, and the extreme value theorem (A4). They are applied to $K = \{\mathbf{y} \in C : \|\mathbf{x} - \mathbf{y}\| \leq R\}$, the part of C within the distance R of $\mathbf{x}$ attained at one chosen point of C, and to the function $\mathbf{y} \mapsto \|\mathbf{x} - \mathbf{y}\|$.

(c) Incorrect. The unit circle is closed and non-empty, and every one of its points is at distance 1 from $\mathbf{0}$. Uniqueness needs convexity.

(d) Incorrect. The region A above the hyperbola $x_1 x_2 = 1$ in the positive quadrant and its asymptote B, the x_1-axis, are disjoint, closed and convex, but the only hyperplane separating them is B itself (Example (A hyperbola and its asymptote)).

17.3.8.2 B. Practice

Exercise B1: Projection onto a half-plane.

In $\mathbb{R}^2$ with the dot product, let $C = \{\mathbf{y} : y_1 + y_2 \leq 1\}$ and $\mathbf{x} = (2, 3)$. Find $P_C(\mathbf{x})$ and $d(\mathbf{x}, C)$, and verify Eq. 17.3.1.

Solution. Here $\mathbf{a} = (1,1)$, $c = 1$, and $\langle \mathbf{a}, \mathbf{x} \rangle = 5 > 1$. By Example (Three projections) (c), $\lambda = (5-1)/2 = 2$ and $P_C(\mathbf{x}) = (2,3) - 2(1,1) = (0,1)$. Check: $0 + 1 = 1$, so $\mathbf{p} = (0,1) \in C$, and $\mathbf{x} - \mathbf{p} = (2,2)$, so $\langle \mathbf{x}-\mathbf{p}, \mathbf{y}-\mathbf{p} \rangle = 2y_1 + 2(y_2 - 1) = 2(y_1 + y_2 - 1) \le 0$ for $\mathbf{y} \in C$. By Theorem 17.3.1 (b) this is the nearest point, and $d(\mathbf{x}, C) = \|(2,2)\| = 2\sqrt{2}$.

Exercise B2: Cutting off a point from a diamond.

Let $C = B_1 = \{\mathbf{y} \in \mathbb{R}^2 : |y_1| + |y_2| \le 1\}$, with the dot product, and $\mathbf{x} = (2,2)$.

(a) Show that $P_C(\mathbf{x}) = (\frac{1}{2}, \frac{1}{2})$.

(b) Hence find the strictly separating hyperplane of Theorem 17.3.2, and check it directly.

(c) Find every supporting hyperplane of C at $(\frac{1}{2}, \frac{1}{2})$.

Solution.

(a) Let $\mathbf{p} = (\frac{1}{2}, \frac{1}{2})$, which lies in C. Then $\mathbf{x} - \mathbf{p} = (\frac{3}{2}, \frac{3}{2})$ and, for $\mathbf{y} \in C$,

$$\langle \mathbf{x} - \mathbf{p}, \mathbf{y} - \mathbf{p} \rangle = \tfrac{3}{2}(y_1 + y_2 - 1) \le 0,$$

because $y_1 + y_2 \le |y_1| + |y_2| \le 1$. By Theorem 17.3.1 (b), $P_C(\mathbf{x}) = \mathbf{p}$.

(b) With $\mathbf{a} = (\frac{3}{2}, \frac{3}{2})$, we have $\|\mathbf{a}\|^2 = \frac{9}{2}$ and $\langle \mathbf{a}, \mathbf{x} \rangle = 6$, so $c = 6 - \frac{9}{4} = \frac{15}{4}$. The hyperplane $\frac{3}{2}(y_1 + y_2) = \frac{15}{4}$ is the line $y_1 + y_2 = \frac{5}{2}$. Directly: on C, $y_1 + y_2 \le 1 < \frac{5}{2}$, while $x_1 + x_2 = 4 > \frac{5}{2}$.

(c) Let $\mathbf{a} \neq \mathbf{0}$ satisfy $\langle \mathbf{a}, \mathbf{y} \rangle \le \langle \mathbf{a}, \mathbf{p} \rangle = \frac{1}{2}(a_1 + a_2)$ for all $\mathbf{y} \in C$. Taking $\mathbf{y} = \mathbf{e}_1$ and $\mathbf{y} = \mathbf{e}_2$ gives $a_1 \le \frac{1}{2}(a_1 + a_2)$ and $a_2 \le \frac{1}{2}(a_1 + a_2)$, that is, $a_1 \le a_2$ and $a_2 \le a_1$; so $a_1 = a_2$. Taking $\mathbf{y} = -\mathbf{e}_1$ gives $-a_1 \le a_1$, so $a_1 \ge 0$, and $a_1 \neq 0$ since $\mathbf{a} \neq \mathbf{0}$. Conversely $\mathbf{a} = (a, a)$ with $a > 0$ works, by the inequality in (a). So the only supporting hyperplane at $\mathbf{p}$ is the line $y_1 + y_2 = 1$ through the edge containing $\mathbf{p}$.

Exercise B3: A unique extension.

On $\mathbb{R}^2$ with $\|\cdot\|_1$, let $U = \operatorname{span}\big((1,2)\big)$ and $f\big(t(1,2)\big) = 3t$. Show that f satisfies the hypothesis of Corollary 17.3.9, and find every extension F that the corollary allows.

Solution. $|f(t(1,2))| = 3|t| = |t| + 2|t| = \|t(1,2)\|_1$, so the hypothesis holds. Every $F \in (\mathbb{R}^2)^*$ is $F(\mathbf{x}) = c_1 x_1 + c_2 x_2$ (Theorem 4.1.1), and it extends f exactly when $F\big((1,2)\big) = 3$, that is, $c_1 + 2c_2 = 3$.

Next, $|F(\mathbf{x})| \le \|\mathbf{x}\|_1$ for all $\mathbf{x}$ holds exactly when $|c_1| \le 1$ and $|c_2| \le 1$. Indeed, if both hold then $|c_1 x_1 + c_2 x_2| \le |x_1| + |x_2|$; and if, say, $|c_1| > 1$, then $\mathbf{x} = \mathbf{e}_1$ gives $|F(\mathbf{e}_1)| > 1 = \|\mathbf{e}_1\|_1$.

So we need $c_1 = 3 - 2c_2$ with $|3 - 2c_2| \le 1$ and $|c_2| \le 1$. The first gives $1 \le c_2 \le 2$, the second $c_2 \le 1$; hence $c_2 = 1$ and $c_1 = 1$. The only extension is $F(\mathbf{x}) = x_1 + x_2$.

17.3.8.3 C. Going deeper

Exercise C1: The projection does not stretch.

Let $C \subseteq V$ be non-empty, closed and convex. Prove that $\|P_C(\mathbf{x}) - P_C(\mathbf{y})\| \le \|\mathbf{x} - \mathbf{y}\|$ for all $\mathbf{x}, \mathbf{y} \in V$.

Hint: write Eq. 17.3.1 once at $\mathbf{x}$, tested with the point $P_C(\mathbf{y})$, and once at $\mathbf{y}$, tested with $P_C(\mathbf{x})$, and add.

Solution. Put $\mathbf{p} = P_C(\mathbf{x})$ and $\mathbf{q} = P_C(\mathbf{y})$. By Theorem 17.3.1 (b), applied at $\mathbf{x}$ with the point $\mathbf{q} \in C$ and at $\mathbf{y}$ with the point $\mathbf{p} \in C$,

$$\langle \mathbf{x} - \mathbf{p}, \mathbf{q} - \mathbf{p} \rangle \le 0, \qquad \langle \mathbf{y} - \mathbf{q}, \mathbf{p} - \mathbf{q} \rangle \le 0.$$

The second is $\langle \mathbf{q} - \mathbf{y}, \mathbf{q} - \mathbf{p} \rangle \le 0$. Adding, $\langle (\mathbf{x} - \mathbf{y}) + (\mathbf{q} - \mathbf{p}), \mathbf{q} - \mathbf{p} \rangle \le 0$, that is,

$$\|\mathbf{q} - \mathbf{p}\|^2 \le \langle \mathbf{y} - \mathbf{x}, \mathbf{q} - \mathbf{p} \rangle \le \|\mathbf{y} - \mathbf{x}\| \, \|\mathbf{q} - \mathbf{p}\|$$

by Theorem 10.1.5. If $\mathbf{q} = \mathbf{p}$ there is nothing to prove; otherwise divide by $\|\mathbf{q} - \mathbf{p}\| > 0$. This proves $\|\mathbf{p} - \mathbf{q}\| \le \|\mathbf{x} - \mathbf{y}\|$.

Exercise C2: Strict separation and distance.

Let $C_1, C_2 \subseteq V$ be non-empty, closed and convex, and put $\delta = \inf\{\|\mathbf{y} - \mathbf{x}\| : \mathbf{x} \in C_1, \mathbf{y} \in C_2\}$.

(a) Prove that if C_1 and C_2 are strictly separated, then $\delta > 0$.

(b) Prove that if $\delta > 0$, then C_1 and C_2 are strictly separated.

(c) Hence deduce, without the computation of Example (A hyperbola and its asymptote), that the sets A and B there are not strictly separated.

Hint for (b): replace the difference set D of Theorem 17.3.7 by its closure.

Solution.

(a) Let $\mathbf{a} \neq \mathbf{0}$, c and $\varepsilon > 0$ strictly separate the sets, with C_1 on the side $\le c - \varepsilon$. For $\mathbf{x} \in C_1$ and $\mathbf{y} \in C_2$, Theorem 10.1.5 gives

$$2\varepsilon \le \langle \mathbf{a}, \mathbf{y} \rangle - \langle \mathbf{a}, \mathbf{x} \rangle = \langle \mathbf{a}, \mathbf{y} - \mathbf{x} \rangle \le \|\mathbf{a}\| \, \|\mathbf{y} - \mathbf{x}\|,$$

so $\|\mathbf{y} - \mathbf{x}\| \ge 2\varepsilon / \|\mathbf{a}\|$. Hence $\delta \ge 2\varepsilon / \|\mathbf{a}\| > 0$.

(b) Let $D = \{\mathbf{y} - \mathbf{x} : \mathbf{x} \in C_1, \mathbf{y} \in C_2\}$, which is convex by the computation in the proof of Theorem 17.3.7. Every $\mathbf{d} \in D$ has $\|\mathbf{d}\| \ge \delta$, and so does every point of $\overline{D}$: if $\mathbf{d}_k \to \mathbf{d}$ with $\mathbf{d}_k \in D$, then $\|\mathbf{d}\| \ge \|\mathbf{d}_k\| - \|\mathbf{d}_k - \mathbf{d}\| \ge \delta - \|\mathbf{d}_k - \mathbf{d}\|$ for every k, and the right side tends to δ. So $\mathbf{0} \notin \overline{D}$, and $\overline{D}$ is non-empty, closed and convex by Lemma 17.3.5 (a). By Theorem 17.3.2 there is $\mathbf{b} \neq \mathbf{0}$ with $\langle \mathbf{b}, \mathbf{d} \rangle \le -\|\mathbf{b}\|^2$ on $\overline{D} \supseteq D$. With $\mathbf{a} = -\mathbf{b}$, this is $\langle \mathbf{a}, \mathbf{x} \rangle + \|\mathbf{a}\|^2 \le \langle \mathbf{a}, \mathbf{y} \rangle$ for all $\mathbf{x} \in C_1$, $\mathbf{y} \in C_2$, and the last paragraph of the proof of Theorem 17.3.7 (a) turns it into strict separation with $\varepsilon = \frac{1}{2}\|\mathbf{a}\|^2$.

(c) The points $(t, 1/t) \in A$ and $(t, 0) \in B$ are at distance $1/t$, so $\delta \le 1/t$ for every $t > 0$, and $\delta = 0$. By (a), A and B are not strictly separated.

17.4 Gauges, Support Functions and Dual Norms

Chapter 15 §01 observed that the closed unit ball of every norm is convex and symmetric, and left the converse alone: does every convex, symmetric set arise as the unit ball of some norm? This section answers yes, by reading a norm off a convex set from the inside, the **gauge**. It then reads a function off a convex set from the outside, the **support function**, which turns §03's description of a closed convex set by half-spaces into a formula. Applied to a unit ball, the support function is the **dual norm**, the measurement Chapter 15 never gave to a linear functional, and the last part of the section proves that taking the dual twice returns the norm we started with.

Throughout, the field is $\mathbb{R}$, and we work in $\mathbb{R}^n$, $n \geq 1$, with the dot product $\langle \mathbf{x}, \mathbf{y} \rangle = \mathbf{x}^\top \mathbf{y}$ and its norm $\|\cdot\|_2$. So everything proved in §03 is available, with $V = \mathbb{R}^n$. A symbol $\|\cdot\|$ without a subscript is an **arbitrary** norm on $\mathbb{R}^n$ in the sense of Definition 15.1.1, and B is its closed unit ball (Definition 15.1.2). Interior points are meant in the sense of Definition 17.3.2, which does not depend on the norm. For a set K and a real t, we write $tK = \{t\mathbf{x} : \mathbf{x} \in K\}$.

17.4.1 Gauges

Every norm can be read off its unit ball. By (N2), for $t > 0$ we have $\|\mathbf{x}\| \leq t$ exactly when $\|\mathbf{x}/t\| \leq 1$, that is, when $\mathbf{x} \in tB$. Hence

$$\|\mathbf{x}\| = \inf\{t > 0 : \mathbf{x} \in tB\},$$

the inflation factor by which B has to be blown up before it reaches $\mathbf{x}$. The right-hand side makes sense for sets that are not unit balls, and this is the formula to study.

The gauge of a convex set measures a vector by how far the set must be inflated to reach it.

Definition 17.4.1 — Gauge

Let $K \subseteq \mathbb{R}^n$ be convex, with $\mathbf{0}$ an **interior point** of K. The **gauge** (or **Minkowski functional**) of K is the function $p_K \colon \mathbb{R}^n \to \mathbb{R}$ given by

$$p_K(\mathbf{x}) = \inf\{t > 0 : \mathbf{x} \in tK\}.$$

The infimum exists. Choose $r > 0$ with every $\mathbf{y}$ satisfying $\|\mathbf{y}\|_2 < r$ in K. If $t > \|\mathbf{x}\|_2/r$, then $\|\mathbf{x}/t\|_2 < r$, so $\mathbf{x}/t \in K$ and $\mathbf{x} \in tK$. So the set of admissible t is non-empty, and it is bounded below by 0; by **the completeness of $\mathbb{R}$, fact (A1) of Chapter 15's introduction**, it has a greatest lower bound, and

$$0 \leq p_K(\mathbf{x}) \leq \|\mathbf{x}\|_2/r \qquad \text{for every } \mathbf{x} \in \mathbb{R}^n.$$

The interior point is what makes p_K finite. For the segment $[-\mathbf{e}_1, \mathbf{e}_1] \subseteq \mathbb{R}^2$, which has no interior points, the vector $\mathbf{e}_2$ lies in no multiple tK, and the formula would give the infimum of the empty set.

Proposition 17.4.1 — Properties of the Gauge

Let $K \subseteq \mathbb{R}^n$ be convex with $\mathbf{0}$ an interior point, and let $\mathbf{x} \in \mathbb{R}^n$.

(a) $\mathbf{x} \in tK$ for **every** $t > p_K(\mathbf{x})$.
(b) p_K is sublinear (Definition 17.3.3).
(c) $\{\mathbf{x} : p_K(\mathbf{x}) < 1\} \subseteq K \subseteq \{\mathbf{x} : p_K(\mathbf{x}) \leq 1\}$.
(d) If K is closed, then $K = \{\mathbf{x} : p_K(\mathbf{x}) \leq 1\}$.

Idea. Everything comes from one observation, (a): since $\mathbf{0} \in K$ and K is convex, shrinking a point of K towards $\mathbf{0}$ keeps it in K, so the admissible t form a whole half-line. Subadditivity is then convexity applied to $\mathbf{x}/s$ and $\mathbf{y}/t$ with weights proportional to s and t.

Proof.

(a) Let $t > p_K(\mathbf{x})$. By the definition of an infimum there is s with $p_K(\mathbf{x}) \leq s < t$ and $\mathbf{x} \in sK$, so $\mathbf{x}/s \in K$. Since $\mathbf{0} \in K$ and K is convex,

$$\frac{\mathbf{x}}{t} = \frac{s}{t} \cdot \frac{\mathbf{x}}{s} + \Big(1 - \frac{s}{t}\Big)\mathbf{0} \in K,$$

that is, $\mathbf{x} \in tK$.

(b) Let $\lambda > 0$. Since $\lambda\mathbf{x} \in tK$ exactly when $\mathbf{x} \in (t/\lambda)K$, the admissible t for $\lambda\mathbf{x}$ are λ times those for $\mathbf{x}$, and $p_K(\lambda\mathbf{x}) = \lambda p_K(\mathbf{x})$. For $\lambda = 0$, $\mathbf{0} \in tK$ for every $t > 0$, so $p_K(\mathbf{0}) = 0$. For subadditivity, let $\varepsilon > 0$, $s = p_K(\mathbf{x}) + \varepsilon$ and $t = p_K(\mathbf{y}) + \varepsilon$. By (a), $\mathbf{x}/s$ and $\mathbf{y}/t$ lie in K, so by convexity

$$\frac{\mathbf{x}+\mathbf{y}}{s+t} = \frac{s}{s+t} \cdot \frac{\mathbf{x}}{s} + \frac{t}{s+t} \cdot \frac{\mathbf{y}}{t} \in K.$$

Hence $p_K(\mathbf{x}+\mathbf{y}) \leq s+t = p_K(\mathbf{x}) + p_K(\mathbf{y}) + 2\varepsilon$, for every $\varepsilon > 0$, and so $p_K(\mathbf{x}+\mathbf{y}) \leq p_K(\mathbf{x}) + p_K(\mathbf{y})$.

(c) If $p_K(\mathbf{x}) < 1$, then $\mathbf{x} \in 1 \cdot K$ by (a). If $\mathbf{x} \in K$, then $t = 1$ is admissible, so $p_K(\mathbf{x}) \leq 1$.

(d) Let $p_K(\mathbf{x}) \leq 1$. By (a), $\mathbf{x} \in (1 + 1/k)K$ for every $k \geq 1$, so the points $\mathbf{x}/(1+1/k)$ lie in K. They converge to $\mathbf{x}$, and K is closed, so $\mathbf{x} \in K$. With (c) this gives $K = \{p_K \leq 1\}$.

■

The gauge of a unit ball is its norm, by the computation that opened this section. A second example: for the rectangle $K = [-2, 2] \times [-1, 1] \subseteq \mathbb{R}^2$, a vector lies in tK exactly when $|x_1| \leq 2t$ and $|x_2| \leq t$, so

$$p_K(\mathbf{x}) = \max\big(\tfrac{1}{2}|x_1|,\ |x_2|\big),$$

a weighted ∞-norm of the kind in Example (Inner products, weights, and a function space) (b). At the degenerate extreme, $K = \mathbb{R}^n$ lies in every tK, and p_K is identically 0: sublinear, but no norm.

The next theorem says exactly when a gauge is a norm. Its part (b) records the facts about unit balls that make the match perfect.

Theorem 17.4.2 — Convex Bodies and Norms (a) Let $K \subseteq \mathbb{R}^n$ be **closed, bounded, convex** and **symmetric** ($-K = K$), with $\mathbf{0}$ an interior point. Then p_K is a norm on $\mathbb{R}^n$, and its closed unit ball is K.

(b) Conversely, the closed unit ball B of any norm $\|\cdot\|$ on $\mathbb{R}^n$ is closed, bounded, convex and symmetric, with $\mathbf{0}$ an interior point, and $p_B = \|\cdot\|$.

So the norms on $\mathbb{R}^n$ correspond one to one with the sets described in (a).

Idea. Sublinearity is two thirds of a norm, and Proposition 17.4.1 already has it. The missing third is absolute homogeneity for a scalar $c < 0$, which is what symmetry buys, and positive definiteness, which is what boundedness buys: a non-zero vector cannot fit inside every shrunken copy tK of a bounded set. Closedness makes the unit ball of p_K equal to K rather than squeezed between the two sets of Proposition 17.4.1 (c).

Proof.

(a) By Proposition 17.4.1 (b), p_K is sublinear, which gives (N3) and (N2) for $c \geq 0$. For $c < 0$, symmetry gives $\mathbf{x} \in tK$ if and only if $-\mathbf{x} \in t(-K) = tK$, so $p_K(-\mathbf{x}) = p_K(\mathbf{x})$ and $p_K(c\mathbf{x}) = |c|p_K(-\mathbf{x}) = |c|p_K(\mathbf{x})$. For (N1), $p_K \geq 0$ by definition. Let R be such that $\|\mathbf{y}\|_2 \leq R$ for all $\mathbf{y} \in K$. If $p_K(\mathbf{x}) = 0$, then $\mathbf{x} \in tK$ for every $t > 0$ by Proposition 17.4.1 (a), so $\|\mathbf{x}\|_2 \leq tR$ for every $t > 0$, and $\mathbf{x} = \mathbf{0}$. So p_K is a norm, and its closed unit ball $\{p_K \leq 1\}$ is K by Proposition 17.4.1 (d).

(b) Chapter 15 §01 showed, right after Definition 15.1.2, that B is convex and symmetric. By Theorem 15.2.2 there are constants $0 < m \leq M$ with $m\|\mathbf{x}\|_2 \leq \|\mathbf{x}\| \leq M\|\mathbf{x}\|_2$. If $\|\mathbf{x}\| \leq 1$, then $\|\mathbf{x}\|_2 \leq 1/m$, so B is bounded. If $\|\mathbf{x}\|_2 < 1/M$, then $\|\mathbf{x}\| < 1$, so $\mathbf{0}$ is an interior point. If $\mathbf{x}_k \in B$ and $\mathbf{x}_k \to \mathbf{x}$, then $|\|\mathbf{x}_k\| - \|\mathbf{x}\|| \leq \|\mathbf{x}_k - \mathbf{x}\| \leq M\|\mathbf{x}_k - \mathbf{x}\|_2 \to 0$ by Lemma 15.1.1, and $\|\mathbf{x}\| \leq 1$ because a non-strict inequality survives the limit; so B is closed. Finally, $\mathbf{x} \in tB$ exactly when $t \geq \|\mathbf{x}\|$, for $t > 0$, so $p_B(\mathbf{x}) = \|\mathbf{x}\|$ (for $\mathbf{x} = \mathbf{0}$, the infimum of all $t > 0$ is 0). This proves the theorem.

■

This is the converse of Chapter 15's "every unit ball is convex". There, a norm produced a convex symmetric set, the ball of Definition 15.1.2, and convexity was what the triangle inequality bought. Here a convex symmetric set produces a norm, and the triangle inequality is what convexity buys: the subadditivity step in Proposition 17.4.1 (b) is the convexity of K, used once. Norms and closed bounded symmetric convex sets with $\mathbf{0}$ inside are the same objects seen two ways, one analytic, one geometric.

Each hypothesis in (a) carries one clause of Definition 15.1.1, and dropping one breaks exactly that clause.

- **Drop symmetry.** The triangle $T = \{\mathbf{x} : x_1 \geq -1,\ x_2 \geq -1,\ x_1 + x_2 \leq 1\}$, with vertices $(-1,-1)$, $(2,-1)$, $(-1,2)$, is closed, bounded and convex, and contains the disc of radius $\frac{1}{2}$ about $\mathbf{0}$. A vector lies in tT exactly when $-x_1 \leq t$, $-x_2 \leq t$ and $x_1 + x_2 \leq t$, so

$$p_T(\mathbf{x}) = \max\big(-x_1,\ -x_2,\ x_1 + x_2\big),$$

  which is never negative, since the three numbers add up to 0. This is sublinear and satisfies (N1), but $p_T\big((1,1)\big) = 2$ while $p_T\big((-1,-1)\big) = 1$, so (N2) fails at $c = -1$.

- **Drop boundedness.** The strip $S = \{\mathbf{x} \in \mathbb{R}^2 : |x_2| \le 1\}$ is closed, convex and symmetric, and $p_S(\mathbf{x}) = |x_2|$. Now (N2) and (N3) hold but (N1) fails: $p_S(\mathbf{e}_1) = 0$. This is the seminorm of Example (Three near misses) (b).

> *Quick check.* Let K be the open unit disc $\{\mathbf{x} \in \mathbb{R}^2 : \|\mathbf{x}\|_2 < 1\}$, which is bounded, symmetric and convex (if $\|\mathbf{x}\|_2, \|\mathbf{y}\|_2 < 1$ and $0 \le t \le 1$, then $\|(1-t)\mathbf{x} + t\mathbf{y}\|_2 \le (1-t)\|\mathbf{x}\|_2 + t\|\mathbf{y}\|_2 < 1$) but not closed. What is p_K, and what is its closed unit ball?

> *Solution.* For $t > 0$, $\mathbf{x} \in tK$ exactly when $\|\mathbf{x}\|_2 < t$, so the admissible t form the interval $(\|\mathbf{x}\|_2, \infty)$ and $p_K(\mathbf{x}) = \|\mathbf{x}\|_2$. So p_K is a norm after all, but its closed unit ball is the closed disc, not K. Closedness is used only for the last claim of Theorem 17.4.2 (a), through Proposition 17.4.1 (d).

17.4.2 Support functions

§03 described a closed convex set from the outside: by Corollary 17.3.3 it is the intersection of the closed half-spaces containing it. For a fixed normal vector $\mathbf{y}$, the half-spaces $\{\mathbf{x} : \langle \mathbf{x}, \mathbf{y} \rangle \le c\}$ containing K are those with $c \ge \langle \mathbf{x}, \mathbf{y} \rangle$ for every $\mathbf{x} \in K$, and the tightest of them has $c = \sup_{\mathbf{x} \in K} \langle \mathbf{x}, \mathbf{y} \rangle$. That number, as a function of the direction $\mathbf{y}$, deserves a name.

The support function of a set records, for each direction, how far the set reaches in that direction.

Definition 17.4.2 — Support Function

Let $K \subseteq \mathbb{R}^n$ be **non-empty**. The **support function** of K is

$$h_K(\mathbf{y}) = \sup_{\mathbf{x} \in K} \langle \mathbf{x}, \mathbf{y} \rangle, \qquad \mathbf{y} \in \mathbb{R}^n,$$

with the value $+\infty$ when the numbers $\langle \mathbf{x}, \mathbf{y} \rangle$, $\mathbf{x} \in K$, are unbounded above.

When the numbers are bounded above, the supremum exists by (A1). If K is **bounded**, say $\|\mathbf{x}\|_2 \le R$ on K, then $\langle \mathbf{x}, \mathbf{y} \rangle \le R\|\mathbf{y}\|_2$ by Theorem 10.1.5, so h_K is real-valued. If K is **compact**, the supremum is a maximum by **the extreme value theorem, fact (A4) of Chapter 15's introduction**, since $\mathbf{x} \mapsto \langle \mathbf{x}, \mathbf{y} \rangle$ is continuous: $|\langle \mathbf{x}, \mathbf{y} \rangle - \langle \mathbf{x}', \mathbf{y} \rangle| \le \|\mathbf{x} - \mathbf{x}'\|_2 \|\mathbf{y}\|_2$. For a unit vector $\mathbf{y}$, the hyperplane $\{\langle \cdot, \mathbf{y} \rangle = h_K(\mathbf{y})\}$ is the one with normal $\mathbf{y}$ that touches K from outside, and $h_K(\mathbf{y})$ is its signed distance from $\mathbf{0}$.

Some examples, each computed from the definition.

- **A point.** $h_{\{\mathbf{x}_0\}}(\mathbf{y}) = \langle \mathbf{x}_0, \mathbf{y} \rangle$, a linear function.
- **The Euclidean ball.** $h_{B_2}(\mathbf{y}) = \|\mathbf{y}\|_2$: at most that by Theorem 10.1.5, and attained at $\mathbf{x} = \mathbf{y}/\|\mathbf{y}\|_2$ when $\mathbf{y} \ne \mathbf{0}$.
- **The standard simplex** $\operatorname{conv}\{\mathbf{e}_1, \dots, \mathbf{e}_n\}$. By Theorem 17.1.3 its points are $\sum_i t_i \mathbf{e}_i$ with $t_i \ge 0$ and $\sum_i t_i = 1$, and $\sum_i t_i y_i \le \max_i y_i$, with equality at a vertex $\mathbf{e}_k$ where y_k is largest. So $h(\mathbf{y}) = \max_i y_i$.
- **A segment.** $h_{[-\mathbf{e}_1, \mathbf{e}_1]}(\mathbf{y}) = |y_1|$ in $\mathbb{R}^2$.
- **An unbounded set.** For the half-line $\{t\mathbf{e}_1 : t \ge 0\}$, $h(\mathbf{y}) = 0$ if $y_1 \le 0$ and $h(\mathbf{y}) = +\infty$ if $y_1 > 0$.

Proposition 17.4.3 — Properties of the Support Function

Let $K, L \subseteq \mathbb{R}^n$ be non-empty and bounded.

(a) h_K is sublinear.
(b) If $K \subseteq L$, then $h_K \le h_L$.
(c) $h_{\operatorname{conv} K} = h_K$.

Idea. A supremum of linear functions of $\mathbf{y}$ inherits whatever inequalities each of them satisfies, which gives (a) and (b). For (c), a linear function takes on a convex combination a weighted average of its values, and an average never exceeds the largest value.

Proof.

(a) For $\mathbf{x} \in K$, $\langle \mathbf{x}, \mathbf{y}+\mathbf{z}\rangle = \langle \mathbf{x}, \mathbf{y}\rangle + \langle \mathbf{x}, \mathbf{z}\rangle \le h_K(\mathbf{y}) + h_K(\mathbf{z})$, and taking the supremum over $\mathbf{x}$ gives $h_K(\mathbf{y}+\mathbf{z}) \le h_K(\mathbf{y}) + h_K(\mathbf{z})$. For $t > 0$, $\langle \mathbf{x}, t\mathbf{y}\rangle = t\langle \mathbf{x}, \mathbf{y}\rangle$, and a positive factor comes out of a supremum; for $t = 0$ both sides are 0, as $K \neq \emptyset$.
(b) A supremum over a larger set is at least as large.
(c) Since $K \subseteq \operatorname{conv} K$, (b) gives $h_K \le h_{\operatorname{conv} K}$, once we know $\operatorname{conv} K$ is bounded: it lies in the ball $\{\|\mathbf{x}\|_2 \le R\}$, which is convex and contains K (Definition 17.1.4). Conversely, by Theorem 17.1.3 a point of $\operatorname{conv} K$ is $\mathbf{x} = \sum_i t_i \mathbf{x}_i$ with $\mathbf{x}_i \in K$, $t_i \ge 0$, $\sum_i t_i = 1$, and then

$$\langle \mathbf{x}, \mathbf{y}\rangle = \sum_i t_i \langle \mathbf{x}_i, \mathbf{y}\rangle \le \sum_i t_i \, h_K(\mathbf{y}) = h_K(\mathbf{y}).$$

So $h_{\operatorname{conv} K} \le h_K$.

■

Warning. **A support function cannot see gaps.** The two-point set $\{\mathbf{e}_1, -\mathbf{e}_1\}$ and the segment $[-\mathbf{e}_1, \mathbf{e}_1]$ in $\mathbb{R}^2$ have the same support function $|y_1|$, by Proposition 17.4.3 (c). So h_K does not determine K in general; it determines only the convex hull, and the next theorem shows that among closed convex sets it determines the set.

Here is the promised formula. It is Corollary 17.3.3 with the family of half-spaces indexed by their normals.

Theorem 17.4.4 — The Support Function Determines a Closed Convex Set

Let $K, L \subseteq \mathbb{R}^n$ be non-empty, closed and convex. Then

(a) $K = \{\mathbf{x} \in \mathbb{R}^n : \langle \mathbf{x}, \mathbf{y}\rangle \le h_K(\mathbf{y}) \text{ for every } \mathbf{y} \in \mathbb{R}^n\}$;
(b) $K \subseteq L$ if and only if $h_K(\mathbf{y}) \le h_L(\mathbf{y})$ for every $\mathbf{y}$; in particular $K = L$ if and only if $h_K = h_L$.

Here h_K and h_L may take the value $+\infty$, with $a \le +\infty$ for every a.

Idea. Part (a) is Corollary 17.3.3, with the half-space for the normal $\mathbf{y}$ chosen as tight as possible, at level $h_K(\mathbf{y})$. Part (b) then compares the two families of half-spaces normal by normal.

Proof.

(a) Every $\mathbf{x} \in K$ satisfies $\langle \mathbf{x}, \mathbf{y} \rangle \le h_K(\mathbf{y})$ by definition. Conversely let $\mathbf{x} \notin K$. By Theorem 17.3.2 there is $\mathbf{a} \neq \mathbf{0}$ with $\langle \mathbf{a}, \mathbf{z} \rangle \le \langle \mathbf{a}, \mathbf{x} \rangle - \|\mathbf{a}\|_2^2$ for all $\mathbf{z} \in K$. Hence $h_K(\mathbf{a}) \le \langle \mathbf{a}, \mathbf{x} \rangle - \|\mathbf{a}\|_2^2 < \langle \mathbf{x}, \mathbf{a} \rangle$, and $\mathbf{x}$ violates the condition at $\mathbf{y} = \mathbf{a}$.

(b) If $K \subseteq L$, then $h_K \le h_L$ because a supremum over a larger set is at least as large. Conversely, suppose $h_K \le h_L$ and let $\mathbf{x} \in K$. For every $\mathbf{y}$, $\langle \mathbf{x}, \mathbf{y} \rangle \le h_K(\mathbf{y}) \le h_L(\mathbf{y})$, so $\mathbf{x} \in L$ by (a) applied to L. The last statement follows by applying this in both directions.

■

17.4.3 Polar sets

The condition $h_K(\mathbf{y}) \le 1$ cuts out a set of directions, and that set turns out to be a mirror image of K.

Definition 17.4.3 — Polar Set

The **polar** of a set $K \subseteq \mathbb{R}^n$ is

$$K^\circ = \{\mathbf{y} \in \mathbb{R}^n : \langle \mathbf{x}, \mathbf{y} \rangle \le 1 \text{ for every } \mathbf{x} \in K\}.$$

For non-empty K, $K^\circ = \{\mathbf{y} : h_K(\mathbf{y}) \le 1\}$. The polar is always closed, convex and contains $\mathbf{0}$, being an intersection of closed half-spaces $\{\mathbf{y} : \langle \mathbf{x}, \mathbf{y} \rangle \le 1\}$, one for each $\mathbf{x} \in K$. Two examples:

- $(B_2)^\circ = B_2$, because $h_{B_2}(\mathbf{y}) = \|\mathbf{y}\|_2$.
- For the single point $K = \{\mathbf{e}_1\}$ in $\mathbb{R}^2$, $K^\circ = \{\mathbf{y} : y_1 \le 1\}$, a half-plane. Its polar consists of the $\mathbf{x}$ with $x_1 y_1 + x_2 y_2 \le 1$ whenever $y_1 \le 1$. Letting y_2 run over $\mathbb{R}$ forces $x_2 = 0$, letting $y_1 \to -\infty$ forces $x_1 \ge 0$, and $y_1 = 1$ forces $x_1 \le 1$. So $K^{\circ\circ}$ is the segment $[\mathbf{0}, \mathbf{e}_1]$, which is not K.

The second example shows what the theorem must assume.

Theorem 17.4.5 — Bipolar Theorem

Let $K \subseteq \mathbb{R}^n$ be closed and convex with $\mathbf{0} \in K$. Then $K^{\circ\circ} = K$.

Idea. One inclusion is the definition read twice. For the other, cut a point $\mathbf{x} \notin K$ off with Theorem 17.3.2, and rescale the normal so that K lies in $\{\langle \cdot, \mathbf{b} \rangle \le 1\}$ while $\mathbf{x}$ does not. That rescaled normal lies in K° and witnesses $\mathbf{x} \notin K^{\circ\circ}$; the rescaling needs $\mathbf{0} \in K$.

Proof. ($\supseteq$) Let $\mathbf{x} \in K$. For every $\mathbf{y} \in K^\circ$, $\langle \mathbf{x}, \mathbf{y} \rangle \leq 1$ by the definition of K°. Hence $\mathbf{x} \in K^{\circ\circ}$.

($\subseteq$) Let $\mathbf{x} \notin K$. By Theorem 17.3.2 there is $\mathbf{a} \neq \mathbf{0}$ with $\langle \mathbf{a}, \mathbf{z} \rangle \leq \langle \mathbf{a}, \mathbf{x} \rangle - \|\mathbf{a}\|_2^2$ for all $\mathbf{z} \in K$. Put $s = \sup_{\mathbf{z} \in K} \langle \mathbf{a}, \mathbf{z} \rangle$, which exists by (A1); since $\mathbf{0} \in K$, $s \geq 0$, and $s < \langle \mathbf{a}, \mathbf{x} \rangle$. If $s > 0$, let $\mathbf{b} = \mathbf{a}/s$. Then $\langle \mathbf{z}, \mathbf{b} \rangle \leq 1$ for all $\mathbf{z} \in K$, so $\mathbf{b} \in K^\circ$, while $\langle \mathbf{x}, \mathbf{b} \rangle > 1$. If $s = 0$, then $\langle \mathbf{a}, \mathbf{x} \rangle > 0$; let $\mathbf{b} = 2\mathbf{a}/\langle \mathbf{a}, \mathbf{x} \rangle$. Then $\langle \mathbf{z}, \mathbf{b} \rangle \leq 0 \leq 1$ on K, so $\mathbf{b} \in K^\circ$, while $\langle \mathbf{x}, \mathbf{b} \rangle = 2 > 1$. In both cases $\mathbf{x} \notin K^{\circ\circ}$.

■

The hypothesis $\mathbf{0} \in K$ was used to make $s \geq 0$, so that dividing by s keeps the direction of the inequality; the counterexample $\{\mathbf{e}_1\}$ above is exactly a closed convex set without it.

17.4.4 Dual norms

Chapter 15 measured vectors (Definition 15.1.1) and matrices (Definition 15.3.2). A third kind of object sits between them and was never measured: a linear functional on $\mathbb{R}^n$, which by Theorem 4.1.1 is $\mathbf{x} \mapsto \mathbf{y}^\top \mathbf{x} = \langle \mathbf{x}, \mathbf{y} \rangle$ for exactly one $\mathbf{y}$. How big is it?

When $\mathbf{x}$ is measured by $\|\cdot\|_2$, Theorem 10.1.5 answers: $|\langle \mathbf{x}, \mathbf{y} \rangle| \leq \|\mathbf{x}\|_2 \|\mathbf{y}\|_2$, and the constant $\|\mathbf{y}\|_2$ is the best possible. When $\mathbf{x}$ is measured by another norm, the question is the same — what is the smallest c with $|\langle \mathbf{x}, \mathbf{y} \rangle| \leq c\|\mathbf{x}\|$ for every $\mathbf{x}$? — and the answer is the largest value of $\langle \mathbf{x}, \mathbf{y} \rangle$ over the unit ball. That is the support function of B, and it is also the operator norm of the $1 \times n$ matrix $\mathbf{y}^\top$. An expression that turns up three ways deserves a name.

The dual norm of $\mathbf{y}$ *is the most that the functional* $\langle \cdot, \mathbf{y} \rangle$ *can extract from a vector of norm at most one.*

Definition 17.4.4 — Dual Norm

Let $\|\cdot\|$ be a norm on $\mathbb{R}^n$, with closed unit ball B. The **dual norm** of $\|\cdot\|$ is the function $\|\cdot\|_* \colon \mathbb{R}^n \to \mathbb{R}$ given by

$$\|\mathbf{y}\|_* = \max\{\langle \mathbf{x}, \mathbf{y} \rangle : \mathbf{x} \in \mathbb{R}^n,\ \|\mathbf{x}\| \leq 1\} = h_B(\mathbf{y}).$$

The maximum exists. By Theorem 17.4.2 (b), B is non-empty, closed and bounded, hence compact by Corollary 15.2.5, which rests on **fact (A3) of Chapter 15's introduction**; and $\mathbf{x} \mapsto \langle \mathbf{x}, \mathbf{y} \rangle$ is continuous, so by **the extreme value theorem, fact (A4)**, it attains its maximum on B.

In words: fix $\mathbf{y}$, let $\mathbf{x}$ range over the vectors that the **given** norm calls short, and record the largest value of $\langle \mathbf{x}, \mathbf{y} \rangle$. The inner product is part of the definition, and so is the norm; changing either changes $\|\cdot\|_*$. No absolute value is needed in the maximum: B is symmetric, so replacing $\mathbf{x}$ by $-\mathbf{x}$ shows that the largest value of $\langle \mathbf{x}, \mathbf{y} \rangle$ on B is also the largest value of $|\langle \mathbf{x}, \mathbf{y} \rangle|$.

Proposition 17.4.6 — Properties of the Dual Norm

Let $\|\cdot\|$ be a norm on $\mathbb{R}^n$, with closed unit ball B.

(a) $\|\cdot\|_*$ is a norm on $\mathbb{R}^n$.

(b) $|\langle \mathbf{x}, \mathbf{y}\rangle| \le \|\mathbf{x}\|\,\|\mathbf{y}\|_*$ for all $\mathbf{x}, \mathbf{y}$, and $\|\mathbf{y}\|_*$ is the smallest constant c with $|\langle \mathbf{x}, \mathbf{y}\rangle| \le c\|\mathbf{x}\|$ for every $\mathbf{x}$.

(c) $\|\mathbf{y}\|_*$ is the operator norm (Definition 15.3.2) of the $1 \times n$ matrix $\mathbf{y}^\top$, with $\|\cdot\|$ on $\mathbb{R}^n$ and $|\cdot|$ on $\mathbb{R}$.

(d) The closed unit ball of $\|\cdot\|_*$ is the polar B°.

Idea. Each norm axiom for $\|\cdot\|_*$ is checked one $\mathbf{x} \in B$ at a time and then survives the maximum; (N1) needs a good test vector, $\mathbf{y}$ itself rescaled into B. For (b), rescale any $\mathbf{x} \neq \mathbf{0}$ into B. Parts (c) and (d) only compare definitions.

Proof.

(a) (N1): $\mathbf{x} = \mathbf{0} \in B$ gives $\|\mathbf{y}\|_* \ge 0$. If $\mathbf{y} \neq \mathbf{0}$, then $\mathbf{x} = \mathbf{y}/\|\mathbf{y}\| \in B$ gives $\|\mathbf{y}\|_* \ge \|\mathbf{y}\|_2^2/\|\mathbf{y}\| > 0$. (N2): for $c \ge 0$, $\max_B \langle \mathbf{x}, c\mathbf{y}\rangle = c \max_B \langle \mathbf{x}, \mathbf{y}\rangle$; for $c < 0$, $\langle \mathbf{x}, c\mathbf{y}\rangle = |c|\langle -\mathbf{x}, \mathbf{y}\rangle$, and $-\mathbf{x}$ runs over B as $\mathbf{x}$ does, by (N2) for $\|\cdot\|$. (N3): for $\mathbf{x} \in B$, $\langle \mathbf{x}, \mathbf{y} + \mathbf{z}\rangle = \langle \mathbf{x}, \mathbf{y}\rangle + \langle \mathbf{x}, \mathbf{z}\rangle \le \|\mathbf{y}\|_* + \|\mathbf{z}\|_*$; take the maximum over $\mathbf{x}$.

(b) For $\mathbf{x} = \mathbf{0}$ there is nothing to prove. For $\mathbf{x} \neq \mathbf{0}$, $\mathbf{x}/\|\mathbf{x}\| \in B$, so $\pm\langle \mathbf{x}, \mathbf{y}\rangle/\|\mathbf{x}\| = \langle \pm\mathbf{x}/\|\mathbf{x}\|, \mathbf{y}\rangle \le \|\mathbf{y}\|_*$, using that B is symmetric. If c is any constant with $|\langle \mathbf{x}, \mathbf{y}\rangle| \le c\|\mathbf{x}\|$ for all $\mathbf{x}$, then $\langle \mathbf{x}, \mathbf{y}\rangle \le c$ on B, so $\|\mathbf{y}\|_* \le c$.

(c) By Definition 15.3.2 and the equivalent descriptions that follow it in Chapter 15 §03, the operator norm of $\mathbf{y}^\top$ is $\max\{|\mathbf{y}^\top \mathbf{x}| : \|\mathbf{x}\| \le 1\}$, which is $\|\mathbf{y}\|_*$ by the remark after Definition 17.4.4.

(d) $\|\mathbf{y}\|_* \le 1$ exactly when $\langle \mathbf{x}, \mathbf{y}\rangle \le 1$ for every $\mathbf{x} \in B$, which is the definition of $\mathbf{y} \in B^\circ$ (Definition 17.4.3).

■

Part (b) is Cauchy–Schwarz for an arbitrary norm, with the price that the two factors are measured differently. Now the three norms of Chapter 15.

Proposition 17.4.7 — Duals of the 1-, 2- and Infinity-Norms

On $\mathbb{R}^n$ with the dot product,

(a) the dual of $\|\cdot\|_1$ is $\|\cdot\|_\infty$;

(b) the dual of $\|\cdot\|_\infty$ is $\|\cdot\|_1$;

(c) the dual of $\|\cdot\|_2$ is $\|\cdot\|_2$.

Idea. Each part is an upper bound and a witness, the same pattern as Theorem 15.3.3. For the 1-norm, all of the budget $\|\mathbf{x}\|_1 \le 1$ goes on the coordinate where $|y_k|$ is largest. For the ∞-norm, every coordinate can be spent at once, each with the sign of y_i, so nothing cancels. For the 2-norm, the witness is $\mathbf{y}$ itself, rescaled.

Proof.

(a) For $\|\mathbf{x}\|_1 \le 1$, $\langle \mathbf{x}, \mathbf{y}\rangle \le \sum_i |x_i||y_i| \le \|\mathbf{y}\|_\infty \sum_i |x_i| \le \|\mathbf{y}\|_\infty$. Choose k with $|y_k| = \|\mathbf{y}\|_\infty$, and let $\mathbf{x} = \pm\mathbf{e}_k$ with the sign of y_k (either sign if $y_k = 0$). Then $\|\mathbf{x}\|_1 = 1$

and $\langle \mathbf{x}, \mathbf{y} \rangle = |y_k| = \|\mathbf{y}\|_\infty$.

(b) For $\|\mathbf{x}\|_\infty \le 1$, $\langle \mathbf{x}, \mathbf{y} \rangle \le \sum_i |x_i||y_i| \le \sum_i |y_i| = \|\mathbf{y}\|_1$. Let $x_i = 1$ if $y_i \ge 0$ and $x_i = -1$ if $y_i < 0$. Then $\|\mathbf{x}\|_\infty = 1$ and $\langle \mathbf{x}, \mathbf{y} \rangle = \sum_i |y_i| = \|\mathbf{y}\|_1$.

(c) For $\|\mathbf{x}\|_2 \le 1$, $\langle \mathbf{x}, \mathbf{y} \rangle \le \|\mathbf{x}\|_2 \|\mathbf{y}\|_2 \le \|\mathbf{y}\|_2$ by Theorem 10.1.5. For $\mathbf{y} \neq \mathbf{0}$, $\mathbf{x} = \mathbf{y}/\|\mathbf{y}\|_2$ gives equality; for $\mathbf{y} = \mathbf{0}$ both sides are 0.

■

So the 1- and ∞-norms are each other's duals, and the Euclidean norm is its own. In the language of polars, (a) and (b) say $(B_1)^\circ = B_\infty$ and $(B_\infty)^\circ = B_1$: the diamond and the square of Chapter 15's picture are polar to each other, and the disc is polar to itself. Part (b) of Proposition 17.4.6 now reads $|\langle \mathbf{x}, \mathbf{y} \rangle| \le \|\mathbf{x}\|_1 \|\mathbf{y}\|_\infty$, the simplest of a family of inequalities. The general member pairs $\|\cdot\|_p$ with $\|\cdot\|_q$, $\frac{1}{p} + \frac{1}{q} = 1$; it is **Hölder's inequality**, and §11 of this chapter proves it and deduces that the dual of $\|\cdot\|_p$ is $\|\cdot\|_q$ for every $1 < p < \infty$. The degenerate case $n = 1$ is worth one line: every norm on $\mathbb{R}$ is $\|x\| = a|x|$ with $a > 0$, its ball is $[-1/a, 1/a]$, and $\|y\|_* = |y|/a$.

A non-example by minimal change. Keep the formula $\max_K \langle \mathbf{x}, \mathbf{y} \rangle$, and replace the symmetric ball by the triangle $K = \operatorname{conv}\{(-1,-1), (2,-1), (-1,2)\}$, which is compact and convex and has $\mathbf{0}$ inside. By Proposition 17.4.3 (c), $h_K(\mathbf{y})$ is the largest of $-y_1 - y_2$, $2y_1 - y_2$ and $-y_1 + 2y_2$. It is sublinear by Proposition 17.4.3 (a), and positive at every $\mathbf{y} \neq \mathbf{0}$, since the three numbers add up to 0 and are not all zero. But $h_K(\mathbf{e}_1) = 2$ and $h_K(-\mathbf{e}_1) = 1$, so (N2) fails at $c = -1$. Symmetry of the ball is exactly what makes a dual norm a norm.

Why this definition, and not another? The measurement of a functional must be compatible with the measurement of its inputs, in the sense that $|\langle \mathbf{x}, \mathbf{y} \rangle| \le c\|\mathbf{x}\|$ for every $\mathbf{x}$, and Proposition 17.4.6 (b) says that $\|\mathbf{y}\|_*$ is the **smallest** compatible c. Any larger choice would be a bound, not a measurement. Abstractly, the dual norm lives on the dual space: for $\varphi \in (\mathbb{R}^n)^*$ one would put $\|\varphi\| = \max_{\|\mathbf{x}\| \le 1} \varphi(\mathbf{x})$, and the dot product is used only to name φ by a vector, through Theorem 4.1.1. That is why a different inner product on $\mathbb{R}^n$ gives a different formula for "the same" dual norm. The name is standard: the dual space carries the dual norm.

Warning. **A larger norm has a smaller dual.** If $\|\mathbf{x}\|_a \le \|\mathbf{x}\|_b$ for all $\mathbf{x}$, then the ball of $\|\cdot\|_b$ lies inside the ball of $\|\cdot\|_a$, and a maximum over a smaller set is smaller: $\|\mathbf{y}\|_{b*} \le \|\mathbf{y}\|_{a*}$. For instance $N(\mathbf{x}) = 2\|\mathbf{x}\|_2$ has ball of radius $\frac{1}{2}$ and dual $N_*(\mathbf{y}) = \frac{1}{2}\|\mathbf{y}\|_2$, not $2\|\mathbf{y}\|_2$. Scaling a norm up scales its dual down.

Chapter 15 measured vectors and matrices but never a linear functional; Definition 17.4.4 fills that gap, and Proposition 17.4.6 (c) shows it is exactly an operator norm of Chapter 15, the one for $1 \times n$ matrices. The one question it leaves open is whether the construction loses information.

17.4.5 The dual of the dual

Apply the construction twice. Since $\|\cdot\|_*$ is a norm, it has a dual $\|\cdot\|_{**}$, and the natural guess is that we are back where we started. For the three norms of Proposition 17.4.7 this is visible: $1 \to \infty \to 1$ and $2 \to 2 \to 2$. In general it is a theorem, and its proof is a supporting hyperplane.

Theorem 17.4.8 — The Dual of the Dual Norm

For every norm $\|\cdot\|$ on $\mathbb{R}^n$, $\|\cdot\|_{**} = \|\cdot\|$.

Idea. One inequality is Cauchy–Schwarz for dual norms. For the other, take $\mathbf{x}$ on the unit sphere of $\|\cdot\|$. It is on the edge of the ball B, so §03 provides a supporting hyperplane of B at $\mathbf{x}$. Its normal $\mathbf{a}$ is a direction in which B reaches no further than $\mathbf{x}$ does, so the maximum defining $\|\mathbf{a}\|_*$ is attained **at** $\mathbf{x}$; rescaling $\mathbf{a}$ produces a functional of dual norm 1 that takes the value 1 at $\mathbf{x}$.

Proof. Let $\mathbf{x} \in \mathbb{R}^n$. For every $\mathbf{y}$ with $\|\mathbf{y}\|_* \le 1$, Proposition 17.4.6 (b) gives $\langle \mathbf{x}, \mathbf{y} \rangle \le \|\mathbf{x}\|\|\mathbf{y}\|_* \le \|\mathbf{x}\|$. By Definition 17.4.4 applied to $\|\cdot\|_*$, whose unit ball is $\{\mathbf{y} : \|\mathbf{y}\|_* \le 1\}$, this says $\|\mathbf{x}\|_{**} \le \|\mathbf{x}\|$.

For the reverse inequality, both sides vanish at $\mathbf{x} = \mathbf{0}$, and both are absolutely homogeneous, so it suffices to take $\|\mathbf{x}\| = 1$. Then $\mathbf{x} \in B$, but $\mathbf{x}$ is not an interior point of B: the vectors $(1 + 1/k)\mathbf{x}$ have norm $1 + 1/k > 1$ and $\|(1 + 1/k)\mathbf{x} - \mathbf{x}\|_2 = \|\mathbf{x}\|_2/k \to 0$. By Theorem 17.3.6, applied to the convex set B and the point $\mathbf{x}$, there is $\mathbf{a} \neq \mathbf{0}$ with $\langle \mathbf{z}, \mathbf{a} \rangle \le \langle \mathbf{x}, \mathbf{a} \rangle$ for every $\mathbf{z} \in B$. Since $\mathbf{x} \in B$, the maximum in Definition 17.4.4 is attained at $\mathbf{x}$:

$$\|\mathbf{a}\|_* = \max_{\mathbf{z} \in B} \langle \mathbf{z}, \mathbf{a} \rangle = \langle \mathbf{x}, \mathbf{a} \rangle.$$

By Proposition 17.4.6 (a), $\|\mathbf{a}\|_* > 0$. Let $\mathbf{y} = \mathbf{a}/\|\mathbf{a}\|_*$. Then $\|\mathbf{y}\|_* = 1$ and $\langle \mathbf{x}, \mathbf{y} \rangle = 1$. Hence $\|\mathbf{x}\|_{**} \ge 1 = \|\mathbf{x}\|$. This proves the theorem.

■

Alternatively, the vector $\mathbf{y}$ can be obtained from Hahn–Banach. Corollary 17.3.9, applied to $U = \operatorname{span}(\mathbf{x})$ and $f(t\mathbf{x}) = t\|\mathbf{x}\|$, gives a functional F with $F(\mathbf{x}) = \|\mathbf{x}\|$ and $|F| \le \|\cdot\|$; writing $F = \langle \cdot, \mathbf{y} \rangle$ by Theorem 4.1.1, the second property says $\|\mathbf{y}\|_* \le 1$ by Proposition 17.4.6 (b), so $\|\mathbf{x}\|_{**} \ge \langle \mathbf{x}, \mathbf{y} \rangle = \|\mathbf{x}\|$. So the analytic and the geometric forms of §03 each prove the theorem, which is one more sign that they are the same fact.

Read with the definition of $\|\cdot\|_{**}$ unwound, the theorem is a formula for the original norm.

Corollary 17.4.9 — A Norm Is a Maximum of Linear Functions

For every norm $\|\cdot\|$ on $\mathbb{R}^n$ and every $\mathbf{x} \in \mathbb{R}^n$,

$$\|\mathbf{x}\| = \max\{\langle \mathbf{x}, \mathbf{y} \rangle : \|\mathbf{y}\|_* \le 1\},$$

and when $\mathbf{x} \neq \mathbf{0}$ the maximum is attained at some $\mathbf{y}$ with $\|\mathbf{y}\|_* = 1$.

Proof. The right-hand side is $\|\mathbf{x}\|_{**}$ by Definition 17.4.4 applied to $\|\cdot\|_*$, and it equals $\|\mathbf{x}\|$ by Theorem 17.4.8. For $\mathbf{x} \neq \mathbf{0}$, the proof of Theorem 17.4.8, applied to $\mathbf{x}/\|\mathbf{x}\|$, produced $\mathbf{y}$ with $\|\mathbf{y}\|_* = 1$ and $\langle \mathbf{x}/\|\mathbf{x}\|, \mathbf{y} \rangle = 1$, so $\langle \mathbf{x}, \mathbf{y} \rangle = \|\mathbf{x}\|$.

■

So every norm is the support function of the unit ball of its dual, $\|\cdot\| = h_{\{\mathbf{y} : \|\mathbf{y}\|_* \le 1\}}$: a maximum of the linear functions $\mathbf{x} \mapsto \langle \mathbf{x}, \mathbf{y} \rangle$, one for each $\mathbf{y}$ in a compact set. §10 of this chapter shows that a pointwise maximum of linear functions is always convex, and norms (their convexity was already the triangle inequality) are among its first examples.

Quick check. For $\mathbf{x} = (3, -4)$, find a $\mathbf{y}$ with $\|\mathbf{y}\|_\infty = 1$ and $\langle \mathbf{x}, \mathbf{y} \rangle = \|\mathbf{x}\|_1$, and a $\mathbf{y}$ with $\|\mathbf{y}\|_1 = 1$ and $\langle \mathbf{x}, \mathbf{y} \rangle = \|\mathbf{x}\|_\infty$.

Solution. The dual of $\|\cdot\|_1$ is $\|\cdot\|_\infty$ (Proposition 17.4.7 (a)), so the first $\mathbf{y}$ is a sign vector: $\mathbf{y} = (1, -1)$ gives $3 + 4 = 7 = \|\mathbf{x}\|_1$. The dual of $\|\cdot\|_\infty$ is $\|\cdot\|_1$, so the second $\mathbf{y}$ puts all its weight on the largest coordinate: $\mathbf{y} = (0, -1)$ gives $4 = \|\mathbf{x}\|_\infty$. Each is the witness from the proof of Proposition 17.4.7, with the roles of $\mathbf{x}$ and $\mathbf{y}$ exchanged.

17.4.6 Operator norms as maxima of bilinear values

The corollary also rewrites Chapter 15's operator norm. Fix a norm $\|\cdot\|_\alpha$ on $\mathbb{R}^n$ and a norm $\|\cdot\|_\beta$ on $\mathbb{R}^m$, and write $\|\mathbf{A}\|_{\alpha\to\beta}$ for the operator norm of $\mathbf{A} \in M_{m\times n}(\mathbb{R})$ that they induce (Definition 15.3.2). By the equivalent descriptions after that definition, $\|\mathbf{A}\|_{\alpha\to\beta} = \max\{\|\mathbf{A}\mathbf{x}\|_\beta : \|\mathbf{x}\|_\alpha \le 1\}$.

Proposition 17.4.10 — Operator Norms through Dual Norms

Let $\mathbf{A} \in M_{m\times n}(\mathbb{R})$, and let $\|\cdot\|_\alpha$, $\|\cdot\|_\beta$ be norms on $\mathbb{R}^n$ and $\mathbb{R}^m$, with duals $\|\cdot\|_{\alpha*}$ and $\|\cdot\|_{\beta*}$. Then

(a) $\|\mathbf{A}\|_{\alpha\to\beta} = \max\{\mathbf{y}^\top \mathbf{A}\mathbf{x} : \|\mathbf{x}\|_\alpha \le 1,\ \|\mathbf{y}\|_{\beta*} \le 1\}$;
(b) $\|\mathbf{A}^\top\|_{\beta*\to\alpha*} = \|\mathbf{A}\|_{\alpha\to\beta}$.

Idea. Write the outer norm $\|\mathbf{A}\mathbf{x}\|_\beta$ as a maximum over its dual ball by Corollary 17.4.9, and the operator norm becomes one maximum over pairs $(\mathbf{x}, \mathbf{y})$. Since $\mathbf{y}^\top \mathbf{A}\mathbf{x} = \mathbf{x}^\top \mathbf{A}^\top \mathbf{y}$, the same double maximum, taken with $\mathbf{x}$ innermost, is the operator norm of $\mathbf{A}^\top$, which gives (b).

Proof.

(a) For $\|\mathbf{x}\|_\alpha \le 1$, Corollary 17.4.9 in $\mathbb{R}^m$ gives $\|\mathbf{A}\mathbf{x}\|_\beta = \max\{\mathbf{y}^\top \mathbf{A}\mathbf{x} : \|\mathbf{y}\|_{\beta*} \le 1\}$. So every value $\mathbf{y}^\top \mathbf{A}\mathbf{x}$ in the set is at most $\|\mathbf{A}\mathbf{x}\|_\beta \le \|\mathbf{A}\|_{\alpha\to\beta}$. Conversely, choose $\mathbf{x}_0$ with $\|\mathbf{x}_0\|_\alpha \le 1$ and $\|\mathbf{A}\mathbf{x}_0\|_\beta = \|\mathbf{A}\|_{\alpha\to\beta}$, which exists by Lemma 15.3.1, and then $\mathbf{y}_0$ attaining the maximum for $\|\mathbf{A}\mathbf{x}_0\|_\beta$. The value $\mathbf{y}_0^\top \mathbf{A}\mathbf{x}_0$ equals $\|\mathbf{A}\|_{\alpha\to\beta}$, so the maximum exists and has this value.

(b) By the equivalent descriptions after Definition 15.3.2, and then Definition 17.4.4 for $\|\cdot\|_{\alpha*}$,

$$\|\mathbf{A}^\top\|_{\beta*\to\alpha*} = \max_{\|\mathbf{y}\|_{\beta*}\le 1} \|\mathbf{A}^\top \mathbf{y}\|_{\alpha*} = \max_{\|\mathbf{y}\|_{\beta*}\le 1} \max_{\|\mathbf{x}\|_\alpha \le 1} \langle \mathbf{x}, \mathbf{A}^\top \mathbf{y} \rangle.$$

Since $\langle \mathbf{x}, \mathbf{A}^\top \mathbf{y} \rangle = \mathbf{x}^\top \mathbf{A}^\top \mathbf{y} = \mathbf{y}^\top \mathbf{A}\mathbf{x}$, this is the maximum in (a).

■

With $\alpha = \beta = \infty$, part (b) and Proposition 17.4.7 say $\|\mathbf{A}^\top\|_1 = \|\mathbf{A}\|_\infty$: the largest column

sum of $\mathbf{A}^\top$ is the largest row sum of $\mathbf{A}$, which is also what Theorem 15.3.3 gives directly. With $\alpha = \beta = 2$ it says $\|\mathbf{A}^\top\|_2 = \|\mathbf{A}\|_2$, that is, $\sigma_1(\mathbf{A}^\top) = \sigma_1(\mathbf{A})$. For the matrix $\mathbf{A} = \left(\begin{smallmatrix} 3 & 0 \\ 4 & 5 \end{smallmatrix}\right)$ of Example (One matrix, four numbers), $\|\mathbf{A}\|_1 = 7$ and $\|\mathbf{A}\|_\infty = 9$. Its transpose $\left(\begin{smallmatrix} 3 & 4 \\ 0 & 5 \end{smallmatrix}\right)$ has column sums 3 and 9 and row sums 7 and 5, so $\|\mathbf{A}^\top\|_1 = 9 = \|\mathbf{A}\|_\infty$ and $\|\mathbf{A}^\top\|_\infty = 7 = \|\mathbf{A}\|_1$, as (b) predicts.

17.4.7 Exercises

17.4.7.1 A. Check your understanding

Exercise A1.

(a) Define the gauge p_K, the support function h_K and the dual norm $\|\cdot\|_*$, stating what each needs of the set or norm involved.

(b) Determine whether the following statement is correct, and justify your answer: the support function of every non-empty bounded subset of $\mathbb{R}^2$ is a norm.

(c) What is the dual of $\|\cdot\|_\infty$ on $\mathbb{R}^n$? What is the dual of that?

(d) Which result of §03 does the proof of Theorem 17.4.8 use, and at which point?

(e) Determine whether the following statement is correct, and justify your answer: $K^{\circ\circ} = K$ for every non-empty closed convex $K \subseteq \mathbb{R}^n$.

Solution.

(a) For K convex with $\mathbf{0}$ an interior point, $p_K(\mathbf{x}) = \inf\{t > 0 : \mathbf{x} \in tK\}$ (Definition 17.4.1). For K non-empty, $h_K(\mathbf{y}) = \sup_{\mathbf{x}\in K}\langle \mathbf{x}, \mathbf{y}\rangle$, possibly $+\infty$ (Definition 17.4.2). For a norm $\|\cdot\|$ with ball B, $\|\mathbf{y}\|_* = \max_{\mathbf{x}\in B}\langle \mathbf{x}, \mathbf{y}\rangle = h_B(\mathbf{y})$ (Definition 17.4.4).

(b) Incorrect. For $K = \{\mathbf{0}\}$, $h_K = 0$, which violates (N1). For the segment $[-\mathbf{e}_1, \mathbf{e}_1]$, $h_K(\mathbf{y}) = |y_1|$ vanishes at $\mathbf{e}_2$. Support functions are sublinear (Proposition 17.4.3 (a)) but need not be norms.

(c) $\|\cdot\|_1$, by Proposition 17.4.7 (b); and the dual of $\|\cdot\|_1$ is $\|\cdot\|_\infty$ again, by (a) of the same proposition, as Theorem 17.4.8 requires.

(d) Theorem 17.3.6, applied to the unit ball B at a point $\mathbf{x}$ with $\|\mathbf{x}\| = 1$, to produce a normal $\mathbf{a}$ at which the maximum defining $\|\mathbf{a}\|_*$ is attained at $\mathbf{x}$.

(e) Incorrect. For $K = \{\mathbf{e}_1\}$ in $\mathbb{R}^2$, $K^{\circ\circ}$ is the segment $[\mathbf{0}, \mathbf{e}_1]$. Theorem 17.4.5 needs $\mathbf{0} \in K$.

17.4.7.2 B. Practice

Exercise B1: A weighted norm and its dual.

On $\mathbb{R}^2$ let $N(\mathbf{x}) = \max\big(|x_1|, 2|x_2|\big)$.

(a) Prove that $N_*(\mathbf{y}) = |y_1| + \tfrac{1}{2}|y_2|$.

(b) Verify Theorem 17.4.8 for N by computing N_{**} directly.

Solution.

(a) The ball of N is the rectangle $|x_1| \le 1$, $|x_2| \le \tfrac{1}{2}$. On it, $\langle \mathbf{x}, \mathbf{y} \rangle \le |x_1||y_1| + |x_2||y_2| \le |y_1| + \tfrac{1}{2}|y_2|$. The point $\mathbf{x} = (s_1, \tfrac{1}{2}s_2)$, where $s_i = 1$ if $y_i \ge 0$ and $s_i = -1$ otherwise, lies in the ball and gives equality. So $N_*(\mathbf{y}) = |y_1| + \tfrac{1}{2}|y_2|$.

(b) The ball of N_* is $\{|y_1| + \tfrac{1}{2}|y_2| \le 1\}$. On it,

$$\langle \mathbf{x}, \mathbf{y} \rangle \le |x_1||y_1| + 2|x_2| \cdot \tfrac{1}{2}|y_2| \le N(\mathbf{x})\big(|y_1| + \tfrac{1}{2}|y_2|\big) \le N(\mathbf{x}).$$

If $N(\mathbf{x}) = |x_1|$, the point $\mathbf{y} = \pm \mathbf{e}_1$ (sign of x_1) lies in the ball and gives $\langle \mathbf{x}, \mathbf{y} \rangle = |x_1|$. If $N(\mathbf{x}) = 2|x_2|$, the point $\mathbf{y} = \pm 2\mathbf{e}_2$ (sign of x_2) lies in the ball, since $\tfrac{1}{2} \cdot 2 = 1$, and gives $\langle \mathbf{x}, \mathbf{y} \rangle = 2|x_2|$. So $N_{**} = N$.

Exercise B2: A hexagonal norm.

Let $K = \{\mathbf{x} \in \mathbb{R}^2 : |x_1| \le 1,\ |x_2| \le 1,\ |x_1 - x_2| \le 1\}$.

(a) Check that K satisfies the hypotheses of Theorem 17.4.2 (a).

(b) Show that $p_K(\mathbf{x}) = \max\big(|x_1|, |x_2|, |x_1 - x_2|\big)$, and compute $p_K\big((2, -1)\big)$.

(c) Determine whether p_K is induced by an inner product. Justify your answer.

Solution.

(a) K is the intersection of six closed half-planes, such as $\{x_1 \le 1\}$ and $\{x_1 - x_2 \ge -1\}$, each closed and convex (§03, before Definition 17.3.1); so K is closed and convex. It is bounded, since $\|\mathbf{x}\|_2 \le \sqrt{2}$ when $|x_1|, |x_2| \le 1$. It is symmetric, since each condition is unchanged by $\mathbf{x} \mapsto -\mathbf{x}$. And if $\|\mathbf{x}\|_2 < \tfrac{1}{2}$, then $|x_1|, |x_2| < \tfrac{1}{2}$ and $|x_1 - x_2| < 1$, so $\mathbf{x} \in K$ and $\mathbf{0}$ is an interior point.

(b) For $t > 0$, $\mathbf{x} \in tK$ exactly when $\mathbf{x}/t \in K$, that is, when $|x_1| \le t$, $|x_2| \le t$ and $|x_1 - x_2| \le t$. The infimum of such t is $M = \max(|x_1|, |x_2|, |x_1 - x_2|)$ when $\mathbf{x} \neq \mathbf{0}$, and $0 = M$ when $\mathbf{x} = \mathbf{0}$. So $p_K\big((2, -1)\big) = \max(2, 1, 3) = 3$.

(c) No. With $\mathbf{u} = \mathbf{e}_1$ and $\mathbf{v} = \mathbf{e}_2$, $p_K(\mathbf{u} + \mathbf{v}) = \max(1, 1, 0) = 1$ and $p_K(\mathbf{u} - \mathbf{v}) = \max(1, 1, 2) = 2$, so the left side of the parallelogram law is $1 + 4 = 5$, while the right side is $2 \cdot 1 + 2 \cdot 1 = 4$. By Theorem 15.1.3, no inner product induces p_K.

Exercise B3: The polar of a triangle.

Let $K = \operatorname{conv}\{(-1, -1), (2, -1), (-1, 2)\} \subseteq \mathbb{R}^2$.

(a) Compute $h_K(\mathbf{e}_1)$, $h_K(-\mathbf{e}_1)$ and $h_K\big((1, 1)\big)$.

(b) Describe K° by three linear inequalities.

(c) Show that $(-1, 0)$, $(0, -1)$ and $(1, 1)$ lie in K°, and that $(1, 0)$ does not.

Solution.

(a) By Proposition 17.4.3 (c), $h_K(\mathbf{y})$ is the largest of $\langle \mathbf{v}, \mathbf{y} \rangle$ over the three vertices $\mathbf{v}$, that is, of $-y_1 - y_2$, $2y_1 - y_2$, $-y_1 + 2y_2$. So $h_K(\mathbf{e}_1) = \max(-1, 2, -1) = 2$, $h_K(-\mathbf{e}_1) = \max(1, -2, 1) = 1$, and $h_K\big((1, 1)\big) = \max(-2, 1, 1) = 1$.

(b) $\mathbf{y} \in K^\circ$ exactly when $h_K(\mathbf{y}) \le 1$, that is,

$$-y_1 - y_2 \le 1, \qquad 2y_1 - y_2 \le 1, \qquad -y_1 + 2y_2 \le 1.$$

(c) At $(-1,0)$ the three left sides are $1, -2, 1$; at $(0,-1)$ they are $1, 1, -2$; at $(1,1)$ they are $-2, 1, 1$. All are ≤ 1. At $(1,0)$ the second is $2 > 1$, so $(1,0) \notin K^\circ$, in agreement with $h_K(\mathbf{e}_1) = 2$.

17.4.7.3 C. Going deeper

Exercise C1: The norm from 1 to infinity.

Let $\mathbf{A} \in M_{m\times n}(\mathbb{R})$, and let $\|\mathbf{A}\|_{1\to\infty}$ be the operator norm with $\|\cdot\|_1$ on $\mathbb{R}^n$ and $\|\cdot\|_\infty$ on $\mathbb{R}^m$.

(a) Using Proposition 17.4.10 (a), prove that $\|\mathbf{A}\|_{1\to\infty} = \max_{i,j}|a_{ij}|$.

(b) Deduce from Proposition 17.4.10 (b) that the operator norm of $\mathbf{A}^\top$ with $\|\cdot\|_1$ on $\mathbb{R}^m$ and $\|\cdot\|_\infty$ on $\mathbb{R}^n$ is the same number.

(c) Explain why this does not contradict the warning of Chapter 15 §03 that the entrywise maximum is not a matrix norm.

Solution.

(a) By Proposition 17.4.7 (b), the dual of $\|\cdot\|_\infty$ is $\|\cdot\|_1$, so Proposition 17.4.10 (a) gives $\|\mathbf{A}\|_{1\to\infty} = \max\{\mathbf{y}^\top\mathbf{A}\mathbf{x} : \|\mathbf{x}\|_1 \le 1,\ \|\mathbf{y}\|_1 \le 1\}$. Write $M = \max_{i,j}|a_{ij}|$. For such $\mathbf{x}, \mathbf{y}$,

$$\mathbf{y}^\top\mathbf{A}\mathbf{x} = \sum_{i,j} y_i a_{ij} x_j \le M \sum_i |y_i| \sum_j |x_j| \le M.$$

If $|a_{kl}| = M$, then $\mathbf{x} = \mathbf{e}_l$ and $\mathbf{y} = \pm\mathbf{e}_k$, with the sign of a_{kl}, give $\mathbf{y}^\top\mathbf{A}\mathbf{x} = M$. So $\|\mathbf{A}\|_{1\to\infty} = M$.

(b) By Proposition 17.4.10 (b) with $\alpha = 1$ and $\beta = \infty$, $\|\mathbf{A}^\top\|_{\beta*\to\alpha*} = \|\mathbf{A}^\top\|_{1\to\infty}$ equals $\|\mathbf{A}\|_{1\to\infty}$, using $\beta* = 1$ and $\alpha* = \infty$ from Proposition 17.4.7. This is consistent with (a), since $\mathbf{A}$ and $\mathbf{A}^\top$ have the same entries.

(c) $\|\cdot\|_{1\to\infty}$ uses **different** norms on the source and the target, so the product $\mathbf{AB}$ of two square matrices is measured by a norm that does not compose: submultiplicativity in Theorem 15.3.2 (d) needs the target norm of $\mathbf{B}$ to be the source norm of $\mathbf{A}$. With one norm on $M_n(\mathbb{R})$ the entrywise maximum is not submultiplicative (Example (The entrywise maximum is not submultiplicative)), and nothing here says otherwise.

Exercise C2: Equivalence constants dualize.

Let N_1, N_2 be norms on $\mathbb{R}^n$ and $0 < m \le M$ constants with $mN_1(\mathbf{x}) \le N_2(\mathbf{x}) \le MN_1(\mathbf{x})$ for every $\mathbf{x}$.

(a) Prove that $\frac{1}{M}N_{1*}(\mathbf{y}) \le N_{2*}(\mathbf{y}) \le \frac{1}{m}N_{1*}(\mathbf{y})$ for every $\mathbf{y}$.

(b) Apply (a) to $\|\mathbf{x}\|_2 \le \|\mathbf{x}\|_1 \le \sqrt{n}\,\|\mathbf{x}\|_2$ from Proposition 15.1.2, and compare the result with that proposition.

Solution.

(a) If $N_2(\mathbf{x}) \le 1$, then $N_1(\mathbf{x}) \le 1/m$, so $\mathbf{x} = \frac{1}{m}\mathbf{x}'$ with $N_1(\mathbf{x}') \le 1$, and $\langle \mathbf{x}, \mathbf{y} \rangle = \frac{1}{m}\langle \mathbf{x}', \mathbf{y} \rangle \le \frac{1}{m} N_{1*}(\mathbf{y})$. Taking the maximum over the ball of N_2 gives $N_{2*}(\mathbf{y}) \le \frac{1}{m} N_{1*}(\mathbf{y})$. If $N_1(\mathbf{x}) \le 1$, then $N_2(\mathbf{x}) \le M$, and Proposition 17.4.6 (b) gives $\langle \mathbf{x}, \mathbf{y} \rangle \le N_2(\mathbf{x}) N_{2*}(\mathbf{y}) \le M N_{2*}(\mathbf{y})$; so $N_{1*}(\mathbf{y}) \le M N_{2*}(\mathbf{y})$.

(b) Take $N_1 = \|\cdot\|_2$, $N_2 = \|\cdot\|_1$, $m = 1$, $M = \sqrt{n}$. The duals are $\|\cdot\|_2$ and $\|\cdot\|_\infty$ (Proposition 17.4.7), so (a) gives $\frac{1}{\sqrt{n}}\|\mathbf{y}\|_2 \le \|\mathbf{y}\|_\infty \le \|\mathbf{y}\|_2$. These are exactly the other two inequalities $\|\mathbf{y}\|_\infty \le \|\mathbf{y}\|_2 \le \sqrt{n}\,\|\mathbf{y}\|_\infty$ of Proposition 15.1.2: that proposition is closed under duality, with the constants carried over unchanged.

Exercise C3: The gauge is the support function of the polar.

Let $K \subseteq \mathbb{R}^n$ be closed and convex, with $\mathbf{0}$ an interior point.

(a) Prove that $p_K(\mathbf{x}) = h_{K^\circ}(\mathbf{x})$ for every $\mathbf{x}$. *Hint: for $t > 0$, rewrite "$\mathbf{x} \in tK$" using Theorem 17.4.5.*

(b) Deduce Theorem 17.4.8 again from (a), Theorem 17.4.2 (b) and Proposition 17.4.6 (d).

Solution.

(a) The polar K° contains $\mathbf{0}$, so $h_{K^\circ}(\mathbf{x}) \ge \langle \mathbf{x}, \mathbf{0} \rangle = 0$. Let $t > 0$. By Theorem 17.4.5, $K = K^{\circ\circ}$, so

$$\mathbf{x} \in tK \iff \mathbf{x}/t \in K^{\circ\circ} \iff \langle \mathbf{x}, \mathbf{y} \rangle \le t \text{ for every } \mathbf{y} \in K^\circ \iff h_{K^\circ}(\mathbf{x}) \le t.$$

So the admissible t in Definition 17.4.1 are the $t > 0$ with $t \ge h_{K^\circ}(\mathbf{x})$, and their infimum is $h_{K^\circ}(\mathbf{x})$ (if $h_{K^\circ}(\mathbf{x}) = 0$, the admissible t are all $t > 0$, with infimum 0). In particular $h_{K^\circ}(\mathbf{x})$ is finite.

(b) Let B be the ball of $\|\cdot\|$. By Theorem 17.4.2 (b), B is closed and convex with $\mathbf{0}$ interior, and $\|\cdot\| = p_B$. By (a), $p_B = h_{B^\circ}$, and B° is the ball of $\|\cdot\|_*$ by Proposition 17.4.6 (d). So $\|\mathbf{x}\| = \max\{\langle \mathbf{x}, \mathbf{y} \rangle : \|\mathbf{y}\|_* \le 1\} = \|\mathbf{x}\|_{**}$, the maximum existing by Definition 17.4.4 applied to $\|\cdot\|_*$.

17.5 Cones and Farkas's Lemma

Chapter 2 answered one question about a linear system completely: $\mathbf{Ax} = \mathbf{b}$ has a solution exactly when $\mathbf{b}$ lies in the column space of $\mathbf{A}$ (Theorem 2.1.1). Its applications section then hit a wall. Traffic flows cannot be negative, and once the unknowns are required to satisfy $\mathbf{x} \ge \mathbf{0}$, the column space is the wrong set to look in. This section finds the right set, which is a **cone**, and answers the new question with the separation theorems of §03: either $\mathbf{Ax} = \mathbf{b}$ has a non-negative solution, or a single vector $\mathbf{y}$ certifies that it has none. That is Farkas's lemma, and the next two sections run on it.

One step is harder than it looks. Separation needs a **closed** set, and nothing proved so far says that the relevant cone is closed. Most of the work goes into that step, and the last part of the section shows, with an explicit cone, that it can really fail.

Throughout, the field is $\mathbb{R}$. Vectors in $\mathbb{R}^n$ are columns, $\langle \mathbf{x}, \mathbf{y} \rangle = \mathbf{y}^\top \mathbf{x}$ is the standard inner product, and $\|\cdot\|$ is the Euclidean norm it induces, the norm that Theorem 17.3.1 uses. Convergence $\mathbf{y}_k \to \mathbf{y}$ means $\|\mathbf{y}_k - \mathbf{y}\| \to 0$, and "closed" is meant in the sequential sense of Definition 17.1.6: a set S is closed when every limit of a convergent sequence of points of S again lies in S. Convergence in this norm is entrywise convergence, by the elementary bound

$$|y_i| \;\le\; \|\mathbf{y}\| \;\le\; |y_1| + \cdots + |y_n| \qquad \text{for } \mathbf{y} \in \mathbb{R}^n \text{ and } 1 \le i \le n. \tag{17.5.1}$$

The left inequality holds because $y_i^2 \le y_1^2 + \cdots + y_n^2$, and the right one is the triangle inequality for $\mathbf{y} = y_1\mathbf{e}_1 + \cdots + y_n\mathbf{e}_n$. Applied to $\mathbf{y}_k - \mathbf{y}$, with the algebra of limits of Chapter 15's introduction on the right, it shows that $\|\mathbf{y}_k - \mathbf{y}\| \to 0$ exactly when every entry of $\mathbf{y}_k - \mathbf{y}$ tends to 0.

17.5.1 Convex cones

For a vector with real entries we write $\mathbf{x} \ge \mathbf{0}$ when **every entry** of $\mathbf{x}$ is ≥ 0, and $\mathbf{x} > \mathbf{0}$ when every entry is > 0. The set

$$\mathbb{R}^m_{\ge 0} = \{\mathbf{x} \in \mathbb{R}^m : \mathbf{x} \ge \mathbf{0}\}$$

is the **non-negative orthant**. The relation $\mathbf{x} \ge \mathbf{0}$ is an entrywise statement about a vector, and it has nothing to do with the Loewner order $\mathbf{A} \succeq 0$ of Chapter 12, which is a statement about a matrix.

Here is the question. Let $\mathbf{A} \in M_{m\times n}(\mathbb{R})$ have columns $\mathbf{a}_1, \ldots, \mathbf{a}_n$. By Theorem 0.9.3, $\mathbf{Ax} = x_1\mathbf{a}_1 + \cdots + x_n\mathbf{a}_n$, so

$$\{\mathbf{b} \in \mathbb{R}^m : \mathbf{Ax} = \mathbf{b} \text{ for some } \mathbf{x} \ge \mathbf{0}\} = \{x_1\mathbf{a}_1 + \cdots + x_n\mathbf{a}_n : \text{every } x_j \ge 0\}.$$

Without the sign condition this set would be the span of the columns, a subspace. With it, the set is closed under addition and under multiplication by **non-negative** scalars, but not under multiplication by -1. Such sets turn up whenever quantities cannot be negative, so they get a name.

A cone is a set you may stretch and add in, but never reflect.

Definition 17.5.1 — Convex Cone

Let V be a vector space over $\mathbb{R}$. A subset $K \subseteq V$ is a **convex cone** if K is **non-empty** and

$$a\mathbf{u} + b\mathbf{v} \in K \qquad \text{for all } \mathbf{u}, \mathbf{v} \in K \text{ and all real } a, b \ge 0.$$

In words: a convex cone contains every **non-negative** combination of two of its members, and hence, by induction on the number of terms, every non-negative combination of finitely many of its members. Three special cases unpack the single condition. Taking $a = b = 0$ shows $\mathbf{0} \in K$, so every convex cone contains the origin. Taking $b = 0$ shows that K is closed under multiplication by non-negative scalars. Taking $a = b = 1$ shows that it is closed under addition, and conversely a non-empty set with these two closure properties is a convex cone.

A convex cone is a convex set in the sense of Definition 17.1.1: take $a = 1 - t$ and $b = t$ with $0 \le t \le 1$. The converse fails, and the next examples show how.

Examples. Each is checked against the one condition of the definition.

- **The orthant.** If $\mathbf{u}, \mathbf{v} \geq \mathbf{0}$ and $a, b \geq 0$, then every entry of $a\mathbf{u} + b\mathbf{v}$ is a sum of products of non-negative numbers, so $a\mathbf{u} + b\mathbf{v} \geq \mathbf{0}$. Hence $\mathbb{R}^m_{\geq 0}$ is a convex cone.
- **A half-space through the origin.** Fix $\mathbf{a} \in \mathbb{R}^n$ and let $H = \{\mathbf{x} : \langle \mathbf{x}, \mathbf{a} \rangle \geq 0\}$. If $\mathbf{u}, \mathbf{v} \in H$ and $a, b \geq 0$, then $\langle a\mathbf{u} + b\mathbf{v}, \mathbf{a} \rangle = a\langle \mathbf{u}, \mathbf{a} \rangle + b\langle \mathbf{v}, \mathbf{a} \rangle \geq 0$. So H is a convex cone. When $\mathbf{a} \neq \mathbf{0}$ it is one of the two closed half-spaces bounded by the hyperplane $\mathbf{a}^{\perp}$.
- **The ice-cream cone.** In $\mathbb{R}^{n+1}$, write vectors as $(\mathbf{x}, t)$ with $\mathbf{x} \in \mathbb{R}^n$ and $t \in \mathbb{R}$, and let $L = \{(\mathbf{x}, t) : \|\mathbf{x}\|_2 \leq t\}$. If $(\mathbf{x}, t), (\mathbf{y}, s) \in L$ and $a, b \geq 0$, the triangle inequality and homogeneity of the norm (Definition 15.1.1) give $\|a\mathbf{x} + b\mathbf{y}\|_2 \leq a\|\mathbf{x}\|_2 + b\|\mathbf{y}\|_2 \leq at + bs$. So L is a convex cone. In $\mathbb{R}^3$ it is the round solid cone that gives the family its name.
- **Positive semidefinite matrices.** In the real vector space of real symmetric $n \times n$ matrices, the set of $\mathbf{A} \succeq 0$ is a convex cone. This is part (a) of Exercise (C2: The cone of positive matrices). Chapter 12 used the phrase there, and this is the definition it was using.
- **Degenerate cases.** $\{\mathbf{0}\}$ and V are convex cones. More generally, **every subspace is a convex cone**, since it is closed under all linear combinations and in particular the non-negative ones. A subspace is the extreme case of a cone that happens to be closed under reflection as well.

Non-examples by minimal change. In $\mathbb{R}^2$, take the union of two opposite quadrants, $Q = \{\mathbf{x} : x_1 x_2 \geq 0\}$. It is closed under non-negative scaling, since $(ax_1)(ax_2) = a^2 x_1 x_2$. The clause that fails is addition: $(1, 0)$ and $(0, -1)$ lie in Q, but their sum $(1, -1)$ does not. Or keep convexity and lose the scaling: the closed unit disc is convex, but $2\mathbf{e}_1$ is not in it. Or translate the orthant to $\mathbf{1} + \mathbb{R}^2_{\geq 0}$: it is convex and closed under addition, but it does not contain $\mathbf{0}$.

Why this definition. The scalars must be non-negative. With all real scalars allowed, the definition becomes the definition of a subspace, and the sign information that started this section would be lost. The requirement $\mathbf{0} \in K$ is a convention that some authors drop: they call $\{\mathbf{x} : \mathbf{x} > \mathbf{0}\}$ a cone as well. Including the origin costs nothing here and keeps the statements below free of exceptions.

> *Warning.* **A convex cone need not be closed.** In $\mathbb{R}^2$ let
>
> $$C = \{(x, y) : x > 0\} \cup \{(0, 0)\}.$$
>
> It is a convex cone. Let $\mathbf{u}, \mathbf{v} \in C$ and $a, b \geq 0$. The first entry of $a\mathbf{u} + b\mathbf{v}$ is $au_1 + bv_1 \geq 0$. If it is positive, the vector lies in C. If it is zero, then $au_1 = 0$ and $bv_1 = 0$; since the only member of C with first entry 0 is $\mathbf{0}$, this forces $a\mathbf{u} = \mathbf{0}$ and $b\mathbf{v} = \mathbf{0}$, and the sum is $\mathbf{0} \in C$. But $(1/k, 1) \in C$ for every $k \geq 1$, while the limit $(0, 1)$ is not in C. Separating a point from a cone needs the cone to be closed, so closedness must be proved. This particular cone comes back at the end of the section as the image of a closed cone.

The cones in the question at the start of this section are the simplest kind.

Definition 17.5.2 — Finitely Generated Cone

Let $\mathbf{a}_1, \ldots, \mathbf{a}_m$ be vectors in a real vector space V. The **cone generated by** them is

$$\operatorname{cone}(\mathbf{a}_1, \ldots, \mathbf{a}_m) = \left\{ \textstyle\sum_{i=1}^m x_i \mathbf{a}_i : x_1, \ldots, x_m \geq 0 \right\}.$$

A cone of this form is **finitely generated**. For the empty list we set $\operatorname{cone}() = \{\mathbf{0}\}$, the value of the empty sum. When $V = \mathbb{R}^n$ and $\mathbf{A}$ is the matrix with columns $\mathbf{a}_1, \ldots, \mathbf{a}_m$,

this is $\{\mathbf{Ax} : \mathbf{x} \in \mathbb{R}^m_{\geq 0}\}$, and we also write it $\mathrm{cone}(\mathbf{A})$.

It is a convex cone: a non-negative combination of two non-negative combinations of the $\mathbf{a}_i$ is again one, with coefficients $ax_i + bx'_i \geq 0$. It is also the **smallest** convex cone containing $\mathbf{a}_1, \ldots, \mathbf{a}_m$, since any convex cone containing the $\mathbf{a}_i$ contains all their non-negative combinations, by the remark after Definition 17.5.1. The orthant is $\mathrm{cone}(\mathbf{e}_1, \ldots, \mathbf{e}_m)$. A subspace with basis $\mathbf{v}_1, \ldots, \mathbf{v}_k$ is $\mathrm{cone}(\mathbf{v}_1, -\mathbf{v}_1, \ldots, \mathbf{v}_k, -\mathbf{v}_k)$, since $c\mathbf{v}_i$ is $c\mathbf{v}_i$ or $|c|(-\mathbf{v}_i)$ according to the sign of c. The ice-cream cone is **not** finitely generated, a fact we shall neither need nor prove.

Quick check. Is $\mathrm{cone}\big((1,0),(1,1),(0,1)\big)$ in $\mathbb{R}^2$ the same as $\mathrm{cone}\big((1,0),(0,1)\big)$? Is $\mathrm{cone}\big((1,0),(-1,0)\big)$ a line or a half-line?

Solution. Both cones are the quadrant $\mathbb{R}^2_{\geq 0}$. The second list's cone is the quadrant because $x_1\mathbf{e}_1 + x_2\mathbf{e}_2 = (x_1, x_2)$. The first contains the second, and every generator of the first lies in the quadrant, which is a convex cone, so the first is contained in the quadrant too. A redundant generator changes nothing. The cone of $(1,0)$ and $(-1,0)$ is the whole x-axis $\{(t,0) : t \in \mathbb{R}\}$, a line: for $t \geq 0$ use $t(1,0)$, and for $t < 0$ use $|t|(-1,0)$.

17.5.2 The dual cone

A certificate that $\mathbf{Ax} = \mathbf{b}$ has no non-negative solution will be a vector $\mathbf{y}$ that makes a non-negative inner product with every column of $\mathbf{A}$ but a negative one with $\mathbf{b}$. Every non-negative combination of the columns then also has a non-negative inner product with $\mathbf{y}$, so $\mathbf{b}$ cannot be such a combination. The set of vectors $\mathbf{y}$ that pass the first test deserves a name.

The dual cone of K is the set of directions that make an angle of at most 90° with everything in K.

Definition 17.5.3 — Dual Cone

Let V be a finite-dimensional real inner product space and let $S \subseteq V$ be **any** subset. The **dual cone** of S is

$$S^* = \{\mathbf{y} \in V : \langle \mathbf{x}, \mathbf{y} \rangle \geq 0 \text{ for every } \mathbf{x} \in S\}.$$

We write S^{**} for $(S^*)^*$.

In words: $\mathbf{y} \in S^*$ when the linear functional $\langle \cdot, \mathbf{y} \rangle$ is non-negative on the whole of S, that is, when S lies in the closed half-space $\{\mathbf{x} : \langle \mathbf{x}, \mathbf{y} \rangle \geq 0\}$. The inner product is what places S^* inside V rather than in the dual space of Chapter 4 (Theorem 4.1.1 is the case $V = \mathbb{R}^n$).

Warning. S^* **is not the dual space.** The star here produces a subset of V itself, not a space of functionals, and it is defined for any subset, not only for a subspace. For a subspace U the dual cone is the orthogonal complement: if $\langle \mathbf{u}, \mathbf{y} \rangle \geq 0$ for every $\mathbf{u} \in U$, then applying this to $-\mathbf{u} \in U$ gives $\langle \mathbf{u}, \mathbf{y} \rangle \leq 0$ as well, so $\langle \mathbf{u}, \mathbf{y} \rangle = 0$, and the converse is immediate. So for a subspace we always write $U^\perp$, never U^*.

The basic properties take one line each, and they explain why every dual cone is a good set to separate from.

Proposition 17.5.1 — Basic Properties of the Dual Cone

Let V be a finite-dimensional real inner product space and let $S, T \subseteq V$.

(a) S^* is a closed convex cone.
(b) If $S \subseteq T$, then $T^* \subseteq S^*$.
(c) $S \subseteq S^{**}$.
(d) $\operatorname{cone}(\mathbf{a}_1, \dots, \mathbf{a}_m)^* = \{\mathbf{y} : \langle \mathbf{a}_i, \mathbf{y} \rangle \geq 0 \text{ for } i = 1, \dots, m\}$. In $\mathbb{R}^n$, with $\mathbf{A}$ the matrix of columns $\mathbf{a}_i$, this is $\{\mathbf{y} : \mathbf{A}^\top \mathbf{y} \geq \mathbf{0}\}$.

Idea. S^* is the intersection of the sets $\{\mathbf{y} : \langle \mathbf{x}, \mathbf{y} \rangle \geq 0\}$, one for each $\mathbf{x} \in S$. Parts (a), (b) and (d) read off this description (more members of S mean more conditions, and for a cone the generators suffice), and (c) is the symmetry of the inner product.

Proof.

(a) $\mathbf{0} \in S^*$, so S^* is non-empty. If $\mathbf{y}, \mathbf{z} \in S^*$ and $a, b \geq 0$, then $\langle \mathbf{x}, a\mathbf{y} + b\mathbf{z} \rangle = a\langle \mathbf{x}, \mathbf{y} \rangle + b\langle \mathbf{x}, \mathbf{z} \rangle \geq 0$ for every $\mathbf{x} \in S$, using linearity in the second slot, which holds because the field is $\mathbb{R}$. Finally $S^* = \bigcap_{\mathbf{x} \in S} \{\mathbf{y} : \langle \mathbf{x}, \mathbf{y} \rangle \geq 0\}$ is an intersection of closed half-spaces (all of V when $\mathbf{x} = \mathbf{0}$), closed by Proposition 17.1.6 (c) and (b), since $\langle \mathbf{x}, \cdot \rangle$ is a linear functional; if $S = \emptyset$, then $S^* = V$, which is closed.

(b) A vector that is non-negative against every member of T is in particular non-negative against every member of S.

(c) If $\mathbf{x} \in S$, then $\langle \mathbf{x}, \mathbf{y} \rangle \geq 0$ for every $\mathbf{y} \in S^*$, by the definition of S^*. Since the inner product is symmetric over $\mathbb{R}$, this says $\langle \mathbf{y}, \mathbf{x} \rangle \geq 0$ for every $\mathbf{y} \in S^*$, which is $\mathbf{x} \in S^{**}$.

(d) The generators lie in the cone, so (b) gives $\subseteq$. Conversely, if $\langle \mathbf{a}_i, \mathbf{y} \rangle \geq 0$ for every i, then $\langle \sum x_i \mathbf{a}_i, \mathbf{y} \rangle = \sum x_i \langle \mathbf{a}_i, \mathbf{y} \rangle \geq 0$ whenever every $x_i \geq 0$. The matrix form follows because the i-th entry of $\mathbf{A}^\top \mathbf{y}$ is $\mathbf{a}_i^\top \mathbf{y} = \langle \mathbf{a}_i, \mathbf{y} \rangle$.

■

Part (a) holds for **every** set S, including one that is neither convex nor closed. Part (c) is only an inclusion, and the question of when it is an equality is really the question of this section.

Examples.

- **The orthant is its own dual.** By (d), $(\mathbb{R}^m_{\geq 0})^* = \operatorname{cone}(\mathbf{e}_1, \dots, \mathbf{e}_m)^* = \{\mathbf{y} : \langle \mathbf{e}_i, \mathbf{y} \rangle = y_i \geq 0 \text{ for all } i\} = \mathbb{R}^m_{\geq 0}$.
- **A single generator.** $\operatorname{cone}(\mathbf{a})^* = \{\mathbf{y} : \langle \mathbf{a}, \mathbf{y} \rangle \geq 0\}$, a closed half-space when $\mathbf{a} \neq \mathbf{0}$. A thin cone has a fat dual.
- **The degenerate cases.** The dual cone of $\{\mathbf{0}\}$ is all of V, and the dual cone of V is $\{\mathbf{0}\}$, because a $\mathbf{y}$ in it must satisfy $\langle -\mathbf{y}, \mathbf{y} \rangle \geq 0$, that is $\|\mathbf{y}\|^2 \leq 0$. As subspaces, by the warning, we write these as $\{\mathbf{0}\}^\perp = V$ and $V^\perp = \{\mathbf{0}\}$.
- **A wedge in the plane.** For $K = \operatorname{cone}\big((1,0), (1,1)\big)$, part (d) gives $K^* = \{\mathbf{y} : y_1 \geq 0,\ y_1 + y_2 \geq 0\}$. This is the wedge between the directions $(0,1)$ and $(1,-1)$, each of which is perpendicular to one edge of K. Exercise (B3: A dual cone and its dual) finishes this computation.

17.5.3 Finitely generated cones are closed

Now the key step. We want to separate a point $\mathbf{b}$ from $\operatorname{cone}(\mathbf{A})$, and §03 separates points only from **closed** convex sets. So we must show that $\operatorname{cone}(\mathbf{A})$ is closed.

Here is why that is not obvious. Suppose $\mathbf{A}\mathbf{x}_k \to \mathbf{b}$ with every $\mathbf{x}_k \geq \mathbf{0}$. The obvious move is to take a limit of the $\mathbf{x}_k$, but they need not converge, or even be bounded. If the columns of $\mathbf{A}$ are dependent, then $\mathbf{A}\mathbf{x}_k$ can stay put while $\mathbf{x}_k$ runs off along the null space. The cure has two parts. First, throw away the dependence, generator by generator, which is the "count, then drop a point" move of Theorem 17.2.2 adapted to cones. Second, once the columns are independent, prove that $\mathbf{x}_k$ is recovered from $\mathbf{A}\mathbf{x}_k$ by a fixed linear map, so that the $\mathbf{x}_k$ cannot escape.

Theorem 17.5.2 — Carathéodory's Theorem for Cones

Let V be a real vector space and let $\mathbf{a}_1, \dots, \mathbf{a}_m \in V$. Every $\mathbf{b} \in \operatorname{cone}(\mathbf{a}_1, \dots, \mathbf{a}_m)$ lies in $\operatorname{cone}(\mathbf{a}_i : i \in S)$ for some set of indices $S \subseteq \{1, \dots, m\}$ such that the list $(\mathbf{a}_i)_{i \in S}$ is **linearly independent**. In particular, if $\dim V = n$, then $\mathbf{b}$ is a non-negative combination of at most n of the $\mathbf{a}_i$.

Idea. Take a representation of $\mathbf{b}$ that uses as few generators as possible. If those generators were dependent, a dependence relation could be added to the representation, with a scalar multiple chosen so that one coefficient reaches zero and none goes negative. That removes a generator, which contradicts minimality. It is the move of Theorem 17.2.2 with a *linear* dependence in place of an affine one, and that difference is why the bound is n rather than $n+1$.

Proof. By Definition 17.5.2, $\mathbf{b} = \sum_{i=1}^{m} x_i \mathbf{a}_i$ with every $x_i \geq 0$. Discarding the terms with $x_i = 0$, we can write $\mathbf{b} = \sum_{i \in S} x_i \mathbf{a}_i$ with $x_i > 0$ for every $i \in S$, for some $S \subseteq \{1, \dots, m\}$. The empty set is allowed, when $\mathbf{b} = \mathbf{0}$. Among all such representations choose one with $|S|$ as small as possible. We claim that $(\mathbf{a}_i)_{i \in S}$ is linearly independent.

Suppose not. Then there are reals c_i, for $i \in S$, not all zero, with $\sum_{i \in S} c_i \mathbf{a}_i = \mathbf{0}$. Replacing every c_i by $-c_i$ if necessary, we may assume that $c_i > 0$ for at least one i. Put

$$t = \min\left\{ \frac{x_i}{c_i} : i \in S,\ c_i > 0 \right\},$$

a minimum over a non-empty finite set, so it exists. It is > 0, and it is attained at some $i_0 \in S$. Then

$$\mathbf{b} = \sum_{i \in S} x_i \mathbf{a}_i - t \sum_{i \in S} c_i \mathbf{a}_i = \sum_{i \in S} (x_i - t c_i)\, \mathbf{a}_i.$$

Every new coefficient is ≥ 0. If $c_i \leq 0$, then $x_i - t c_i \geq x_i > 0$. If $c_i > 0$, then $t \leq x_i / c_i$, so $x_i - t c_i \geq 0$. Also $x_{i_0} - t c_{i_0} = 0$. Discarding the zero coefficients leaves a representation of $\mathbf{b}$ with positive coefficients on a subset of $S \setminus \{i_0\}$, which contradicts the minimality of $|S|$. Hence $(\mathbf{a}_i)_{i \in S}$ is linearly independent, and $\mathbf{b} \in \operatorname{cone}(\mathbf{a}_i : i \in S)$.

If $\dim V = n$, a linearly independent list in V has length at most n by Theorem 1.6.3 (a), so $|S| \leq n$. This proves the theorem.

■

The second part is a statement about one cone with independent generators.

Lemma 17.5.3 — Injective Images of the Orthant Are Closed

Let $\mathbf{B} \in M_{n\times k}(\mathbb{R})$ have **linearly independent columns**. Then $\operatorname{cone}(\mathbf{B}) = \{\mathbf{Bx} : \mathbf{x} \in \mathbb{R}^k_{\geq 0}\}$ is a closed subset of $\mathbb{R}^n$.

Idea. Independent columns make $\mathbf{x} \mapsto \mathbf{Bx}$ injective, and an injective matrix has a left inverse Ł with Ł$\mathbf{B} = \mathbf{I}_k$. So if $\mathbf{Bx}_j$ converges, then $\mathbf{x}_j = $ Ł$(\mathbf{Bx}_j)$ converges too, because Ł is a fixed matrix. The limit is still $\geq \mathbf{0}$, and it maps to the limit of the $\mathbf{Bx}_j$. The left inverse is what keeps the $\mathbf{x}_j$ from running away, and injectivity is exactly what provides it.

Proof. If $k = 0$, the cone is $\{\mathbf{0}\}$, which is closed. Let $k \geq 1$. Since the columns of $\mathbf{B}$ are linearly independent, Corollary 10.4.4 ((b) $\Rightarrow$ (c), with $F = \mathbb{R}$, where $\mathbf{B}^* = \mathbf{B}^\top$) shows that $\mathbf{B}^\top\mathbf{B} \in M_k(\mathbb{R})$ is invertible. Put Ł $= (\mathbf{B}^\top\mathbf{B})^{-1}\mathbf{B}^\top \in M_{k\times n}(\mathbb{R})$, so that Ł$\mathbf{B} = \mathbf{I}_k$.

Let $\mathbf{y}_j \in \operatorname{cone}(\mathbf{B})$ with $\mathbf{y}_j \to \mathbf{y}$. Write $\mathbf{y}_j = \mathbf{Bx}_j$ with $\mathbf{x}_j \geq \mathbf{0}$. Then $\mathbf{x}_j =$ Ł$\mathbf{Bx}_j =$ Ł$\mathbf{y}_j$. By Eq. 17.5.1, $\mathbf{y}_j \to \mathbf{y}$ entrywise. Each entry of Ł$\mathbf{y}_j$ is a fixed linear combination of the entries of $\mathbf{y}_j$, so by the algebra of limits $\mathbf{x}_j =$ Ł$\mathbf{y}_j \to$ Ł$\mathbf{y}$ entrywise. Put $\mathbf{x} =$ Ł$\mathbf{y}$.

Each entry of $\mathbf{x}_j$ is ≥ 0, and a non-strict inequality survives a limit, so $\mathbf{x} \geq \mathbf{0}$. By the same reasoning with the fixed matrix $\mathbf{B}$, we have $\mathbf{y}_j = \mathbf{Bx}_j \to \mathbf{Bx}$ entrywise. A convergent sequence of real numbers has only one limit, so $\mathbf{Bx} = \mathbf{y}$. Hence $\mathbf{y} = \mathbf{Bx}$ with $\mathbf{x} \geq \mathbf{0}$, that is, $\mathbf{y} \in \operatorname{cone}(\mathbf{B})$. This proves that the cone is closed.

■

The two pieces now fit together.

Theorem 17.5.4 — Finitely Generated Cones Are Closed

Let $\mathbf{a}_1, \ldots, \mathbf{a}_m \in \mathbb{R}^n$. Then $\operatorname{cone}(\mathbf{a}_1, \ldots, \mathbf{a}_m)$ is a closed convex cone.

Idea. By Theorem 17.5.2 the cone is the union of the cones of its independent sublists. There are finitely many of them, and each is closed by Lemma 17.5.3. A finite union of closed sets is closed, by Proposition 17.1.6 (b).

Proof. Write $K = \operatorname{cone}(\mathbf{a}_1, \ldots, \mathbf{a}_m)$, a convex cone by the remark after Definition 17.5.2. Let $\mathcal{S}$ be the set of those $S \subseteq \{1, \ldots, m\}$ for which $(\mathbf{a}_i)_{i\in S}$ is linearly independent, and for $S \in \mathcal{S}$ put $K_S = \operatorname{cone}(\mathbf{a}_i : i \in S)$. The empty set is in $\mathcal{S}$, and $\mathcal{S}$ is finite, with at most 2^m members.

First, $K = \bigcup_{S\in\mathcal{S}} K_S$. Each $K_S \subseteq K$, because a non-negative combination of some of the $\mathbf{a}_i$ is a non-negative combination of all of them with the remaining coefficients zero. And $K \subseteq \bigcup_S K_S$ is Theorem 17.5.2.

Next, each K_S is closed. If $S = \emptyset$, then $K_S = \{\mathbf{0}\}$. Otherwise $K_S = \operatorname{cone}(\mathbf{B}_S)$, where $\mathbf{B}_S$ is the matrix whose columns are the $\mathbf{a}_i$ with $i \in S$. Those columns are linearly independent, so Lemma 17.5.3 applies.

Hence K is a finite union of closed sets, closed by Proposition 17.1.6 (b).

■

The proof uses no analysis beyond the algebra of limits of Chapter 15's introduction, through Eq. 17.5.1 and the subsequence argument of Proposition 17.1.6 (b). In particular it never uses compactness, fact (A3) (the only compactness in the background would be the equivalence of norms, which fixing the Euclidean norm avoids); a finitely generated cone other than $\{\mathbf{0}\}$ is unbounded, so compactness had nothing to offer anyway. What the proof uses is **finite generation**, twice: for finitely many pieces, and for writing each piece as the image of an orthant under a matrix with a left inverse. The last part of the section shows that without it the conclusion can fail. In Farkas's lemma below, compactness enters only through the existence half of Theorem 17.3.1.

17.5.4 Farkas's lemma

We can now separate. Theorem 17.3.2 would give some hyperplane between $\mathbf{b}$ and the cone, but for a cone we want one **through the origin**, with a normal vector whose sign on the cone we control. Both come most cleanly from the nearest point of Theorem 17.3.1.

Lemma 17.5.5 — Separating a Point from a Closed Cone

Let V be a finite-dimensional real inner product space, let $K \subseteq V$ be a **closed** convex cone, and let $\mathbf{b} \in V$ with $\mathbf{b} \notin K$. Then there is $\mathbf{y} \in K^*$ with $\langle \mathbf{b}, \mathbf{y} \rangle < 0$.

Idea. Let $\mathbf{p}$ be the point of K nearest to $\mathbf{b}$, and use $\mathbf{y} = \mathbf{p} - \mathbf{b}$, the vector from $\mathbf{b}$ back to the cone. The inequality of Theorem 17.3.1 says that every point of K is seen from $\mathbf{p}$ at an angle of at least 90° from $\mathbf{b}$. Because K is a cone, we may test it against $\mathbf{0}$ and $2\mathbf{p}$, which shows that the separating hyperplane passes through the origin.

Proof. K is non-empty, closed and convex, so by Theorem 17.3.1 (a) there is a point $\mathbf{p} \in K$ nearest to $\mathbf{b}$, and by part (b) of the same theorem

$$\langle \mathbf{b} - \mathbf{p}, \mathbf{z} - \mathbf{p} \rangle \leq 0 \qquad \text{for every } \mathbf{z} \in K. \tag{17.5.2}$$

Put $\mathbf{y} = \mathbf{p} - \mathbf{b}$, which is non-zero since $\mathbf{p} \in K$ and $\mathbf{b} \notin K$. The points $\mathbf{z} = \mathbf{0}$ and $\mathbf{z} = 2\mathbf{p}$ lie in K, since K is a cone. Substituting them into Eq. 17.5.2 gives $\langle \mathbf{b} - \mathbf{p}, \mathbf{p} \rangle \geq 0$ and $\langle \mathbf{b} - \mathbf{p}, \mathbf{p} \rangle \leq 0$, so $\langle \mathbf{y}, \mathbf{p} \rangle = 0$. Now Eq. 17.5.2 reads $\langle \mathbf{b} - \mathbf{p}, \mathbf{z} \rangle \leq 0$, that is $\langle \mathbf{z}, \mathbf{y} \rangle \geq 0$, for every $\mathbf{z} \in K$. So $\mathbf{y} \in K^*$. Finally,

$$\langle \mathbf{b}, \mathbf{y} \rangle = \langle \mathbf{p} - \mathbf{y}, \mathbf{y} \rangle = \langle \mathbf{p}, \mathbf{y} \rangle - \langle \mathbf{y}, \mathbf{y} \rangle = -\|\mathbf{y}\|^2 < 0,$$

since $\mathbf{y} \neq \mathbf{0}$. This proves the lemma.

■

With $K = \operatorname{cone}(\mathbf{A})$, the lemma becomes the theorem this section is named after. It is stated for a matrix, since that is how it will be used.

Theorem 17.5.6 — Farkas's Lemma

Let $\mathbf{A} \in M_{m\times n}(\mathbb{R})$ and $\mathbf{b} \in \mathbb{R}^m$. **Exactly one** of the following has a solution:

(F1) $\mathbf{Ax} = \mathbf{b}$ with $\mathbf{x} \in \mathbb{R}^n$, $\mathbf{x} \geq \mathbf{0}$;
(F2) $\mathbf{A}^\top \mathbf{y} \geq \mathbf{0}$ and $\mathbf{b}^\top \mathbf{y} < 0$, with $\mathbf{y} \in \mathbb{R}^m$.

Idea. The two systems cannot both be solvable, which is one line of algebra: pair $\mathbf{Ax} = \mathbf{b}$ with $\mathbf{y}$. That at least one is solvable is geometry. If (F1) fails, then $\mathbf{b}$ lies outside the cone of the columns, the cone is closed by Theorem 17.5.4, and Lemma 17.5.5 produces $\mathbf{y}$.

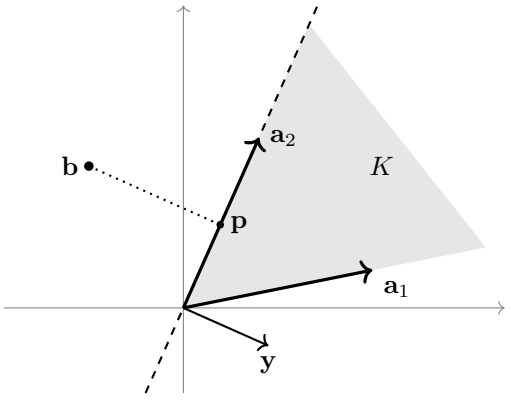
Proof. Not both. Suppose $\mathbf{Ax} = \mathbf{b}$ with $\mathbf{x} \geq \mathbf{0}$, and $\mathbf{A}^\top \mathbf{y} \geq \mathbf{0}$. Then

$$\mathbf{b}^\top \mathbf{y} = (\mathbf{Ax})^\top \mathbf{y} = \mathbf{x}^\top (\mathbf{A}^\top \mathbf{y}) \geq 0,$$

since it is a sum of products of the non-negative entries of $\mathbf{x}$ and $\mathbf{A}^\top \mathbf{y}$. So $\mathbf{b}^\top \mathbf{y} < 0$ is impossible.

At least one. Suppose (F1) has no solution. Let $K = \operatorname{cone}(\mathbf{A})$. By Definition 17.5.2, (F1) says exactly that $\mathbf{b} \in K$, so $\mathbf{b} \notin K$. By Theorem 17.5.4, K is a closed convex cone, so Lemma 17.5.5 gives $\mathbf{y} \in K^*$ with $\langle \mathbf{b}, \mathbf{y} \rangle = \mathbf{b}^\top \mathbf{y} < 0$. By Proposition 17.5.1 (d), $\mathbf{y} \in K^*$ means $\mathbf{A}^\top \mathbf{y} \geq \mathbf{0}$. So $\mathbf{y}$ solves (F2). This proves the theorem. ∎

The geometric reading. Either $\mathbf{b}$ lies in the cone spanned by the columns of $\mathbf{A}$, or there is a hyperplane through the origin, $\{\mathbf{z} : \langle \mathbf{z}, \mathbf{y} \rangle = 0\}$, with every column on one side ($\langle \mathbf{a}_j, \mathbf{y} \rangle \geq 0$) and $\mathbf{b}$ strictly on the other ($\langle \mathbf{b}, \mathbf{y} \rangle < 0$). The vector $\mathbf{y}$ is a **certificate of infeasibility**: anyone can check (F2) by multiplying out, and the "not both" computation then proves that (F1) has no solution.



$\mathbf{b}$ lies outside $K = \operatorname{cone}(\mathbf{a}_1, \mathbf{a}_2)$, and $\mathbf{p}$ is the point of K nearest to it. The vector $\mathbf{y}$ points along $\mathbf{p} - \mathbf{b}$. The dashed line $\langle \mathbf{z}, \mathbf{y} \rangle = 0$ passes through $\mathbf{0}$, with K on the side $\langle \mathbf{z}, \mathbf{y} \rangle \geq 0$ and $\mathbf{b}$ strictly on the other

Example. (Deciding a system both ways)

Let

$$\mathbf{A} = \begin{pmatrix} 1 & 2 & 0 \\ 0 & 1 & 1 \end{pmatrix}, \qquad \mathbf{b} = \begin{pmatrix} 3 \\ 2 \end{pmatrix}, \qquad \mathbf{b}' = \begin{pmatrix} -1 \\ 1 \end{pmatrix}.$$

Decide, for $\mathbf{b}$ and for $\mathbf{b}'$, which alternative of Theorem 17.5.6 holds, and exhibit the solution.

Solution. The columns are $\mathbf{a}_1 = \mathbf{e}_1$, $\mathbf{a}_2 = (2,1)$ and $\mathbf{a}_3 = \mathbf{e}_2$, all in the closed first quadrant. So $\operatorname{cone}(\mathbf{A}) \subseteq \mathbb{R}^2_{\geq 0}$, and in fact the two are equal, since $\mathbf{e}_1$ and $\mathbf{e}_2$ are among the generators.

For $\mathbf{b} = (3,2)$ we expect (F1). The system $x_1 + 2x_2 = 3$, $x_2 + x_3 = 2$ has, for example, the solution $\mathbf{x} = (3,0,2) \geq \mathbf{0}$, and also $\mathbf{x} = (1,1,1)$. Non-negative solutions need not be unique.

For $\mathbf{b}' = (-1,1)$ we expect (F2), since $\mathbf{b}'$ has a negative first entry. Try $\mathbf{y} = \mathbf{e}_1$: then $\mathbf{A}^\top \mathbf{y} = (1,2,0) \geq \mathbf{0}$ and $\mathbf{b}'^\top \mathbf{y} = -1 < 0$. So $\mathbf{y} = \mathbf{e}_1$ is a certificate, and by the "not both" half of Theorem 17.5.6 the system $\mathbf{Ax} = \mathbf{b}'$, $\mathbf{x} \geq \mathbf{0}$ has no solution. The certificate encodes a one-line argument: the first equation reads $x_1 + 2x_2 = -1$, and its left side is ≥ 0 whenever $\mathbf{x} \geq \mathbf{0}$.

Linear programming, in the next section, meets systems of **inequalities**, $\mathbf{Ax} \leq \mathbf{b}$ with $\mathbf{x} \geq \mathbf{0}$. Farkas's lemma handles them after one standard move: add a **slack** variable to turn each inequality into an equation.

Corollary 17.5.7 — Farkas's Lemma for Inequalities

Let $\mathbf{M} \in M_{m\times n}(\mathbb{R})$ and $\mathbf{d} \in \mathbb{R}^m$. Exactly one of the following has a solution:

(i) $\mathbf{Mz} \leq \mathbf{d}$ with $\mathbf{z} \in \mathbb{R}^n$, $\mathbf{z} \geq \mathbf{0}$;
(ii) $\mathbf{w} \geq \mathbf{0}$, $\mathbf{M}^\top \mathbf{w} \geq \mathbf{0}$ and $\mathbf{d}^\top \mathbf{w} < 0$, with $\mathbf{w} \in \mathbb{R}^m$.

Idea. A slack vector $\mathbf{s} = \mathbf{d} - \mathbf{Mz} \geq \mathbf{0}$ turns the inequalities into equations with matrix $\begin{pmatrix} \mathbf{M} & \mathbf{I}_m \end{pmatrix}$, and in Theorem 17.5.6 the identity block becomes the extra condition $\mathbf{w} \geq \mathbf{0}$.

Proof. Here $\mathbf{Mz} \leq \mathbf{d}$ means $\mathbf{d} - \mathbf{Mz} \geq \mathbf{0}$. So (i) has a solution if and only if there are $\mathbf{z} \geq \mathbf{0}$ and $\mathbf{s} \geq \mathbf{0}$ in $\mathbb{R}^m$ with $\mathbf{Mz} + \mathbf{s} = \mathbf{d}$: given $\mathbf{z}$, take $\mathbf{s} = \mathbf{d} - \mathbf{Mz}$, and given $\mathbf{z}$ and $\mathbf{s}$, drop $\mathbf{s}$. In block form this reads

$$\begin{pmatrix} \mathbf{M} & \mathbf{I}_m \end{pmatrix} \begin{pmatrix} \mathbf{z} \\ \mathbf{s} \end{pmatrix} = \mathbf{d}, \qquad \begin{pmatrix} \mathbf{z} \\ \mathbf{s} \end{pmatrix} \geq \mathbf{0}.$$

Apply Theorem 17.5.6 to the $m \times (n+m)$ matrix $\begin{pmatrix} \mathbf{M} & \mathbf{I}_m \end{pmatrix}$ and to $\mathbf{d}$. Exactly one of the system above and the following is solvable: $\begin{pmatrix} \mathbf{M} & \mathbf{I}_m \end{pmatrix}^\top \mathbf{w} \geq \mathbf{0}$ and $\mathbf{d}^\top \mathbf{w} < 0$. The transpose has the blocks $\mathbf{M}^\top$ and $\mathbf{I}_m$ stacked, so the first condition says $\mathbf{M}^\top \mathbf{w} \geq \mathbf{0}$ and $\mathbf{w} \geq \mathbf{0}$. That is (ii).

■

17.5.5 The dual of the dual

Farkas's lemma has a coordinate-free form, which says that nothing is lost by passing to the dual cone twice, provided the cone is closed.

Theorem 17.5.8 — The Bidual of a Closed Cone

Let V be a finite-dimensional real inner product space and let $K \subseteq V$ be a **closed** convex cone. Then $K^{**} = K$.

Proof. $K \subseteq K^{**}$ is Proposition 17.5.1 (c). Conversely, let $\mathbf{b} \notin K$. By Lemma 17.5.5 there is $\mathbf{y} \in K^*$ with $\langle \mathbf{b}, \mathbf{y} \rangle < 0$. That single $\mathbf{y}$ shows $\mathbf{b} \notin K^{**}$. Hence $K^{**} \subseteq K$, and the two are equal. ∎

For $K = \operatorname{cone}(\mathbf{A})$, which is closed by Theorem 17.5.4, the theorem **is** Farkas's lemma. By Proposition 17.5.1 (d), $K^* = \{\mathbf{y} : \mathbf{A}^{\top}\mathbf{y} \geq \mathbf{0}\}$, so "$\mathbf{b} \in K^{**}$" says that every $\mathbf{y}$ with $\mathbf{A}^{\top}\mathbf{y} \geq \mathbf{0}$ has $\mathbf{b}^{\top}\mathbf{y} \geq 0$, that is, (F2) has no solution. And "$\mathbf{b} \in K$" is (F1). This is the "dualize" move in its purest form: a question about a cone (is $\mathbf{b}$ in it?) is traded for one about its dual (does every member of the dual approve of $\mathbf{b}$?), and the trade is exact when the cone is closed.

Remark. For the wedge $K = \operatorname{cone}\big((1,0),(1,1)\big)$, whose dual is $\operatorname{cone}\big((0,1),(1,-1)\big)$ by Exercise (B3: A dual cone and its dual), the theorem and Proposition 17.5.1 (d) say that $K = \{\mathbf{x} : \langle \mathbf{x}, (0,1) \rangle \geq 0,\ \langle \mathbf{x}, (1,-1) \rangle \geq 0\}$, one inequality for each generator of K^*. In general the theorem describes a closed convex cone from outside, as an intersection of half-spaces through the origin; for a finitely generated cone finitely many suffice, which is one half of the Minkowski–Weyl theorem of Section 9.

17.5.6 When the cone is not finitely generated

The system "$\mathbf{Ax} = \mathbf{b},\ \mathbf{x} \geq \mathbf{0}$" asks whether $\mathbf{b}$ lies in the image of the orthant under $\mathbf{x} \mapsto \mathbf{Ax}$. Replace the orthant by a closed convex cone $K \subseteq \mathbb{R}^k$ and $\mathbf{A}$ by a matrix $\mathbf{P} \in M_{m \times k}(\mathbb{R})$, and ask whether $\mathbf{b} \in \mathbf{P}(K)$. The "not both" half of the proof of Theorem 17.5.6 survives unchanged. The "at least one" half needs $\mathbf{P}(K)$ to be closed, and the next example shows that this can fail.

Example. (A closed cone with a non-closed shadow)

In $\mathbb{R}^3$, with coordinates (x, y, z), let

$$K = \{(x,y,z) : xs^2 + 2y\,st + zt^2 \geq 0 \text{ for all } s,t \in \mathbb{R}\},$$

the set of triples for which the symmetric matrix $\left(\begin{smallmatrix} x & y \\ y & z \end{smallmatrix}\right)$ is positive semidefinite (Definition 12.1.1). Let $\mathbf{P} = \left(\begin{smallmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \end{smallmatrix}\right)$, so that $\mathbf{P}(x,y,z) = (x,y)$ is the projection onto the first two coordinates, and write $\mathbf{P}(K) = \{\mathbf{Pk} : \mathbf{k} \in K\}$. Show that K is a closed convex cone, but that

$$\mathbf{P}(K) = \{(x,y) : x > 0\} \cup \{(0,0)\},$$

the cone of the earlier warning, which is not closed. Then show that for $\mathbf{b} = (0,1)$

neither of the two alternatives holds:

(i) $\mathbf{Pk} = \mathbf{b}$ for some $\mathbf{k} \in K$;

(ii) $\langle \mathbf{Pk}, \mathbf{y} \rangle \geq 0$ for every $\mathbf{k} \in K$, and $\langle \mathbf{b}, \mathbf{y} \rangle < 0$, for some $\mathbf{y} \in \mathbb{R}^2$.

Solution. K is a closed convex cone. Write $q_{\mathbf{k}}(s,t) = xs^2 + 2yst + zt^2$ for $\mathbf{k} = (x,y,z)$. It is linear in $\mathbf{k}$: $q_{a\mathbf{k}+b\mathbf{k}'} = aq_{\mathbf{k}} + bq_{\mathbf{k}'}$. So if $\mathbf{k}, \mathbf{k}' \in K$ and $a, b \geq 0$, then $q_{a\mathbf{k}+b\mathbf{k}'}(s,t) \geq 0$ for all s,t, and K is a convex cone that contains $\mathbf{0}$. If $\mathbf{k}_j \to \mathbf{k}$ with $\mathbf{k}_j \in K$, then for fixed s,t the number $q_{\mathbf{k}_j}(s,t)$ is a fixed linear combination of the entries of $\mathbf{k}_j$. So it converges to $q_{\mathbf{k}}(s,t)$, and $q_{\mathbf{k}}(s,t) \geq 0$ because a non-strict inequality survives a limit. Hence K is closed.

Membership. By Theorem 12.1.4 (a) $\Leftrightarrow$ (e), $(x,y,z) \in K$ exactly when the principal minors x, z and $xz - y^2$ are all ≥ 0.

The image. $(0,0) = \mathbf{P}(\mathbf{0}) \in \mathbf{P}(K)$. If $x > 0$ and y is arbitrary, put $z = y^2/x$. Then $x \geq 0$, $z \geq 0$ and $xz - y^2 = 0$, so $(x,y,z) \in K$ and $(x,y) \in \mathbf{P}(K)$. Conversely, if $(x,y,z) \in K$, then $x \geq 0$, and if $x = 0$ then $0 = xz \geq y^2$ forces $y = 0$. So $\mathbf{P}(K)$ is exactly the displayed set. It is not closed: $(1/k, 1) \in \mathbf{P}(K)$ converges to $(0,1) \notin \mathbf{P}(K)$.

Neither alternative holds for $\mathbf{b} = (0,1)$. Alternative (i) fails because $\mathbf{b} \notin \mathbf{P}(K)$. For (ii), suppose $\mathbf{y} = (y_1, y_2)$ has $\langle \mathbf{Pk}, \mathbf{y} \rangle \geq 0$ for every $\mathbf{k} \in K$. Since $(1,t) \in \mathbf{P}(K)$ for every real t, we get $y_1 + ty_2 \geq 0$ for all t. A non-constant affine function of t takes negative values, so $y_2 = 0$. But then $\langle \mathbf{b}, \mathbf{y} \rangle = y_2 = 0$, which is not < 0. So (ii) fails too.

It is worth seeing exactly where the proof of Theorem 17.5.6 breaks. The vectors $\mathbf{k}_j = (1/j, 1, j)$ lie in K, their images $(1/j, 1)$ converge to $\mathbf{b}$, and the $\mathbf{k}_j$ themselves run off to infinity in the third coordinate. This is the escape that the left inverse in Lemma 17.5.3 prevented. There is no nearest point of $\mathbf{P}(K)$ to $\mathbf{b}$: the distance is 0, but $\mathbf{b}$ is not in the set, so Lemma 17.5.5 has nothing to start from. What fails is **closedness**, which is why the finitely generated case needed its own theorem.

The dual cone cannot see the difference either: $\mathbf{P}(K)^{**}$ is the closed half-plane $\{x \geq 0\}$, strictly larger than $\mathbf{P}(K)$, as Exercise (C3: The bidual sees only the closure) shows.

17.5.7 Exercises

17.5.7.1 A. Check your understanding

Exercise A1.

(a) Define a convex cone and the dual cone of a subset S of $\mathbb{R}^n$.

(b) State Farkas's lemma, and say in one sentence what the vector $\mathbf{y}$ in the second alternative certifies.

(c) Determine whether the following is correct, and justify your answer: every convex cone in $\mathbb{R}^2$ is closed.

(d) Determine whether the following is correct, and justify your answer: the union of two convex cones in $\mathbb{R}^2$ is a convex cone.

(e) In Theorem 17.5.2 the bound is n generators, while Theorem 17.2.2 allows $n+1$

points. Which feature of the proof accounts for the difference?

Solution.

(a) A convex cone is a non-empty $K \subseteq \mathbb{R}^n$ with $a\mathbf{u} + b\mathbf{v} \in K$ for all $\mathbf{u}, \mathbf{v} \in K$ and all real $a, b \geq 0$. The dual cone of S is $S^* = \{\mathbf{y} : \langle \mathbf{x}, \mathbf{y} \rangle \geq 0 \text{ for every } \mathbf{x} \in S\}$.

(b) For $\mathbf{A} \in M_{m\times n}(\mathbb{R})$ and $\mathbf{b} \in \mathbb{R}^m$, exactly one of the following is solvable: $\mathbf{Ax} = \mathbf{b}$ with $\mathbf{x} \geq \mathbf{0}$, or $\mathbf{A}^\top \mathbf{y} \geq \mathbf{0}$ with $\mathbf{b}^\top \mathbf{y} < 0$. Such a $\mathbf{y}$ certifies that the first system has no solution, since any solution $\mathbf{x}$ would give $0 > \mathbf{b}^\top \mathbf{y} = \mathbf{x}^\top \mathbf{A}^\top \mathbf{y} \geq 0$.

(c) Incorrect. The cone $\{(x, y) : x > 0\} \cup \{\mathbf{0}\}$ of the warning in this section is a convex cone, but $(1/k, 1) \to (0, 1)$ leaves it.

(d) Incorrect. The two quadrants $\mathbb{R}^2_{\geq 0}$ and $-\mathbb{R}^2_{\geq 0}$ are convex cones, and their union contains $(1, 0)$ and $(0, -1)$ but not their sum $(1, -1)$.

(e) For cones the dependence to be removed is a **linear** dependence $\sum c_i \mathbf{a}_i = \mathbf{0}$, and a linearly independent list in an n-dimensional space has at most n members. For convex hulls it is an **affine** dependence (coefficients also summing to 0), and an affinely independent list can have $n + 1$ members.

17.5.7.2 B. Practice

Exercise B1: Recognizing cones.

Determine which of the following subsets of $\mathbb{R}^2$ or $\mathbb{R}^3$ are convex cones. Justify your answers.

(a) $\{\mathbf{x} \in \mathbb{R}^2 : x_1 \geq |x_2|\}$.

(b) $\{\mathbf{x} \in \mathbb{R}^3 : x_1 + x_2 + x_3 = 0\}$.

(c) $\{\mathbf{x} \in \mathbb{R}^2 : x_1 \geq 1\}$.

(d) $\{\mathbf{x} \in \mathbb{R}^2 : x_2 \geq x_1^2\}$.

(e) $\{\mathbf{x} \in \mathbb{R}^3 : x_1 \geq 0,\ x_2 \geq 0,\ x_3 \leq x_1 + x_2\}$.

Solution.

(a) A convex cone. It is non-empty, containing $\mathbf{0}$. If $x_1 \geq |x_2|$, $y_1 \geq |y_2|$ and $a, b \geq 0$, then by the triangle inequality for real numbers

$$|ax_2 + by_2| \leq a|x_2| + b|y_2| \leq ax_1 + by_1.$$

It is $\operatorname{cone}\big((1, 1), (1, -1)\big)$, a quarter-plane turned by $45°$.

(b) A convex cone. It is a subspace, being the null space of $\begin{pmatrix} 1 & 1 & 1 \end{pmatrix}$, and every subspace is a convex cone.

(c) Not a convex cone: it does not contain $\mathbf{0}$, which taking $a = b = 0$ in the definition would force into it. It is convex and closed under addition; what fails is scaling by $0 \leq a < 1$, for instance $\frac{1}{2}(1, 0) = (\frac{1}{2}, 0)$ is not in it.

(d) Not a convex cone. It is convex, but it is not closed under non-negative scaling: $(1, 1)$ is in it, and $2(1, 1) = (2, 2)$ is not, since $2 < 4$.

(e) A convex cone. Each of the three conditions is a homogeneous linear inequality $\langle \mathbf{x}, \mathbf{a} \rangle \geq 0$, with $\mathbf{a} = \mathbf{e}_1$, $\mathbf{e}_2$ and $(1, 1, -1)$, so the set is an intersection of three half-

spaces through the origin. Each is a convex cone by the examples of this section, and an intersection of convex cones is a convex cone: it contains $\mathbf{0}$, and each member cone contains every non-negative combination of points of the intersection.

Exercise B2: A certificate either way.

Let $\mathbf{A} = \begin{pmatrix} 1 & 1 & -1 \\ 0 & 1 & 2 \end{pmatrix}$. For each of $\mathbf{b} = (0, 3)$ and $\mathbf{b} = (-1, 1)$, decide which alternative of Theorem 17.5.6 holds, and exhibit a solution of that alternative.

Solution. The columns are $\mathbf{a}_1 = (1, 0)$, $\mathbf{a}_2 = (1, 1)$ and $\mathbf{a}_3 = (-1, 2)$.

For $\mathbf{b} = (0, 3)$, try $\mathbf{x} = (0, x_2, x_3)$: the equations $x_2 - x_3 = 0$ and $x_2 + 2x_3 = 3$ give $x_2 = x_3 = 1$. So $\mathbf{x} = (0, 1, 1) \geq \mathbf{0}$ solves $\mathbf{Ax} = \mathbf{b}$, and (F1) holds.

For $\mathbf{b} = (-1, 1)$, look for $\mathbf{y}$ perpendicular to the "outermost" generator $\mathbf{a}_3$ and non-negative on the others. The vector $\mathbf{y} = (2, 1)$ gives $\mathbf{A}^\top \mathbf{y} = (2, 3, 0) \geq \mathbf{0}$ and $\mathbf{b}^\top \mathbf{y} = -2 + 1 = -1 < 0$. So (F2) holds, and by Theorem 17.5.6 the system $\mathbf{Ax} = (-1, 1)$, $\mathbf{x} \geq \mathbf{0}$ has no solution. As a direct check, adding twice the first equation to the second gives $2x_1 + 3x_2 = -1$, whose left side is ≥ 0 for $\mathbf{x} \geq \mathbf{0}$.

Exercise B3: A dual cone and its dual.

Let $K = \operatorname{cone}\big((1, 0), (1, 1)\big) \subseteq \mathbb{R}^2$.

(a) Show that $K^* = \operatorname{cone}\big((0, 1), (1, -1)\big)$.

(b) Compute K^{**} and check that it equals K, as Theorem 17.5.8 predicts.

Solution.

(a) By Proposition 17.5.1 (d), $K^* = \{\mathbf{y} : y_1 \geq 0,\ y_1 + y_2 \geq 0\}$. Given such a $\mathbf{y}$, write $\mathbf{y} = (y_1 + y_2)(0, 1) + y_1(1, -1)$: indeed the right side is $(y_1, y_1 + y_2 - y_1) = (y_1, y_2)$, and both coefficients are ≥ 0. So $\mathbf{y} \in \operatorname{cone}\big((0, 1), (1, -1)\big)$. Conversely, both generators satisfy the two inequalities, and the set defined by the inequalities is a convex cone, so it contains the cone they generate.

(b) Applying Proposition 17.5.1 (d) to the generators found in (a), $K^{**} = \{\mathbf{x} : x_2 \geq 0,\ x_1 - x_2 \geq 0\}$. The same decomposition argument, now with $\mathbf{x} = (x_1 - x_2)(1, 0) + x_2(1, 1)$, shows this set is $\operatorname{cone}\big((1, 0), (1, 1)\big) = K$.

17.5.7.3 C. Going deeper

Exercise C1: Gordan's alternative.

Let $\mathbf{A} \in M_{m \times n}(\mathbb{R})$.

(a) Prove that exactly one of the following has a solution: $\mathbf{Ax} = \mathbf{0}$ with $\mathbf{x} \geq \mathbf{0}$ and $\mathbf{x} \neq \mathbf{0}$; or $\mathbf{A}^\top \mathbf{y} > \mathbf{0}$ with $\mathbf{y} \in \mathbb{R}^m$.

(b) Deduce that if the columns of $\mathbf{A}$ are $(1, 0)$, $(0, 1)$ and $(-1, -1)$, then some non-trivial non-negative combination of them is $\mathbf{0}$, and find one.

Hint for (a): scale $\mathbf{x}$ *so that its entries sum to* 1*, and apply Theorem 17.5.6 to* $\mathbf{A}$ *with an extra row of ones.*

Solution.

(a) *Not both.* If $\mathbf{Ax} = \mathbf{0}$ with $\mathbf{x} \geq \mathbf{0}$, $\mathbf{x} \neq \mathbf{0}$, and $\mathbf{A}^\top \mathbf{y} > \mathbf{0}$, then $0 = \mathbf{y}^\top \mathbf{Ax} = \sum_j x_j (\mathbf{A}^\top \mathbf{y})_j$. Every term is ≥ 0, and the term for an index with $x_j > 0$ is > 0. That is a contradiction.
At least one. Suppose the first system has no solution. If $\mathbf{Ax} = \mathbf{0}$, $\mathbf{x} \geq \mathbf{0}$ and $\mathbf{1}^\top \mathbf{x} = 1$, then $\mathbf{x} \neq \mathbf{0}$ would solve it. So the system

$$\begin{pmatrix} \mathbf{A} \\ \mathbf{1}^\top \end{pmatrix} \mathbf{x} = \begin{pmatrix} \mathbf{0} \\ 1 \end{pmatrix}, \qquad \mathbf{x} \geq \mathbf{0},$$

has no solution. By Theorem 17.5.6 there is $(\mathbf{y}, s) \in \mathbb{R}^m \times \mathbb{R}$ with $\mathbf{A}^\top \mathbf{y} + s\mathbf{1} \geq \mathbf{0}$ and $\mathbf{0}^\top \mathbf{y} + 1 \cdot s < 0$, that is, $s < 0$. Then $\mathbf{A}^\top \mathbf{y} \geq -s\mathbf{1} > \mathbf{0}$, so $\mathbf{y}$ solves the second system.

(b) Here $\mathbf{A} = \left(\begin{smallmatrix} 1 & 0 & -1 \\ 0 & 1 & -1 \end{smallmatrix}\right)$. The second system is impossible: $\mathbf{A}^\top \mathbf{y} = (y_1, y_2, -y_1 - y_2)$, and its entries sum to 0, so they cannot all be positive. By (a) the first system is solvable. Indeed $\mathbf{x} = (1, 1, 1)$ gives $\mathbf{Ax} = (1 - 1, 1 - 1) = \mathbf{0}$.

Exercise C2: The ice-cream cone is its own dual.

Let $L = \{(\mathbf{x}, t) \in \mathbb{R}^n \times \mathbb{R} : \|\mathbf{x}\|_2 \leq t\}$, with the inner product $\langle (\mathbf{x}, t), (\mathbf{y}, s) \rangle = \mathbf{y}^\top \mathbf{x} + ts$ on $\mathbb{R}^{n+1}$.

(a) Prove that $L \subseteq L^*$.

(b) Prove that $L^* \subseteq L$.

(c) Deduce that L is closed.

Hint for (b): test $(\mathbf{y}, s) \in L^*$ *against the member* $(-\mathbf{y}, \|\mathbf{y}\|_2)$ *of* L*.*

Solution.

(a) Let $(\mathbf{x}, t), (\mathbf{y}, s) \in L$. By Theorem 10.1.5, $|\mathbf{y}^\top \mathbf{x}| \leq \|\mathbf{x}\|_2 \|\mathbf{y}\|_2 \leq ts$, where the last step multiplies the inequalities $0 \leq \|\mathbf{x}\|_2 \leq t$ and $0 \leq \|\mathbf{y}\|_2 \leq s$. Hence $\mathbf{y}^\top \mathbf{x} + ts \geq ts - |\mathbf{y}^\top \mathbf{x}| \geq 0$. Fix $(\mathbf{y}, s) \in L$: we have shown that its inner product with every $(\mathbf{x}, t) \in L$ is ≥ 0, so $(\mathbf{y}, s) \in L^*$. Hence $L \subseteq L^*$.

(b) Let $(\mathbf{y}, s) \in L^*$. The point $(-\mathbf{y}, \|\mathbf{y}\|_2)$ lies in L, so

$$0 \leq \langle (-\mathbf{y}, \|\mathbf{y}\|_2), (\mathbf{y}, s) \rangle = -\|\mathbf{y}\|_2^2 + s\|\mathbf{y}\|_2 = \|\mathbf{y}\|_2 \big(s - \|\mathbf{y}\|_2\big).$$

If $\mathbf{y} \neq \mathbf{0}$, dividing by $\|\mathbf{y}\|_2 > 0$ gives $s \geq \|\mathbf{y}\|_2$. If $\mathbf{y} = \mathbf{0}$, test against $(\mathbf{0}, 1) \in L$ instead: $s \geq 0 = \|\mathbf{y}\|_2$. Either way $(\mathbf{y}, s) \in L$.

(c) By (a) and (b), $L = L^*$, and every dual cone is closed by Proposition 17.5.1 (a).

Exercise C3: The bidual sees only the closure.

Let $C = \{(x, y) : x > 0\} \cup \{(0, 0)\} \subseteq \mathbb{R}^2$, the image cone of Example (A closed cone

with a non-closed shadow).

(a) Prove that $C^* = \{(y_1, 0) : y_1 \geq 0\}$.

(b) Prove that $C^{**} = \{(x, y) : x \geq 0\}$.

(c) Explain why this does not contradict Theorem 17.5.8, and show that C^{**} is the set of all limits of convergent sequences of points of C.

Solution.

(a) If $(y_1, y_2) \in C^*$, then testing against $(1, t) \in C$ gives $y_1 + ty_2 \geq 0$ for every real t. This forces $y_2 = 0$, as in the example, and then $t = 0$ gives $y_1 \geq 0$. Conversely, if $y_2 = 0$ and $y_1 \geq 0$, then $\langle (x, y), (y_1, 0) \rangle = xy_1 \geq 0$ for every $(x, y) \in C$, since $x \geq 0$ on C.

(b) By (a), $C^* = \operatorname{cone}\big((1, 0)\big)$, so by Proposition 17.5.1 (d),

$$C^{**} = \{(x, y) : \langle (x, y), (1, 0) \rangle \geq 0\} = \{(x, y) : x \geq 0\}.$$

(c) Theorem 17.5.8 assumes the cone is closed, and C is not. Every point of C^{**} is such a limit: if $x > 0$ or $(x, y) = \mathbf{0}$, use the constant sequence; if $x = 0$, use $(1/k, y) \in C$, which tends to $(0, y)$. Conversely, a limit of points of $C \subseteq C^{**}$ lies in C^{**}, because C^{**} is closed by Proposition 17.5.1 (a). So C^{**} is exactly the set of limits of sequences in C.

17.6 Linear Programming Duality

Chapter 2 ended its traffic example (Example (Traffic in a town center)) by admitting what linear algebra alone cannot do: "Non-negativity and street capacities turn the problem into one about inequalities, which is the subject of linear programming." This section takes up that subject. A **linear program** asks for the largest value of a linear function on a region cut out by finitely many linear inequalities. The theory is almost entirely one idea. Every such maximum comes with a companion minimum, the **dual** program, and the two optimal values are equal. The proof of that equality is Farkas's lemma of §05, applied to one combined system.

The equality has a practical meaning that goes beyond the theorem. A feasible point proves a lower bound on the maximum, a dual feasible point proves an upper bound, and when the two bounds meet, the answer has been **certified**: anyone can check it by multiplying out, with no need to trust how it was found.

Throughout, the field is $\mathbb{R}$, vectors are columns, and $\mathbf{x} \geq \mathbf{0}$, $\mathbf{u} \leq \mathbf{v}$ are the entrywise relations of §05.

17.6.1 Linear programs

Here is a small instance of the kind of question we want to answer. A workshop makes two products. Each unit of the first uses 2 hours of machine time and 1 hour of labor, each unit of the second uses 1 hour of machine time and 3 hours of labor, and at most 3 units of the first can be sold. Machine time is limited to 7 hours, labor to 9, and the profits are 4 and 3 per unit.

With x_1, x_2 units made, the question is:

$$\begin{aligned} \text{maximize} \quad & 4x_1 + 3x_2 \\ \text{subject to} \quad & 2x_1 + x_2 \le 7, \quad x_1 + 3x_2 \le 9, \quad x_1 \le 3, \\ & x_1 \ge 0, \quad x_2 \ge 0. \end{aligned}$$

The objective and every constraint are linear, and there are finitely many constraints. In matrix form it reads "maximize $\mathbf{c}^\top \mathbf{x}$ subject to $\mathbf{A}\mathbf{x} \le \mathbf{b}$, $\mathbf{x} \ge \mathbf{0}$". That shape deserves a name.

A linear program is the search for the best value of a linear function over a region defined by finitely many linear inequalities.

Definition 17.6.1 — Linear Program

Let $\mathbf{A} \in M_{m\times n}(\mathbb{R})$, $\mathbf{b} \in \mathbb{R}^m$ and $\mathbf{c} \in \mathbb{R}^n$. The **linear program** with these data, in **inequality form**, is the problem

$$\text{(P)} \qquad \text{maximize } \mathbf{c}^\top \mathbf{x} \quad \text{subject to} \quad \mathbf{A}\mathbf{x} \le \mathbf{b}, \quad \mathbf{x} \ge \mathbf{0}.$$

A vector $\mathbf{x} \in \mathbb{R}^n$ with $\mathbf{A}\mathbf{x} \le \mathbf{b}$ and $\mathbf{x} \ge \mathbf{0}$ is a **feasible point**, and the set of all of them is the **feasible region**. The program is **feasible** if it has a feasible point and **infeasible** otherwise. It is **unbounded** if it is feasible and $\mathbf{c}^\top \mathbf{x}$ takes **arbitrarily large** values on the feasible region. A feasible $\mathbf{x}^\star$ is an **optimal solution** if $\mathbf{c}^\top \mathbf{x}^\star \ge \mathbf{c}^\top \mathbf{x}$ for **every** feasible $\mathbf{x}$, and then $\mathbf{c}^\top \mathbf{x}^\star$ is the **optimal value**.

Clause by clause. The function $\mathbf{x} \mapsto \mathbf{c}^\top \mathbf{x}$ is the **objective**. The m rows of $\mathbf{A}\mathbf{x} \le \mathbf{b}$ are the **constraints**, and $\mathbf{x} \ge \mathbf{0}$ adds n more. An optimal solution is a feasible point at which the objective is **as large as anywhere** on the feasible region, and it need not be unique. The optimal value is unique when it exists. A program can fail to have an optimal solution in two ways: it can have no feasible point, or its objective can be unbounded above. Whether those are the **only** two ways is the question the section's second theorem settles.

Examples. The workshop problem is (P) with

$$\mathbf{A} = \begin{pmatrix} 2 & 1 \\ 1 & 3 \\ 1 & 0 \end{pmatrix}, \qquad \mathbf{b} = \begin{pmatrix} 7 \\ 9 \\ 3 \end{pmatrix}, \qquad \mathbf{c} = \begin{pmatrix} 4 \\ 3 \end{pmatrix}.$$

- **One variable.** With $n = m = 1$, "maximize x subject to $x \le 2$, $x \ge 0$" has the optimal solution $x = 2$. "Maximize x subject to $-x \le -1$, $x \ge 0$" asks for the largest $x \ge 1$, and it is unbounded. "Maximize x subject to $x \le -1$, $x \ge 0$" is infeasible.
- **Degenerate case.** If $\mathbf{c} = \mathbf{0}$, every feasible point is optimal, with value 0. The program then asks only whether the system $\mathbf{A}\mathbf{x} \le \mathbf{b}$, $\mathbf{x} \ge \mathbf{0}$ has a solution. So the feasibility question of Corollary 17.5.7 is itself a linear program, the one with no objective.

Non-example by minimal change. Make one inequality strict: "maximize x subject to $x < 2$, $x \ge 0$". Everything is still linear, but the supremum 2 is not attained, and no feasible point is optimal. The definition allows only non-strict inequalities. They define **closed** regions, and closedness will again be what the proofs need.

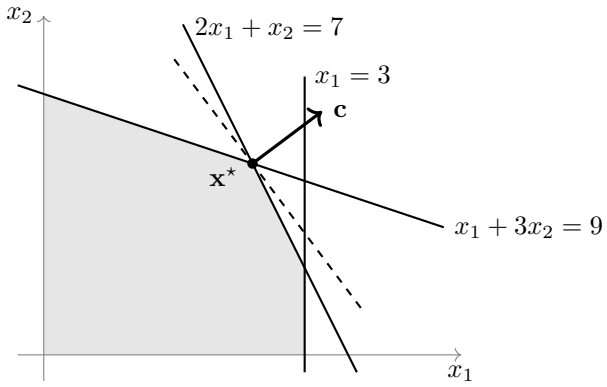
Why this form. Every problem with a linear objective and finitely many linear constraints can be brought to the shape (P). To minimize $\mathbf{c}^\top \mathbf{x}$, maximize $(-\mathbf{c})^\top \mathbf{x}$. A constraint $\mathbf{a}^\top \mathbf{x} \ge \beta$ is $(-\mathbf{a})^\top \mathbf{x} \le -\beta$. An equation $\mathbf{a}^\top \mathbf{x} = \beta$ is the pair $\mathbf{a}^\top \mathbf{x} \le \beta$, $-\mathbf{a}^\top \mathbf{x} \le -\beta$. A variable x_j without

a sign constraint can be written $x_j = u_j - v_j$ with $u_j, v_j \geq 0$. Exercise (C2: Free variables) carries out the last conversion. The form (P), with its sign constraints on $\mathbf{x}$, is chosen because its dual, below, has the same shape, which makes the theory symmetric.

Example. (The workshop problem, drawn)

Find the optimal solution of the workshop problem, and explain why it is optimal.

Solution. The feasible region is the pentagon with corners $(0,0)$, $(3,0)$, $(3,1)$, $\left(\frac{12}{5}, \frac{11}{5}\right)$ and $(0,3)$. For example, $(3,1)$ is where $x_1 = 3$ meets $2x_1 + x_2 = 7$, and $\left(\frac{12}{5}, \frac{11}{5}\right)$ solves $2x_1 + x_2 = 7$, $x_1 + 3x_2 = 9$: subtracting twice the second equation from the first gives $-5x_2 = -11$.



The feasible region (shaded). The dashed line is the level set $4x_1 + 3x_2 = 81/5$. Moving it in the direction $\mathbf{c} = (4,3)$ leaves the region, which it last touches at $\mathbf{x}^\star = (12/5, 11/5)$

The level sets $4x_1 + 3x_2 = \text{const}$ are parallel lines, and the value grows in the direction $\mathbf{c} = (4,3)$. Sliding the line in that direction, the last point of the region it meets appears to be $\mathbf{x}^\star = \left(\frac{12}{5}, \frac{11}{5}\right)$, with value

$$4 \cdot \tfrac{12}{5} + 3 \cdot \tfrac{11}{5} = \tfrac{48+33}{5} = \tfrac{81}{5}.$$

Comparing the corners supports this: they give 0, 12, 15, $\frac{81}{5} = 16.2$ and 9.

A picture is not a proof, and neither is a list of five corners, since we have not proved that an optimum sits at a corner. Here is a proof. Multiply the first constraint by $\frac{9}{5}$ and the second by $\frac{2}{5}$, both non-negative, and add:

$$\tfrac{9}{5}(2x_1 + x_2) + \tfrac{2}{5}(x_1 + 3x_2) \leq \tfrac{9}{5} \cdot 7 + \tfrac{2}{5} \cdot 9 = \tfrac{81}{5}.$$

The left side is $\left(\frac{18}{5} + \frac{2}{5}\right)x_1 + \left(\frac{9}{5} + \frac{6}{5}\right)x_2 = 4x_1 + 3x_2$. So **every** feasible point has $4x_1 + 3x_2 \leq \frac{81}{5}$, and $\mathbf{x}^\star$, which is feasible ($\frac{12}{5} \leq 3$ as well), reaches this bound. It is optimal, and the optimal value is $\frac{81}{5}$.

The multipliers $\frac{9}{5}$ and $\frac{2}{5}$ are the heart of the matter. They were chosen so that the combined constraint had exactly the objective as its left side. The best upper bound obtainable this way is itself the answer to a linear program.

17.6.2 The dual program

Multiply the i-th constraint of (P) by a number $y_i \geq 0$ and add. For every feasible $\mathbf{x}$ this gives $\mathbf{y}^\top \mathbf{A}\mathbf{x} \leq \mathbf{y}^\top \mathbf{b}$. If the combination dominates the objective coefficient by coefficient, $\mathbf{A}^\top \mathbf{y} \geq \mathbf{c}$, then, since $\mathbf{x} \geq \mathbf{0}$,

$$\mathbf{c}^\top \mathbf{x} \leq (\mathbf{A}^\top \mathbf{y})^\top \mathbf{x} = \mathbf{y}^\top \mathbf{A}\mathbf{x} \leq \mathbf{y}^\top \mathbf{b}.$$

Each such $\mathbf{y}$ proves an upper bound $\mathbf{b}^\top \mathbf{y}$ on the objective, and the natural question is how small that bound can be made.

The dual program searches for the best upper bound that non-negative combinations of the constraints can prove.

Definition 17.6.2 — Dual Program

The **dual** of the linear program (P) of Definition 17.6.1 is the problem

$$\text{(D)} \qquad \text{minimize } \mathbf{b}^\top \mathbf{y} \quad \text{subject to} \quad \mathbf{A}^\top \mathbf{y} \geq \mathbf{c}, \quad \mathbf{y} \geq \mathbf{0},$$

with $\mathbf{y} \in \mathbb{R}^m$. The words **feasible**, **infeasible** and **optimal** are used as for (P). (D) is **unbounded** if it is feasible and $\mathbf{b}^\top \mathbf{y}$ takes **arbitrarily negative** values on its feasible region. In this context (P) is called the **primal** program.

The dual has one variable for each constraint of the primal and one constraint for each variable of the primal. The matrix is transposed, the roles of $\mathbf{b}$ and $\mathbf{c}$ are exchanged, and maximization becomes minimization. The dual of (D), written back in inequality form, is (P) again. Exercise (C1: The dual of the dual) checks this, and it explains why a statement about (P) always has a mirror statement about (D).

For the workshop problem the dual is

$$\begin{aligned} \text{minimize} \quad & 7y_1 + 9y_2 + 3y_3 \\ \text{subject to} \quad & 2y_1 + y_2 + y_3 \geq 4, \quad y_1 + 3y_2 \geq 3, \\ & y_1, y_2, y_3 \geq 0, \end{aligned}$$

and the multipliers of Example (The workshop problem, drawn) form the dual feasible point $\mathbf{y}^\star = \left(\frac{9}{5}, \frac{2}{5}, 0\right)$, with $\mathbf{b}^\top \mathbf{y}^\star = \frac{81}{5}$. The dual has an economic reading too. y_i is a price for one unit of the i-th resource, and the constraints say that at these prices the resources used by one unit of each product are worth at least the profit it brings.

17.6.3 Weak duality

The computation that motivated (D) is the first theorem, and it is one line long.

Theorem 17.6.1 — Weak Duality

If $\mathbf{x}$ is feasible for (P) and $\mathbf{y}$ is feasible for (D), then

$$\mathbf{c}^\top \mathbf{x} \leq \mathbf{b}^\top \mathbf{y}.$$

Proof. Since $\mathbf{A}^\top\mathbf{y} - \mathbf{c} \geq \mathbf{0}$ and $\mathbf{x} \geq \mathbf{0}$, the number $(\mathbf{A}^\top\mathbf{y} - \mathbf{c})^\top\mathbf{x}$ is a sum of products of non-negative numbers, so $\mathbf{c}^\top\mathbf{x} \leq (\mathbf{A}^\top\mathbf{y})^\top\mathbf{x} = \mathbf{y}^\top(\mathbf{A}\mathbf{x})$. Since $\mathbf{b} - \mathbf{A}\mathbf{x} \geq \mathbf{0}$ and $\mathbf{y} \geq \mathbf{0}$, in the same way $\mathbf{y}^\top(\mathbf{A}\mathbf{x}) \leq \mathbf{y}^\top\mathbf{b} = \mathbf{b}^\top\mathbf{y}$. Chaining the two inequalities proves the theorem. ■

Corollary 17.6.2 — Certificates from Weak Duality (a) If $\mathbf{x}$ is feasible for (P), $\mathbf{y}$ is feasible for (D), and $\mathbf{c}^\top\mathbf{x} = \mathbf{b}^\top\mathbf{y}$, then $\mathbf{x}$ is optimal for (P) and $\mathbf{y}$ is optimal for (D).

(b) If (P) is unbounded, then (D) is infeasible. If (D) is unbounded, then (P) is infeasible.

Idea. Weak duality makes every dual value an upper bound for every primal value. A primal value that meets one of these bounds cannot be beaten, and neither can the bound; an unbounded program leaves no room for any bound at all.

Proof.

(a) For every feasible $\mathbf{x}'$, Theorem 17.6.1 gives $\mathbf{c}^\top\mathbf{x}' \leq \mathbf{b}^\top\mathbf{y} = \mathbf{c}^\top\mathbf{x}$, so $\mathbf{x}$ is optimal. For every dual feasible $\mathbf{y}'$, it gives $\mathbf{b}^\top\mathbf{y}' \geq \mathbf{c}^\top\mathbf{x} = \mathbf{b}^\top\mathbf{y}$, so $\mathbf{y}$ is optimal.

(b) If (D) had a feasible point $\mathbf{y}$, Theorem 17.6.1 would bound $\mathbf{c}^\top\mathbf{x}$ above by $\mathbf{b}^\top\mathbf{y}$ for every feasible $\mathbf{x}$, so (P) would not be unbounded. The second statement is the same argument with the roles exchanged.

■

Part (a) is exactly what Example (The workshop problem, drawn) did: $\mathbf{c}^\top\mathbf{x}^\star = \frac{81}{5} = \mathbf{b}^\top\mathbf{y}^\star$, so both points are optimal. It gives a certificate of optimality that can be checked by arithmetic alone. The question is whether such a certificate **always** exists. Weak duality allows the best lower bound to stay strictly below the best upper bound.

Quick check. Without solving anything, give an upper bound for $4x_1 + 3x_2$ on the workshop's feasible region using only the second constraint $x_1 + 3x_2 \leq 9$ and $x \geq \mathbf{0}$. Which dual feasible point is that?

Solution. We need $y_2 \geq 0$ with $y_2 \geq 4$ and $3y_2 \geq 3$, so $y_2 = 4$. Then $4x_1 + 3x_2 \leq 4x_1 + 12x_2 = 4(x_1 + 3x_2) \leq 36$, using $x_2 \geq 0$. This is the dual feasible point $\mathbf{y} = (0, 4, 0)$, with $\mathbf{b}^\top\mathbf{y} = 36$. It is a valid bound, but a poor one compared with the optimal $\frac{81}{5}$.

17.6.4 Strong duality

The main theorem says that the gap allowed by weak duality never occurs, and it gives the complete list of what can happen.

Theorem 17.6.3 — Strong Duality for Linear Programs

Let $\mathbf{A} \in M_{m\times n}(\mathbb{R})$, $\mathbf{b} \in \mathbb{R}^m$ and $\mathbf{c} \in \mathbb{R}^n$, and let (P) and (D) be as in Definition 17.6.1

and Definition 17.6.2.

(a) If (P) and (D) are both feasible, then both have optimal solutions, and their optimal values are **equal**: there are feasible $\mathbf{x}^\star$ and $\mathbf{y}^\star$ with $\mathbf{c}^\top\mathbf{x}^\star = \mathbf{b}^\top\mathbf{y}^\star$.

(b) If (P) is feasible and (D) is infeasible, then (P) is unbounded.

(c) If (D) is feasible and (P) is infeasible, then (D) is unbounded.

Idea. Parts (b) and (c) are each one application of Corollary 17.5.7. The infeasibility of one program yields a vector that the other program can move along forever, with its objective improving without bound.

For (a) we want a single pair $(\mathbf{x}, \mathbf{y})$ that is feasible for both programs and has $\mathbf{c}^\top\mathbf{x} \geq \mathbf{b}^\top\mathbf{y}$. Weak duality then forces equality, and Corollary 17.6.2 forces optimality. The pair is a solution of one big system of inequalities in $(\mathbf{x}, \mathbf{y})$, so we ask Farkas whether it has one. If it had none, Farkas would hand us a certificate $(\mathbf{u}, \mathbf{v}, t)$. The number t is the multiplier on the row $\mathbf{b}^\top\mathbf{y} \leq \mathbf{c}^\top\mathbf{x}$. If $t > 0$, rescaling the certificate by $1/t$ produces a primal and a dual feasible point that violate weak duality. If $t = 0$, the certificate is a pair of directions along which one of the two programs is unbounded, which contradicts weak duality against a feasible point of the other.

Proof. **(b)** Let $\mathbf{x}_0$ be feasible for (P). That (D) is infeasible says that the system $(-\mathbf{A}^\top)\mathbf{y} \leq -\mathbf{c}$, $\mathbf{y} \geq \mathbf{0}$ has no solution. By Corollary 17.5.7, applied with $\mathbf{M} = -\mathbf{A}^\top$ and $\mathbf{d} = -\mathbf{c}$, there is $\mathbf{w} \in \mathbb{R}^n$ with $\mathbf{w} \geq \mathbf{0}$, $(-\mathbf{A}^\top)^\top\mathbf{w} = -\mathbf{A}\mathbf{w} \geq \mathbf{0}$ and $-\mathbf{c}^\top\mathbf{w} < 0$. That is, $\mathbf{A}\mathbf{w} \leq \mathbf{0}$ and $\mathbf{c}^\top\mathbf{w} > 0$. For every $s \geq 0$ the point $\mathbf{x}_0 + s\mathbf{w}$ is feasible, since $\mathbf{A}(\mathbf{x}_0 + s\mathbf{w}) = \mathbf{A}\mathbf{x}_0 + s\mathbf{A}\mathbf{w} \leq \mathbf{b}$ and $\mathbf{x}_0 + s\mathbf{w} \geq \mathbf{0}$. Its objective value is $\mathbf{c}^\top\mathbf{x}_0 + s\,\mathbf{c}^\top\mathbf{w}$, which is larger than any given number once s is large enough, because $\mathbf{c}^\top\mathbf{w} > 0$. So (P) is unbounded.

(c) Let $\mathbf{y}_0$ be feasible for (D). That (P) is infeasible says that $\mathbf{A}\mathbf{x} \leq \mathbf{b}$, $\mathbf{x} \geq \mathbf{0}$ has no solution. By Corollary 17.5.7 with $\mathbf{M} = \mathbf{A}$ and $\mathbf{d} = \mathbf{b}$, there is $\mathbf{w} \in \mathbb{R}^m$ with $\mathbf{w} \geq \mathbf{0}$, $\mathbf{A}^\top\mathbf{w} \geq \mathbf{0}$ and $\mathbf{b}^\top\mathbf{w} < 0$. For $s \geq 0$ the point $\mathbf{y}_0 + s\mathbf{w}$ is feasible for (D), since $\mathbf{A}^\top(\mathbf{y}_0 + s\mathbf{w}) \geq \mathbf{A}^\top\mathbf{y}_0 \geq \mathbf{c}$ and $\mathbf{y}_0 + s\mathbf{w} \geq \mathbf{0}$. Its value $\mathbf{b}^\top\mathbf{y}_0 + s\,\mathbf{b}^\top\mathbf{w}$ is below any given number for large s. So (D) is unbounded.

(a) Let $\mathbf{x}_0$ be feasible for (P) and $\mathbf{y}_0$ feasible for (D). Consider the $(m+n+1) \times (n+m)$ matrix and the vector

$$\mathbf{M} = \begin{pmatrix} \mathbf{A} & \mathbf{0} \\ \mathbf{0} & -\mathbf{A}^\top \\ -\mathbf{c}^\top & \mathbf{b}^\top \end{pmatrix}, \qquad \mathbf{d} = \begin{pmatrix} \mathbf{b} \\ -\mathbf{c} \\ 0 \end{pmatrix}.$$

For $\mathbf{z} = (\mathbf{x}, \mathbf{y})$ with $\mathbf{x} \in \mathbb{R}^n$ and $\mathbf{y} \in \mathbb{R}^m$, the system $\mathbf{M}\mathbf{z} \leq \mathbf{d}$, $\mathbf{z} \geq \mathbf{0}$ says exactly that

$$\mathbf{A}\mathbf{x} \leq \mathbf{b}, \quad \mathbf{A}^\top\mathbf{y} \geq \mathbf{c}, \quad \mathbf{b}^\top\mathbf{y} \leq \mathbf{c}^\top\mathbf{x}, \quad \mathbf{x} \geq \mathbf{0}, \quad \mathbf{y} \geq \mathbf{0}. \tag{17.6.1}$$

Suppose Eq. 17.6.1 has a solution $(\mathbf{x}^\star, \mathbf{y}^\star)$. Then $\mathbf{x}^\star$ is feasible for (P) and $\mathbf{y}^\star$ is feasible for (D), so Theorem 17.6.1 gives $\mathbf{c}^\top\mathbf{x}^\star \leq \mathbf{b}^\top\mathbf{y}^\star$. Together with $\mathbf{b}^\top\mathbf{y}^\star \leq \mathbf{c}^\top\mathbf{x}^\star$, this gives equality, and by Corollary 17.6.2 (a) both points are optimal. That is (a).

It remains to show that Eq. 17.6.1 has a solution. Suppose not. By Corollary 17.5.7 there is $\mathbf{w} \geq \mathbf{0}$ with $\mathbf{M}^\top\mathbf{w} \geq \mathbf{0}$ and $\mathbf{d}^\top\mathbf{w} < 0$. Write $\mathbf{w} = (\mathbf{u}, \mathbf{v}, t)$ with $\mathbf{u} \in \mathbb{R}^m$, $\mathbf{v} \in \mathbb{R}^n$

and $t \in \mathbb{R}$, all ≥ 0. Since

$$\mathbf{M}^{\top} = \begin{pmatrix} \mathbf{A}^{\top} & \mathbf{0} & -\mathbf{c} \\ \mathbf{0} & -\mathbf{A} & \mathbf{b} \end{pmatrix},$$

the conditions read

$$\mathbf{A}^{\top}\mathbf{u} \geq t\mathbf{c}, \qquad \mathbf{A}\mathbf{v} \leq t\mathbf{b}, \qquad \mathbf{b}^{\top}\mathbf{u} < \mathbf{c}^{\top}\mathbf{v}. \tag{17.6.2}$$

Case 1: $t > 0$. Dividing Eq. 17.6.2 by t shows that $\mathbf{v}/t \geq \mathbf{0}$ is feasible for (P), that $\mathbf{u}/t \geq \mathbf{0}$ is feasible for (D), and that $\mathbf{b}^{\top}(\mathbf{u}/t) < \mathbf{c}^{\top}(\mathbf{v}/t)$. This contradicts Theorem 17.6.1.

Case 2: $t = 0$. Now $\mathbf{A}^{\top}\mathbf{u} \geq \mathbf{0}$, $\mathbf{A}\mathbf{v} \leq \mathbf{0}$ and $\mathbf{b}^{\top}\mathbf{u} < \mathbf{c}^{\top}\mathbf{v}$, with $\mathbf{u}, \mathbf{v} \geq \mathbf{0}$. The strict inequality forces $\mathbf{c}^{\top}\mathbf{v} > 0$ or $\mathbf{b}^{\top}\mathbf{u} < 0$, since otherwise $\mathbf{b}^{\top}\mathbf{u} \geq 0 \geq \mathbf{c}^{\top}\mathbf{v}$. If $\mathbf{c}^{\top}\mathbf{v} > 0$, then, exactly as in the proof of (b), the points $\mathbf{x}_0 + s\mathbf{v}$ with $s \geq 0$ are feasible for (P) with objective values tending to $+\infty$. That contradicts the bound $\mathbf{c}^{\top}\mathbf{x} \leq \mathbf{b}^{\top}\mathbf{y}_0$ that Theorem 17.6.1 gives for every feasible $\mathbf{x}$. If $\mathbf{b}^{\top}\mathbf{u} < 0$, then, as in the proof of (c), the points $\mathbf{y}_0 + s\mathbf{u}$ are feasible for (D) with values tending to $-\infty$, which contradicts $\mathbf{b}^{\top}\mathbf{y} \geq \mathbf{c}^{\top}\mathbf{x}_0$.

Both cases are impossible, so Eq. 17.6.1 has a solution, and (a) is proved. This proves the theorem.

■

Together with Corollary 17.6.2 (b), the theorem sorts every pair (P), (D) into exactly one of four cases:

(P)	(D)	what happens
feasible	feasible	both optimal, equal values (a)
feasible	infeasible	(P) unbounded (b)
infeasible	feasible	(D) unbounded (c)
infeasible	infeasible	nothing more to say

All four occur. The workshop problem is the first. The one-variable program "maximize x subject to $-x \leq -1$, $x \geq 0$" is the second: its dual, "minimize $-y$ subject to $-y \geq 1$, $y \geq 0$", is infeasible. "Maximize $0 \cdot x$ subject to $x \leq -1$, $x \geq 0$" is the third: its dual, "minimize $-y$ subject to $y \geq 0$", is unbounded. For the fourth, take

$$\mathbf{A} = \begin{pmatrix} 1 & -1 \\ -1 & 1 \end{pmatrix}, \qquad \mathbf{b} = \begin{pmatrix} -1 \\ -1 \end{pmatrix}, \qquad \mathbf{c} = \begin{pmatrix} 1 \\ 1 \end{pmatrix}.$$

Adding the two primal constraints gives $0 \leq -2$, and adding the two dual constraints gives $0 \geq 2$, so neither program is feasible.

The table has a consequence that is easy to state and not at all obvious.

Corollary 17.6.4 — Bounded Linear Programs Attain Their Optimum

If (P) is feasible and its objective is bounded above on the feasible region, that is,

$\mathbf{c}^\top \mathbf{x} \le N$ for some N and every feasible $\mathbf{x}$, then (P) has an optimal solution. The same holds for (D) with "bounded below".

Proof. Since (P) is feasible and not unbounded, part (b) of Theorem 17.6.3 shows that (D) is not infeasible. So both programs are feasible, and part (a) gives an optimal solution of (P). The statement for (D) follows in the same way from part (c). ∎

Why is this not obvious? The feasible region is closed, but it may be unbounded, so the extreme value theorem (A4) of Chapter 15's introduction does not apply to it. And a linear function that is bounded above on a closed convex set need not attain its supremum. On the region $R = \{(x_1, x_2) : x_1 > 0,\ x_1 x_2 \ge 1\}$, bounded by a branch of a hyperbola, the linear function $-x_2$ is negative everywhere, and it takes values arbitrarily close to 0 at the points $(k, 1/k)$, so its supremum is 0. That supremum is never reached. The region R is the set A of Example (A hyperbola and its asymptote), since $x_1 > 0$ and $x_1 x_2 \ge 1$ force $x_2 > 0$, and that example shows it is closed and convex. But it is not cut out by **finitely many** linear inequalities. That finiteness is what made the cones in the proof finitely generated, and hence closed, by Theorem 17.5.4. The corollary is where finite generation pays off.

Warning. **Strong duality is a theorem about linear programs, not about optimization in general.** For programs whose objective or constraints are convex but not linear, one can still write down a dual problem, and weak duality still holds, but the two optimal values may differ: a **duality gap**. Extra hypotheses are needed to close it, of which the best known is a strictly feasible point (Slater's condition). That theory belongs to convex optimization and is not developed in this book. For linear programs no hypothesis beyond feasibility is needed, as Theorem 17.6.3 shows.

17.6.5 Complementary slackness

Strong duality says that at the optimum the two chains of inequalities in the proof of Theorem 17.6.1 are equalities. Reading that off term by term gives a test that locates the dual solution once the primal one is known.

Theorem 17.6.5 — Complementary Slackness

Let $\mathbf{x}$ be feasible for (P) and $\mathbf{y}$ feasible for (D). Then $\mathbf{x}$ and $\mathbf{y}$ are **both** optimal if and only if

(i) for every i, $y_i > 0$ implies $(\mathbf{A}\mathbf{x})_i = b_i$; and
(ii) for every j, $x_j > 0$ implies $(\mathbf{A}^\top \mathbf{y})_j = c_j$.

Idea. The gap $\mathbf{b}^\top \mathbf{y} - \mathbf{c}^\top \mathbf{x}$ is a sum of products of non-negative numbers, one product for each constraint of either program. Optimality means the gap is zero, which means every product is zero.

Proof. Expanding and using $\mathbf{y}^\top \mathbf{A}\mathbf{x} = \mathbf{x}^\top \mathbf{A}^\top \mathbf{y}$,

$$\mathbf{b}^\top \mathbf{y} - \mathbf{c}^\top \mathbf{x} = \mathbf{y}^\top(\mathbf{b} - \mathbf{A}\mathbf{x}) + \mathbf{x}^\top(\mathbf{A}^\top \mathbf{y} - \mathbf{c}). \tag{17.6.3}$$

The first term on the right is $\sum_i y_i(\mathbf{b}-\mathbf{A}\mathbf{x})_i$, a sum of products of non-negative numbers, and so is the second. Condition (i) says that every product in the first sum is zero, and (ii) says the same for the second. So (i) and (ii) together hold exactly when the right side of Eq. 17.6.3 is 0, because a sum of non-negative numbers is zero only when every term is.

($\Leftarrow$) If (i) and (ii) hold, then $\mathbf{c}^\top \mathbf{x} = \mathbf{b}^\top \mathbf{y}$, and both points are optimal by Corollary 17.6.2 (a).

($\Rightarrow$) If both are optimal, then both programs are feasible, and by Theorem 17.6.3 (a) their optimal values are equal. So $\mathbf{c}^\top \mathbf{x} = \mathbf{b}^\top \mathbf{y}$, the right side of Eq. 17.6.3 is 0, and (i) and (ii) hold.

■

In words: a constraint with a positive price must be tight, and a product that is actually made must exactly pay for its resources. For the workshop problem, $\mathbf{x}^\star = \left(\frac{12}{5}, \frac{11}{5}\right)$ has both entries positive, so (ii) requires both dual constraints to be tight:

$$2y_1 + y_2 + y_3 = 4, \qquad y_1 + 3y_2 = 3.$$

The third primal constraint is slack at $\mathbf{x}^\star$, since $\frac{12}{5} < 3$, so (i) forces $y_3 = 0$. The two equations then give $y_1 = \frac{9}{5}$ and $y_2 = \frac{2}{5}$, both ≥ 0, which recovers the multipliers of Example (The workshop problem, drawn). So the multipliers were not a lucky guess: complementary slackness **finds** them from the primal solution.

17.6.6 Traffic, with inequalities

We return to Chapter 2's town center, to answer the remark made there. Recall from Example (Traffic in a town center) the four intersections, the five one-way streets $1 \to 2$, $2 \to 3$, $3 \to 4$, $4 \to 1$, $1 \to 3$ with flows $f_1, \dots, f_5$, and the incidence matrix $\mathbf{N}$. Conservation of cars is $\mathbf{N}\mathbf{f} = \mathbf{s}$ with $\mathbf{s} = (40, 20, -35, -25)$, and the flows that conserve cars are

$$\mathbf{f} = (40 - \beta + \alpha,\ 60 - \beta + \alpha,\ 25 + \alpha,\ \alpha,\ \beta), \qquad \alpha, \beta \in \mathbb{R}.$$

Chapter 2 asked, with street $4 \to 1$ closed, for the largest possible flow on the diagonal $1 \to 3$, and found 40 by inspecting the one remaining parameter. That was already a linear program: maximize f_5 subject to $\mathbf{N}\mathbf{f} = \mathbf{s}$, $\mathbf{f} \geq \mathbf{0}$, $f_4 = 0$. Its answer has a one-line certificate. The first row of $\mathbf{N}\mathbf{f} = \mathbf{s}$, the balance at intersection 1, reads $f_1 - f_4 + f_5 = 40$, so $f_5 = 40 - f_1 + f_4 = 40 - f_1 \leq 40$ because $f_1 \geq 0$.

Example. (Capacities on every street)

Suppose street $4 \to 1$ is open again, but every street can carry at most 35 cars per minute. What is the **smallest** flow the diagonal street $1 \to 3$ can carry, and how would you convince someone that it cannot be smaller?

Solution. The linear program is: minimize f_5 subject to $\mathbf{Nf} = \mathbf{s}$ and $\mathbf{0} \le \mathbf{f} \le 35 \cdot \mathbf{1}$. In the parameters, the capacity of street $2 \to 3$ reads $60 - \beta + \alpha \le 35$, so $\beta \ge 25 + \alpha \ge 25$, since $\alpha = f_4 \ge 0$. The value $\beta = 25$ is achieved: with $\alpha = 0$ the flow is

$$\mathbf{f} = (15, 35, 25, 0, 25),$$

every entry of which lies between 0 and 35. So the minimum is 25.

The certificate, in the spirit of the dual, is a non-negative combination of the constraints. Add the balance equations at intersections 1 and 2, $f_1 - f_4 + f_5 = 40$ and $-f_1 + f_2 = 20$:

$$f_2 - f_4 + f_5 = 60, \qquad \text{so} \qquad f_5 = 60 - f_2 + f_4 \;\ge\; 60 - 35 + 0 = 25,$$

using the capacity $f_2 \le 35$ and the sign constraint $f_4 \ge 0$. In words: at least sixty cars per minute arrive at the pair of intersections $\{1, 2\}$ (sixty from outside, plus whatever street $4 \to 1$ brings), and only two streets leave that pair, $2 \to 3$ and the diagonal. The first can take at most 35, so the diagonal must take at least 25. This is a **cut** argument, and it is exactly what the dual program of a flow problem computes. The balance equations carry multipliers of either sign, the "potentials" of the intersections, and here they are 1 at intersections 1 and 2 and 0 at the others.

This is the answer to Chapter 2's remark. Linear algebra describes the conserving flows as a coset of the null space of $\mathbf{N}$. Linear programming chooses among them, and duality explains each choice with a certificate that can be read as a statement about the network.

Remark. Computing optimal solutions of large linear programs is a subject in its own right. The best known method, the simplex method, moves from corner to corner of the feasible region, each time improving the objective. This book does not develop algorithms for linear programming. Section 9 returns to the corners themselves, as the vertices of a polyhedron.

17.6.7 Exercises

17.6.7.1 A. Check your understanding

Exercise A1.

(a) Write down the dual of: maximize $2x_1 + x_2$ subject to $x_1 + x_2 \le 3$, $x_1 - x_2 \le 1$, $\mathbf{x} \ge \mathbf{0}$.

(b) State weak duality and strong duality.

(c) Determine whether the following is correct, and justify your answer: if (P) is infeasible, then (D) is unbounded.

(d) Determine whether the following is correct, and justify your answer: if (P) is feasible and $\mathbf{c}^\top \mathbf{x} \le 100$ for every feasible $\mathbf{x}$, then (P) has an optimal solution.

(e) At an optimal pair $\mathbf{x}, \mathbf{y}$, suppose $x_2 > 0$. What does complementary slackness say about the second constraint of (D)?

Solution.

(a) Minimize $3y_1 + y_2$ subject to $y_1 + y_2 \geq 2$, $y_1 - y_2 \geq 1$, $\mathbf{y} \geq \mathbf{0}$. The columns of $\mathbf{A}$ become the rows of $\mathbf{A}^\top$, and $\mathbf{b} = (3, 1)$ and $\mathbf{c} = (2, 1)$ exchange roles.

(b) Weak duality: if $\mathbf{x}$ is feasible for (P) and $\mathbf{y}$ for (D), then $\mathbf{c}^\top \mathbf{x} \leq \mathbf{b}^\top \mathbf{y}$. Strong duality: if both are feasible, both have optimal solutions with equal values. If exactly one is feasible, that one is unbounded.

(c) Incorrect. Both programs can be infeasible, as for $\mathbf{A} = \left(\begin{smallmatrix} 1 & -1 \\ -1 & 1 \end{smallmatrix}\right)$, $\mathbf{b} = (-1, -1)$, $\mathbf{c} = (1, 1)$ in this section. What is true, by Theorem 17.6.3 (c), is that if (P) is infeasible **and** (D) is feasible, then (D) is unbounded.

(d) Correct, by Corollary 17.6.4. The bound shows that (P) is not unbounded, so by Theorem 17.6.3 (b) the dual is feasible, and then (a) gives an optimal solution.

(e) By Theorem 17.6.5 (ii), the second dual constraint is tight: $(\mathbf{A}^\top \mathbf{y})_2 = c_2$.

17.6.7.2 B. Practice

Exercise B1: Solve and certify.

Consider: maximize $x_1 + 2x_2$ subject to

$$x_1 + x_2 \leq 5, \qquad -x_1 + x_2 \leq 1, \qquad 2x_1 - x_2 \leq 4, \qquad \mathbf{x} \geq \mathbf{0}.$$

(a) Sketch the feasible region and guess an optimal solution.

(b) Write down the dual, and use complementary slackness to find a candidate dual solution.

(c) Prove that both candidates are optimal, and state the optimal value.

Solution.

(a) The region is the pentagon with corners $(0, 0)$, $(2, 0)$, $(3, 2)$, $(2, 3)$ and $(0, 1)$, where the objective takes the values $0, 2, 7, 8, 2$. The guess is $\mathbf{x}^\star = (2, 3)$, where $x_1 + x_2 = 5$ meets $-x_1 + x_2 = 1$.

(b) The dual is: minimize $5y_1 + y_2 + 4y_3$ subject to $y_1 - y_2 + 2y_3 \geq 1$, $y_1 + y_2 - y_3 \geq 2$, $\mathbf{y} \geq \mathbf{0}$. At $\mathbf{x}^\star$ the third constraint is slack, since $2 \cdot 2 - 3 = 1 < 4$, so (i) of Theorem 17.6.5 requires $y_3 = 0$. Both $x_j^\star > 0$, so (ii) requires both dual constraints to be tight: $y_1 - y_2 = 1$ and $y_1 + y_2 = 2$. Hence $\mathbf{y}^\star = \left(\frac{3}{2}, \frac{1}{2}, 0\right)$.

(c) $\mathbf{x}^\star$ is feasible: $5 \leq 5$, $1 \leq 1$, $1 \leq 4$, and $\mathbf{x}^\star \geq \mathbf{0}$. $\mathbf{y}^\star$ is feasible: $\mathbf{y}^\star \geq \mathbf{0}$, $\frac{3}{2} - \frac{1}{2} = 1 \geq 1$ and $\frac{3}{2} + \frac{1}{2} = 2 \geq 2$. The objective values are $\mathbf{c}^\top \mathbf{x}^\star = 2 + 6 = 8$ and $\mathbf{b}^\top \mathbf{y}^\star = \frac{15}{2} + \frac{1}{2} = 8$. They are equal, so both points are optimal by Corollary 17.6.2 (a), and the optimal value is 8.

Exercise B2: Which case?.

For each program, write down its dual, and determine which of the four cases of Theorem 17.6.3 occurs. Justify your answer, giving the optimal values where they exist.

(a) Maximize $x_1 + x_2$ subject to $x_1 - x_2 \leq 1$, $\mathbf{x} \geq \mathbf{0}$.

(b) Maximize $-x_1$ subject to $x_1 \leq 2$, $-x_1 \leq -1$, $x_1 \geq 0$.

(c) Maximize x_1 subject to $x_1 + x_2 \leq -1$, $\mathbf{x} \geq \mathbf{0}$.

Solution.

(a) The dual is: minimize y subject to $y \geq 1$, $-y \geq 1$, $y \geq 0$. The last two constraints conflict, so the dual is infeasible. The primal is feasible, with $\mathbf{0}$ a feasible point, so by Theorem 17.6.3 (b) it is unbounded. Directly, $(0, s)$ is feasible for every $s \geq 0$, with value s.

(b) The dual is: minimize $2y_1 - y_2$ subject to $y_1 - y_2 \geq -1$, $\mathbf{y} \geq \mathbf{0}$. Both programs are feasible: $x_1 = 1$ and $\mathbf{y} = (0, 1)$. Their values are -1 and $2 \cdot 0 - 1 = -1$, which are equal, so both are optimal by Corollary 17.6.2 (a), with optimal value -1. This is the first case.

(c) The primal is infeasible, since $x_1 + x_2 \geq 0 > -1$ for $\mathbf{x} \geq \mathbf{0}$. The dual is: minimize $-y$ subject to $y \geq 1$, $y \geq 0$, $y \geq 0$. It is feasible, and $-y$ takes arbitrarily negative values, so it is unbounded, as Theorem 17.6.3 (c) predicts.

Exercise B3: A network with one flow.

In the traffic network of this section, close street $4 \to 1$ and give every other street a capacity of 30 cars per minute. Show that there is exactly one feasible flow. For its diagonal flow $f_5 = 30$, give a certificate, in the style of Example (Capacities on every street), that $f_5 \geq 30$ for every feasible flow, and one that $f_5 \leq 30$.

Solution. With $f_4 = \alpha = 0$ the conserving flows are $\mathbf{f} = (40 - \beta, 60 - \beta, 25, 0, \beta)$. The capacity of street $2 \to 3$ gives $60 - \beta \leq 30$, so $\beta \geq 30$. The capacity of the diagonal gives $\beta \leq 30$. So $\beta = 30$, and the only candidate is $\mathbf{f} = (10, 30, 25, 0, 30)$, which satisfies $0 \leq f_i \leq 30$ for every street. It is the unique feasible flow.

Lower bound: adding the balance equations at intersections 1 and 2 gives $f_2 - f_4 + f_5 = 60$, so $f_5 = 60 - f_2 + f_4 = 60 - f_2 \geq 30$ by the capacity $f_2 \leq 30$, using $f_4 = 0$. Upper bound: $f_5 \leq 30$ is itself a capacity constraint. Each certificate is a non-negative combination of constraints, with free multipliers on the balance equations, as in the example.

17.6.7.3 C. Going deeper

Exercise C1: The dual of the dual.

(a) Rewrite (D) as a program in the inequality form of Definition 17.6.1, with data $(-\mathbf{A}^\top, -\mathbf{c}, -\mathbf{b})$. Show that the dual of that program, rewritten as a maximization, is (P).

(b) Deduce part (c) of Theorem 17.6.3 from part (b).

Solution.

(a) Minimizing $\mathbf{b}^\top\mathbf{y}$ is maximizing $(-\mathbf{b})^\top\mathbf{y}$, and $\mathbf{A}^\top\mathbf{y} \geq \mathbf{c}$ is $(-\mathbf{A}^\top)\mathbf{y} \leq -\mathbf{c}$. So (D) is the inequality-form program (D′): maximize $(-\mathbf{b})^\top\mathbf{y}$ subject to $(-\mathbf{A}^\top)\mathbf{y} \leq -\mathbf{c}$, $\mathbf{y} \geq \mathbf{0}$, whose data are $\mathbf{A}' = -\mathbf{A}^\top$, $\mathbf{b}' = -\mathbf{c}$, $\mathbf{c}' = -\mathbf{b}$. By Definition 17.6.2 its dual is: minimize $\mathbf{b}'^\top\mathbf{x} = (-\mathbf{c})^\top\mathbf{x}$ subject to $\mathbf{A}'^\top\mathbf{x} = -\mathbf{A}\mathbf{x} \geq \mathbf{c}' = -\mathbf{b}$, $\mathbf{x} \geq \mathbf{0}$. That is: maximize $\mathbf{c}^\top\mathbf{x}$ subject to $\mathbf{A}\mathbf{x} \leq \mathbf{b}$, $\mathbf{x} \geq \mathbf{0}$, which is (P). Its optimal value is the negative of the minimum above.

(b) Suppose (D) is feasible and (P) is infeasible. Then (D′) is feasible, with the same feasible points, and its dual, which by (a) has the same feasible points as (P), is infeasible. By Theorem 17.6.3 (b) applied to (D′), the objective $(-\mathbf{b})^{\top}\mathbf{y}$ takes arbitrarily large values on the feasible region. So $\mathbf{b}^{\top}\mathbf{y}$ takes arbitrarily negative values, and (D) is unbounded.

Exercise C2: Free variables.

Let $\mathbf{A} \in M_{m\times n}(\mathbb{R})$, $\mathbf{b} \in \mathbb{R}^m$, $\mathbf{c} \in \mathbb{R}^n$, and consider the program with **no sign constraint** on $\mathbf{x}$:

$$(\mathrm{P}_{\mathrm{free}}) \qquad \text{maximize } \mathbf{c}^{\top}\mathbf{x} \ \text{ subject to } \ \mathbf{A}\mathbf{x} \le \mathbf{b}.$$

(a) Prove weak duality between $(\mathrm{P}_{\mathrm{free}})$ and $(\mathrm{D}_{\mathrm{eq}})$: minimize $\mathbf{b}^{\top}\mathbf{y}$ subject to $\mathbf{A}^{\top}\mathbf{y} = \mathbf{c}$, $\mathbf{y} \ge \mathbf{0}$.

(b) Writing $\mathbf{x} = \mathbf{u} - \mathbf{v}$ with $\mathbf{u}, \mathbf{v} \ge \mathbf{0}$, show that $(\mathrm{P}_{\mathrm{free}})$ has the same values as an inequality-form program whose dual is $(\mathrm{D}_{\mathrm{eq}})$. Deduce that if both are feasible, both have optimal solutions with equal values.

Solution.

(a) If $\mathbf{A}\mathbf{x} \le \mathbf{b}$ and $\mathbf{A}^{\top}\mathbf{y} = \mathbf{c}$ with $\mathbf{y} \ge \mathbf{0}$, then $\mathbf{c}^{\top}\mathbf{x} = (\mathbf{A}^{\top}\mathbf{y})^{\top}\mathbf{x} = \mathbf{y}^{\top}\mathbf{A}\mathbf{x} \le \mathbf{y}^{\top}\mathbf{b}$, the last step because $\mathbf{y} \ge \mathbf{0}$ and $\mathbf{b} - \mathbf{A}\mathbf{x} \ge \mathbf{0}$. No sign condition on $\mathbf{x}$ is needed, because the first step is an equality.

(b) Every $\mathbf{x} \in \mathbb{R}^n$ can be written as $\mathbf{u} - \mathbf{v}$ with $\mathbf{u}, \mathbf{v} \ge \mathbf{0}$: take $u_j = \max(x_j, 0)$ and $v_j = \max(-x_j, 0)$. So $(\mathrm{P}_{\mathrm{free}})$ has the same feasible objective values as the inequality-form program

$$\text{maximize } \begin{pmatrix}\mathbf{c}\\ -\mathbf{c}\end{pmatrix}^{\top}\begin{pmatrix}\mathbf{u}\\ \mathbf{v}\end{pmatrix} \ \text{ subject to } \ \begin{pmatrix}\mathbf{A} & -\mathbf{A}\end{pmatrix}\begin{pmatrix}\mathbf{u}\\ \mathbf{v}\end{pmatrix} \le \mathbf{b}, \quad \begin{pmatrix}\mathbf{u}\\ \mathbf{v}\end{pmatrix} \ge \mathbf{0},$$

with an optimal $(\mathbf{u}, \mathbf{v})$ giving an optimal $\mathbf{x} = \mathbf{u} - \mathbf{v}$, and conversely. By Definition 17.6.2 its dual is: minimize $\mathbf{b}^{\top}\mathbf{y}$ subject to $\begin{pmatrix}\mathbf{A} & -\mathbf{A}\end{pmatrix}^{\top}\mathbf{y} \ge (\mathbf{c}, -\mathbf{c})$, $\mathbf{y} \ge \mathbf{0}$. The constraint reads $\mathbf{A}^{\top}\mathbf{y} \ge \mathbf{c}$ and $-\mathbf{A}^{\top}\mathbf{y} \ge -\mathbf{c}$, that is, $\mathbf{A}^{\top}\mathbf{y} = \mathbf{c}$. So the dual is $(\mathrm{D}_{\mathrm{eq}})$. If both programs are feasible, Theorem 17.6.3 (a) gives optimal $(\mathbf{u}^{\star}, \mathbf{v}^{\star})$ and $\mathbf{y}^{\star}$ with equal values, and $\mathbf{x}^{\star} = \mathbf{u}^{\star} - \mathbf{v}^{\star}$ is optimal for $(\mathrm{P}_{\mathrm{free}})$.

17.7 Matrix Games and the Minimax Theorem

Chapter 16 was built on a min–max formula: the Courant–Fischer theorem describes each eigenvalue of a Hermitian matrix as a minimum of maxima over subspaces. This section proves a second min–max theorem that looks similar and works for a completely different reason. It concerns a game in which two players choose simultaneously, and it says that if the players are allowed to **randomize**, it does not matter which of them has to reveal a plan first. The theorem is due to von Neumann, and with linear programming duality in hand (§06) it takes a page to prove.

The two theorems are easy to confuse, and a reader who has just finished Chapter 16 will be tempted to. So the section also says precisely how they differ. Courant–Fischer is a statement about **subspaces**, and its equality comes from a **dimension count**. The minimax theorem is a statement about **simplices**, and its equality comes from **convexity**.

Throughout, the field is $\mathbb{R}$, $\mathbf{1}$ is the all-ones vector of whatever length the context requires, and $\mathbf{J} = \mathbf{1}\mathbf{1}^{\top}$ is the all-ones matrix. Inequalities between vectors are entrywise, as in §05.

17.7.1 Matrix games

Two players, Row and Column, play a game described by a real matrix $\mathbf{A} \in M_{m\times n}(\mathbb{R})$, the **payoff matrix**. Row secretly chooses a row i, Column secretly chooses a column j, both reveal their choices, and Column pays Row the amount a_{ij}. A negative entry means that Row pays Column. Whatever one player wins, the other loses, so the game is called **zero-sum**. Row wants a_{ij} large and Column wants it small. A choice of a row, or of a column, is a **pure strategy**.

Suppose Row must announce a row in advance. Column will then answer with the smallest entry in that row, so the best Row can guarantee is

$$\max_{i} \min_{j} a_{ij}.$$

If instead Column must announce first, the best Column can guarantee is to pay at most $\min_j \max_i a_{ij}$. Announcing first is never an advantage, and that holds for any payoff function whatsoever.

Lemma 17.7.1 — Max–Min Never Exceeds Min–Max

Let X and Y be sets and $f\colon X \times Y \to \mathbb{R}$ a function for which the extrema below exist. Then

$$\max_{x\in X} \min_{y\in Y} f(x,y) \;\le\; \min_{y\in Y} \max_{x\in X} f(x,y).$$

Proof. Let $x_0 \in X$ and $y_0 \in Y$. Then

$$\min_{y\in Y} f(x_0,y) \;\le\; f(x_0,y_0) \;\le\; \max_{x\in X} f(x,y_0).$$

The left side does not depend on y_0 and the right side does not depend on x_0. Taking the maximum over x_0 on the left and then the minimum over y_0 on the right proves the lemma. ∎

The inequality can be strict. In the game with

$$\mathbf{A} = \begin{pmatrix} 1 & -1 \\ -1 & 1 \end{pmatrix},$$

Row wins when the two choices match and loses when they differ. Every row contains a -1, so $\max_i \min_j a_{ij} = -1$. Every column contains a 1, so $\min_j \max_i a_{ij} = 1$. Whoever announces first loses a unit, and there is a gap of 2 between what the players can guarantee.

Some games have no gap. In

$$\mathbf{A} = \begin{pmatrix} 3 & 1 & 4 \\ 2 & 0 & 1 \end{pmatrix}$$

the row minima are 1 and 0, whose maximum is 1, and the column maxima are $3, 1, 4$, whose minimum is also 1. The entry $a_{12} = 1$ is the smallest in its row and the largest in its column. Such an entry is a **saddle point**. If Row plays row 1 and Column plays column 2, neither can gain by changing unilaterally, and the game is settled in pure strategies. The first game has no saddle point, and in that game the natural advice is: do not be predictable.

17.7.2 Mixed strategies

The way to be unpredictable is to randomize. Row chooses row i with probability x_i, and Column chooses column j with probability y_j, independently. The probabilities of the m rows form a vector with non-negative entries summing to 1, that is, a point of the standard simplex of Definition 17.1.2,

$$\Delta_m = \{\mathbf{x} \in \mathbb{R}^m : \mathbf{x} \geq \mathbf{0} \text{ and } x_1 + \cdots + x_m = 1\}.$$

A mixed strategy is a probability distribution over the pure strategies, and the simplex is the set of all of them.

Definition 17.7.1 — Mixed Strategy

In the game with payoff matrix $\mathbf{A} \in M_{m\times n}(\mathbb{R})$, a **mixed strategy** for Row is a vector $\mathbf{x} \in \Delta_m$, a mixed strategy for Column is a vector $\mathbf{y} \in \Delta_n$, and the **expected payoff** is

$$\mathbf{x}^{\top}\mathbf{A}\mathbf{y} = \sum_{i=1}^{m}\sum_{j=1}^{n} x_i\, a_{ij}\, y_j.$$

In words: a mixed strategy assigns to each pure strategy a weight that is **non-negative**, and the weights **sum to exactly** 1. The payoff a_{ij} occurs with probability $x_i y_j$, since the two choices are independent, so $\mathbf{x}^{\top}\mathbf{A}\mathbf{y}$ is the average payoff over many plays. The pure strategy "row i" is the mixed strategy $\mathbf{e}_i$, a vertex of the simplex, and $\mathbf{e}_i^{\top}\mathbf{A}\mathbf{e}_j = a_{ij}$. So mixed strategies extend pure ones, and the expected payoff extends the payoff.

Examples. Δ_2 is the segment from $(1,0)$ to $(0,1)$ in the plane, whose points $(p, 1-p)$ with $0 \leq p \leq 1$ mean "row 1 with probability p". Δ_3 is the triangle with vertices $\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3$ in $\mathbb{R}^3$, and its center $\frac{1}{3}\mathbf{1}$ is the uniform strategy. The degenerate case is $\Delta_1 = \{1\}$: a player with only one pure strategy has no choice, and the game is a single row or a single column.

Non-examples by minimal change. $\left(\frac{1}{2}, \frac{1}{2}, \frac{1}{2}\right)$ has non-negative entries, but they sum to $\frac{3}{2}$, so it is not a probability distribution. $\left(\frac{3}{2}, -\frac{1}{2}\right)$ sums to 1, but it has a negative entry. It lies on the line through Δ_2, outside the segment.

Why this definition. Δ_n is exactly the set of convex combinations of $\mathbf{e}_1, \ldots, \mathbf{e}_n$, since $\mathbf{x} = \sum x_j \mathbf{e}_j$. So it is the convex hull of the pure strategies, by Theorem 17.1.3, and in particular it is a convex set (Definition 17.1.1). That convexity is what makes the theorem below true. The convention of Definition 17.1.2, n weights for n pure strategies, is the one a game needs. The payoff $\mathbf{x}^{\top}\mathbf{A}\mathbf{y}$ is linear in $\mathbf{y}$ for fixed $\mathbf{x}$, and linear in $\mathbf{x}$ for fixed $\mathbf{y}$, so a mixture of strategies earns the same mixture of payoffs.

Warning. **A mixed strategy is not a compromise move.** Playing $\left(\frac{1}{2}, \frac{1}{2}\right)$ in the matching game does not mean playing "half of row 1 and half of row 2" in a single round. Each round Row plays one actual row, chosen at random, and $\mathbf{x}^\top \mathbf{A}\mathbf{y}$ is an average over rounds. In the matching game with $\mathbf{x} = \mathbf{y} = \left(\frac{1}{2}, \frac{1}{2}\right)$, the expected payoff is 0, yet every single round pays $+1$ or -1, never 0.

Against a fixed mixed strategy, the opponent never needs to randomize. That observation turns every "min over a simplex" into a min over finitely many numbers.

Lemma 17.7.2 — A Pure Best Response Exists

Let $\mathbf{A} \in M_{m\times n}(\mathbb{R})$. For every $\mathbf{x} \in \Delta_m$,

$$\min_{\mathbf{y}\in\Delta_n} \mathbf{x}^\top \mathbf{A}\mathbf{y} = \min_{1\le j\le n} (\mathbf{A}^\top \mathbf{x})_j,$$

and the minimum on the left is attained at $\mathbf{y} = \mathbf{e}_j$ for any j attaining the minimum on the right. Likewise, for every $\mathbf{y} \in \Delta_n$, $\max_{\mathbf{x}\in\Delta_m} \mathbf{x}^\top \mathbf{A}\mathbf{y} = \max_{1\le i\le m} (\mathbf{A}\mathbf{y})_i$, attained at a vertex $\mathbf{e}_i$.

Idea. For fixed $\mathbf{x}$, the payoff $\mathbf{x}^\top \mathbf{A}\mathbf{y}$ is an average of the entries of $\mathbf{A}^\top \mathbf{x}$ with weights y_j, and an average is never below the smallest entry, which the vertex $\mathbf{e}_j$ attains.

Proof. Write $\mathbf{w} = \mathbf{A}^\top \mathbf{x} \in \mathbb{R}^n$ and $\mu = \min_j w_j$, a minimum of finitely many numbers. For $\mathbf{y} \in \Delta_n$,

$$\mathbf{x}^\top \mathbf{A}\mathbf{y} = \mathbf{w}^\top \mathbf{y} = \sum_{j=1}^{n} y_j w_j \;\ge\; \sum_{j=1}^{n} y_j \mu = \mu,$$

because every $y_j \ge 0$ and $\sum_j y_j = 1$. If $w_{j_0} = \mu$, then $\mathbf{e}_{j_0} \in \Delta_n$ gives $\mathbf{x}^\top \mathbf{A}\mathbf{e}_{j_0} = w_{j_0} = \mu$. So μ is a value of $\mathbf{y} \mapsto \mathbf{x}^\top \mathbf{A}\mathbf{y}$ on Δ_n and a lower bound for all its values, hence its minimum. The second statement is the same argument applied to $\mathbf{A}\mathbf{y}$ with the inequality reversed.

■

So once Row fixes $\mathbf{x}$, the amount Row can **guarantee** is

$$g(\mathbf{x}) = \min_{\mathbf{y}\in\Delta_n} \mathbf{x}^\top \mathbf{A}\mathbf{y} = \min_j (\mathbf{A}^\top \mathbf{x})_j,$$

the smallest entry of $\mathbf{A}^\top \mathbf{x}$. Column, in the same way, guarantees by the second half of the lemma to pay at most $h(\mathbf{y}) = \max_{\mathbf{x}\in\Delta_m} \mathbf{x}^\top \mathbf{A}\mathbf{y} = \max_i (\mathbf{A}\mathbf{y})_i$. In the matching game, $\mathbf{x} = \left(\frac{1}{2}, \frac{1}{2}\right)$ gives $\mathbf{A}^\top \mathbf{x} = (0, 0)$ and $g(\mathbf{x}) = 0$, and the same holds for Column's h. With mixing, both players can guarantee 0, and the gap of 2 has closed. The theorem says this always happens.

17.7.3 The minimax theorem

Theorem 17.7.3 — Von Neumann's Minimax Theorem

Let $\mathbf{A} \in M_{m\times n}(\mathbb{R})$. There are $\mathbf{x}^\star \in \Delta_m$, $\mathbf{y}^\star \in \Delta_n$ and $v \in \mathbb{R}$ such that

$$\mathbf{x}^{\top}\mathbf{A}\mathbf{y}^{\star} \;\le\; v \;\le\; \mathbf{x}^{\star\top}\mathbf{A}\mathbf{y} \qquad \text{for all } \mathbf{x}\in\Delta_m,\ \mathbf{y}\in\Delta_n. \tag{17.7.1}$$

Consequently

$$\max_{\mathbf{x}\in\Delta_m}\min_{\mathbf{y}\in\Delta_n}\mathbf{x}^{\top}\mathbf{A}\mathbf{y} \;=\; v \;=\; \min_{\mathbf{y}\in\Delta_n}\max_{\mathbf{x}\in\Delta_m}\mathbf{x}^{\top}\mathbf{A}\mathbf{y},$$

where the outer maximum is attained at $\mathbf{x}^{\star}$ and the outer minimum at $\mathbf{y}^{\star}$.

Idea. Row wants the $\mathbf{x}\in\Delta_m$ that maximizes the smallest entry of $\mathbf{A}^{\top}\mathbf{x}$. If every entry of $\mathbf{A}$ is positive, this can be rescaled into a linear program. Put $\mathbf{p}=\mathbf{x}/v$, where v is the guaranteed amount. Then "$\mathbf{A}^{\top}\mathbf{x}\ge v\mathbf{1}$ with $\mathbf{1}^{\top}\mathbf{x}=1$, v as large as possible" becomes "$\mathbf{A}^{\top}\mathbf{p}\ge\mathbf{1}$, $\mathbf{p}\ge\mathbf{0}$, $\mathbf{1}^{\top}\mathbf{p}$ as small as possible". Column's problem becomes the dual of that program, by the same substitution. Strong duality (§06) says the two optimal values agree, and that common value is $1/v$. The plan:

① shift the entries by a constant to make them positive, which changes every payoff by the same constant; ② write down the two linear programs, check that both are feasible, and apply Theorem 17.6.3; ③ rescale the optimal solutions into strategies and read off Eq. 17.7.1.

Proof. **Step 1. We may assume every $a_{ij}>0$.** Choose $c\in\mathbb{R}$ with $a_{ij}+c>0$ for all i,j, and put $\mathbf{B}=\mathbf{A}+c\mathbf{J}$. For $\mathbf{x}\in\Delta_m$ and $\mathbf{y}\in\Delta_n$,

$$\mathbf{x}^{\top}\mathbf{J}\mathbf{y}=(\mathbf{x}^{\top}\mathbf{1})(\mathbf{1}^{\top}\mathbf{y})=1, \qquad \text{so} \qquad \mathbf{x}^{\top}\mathbf{B}\mathbf{y}=\mathbf{x}^{\top}\mathbf{A}\mathbf{y}+c.$$

Hence if $\mathbf{x}^{\star},\mathbf{y}^{\star},w$ satisfy Eq. 17.7.1 for $\mathbf{B}$, then $\mathbf{x}^{\star},\mathbf{y}^{\star},w-c$ satisfy it for $\mathbf{A}$. So it suffices to prove Eq. 17.7.1 when every entry of $\mathbf{A}$ is positive, and we assume this from now on. Let $\mu=\min_{i,j}a_{ij}>0$.

Step 2. Two linear programs. Consider

$$\begin{aligned}&\text{(P)}\quad \text{maximize } \mathbf{1}^{\top}\mathbf{q} \ \text{ subject to } \ \mathbf{A}\mathbf{q}\le\mathbf{1},\ \mathbf{q}\ge\mathbf{0} \quad (\mathbf{q}\in\mathbb{R}^n),\\ &\text{(D)}\quad \text{minimize } \mathbf{1}^{\top}\mathbf{p} \ \text{ subject to } \ \mathbf{A}^{\top}\mathbf{p}\ge\mathbf{1},\ \mathbf{p}\ge\mathbf{0} \quad (\mathbf{p}\in\mathbb{R}^m).\end{aligned}$$

(P) is a linear program in the inequality form of Definition 17.6.1, with data $(\mathbf{A},\mathbf{1},\mathbf{1})$, and (D) is its dual (Definition 17.6.2). (P) is feasible, with $\mathbf{q}=\mathbf{0}$. (D) is feasible, with $\mathbf{p}=\mu^{-1}\mathbf{1}$: the j-th entry of $\mathbf{A}^{\top}\mathbf{p}$ is $\mu^{-1}\sum_i a_{ij}\ge\mu^{-1}a_{1j}\ge 1$. By Theorem 17.6.3 (a), there are optimal $\mathbf{q}^{\star}$ and $\mathbf{p}^{\star}$ with equal values; call the common value ω, so that

$$\mathbf{1}^{\top}\mathbf{q}^{\star}=\mathbf{1}^{\top}\mathbf{p}^{\star}=\omega.$$

Moreover $\omega>0$. Since $\mathbf{A}^{\top}\mathbf{p}^{\star}\ge\mathbf{1}$, we have $\mathbf{p}^{\star}\neq\mathbf{0}$, and a non-zero vector with non-negative entries has a positive entry sum.

Step 3. Strategies from the programs. Put

$$\mathbf{x}^{\star}=\omega^{-1}\mathbf{p}^{\star}, \qquad \mathbf{y}^{\star}=\omega^{-1}\mathbf{q}^{\star}, \qquad v=\omega^{-1}.$$

Then $\mathbf{x}^{\star}\ge\mathbf{0}$ with $\mathbf{1}^{\top}\mathbf{x}^{\star}=\omega^{-1}\omega=1$, so $\mathbf{x}^{\star}\in\Delta_m$, and likewise $\mathbf{y}^{\star}\in\Delta_n$. The constraints of the two programs give

$$\mathbf{A}^{\top}\mathbf{x}^{\star}=\omega^{-1}\mathbf{A}^{\top}\mathbf{p}^{\star}\ge v\mathbf{1}, \qquad \mathbf{A}\mathbf{y}^{\star}=\omega^{-1}\mathbf{A}\mathbf{q}^{\star}\le v\mathbf{1}.$$

For every $\mathbf{y} \in \Delta_n$, therefore, $\mathbf{x}^{\star\top}\mathbf{A}\mathbf{y} = \sum_j y_j (\mathbf{A}^\top \mathbf{x}^\star)_j \geq v \sum_j y_j = v$. For every $\mathbf{x} \in \Delta_m$, $\mathbf{x}^\top \mathbf{A}\mathbf{y}^\star = \sum_i x_i (\mathbf{A}\mathbf{y}^\star)_i \leq v$. This is Eq. 17.7.1.

Step 4. The two extrema. For $\mathbf{x} \in \Delta_m$ let $g(\mathbf{x}) = \min_{\mathbf{y}\in\Delta_n} \mathbf{x}^\top \mathbf{A}\mathbf{y}$, which exists by Lemma 17.7.2. By Eq. 17.7.1, $g(\mathbf{x}^\star) \geq v$, since every value of $\mathbf{y} \mapsto \mathbf{x}^{\star\top}\mathbf{A}\mathbf{y}$ is at least v. And $g(\mathbf{x}) \leq \mathbf{x}^\top \mathbf{A}\mathbf{y}^\star \leq v$ for every $\mathbf{x}$. So v is a value of g and an upper bound for all its values: $\max_{\mathbf{x}} g(\mathbf{x})$ exists, equals v, and is attained at $\mathbf{x}^\star$. In the same way $h(\mathbf{y}) = \max_{\mathbf{x}} \mathbf{x}^\top \mathbf{A}\mathbf{y}$ satisfies $h(\mathbf{y}^\star) \leq v \leq \mathbf{x}^{\star\top}\mathbf{A}\mathbf{y} \leq h(\mathbf{y})$ for every $\mathbf{y}$, so $\min_{\mathbf{y}} h(\mathbf{y}) = v$, attained at $\mathbf{y}^\star$. This proves the theorem.

■

Definition 17.7.2 — Value and Optimal Strategies

The number v of Theorem 17.7.3 is the **value** of the game with payoff matrix $\mathbf{A}$, written $v(\mathbf{A})$. A strategy $\mathbf{x} \in \Delta_m$ is **optimal for Row** if it guarantees the value, $\min_{\mathbf{y}} \mathbf{x}^\top \mathbf{A}\mathbf{y} = v(\mathbf{A})$, and $\mathbf{y} \in \Delta_n$ is **optimal for Column** if $\max_{\mathbf{x}} \mathbf{x}^\top \mathbf{A}\mathbf{y} = v(\mathbf{A})$.

The value is well defined: it equals the max–min, and that depends only on $\mathbf{A}$. A strategy $\mathbf{x}$ is optimal for Row exactly when every entry of $\mathbf{A}^\top \mathbf{x}$ is at least $v(\mathbf{A})$, and $\mathbf{y}$ is optimal for Column exactly when every entry of $\mathbf{A}\mathbf{y}$ is at most $v(\mathbf{A})$; both statements are Lemma 17.7.2. These are linear conditions, so each player's set of optimal strategies is a convex subset of the simplex. Inequality Eq. 17.7.1 says that $(\mathbf{x}^\star, \mathbf{y}^\star)$ is a **saddle point in mixed strategies**. If Row plays $\mathbf{x}^\star$, Column cannot push the expected payment below v. If Column plays $\mathbf{y}^\star$, Row cannot push it above v. Neither player gains by deviating alone, and announcing an optimal strategy in advance costs nothing.

Alternatively, the theorem can be proved with no linear programming, by separation. The key fact is an alternative in the style of Farkas: either some $\mathbf{y} \in \Delta_n$ has $\mathbf{A}\mathbf{y} \leq \mathbf{0}$, or some $\mathbf{x} \in \Delta_m$ has $\mathbf{A}^\top \mathbf{x} > \mathbf{0}$. To prove it, separate the origin from the closed convex set $\{\mathbf{A}\mathbf{y} + \mathbf{z} : \mathbf{y} \in \Delta_n,\ \mathbf{z} \geq \mathbf{0}\}$ using §03, and apply the result to $\mathbf{A} - t\mathbf{J}$ for every real t. That route shows most directly that the theorem is about convexity. It also needs the compactness of Δ_n, (A3) of Chapter 15's introduction, to know that the set being separated is closed. The route taken above hides all of the analysis inside Farkas's lemma.

17.7.4 Two min–max theorems

Theorem 17.7.3 and the Courant–Fischer theorem of Chapter 16 (Theorem 16.2.3) both have "min" and "max" in them, and both are called min–max theorems. They are different theorems, with different proofs. Put side by side, for a Hermitian $\mathbf{A} \in M_n(F)$ ($F = \mathbb{R}$ or $\mathbb{C}$) and a real $\mathbf{B} \in M_{m\times n}(\mathbb{R})$:

$$\begin{aligned} \lambda_k(\mathbf{A}) &= \min_{\dim W = n-k+1} \ \max_{\mathbf{0}\neq\mathbf{x}\in W} R_{\mathbf{A}}(\mathbf{x}) \\ &= \max_{\dim W = k} \ \min_{\mathbf{0}\neq\mathbf{x}\in W} R_{\mathbf{A}}(\mathbf{x}), \end{aligned}$$

$$\begin{aligned} v(\mathbf{B}) &= \min_{\mathbf{y}\in\Delta_n} \ \max_{\mathbf{x}\in\Delta_m} \mathbf{x}^\top \mathbf{B}\mathbf{y} \\ &= \max_{\mathbf{x}\in\Delta_m} \ \min_{\mathbf{y}\in\Delta_n} \mathbf{x}^\top \mathbf{B}\mathbf{y}. \end{aligned}$$

What is being chosen. In Courant–Fischer the outer variable is a **subspace** W, and the inner variable is a vector **inside that subspace**. The inner set depends on the outer choice, so the formula is a nested optimization, not a game between two independent players. In von Neumann's theorem the two variables range over **fixed** sets, Δ_m and Δ_n, neither of which depends on the other.

What the theorem asserts. Von Neumann's theorem is an **exchange of order**: the same function, with the max and the min taken in both orders, gives the same number. Courant–Fischer exchanges nothing. Its two forms use different dimensions, $n-k+1$ and k, and swapping the order while keeping the dimension gives $\lambda_{n+1-k}(\mathbf{A})$, which differs from $\lambda_k(\mathbf{A})$ unless $n = 2k-1$ or the two eigenvalues happen to be equal (the warning after Theorem 16.2.3). The sharpest contrast is in the inequality between the two forms. In von Neumann's theorem, "max–min $\leq$ min–max" is Lemma 17.7.1, and it is free for every function. In Courant–Fischer the corresponding inequality

$$\max_{\dim W=k} \min_{\mathbf{0}\neq\mathbf{x}\in W} R_{\mathbf{A}}(\mathbf{x}) \;\leq\; \min_{\dim W'=n-k+1} \max_{\mathbf{0}\neq\mathbf{x}\in W'} R_{\mathbf{A}}(\mathbf{x})$$

is **not** free: it is exactly the dimension count. Since $k+(n-k+1) > n$, any W of dimension k meets any W' of dimension $n-k+1$ in a non-zero vector $\mathbf{x}$ (Lemma 16.2.1), and then $\min_W R_{\mathbf{A}} \leq R_{\mathbf{A}}(\mathbf{x}) \leq \max_{W'} R_{\mathbf{A}}$.

Where the equality comes from. In Courant–Fischer it is a **dimension count**. Any subspace of dimension $n-k+1$ must meet the span of the top k eigenvectors, by Lemma 16.2.1, and on the shared vector the Rayleigh quotient is pinned. Convexity plays no role: the subspaces of dimension $n-k+1$ do not form a convex set in any sense used here, and $R_{\mathbf{A}}$ is not linear. In von Neumann's theorem it is **convexity**. The strategy sets are simplices, the payoff is linear in each variable separately, and the equality is linear programming duality, which is Farkas's lemma, which is a separating hyperplane. No dimension is counted anywhere.

What they need. Courant–Fischer needs a Hermitian matrix, since the spectral theorem supplies the eigenvectors that are its witnesses. Von Neumann's theorem holds for **every** real matrix, square or not.

How each fails when its key ingredient is removed. Replace the simplices by the finite sets of pure strategies, which are not convex, and von Neumann's equality fails, as in the matching game above. Replace the dimension $n-k+1$ by $n-k$, which is possible when $k < n$, so that the dimension count no longer forces an intersection, and Courant–Fischer's formula returns $\lambda_{k+1}(\mathbf{A})$ instead of $\lambda_k(\mathbf{A})$.

17.7.5 Solving a game

Example. (A game with an unused column)

Find the value and optimal strategies for the game with payoff matrix

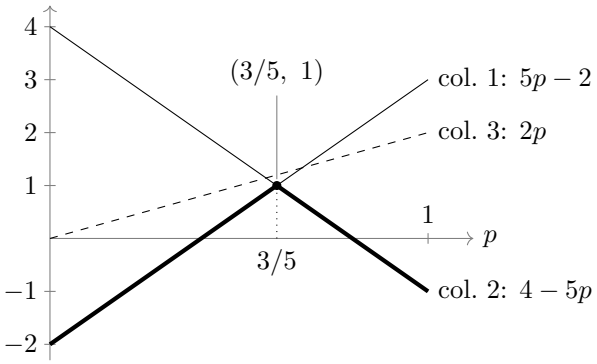
$$\mathbf{A} = \begin{pmatrix} 3 & -1 & 2 \\ -2 & 4 & 0 \end{pmatrix}.$$

Solution. No saddle point. The row minima are -1 and -2, so $\max_i \min_j a_{ij} = -1$. The column maxima are $3, 4, 2$, so $\min_j \max_i a_{ij} = 2$. The two differ, so both players must mix.

Row's side. Write $\mathbf{x} = (p, 1-p)$ with $0 \le p \le 1$. Then

$$\mathbf{A}^\top \mathbf{x} = \big(5p - 2,\ 4 - 5p,\ 2p\big),$$

and by Lemma 17.7.2 Row guarantees $g(p) = \min\{5p-2,\ 4-5p,\ 2p\}$. The graph of g is the lower envelope of three lines.



Row's guarantee $g(p)$ is the lower envelope (thick). It is highest at $p = 3/5$, where columns 1 and 2 cross at height 1. The dashed line never touches it

For $p \le \frac{3}{5}$ the first line is the lowest: $5p-2 \le 4-5p$ exactly when $p \le \frac{3}{5}$, and $5p-2 \le 2p$ exactly when $p \le \frac{2}{3}$. For $p \ge \frac{3}{5}$ the second line is the lowest: $4-5p \le 2p$ exactly when $p \ge \frac{4}{7}$, which holds since $\frac{3}{5} > \frac{4}{7}$. So $g(p) = 5p-2$ on $[0, \frac{3}{5}]$ and $g(p) = 4-5p$ on $[\frac{3}{5}, 1]$. With slopes 5 and -5, g **strictly** increases on the first interval and **strictly** decreases on the second, so its maximum $g\big(\frac{3}{5}\big) = 1$ is attained at $p = \frac{3}{5}$ and nowhere else. The only optimal strategy for Row is $\mathbf{x}^\star = \big(\frac{3}{5}, \frac{2}{5}\big)$, and $\mathbf{A}^\top \mathbf{x}^\star = \big(1, 1, \frac{6}{5}\big)$.

Column's side. Against $\mathbf{x}^\star$, column 3 costs Column $\frac{6}{5}$, which is more than the value, so we expect Column never to use it. Try $\mathbf{y} = (q, 1-q, 0)$: then $\mathbf{A}\mathbf{y} = (4q-1,\ 4-6q)$, and the two entries are equal when $q = \frac{1}{2}$. So $\mathbf{y}^\star = \big(\frac{1}{2}, \frac{1}{2}, 0\big)$, with $\mathbf{A}\mathbf{y}^\star = (1, 1)$.

Verification. $\mathbf{A}^\top \mathbf{x}^\star = \big(1, 1, \frac{6}{5}\big) \ge 1 \cdot \mathbf{1}$ and $\mathbf{A}\mathbf{y}^\star = (1, 1) \le 1 \cdot \mathbf{1}$. As in Step 3 of the proof, these two inequalities give Eq. 17.7.1 with $v = 1$. So the value is $v(\mathbf{A}) = 1$, Row's optimal strategy is $\big(\frac{3}{5}, \frac{2}{5}\big)$, and $\big(\frac{1}{2}, \frac{1}{2}, 0\big)$ is optimal for Column.

Column's optimal strategy is unique too. If $\mathbf{y}$ is optimal for Column, then $\mathbf{A}\mathbf{y} \le \mathbf{1}$, so $\mathbf{x}^{\star\top}\mathbf{A}\mathbf{y} \le 1$. But $\mathbf{x}^{\star\top}\mathbf{A}\mathbf{y} = y_1 + y_2 + \frac{6}{5}y_3 = 1 + \frac{1}{5}y_3$, so $y_3 = 0$. With $\mathbf{y} = (q, 1-q, 0)$, the conditions $4q - 1 \le 1$ and $4 - 6q \le 1$ give $q \le \frac{1}{2}$ and $q \ge \frac{1}{2}$. This is complementary slackness (Theorem 17.6.5) in the language of games: a column whose payoff against an optimal $\mathbf{x}$ exceeds the value is never used.

Quick check. In the game of Example (A game with an unused column), is $\mathbf{x} = \big(\frac{1}{2}, \frac{1}{2}\big)$ an optimal strategy for Row? What does Column do against it?

Solution. No. $\mathbf{A}^\top \mathbf{x} = \big(\frac{1}{2}, \frac{3}{2}, 1\big)$, so $g(\mathbf{x}) = \frac{1}{2} < 1 = v(\mathbf{A})$. Column answers with column 1 and pays only $\frac{1}{2}$ on average. The symmetric-looking strategy is not the safe one.

Warning. **"Make the opponent indifferent between all columns" is not a method.** In Example (A game with an unused column), no $\mathbf{x} \in \Delta_2$ makes all three entries of $\mathbf{A}^\top \mathbf{x}$ equal: the first two are equal only at $p = \frac{3}{5}$, where the third is $\frac{6}{5}$, not 1.

The optimal $\mathbf{x}$ equalizes only the columns that Column actually uses. Deciding **which** columns those are is the real content of solving the game, and it is what the linear program decides. Equalizing the wrong set of columns produces a strategy that is not optimal, or a "solution" with negative probabilities.

Finally, optimal strategies need not be unique, although in the example both were. Exercise (B3: Many optimal strategies) gives a game in which Row has a whole segment of optimal strategies, which is what the convexity of the optimal set allows.

17.7.6 Exercises

17.7.6.1 A. Check your understanding

Exercise A1.

(a) Define the standard simplex Δ_n, a mixed strategy, and the value of a matrix game.

(b) State von Neumann's minimax theorem.

(c) Determine whether the following is correct, and justify your answer: every matrix game has a saddle point in pure strategies.

(d) Explain in two sentences why $\max_{\mathbf{x}} \min_{\mathbf{y}} f(\mathbf{x},\mathbf{y}) \le \min_{\mathbf{y}} \max_{\mathbf{x}} f(\mathbf{x},\mathbf{y})$ for every function f for which the extrema exist.

(e) Name the mechanism that produces the equality in Theorem 16.2.3 and the one that produces it in Theorem 17.7.3.

Solution.

(a) $\Delta_n = \{\mathbf{x} \in \mathbb{R}^n : \mathbf{x} \ge \mathbf{0},\ \sum_i x_i = 1\}$. In a game with payoff matrix $\mathbf{A} \in M_{m\times n}(\mathbb{R})$, a mixed strategy for Row is an $\mathbf{x} \in \Delta_m$ and one for Column is a $\mathbf{y} \in \Delta_n$. The value is $v(\mathbf{A}) = \max_{\mathbf{x}\in\Delta_m} \min_{\mathbf{y}\in\Delta_n} \mathbf{x}^{\top}\mathbf{A}\mathbf{y}$.

(b) For every $\mathbf{A} \in M_{m\times n}(\mathbb{R})$, $\max_{\mathbf{x}\in\Delta_m} \min_{\mathbf{y}\in\Delta_n} \mathbf{x}^{\top}\mathbf{A}\mathbf{y} = \min_{\mathbf{y}\in\Delta_n} \max_{\mathbf{x}\in\Delta_m} \mathbf{x}^{\top}\mathbf{A}\mathbf{y}$, both extrema being attained. Equivalently, there are $\mathbf{x}^\star, \mathbf{y}^\star$ and v with $\mathbf{x}^{\top}\mathbf{A}\mathbf{y}^\star \le v \le \mathbf{x}^{\star\top}\mathbf{A}\mathbf{y}$ for all $\mathbf{x}, \mathbf{y}$.

(c) Incorrect. In the matching game with $\mathbf{A} = \left(\begin{smallmatrix} 1 & -1 \\ -1 & 1 \end{smallmatrix}\right)$, $\max_i \min_j a_{ij} = -1 < 1 = \min_j \max_i a_{ij}$. An entry that is smallest in its row and largest in its column would make these equal.

(d) For any $\mathbf{x}_0, \mathbf{y}_0$, $\min_{\mathbf{y}} f(\mathbf{x}_0,\mathbf{y}) \le f(\mathbf{x}_0,\mathbf{y}_0) \le \max_{\mathbf{x}} f(\mathbf{x},\mathbf{y}_0)$. The left side does not involve $\mathbf{y}_0$ and the right side does not involve $\mathbf{x}_0$, so we may maximize the left over $\mathbf{x}_0$ and minimize the right over $\mathbf{y}_0$.

(e) For Courant–Fischer, a dimension count: Lemma 16.2.1 forces every competing subspace to meet a span of eigenvectors. For von Neumann, convexity: the strategy sets are simplices and the payoff is linear in each variable, and the equality is linear programming duality, which rests on separation.

17.7.6.2 B. Practice

Exercise B1: A two-by-two game.

Let $\mathbf{A} = \begin{pmatrix} 2 & -3 \\ -1 & 1 \end{pmatrix}$.

(a) Show that the game has no saddle point in pure strategies.

(b) Find the value and optimal strategies for both players, and verify the saddle inequality Eq. 17.7.1.

Solution.

(a) The row minima are -3 and -1, so $\max_i \min_j a_{ij} = -1$. The column maxima are 2 and 1, so $\min_j \max_i a_{ij} = 1$. These differ, so no entry is both smallest in its row and largest in its column.

(b) For $\mathbf{x} = (p, 1-p)$, $\mathbf{A}^\top \mathbf{x} = (3p-1,\ 1-4p)$. The first entry increases and the second decreases in p, so their minimum is largest where they are equal: $3p - 1 = 1 - 4p$, that is, $p = \frac{2}{7}$, with common value $-\frac{1}{7}$. For $\mathbf{y} = (q, 1-q)$, $\mathbf{A}\mathbf{y} = (5q - 3,\ 1 - 2q)$, and the entries are equal when $q = \frac{4}{7}$, with common value $-\frac{1}{7}$. So take $\mathbf{x}^\star = \left(\frac{2}{7}, \frac{5}{7}\right)$, $\mathbf{y}^\star = \left(\frac{4}{7}, \frac{3}{7}\right)$ and $v = -\frac{1}{7}$. Then $\mathbf{A}^\top \mathbf{x}^\star = -\frac{1}{7}\mathbf{1}$ and $\mathbf{A}\mathbf{y}^\star = -\frac{1}{7}\mathbf{1}$. For every $\mathbf{y} \in \Delta_2$, $\mathbf{x}^{\star\top} \mathbf{A}\mathbf{y} = -\frac{1}{7}(y_1 + y_2) = -\frac{1}{7}$, and, since $\mathbf{A}\mathbf{y}^\star = -\frac{1}{7}\mathbf{1}$, for every $\mathbf{x} \in \Delta_2$ we have $\mathbf{x}^\top \mathbf{A}\mathbf{y}^\star = -\frac{1}{7}(x_1 + x_2) = -\frac{1}{7}$. So Eq. 17.7.1 holds with equality throughout, and $v(\mathbf{A}) = -\frac{1}{7}$. The game slightly favors Column.

Exercise B2: A saddle point.

Let $\mathbf{A} = \begin{pmatrix} 3 & 1 & 4 \\ 2 & 0 & 1 \end{pmatrix}$, the second game of this section. Show that $\mathbf{x}^\star = \mathbf{e}_1$, $\mathbf{y}^\star = \mathbf{e}_2$ satisfy Eq. 17.7.1 with $v = 1$, and deduce the value of the game.

Solution. For $\mathbf{x} \in \Delta_2$, $\mathbf{x}^\top \mathbf{A}\mathbf{e}_2 = x_1 \cdot 1 + x_2 \cdot 0 = x_1 \le 1$, since $x_1 \le x_1 + x_2 = 1$. For $\mathbf{y} \in \Delta_3$, $\mathbf{e}_1^\top \mathbf{A}\mathbf{y} = 3y_1 + y_2 + 4y_3 \ge y_1 + y_2 + y_3 = 1$. So $\mathbf{x}^\top \mathbf{A}\mathbf{e}_2 \le 1 \le \mathbf{e}_1^\top \mathbf{A}\mathbf{y}$ for all $\mathbf{x}, \mathbf{y}$, which is Eq. 17.7.1 with $v = 1$. By Step 4 of the proof of Theorem 17.7.3 (whose argument uses only Eq. 17.7.1), the max–min and the min–max both equal 1, so $v(\mathbf{A}) = 1$. A pure saddle point is a special case of a mixed one.

Exercise B3: Many optimal strategies.

Let $\mathbf{A} = \begin{pmatrix} 4 & 0 & 1 \\ -1 & 3 & 1 \end{pmatrix}$.

(a) Show that $v(\mathbf{A}) = 1$.

(b) Find **all** optimal strategies for Row.

(c) Show that Column has exactly one optimal strategy.

Solution.

(a) Column can play $\mathbf{e}_3$, which gives $\mathbf{x}^\top \mathbf{A}\mathbf{e}_3 = x_1 + x_2 = 1$ for every $\mathbf{x}$. Hence

$$\min_{\mathbf{y}} \max_{\mathbf{x}} \mathbf{x}^\top \mathbf{A}\mathbf{y} \le \max_{\mathbf{x}} \mathbf{x}^\top \mathbf{A}\mathbf{e}_3 = 1.$$

Row can play $\mathbf{x} = \left(\frac{1}{2}, \frac{1}{2}\right)$, with $\mathbf{A}^\top \mathbf{x} = \left(\frac{3}{2}, \frac{3}{2}, 1\right) \geq \mathbf{1}$, so $\max_{\mathbf{x}} \min_{\mathbf{y}} \mathbf{x}^\top \mathbf{A} \mathbf{y} \geq 1$ by Lemma 17.7.2. By Theorem 17.7.3 both equal $v(\mathbf{A})$, which is therefore 1.

(b) By the remark after Definition 17.7.2, $\mathbf{x} = (p, 1-p)$ is optimal exactly when $\mathbf{A}^\top \mathbf{x} = (5p-1,\ 3-3p,\ 1) \geq \mathbf{1}$, that is, $p \geq \frac{2}{5}$ and $p \leq \frac{2}{3}$. So the optimal strategies for Row are the whole segment $\left\{(p, 1-p) : \frac{2}{5} \leq p \leq \frac{2}{3}\right\}$.

(c) $\mathbf{y} = (a, b, c) \in \Delta_3$ is optimal exactly when $\mathbf{A}\mathbf{y} \leq \mathbf{1}$: $4a + c \leq 1$ and $-a + 3b + c \leq 1$. Substituting $c = 1 - a - b$, these become $3a \leq b$ and $2b \leq 2a$. Hence $3a \leq b \leq a$, so $a \leq 0$, and with $a \geq 0$ we get $a = 0$ and then $b = 0$. So $\mathbf{y} = \mathbf{e}_3$ is the unique optimal strategy for Column.

17.7.6.3 C. Going deeper

Exercise C1: Symmetric games.

Let $\mathbf{A} \in M_n(\mathbb{R})$ be skew-symmetric, $\mathbf{A}^\top = -\mathbf{A}$. Such a game is **symmetric**: the two players have the same options, and swapping their roles swaps the payoff's sign.

(a) Prove that $\mathbf{x}^\top \mathbf{A} \mathbf{x} = 0$ for every $\mathbf{x} \in \mathbb{R}^n$, and deduce that $v(\mathbf{A}) = 0$.

(b) Prove that $\mathbf{x}$ is optimal for Row if and only if it is optimal for Column.

(c) In rock–paper–scissors, with the pure strategies in that order and payoff 1 for a win, -1 for a loss and 0 for a tie,

$$\mathbf{A} = \begin{pmatrix} 0 & -1 & 1 \\ 1 & 0 & -1 \\ -1 & 1 & 0 \end{pmatrix}.$$

Prove that the uniform strategy $\frac{1}{3}\mathbf{1}$ is the **only** optimal strategy.

Solution.

(a) $\mathbf{x}^\top \mathbf{A} \mathbf{x}$ is a 1×1 matrix, so it equals its transpose: $\mathbf{x}^\top \mathbf{A} \mathbf{x} = \mathbf{x}^\top \mathbf{A}^\top \mathbf{x} = -\mathbf{x}^\top \mathbf{A} \mathbf{x}$. Hence $\mathbf{x}^\top \mathbf{A} \mathbf{x} = 0$. Let $\mathbf{x}^\star, \mathbf{y}^\star, v$ be as in Theorem 17.7.3. Taking $\mathbf{y} = \mathbf{x}^\star$ in the right half of Eq. 17.7.1 gives $v \leq \mathbf{x}^{\star\top} \mathbf{A} \mathbf{x}^\star = 0$. Taking $\mathbf{x} = \mathbf{y}^\star$ in the left half gives $0 = \mathbf{y}^{\star\top} \mathbf{A} \mathbf{y}^\star \leq v$. So $v(\mathbf{A}) = 0$.

(b) By the remark after Definition 17.7.2 and (a), $\mathbf{x}$ is optimal for Row exactly when $\mathbf{A}^\top \mathbf{x} \geq \mathbf{0}$, and optimal for Column exactly when $\mathbf{A}\mathbf{x} \leq \mathbf{0}$. Since $\mathbf{A}^\top \mathbf{x} = -\mathbf{A}\mathbf{x}$, the two conditions are the same.

(c) With $\mathbf{x} = (x_1, x_2, x_3) \in \Delta_3$, the condition $\mathbf{A}^\top \mathbf{x} \geq \mathbf{0}$ reads

$$x_2 - x_3 \geq 0, \qquad x_3 - x_1 \geq 0, \qquad x_1 - x_2 \geq 0.$$

So $x_2 \geq x_3 \geq x_1 \geq x_2$, all three are equal, and since they sum to 1, each is $\frac{1}{3}$. By (a) and (b), $\frac{1}{3}\mathbf{1}$ is the unique optimal strategy for either player, and the value is 0.

Exercise C2: The value depends continuously on the payoffs.

For $\mathbf{A}, \mathbf{B} \in M_{m \times n}(\mathbb{R})$, put $\varepsilon = \max_{i,j} |a_{ij} - b_{ij}|$.

(a) Prove that $|v(\mathbf{A}) - v(\mathbf{B})| \leq \varepsilon$.

(b) Prove also that if $a_{ij} \geq b_{ij}$ for all i, j, then $v(\mathbf{A}) \geq v(\mathbf{B})$, and that $v(\mathbf{A} + c\mathbf{J}) = v(\mathbf{A}) + c$ for every real c.

Solution.

(a) For $\mathbf{x} \in \Delta_m$ and $\mathbf{y} \in \Delta_n$,

$$|\mathbf{x}^\top \mathbf{A}\mathbf{y} - \mathbf{x}^\top \mathbf{B}\mathbf{y}| \leq \sum_{i,j} x_i y_j |a_{ij} - b_{ij}| \leq \varepsilon \sum_{i,j} x_i y_j = \varepsilon,$$

since $\sum_{i,j} x_i y_j = (\sum_i x_i)(\sum_j y_j) = 1$. So $\mathbf{x}^\top \mathbf{A}\mathbf{y} \leq \mathbf{x}^\top \mathbf{B}\mathbf{y} + \varepsilon$ for all $\mathbf{x}, \mathbf{y}$. Taking the minimum over $\mathbf{y}$ preserves this inequality between two functions of $\mathbf{y}$, and so does taking the maximum over $\mathbf{x}$. By Theorem 17.7.3 the resulting max–mins are the values, so $v(\mathbf{A}) \leq v(\mathbf{B}) + \varepsilon$. Exchanging $\mathbf{A}$ and $\mathbf{B}$ gives $v(\mathbf{B}) \leq v(\mathbf{A}) + \varepsilon$.

(b) If $a_{ij} \geq b_{ij}$, then $\mathbf{x}^\top \mathbf{A}\mathbf{y} \geq \mathbf{x}^\top \mathbf{B}\mathbf{y}$ for all strategies, since every $x_i y_j \geq 0$, and the same two steps give $v(\mathbf{A}) \geq v(\mathbf{B})$. For the shift, $\mathbf{x}^\top (\mathbf{A} + c\mathbf{J})\mathbf{y} = \mathbf{x}^\top \mathbf{A}\mathbf{y} + c$ for all strategies, as in Step 1 of the proof of Theorem 17.7.3, and adding a constant to a function adds it to every minimum and maximum. So $v(\mathbf{A} + c\mathbf{J}) = v(\mathbf{A}) + c$.

17.8 Extreme Points

Everything so far has gone from points to convex sets: a set of points has a convex hull, and Carathéodory's theorem says how few points each element of the hull needs. This section asks the reverse question: given a convex set, which of its points cannot be manufactured from the others? A triangle is the hull of its three corners, and no smaller set will do. The corners are the **extreme points**, and the main theorem, due to Minkowski, says that a compact convex set is always the hull of its extreme points. We then find the extreme points of three unit balls and of the density matrices, show that the permutation matrices are extreme among the doubly stochastic matrices, and end with a compact convex set whose extreme points do not form a closed set.

Throughout, the field is $\mathbb{R}$, and V is a finite-dimensional real inner product space: $\mathbb{R}^n$ with the dot product, or $M_n(\mathbb{R})$ with the Frobenius inner product $\langle \mathbf{A}, \mathbf{B} \rangle = \operatorname{tr}(\mathbf{B}^\top \mathbf{A})$ of Chapter 10 §01. **Compact** is meant as in §03, and closed bounded sets are compact by Corollary 15.2.5. Conversely a compact set is closed, as a subsequence has the limit of the whole sequence, and bounded, as a sequence with $\|\mathbf{x}_k\| > k$ has no convergent subsequence, convergent sequences being bounded; both facts belong to the elementary algebra of limits that Chapter 15's introduction imports.

17.8.1 Points that are not in between

A convex set contains the segment between any two of its points (Definition 17.1.1). In a filled triangle, a point in the middle of an edge sits between the two ends of that edge, and an interior point sits between many pairs. A corner sits between no pair: any segment of the triangle through a corner has the corner as an end. So the corners are the points you cannot do without: delete one from the list of points whose hull you take, and the hull shrinks.

An extreme point of a convex set is a point that is not strictly between two other points of the

set.

Definition 17.8.1 — Extreme Point

Let $C \subseteq V$ be a convex set. A point $\mathbf{x} \in C$ is an **extreme point** of C if, **whenever** $\mathbf{x} = t\mathbf{y} + (1-t)\mathbf{z}$ with $\mathbf{y}, \mathbf{z} \in C$ and $0 < t < 1$ **strictly**, then $\mathbf{y} = \mathbf{z} = \mathbf{x}$. The set of extreme points of C is written $\operatorname{ext} C$.

In words: the only way to put $\mathbf{x}$ strictly inside a segment of C is the useless way, with both ends equal to $\mathbf{x}$. The word **strictly** matters. With $t = 1$ allowed, every point would be $1 \cdot \mathbf{x} + 0 \cdot \mathbf{z}$ for any $\mathbf{z} \in C$, and no point of a set with two elements or more would be extreme.

To test the definition, midpoints are enough.

Lemma 17.8.1 — The Midpoint Test

Let $C \subseteq V$ be convex and $\mathbf{x} \in C$. Then $\mathbf{x}$ is an extreme point of C if and only if, whenever $\mathbf{x} = \frac{1}{2}(\mathbf{y} + \mathbf{z})$ with $\mathbf{y}, \mathbf{z} \in C$, we have $\mathbf{y} = \mathbf{z}$.

Idea. If $\mathbf{x}$ sits at parameter $t \le \frac{1}{2}$ on a segment $[\mathbf{z}, \mathbf{y}]$, shorten the segment to $[\mathbf{z}, \mathbf{y}']$ with $\mathbf{y}'$ at parameter $2t$; then $\mathbf{x}$ is its midpoint.

Proof. ($\Rightarrow$) Take $t = \frac{1}{2}$ in Definition 17.8.1.

($\Leftarrow$) Let $\mathbf{x} = t\mathbf{y} + (1-t)\mathbf{z}$ with $\mathbf{y}, \mathbf{z} \in C$ and $0 < t < 1$. Swapping the names of $\mathbf{y}$ and $\mathbf{z}$ if necessary, we may assume $t \le \frac{1}{2}$. Put $\mathbf{y}' = 2t\mathbf{y} + (1-2t)\mathbf{z}$. Since $0 < 2t \le 1$, $\mathbf{y}'$ lies on the segment from $\mathbf{z}$ to $\mathbf{y}$, so $\mathbf{y}' \in C$ by convexity. Moreover

$$\tfrac{1}{2}(\mathbf{y}' + \mathbf{z}) = t\mathbf{y} + (1-t)\mathbf{z} = \mathbf{x},$$

so the hypothesis gives $\mathbf{y}' = \mathbf{z}$, that is, $2t(\mathbf{y} - \mathbf{z}) = \mathbf{0}$. As $t \neq 0$, $\mathbf{y} = \mathbf{z}$, and then $\mathbf{x} = t\mathbf{y} + (1-t)\mathbf{y} = \mathbf{y}$. So $\mathbf{y} = \mathbf{z} = \mathbf{x}$, as claimed.

■

Now some examples, simplest first.

1. **A single point.** $C = \{\mathbf{x}\}$ is convex, and $\mathbf{x}$ is extreme: any $\mathbf{y}, \mathbf{z} \in C$ equal $\mathbf{x}$.
2. **A closed segment** $C = \{t\mathbf{a} + (1-t)\mathbf{b} : 0 \le t \le 1\}$ with $\mathbf{a} \neq \mathbf{b}$ has exactly two extreme points, $\mathbf{a}$ and $\mathbf{b}$. A point $\mathbf{x}$ with parameter $0 < s < 1$ is not extreme, since $\mathbf{x} = s\mathbf{a} + (1-s)\mathbf{b}$ with $\mathbf{a} \neq \mathbf{b}$. The end $\mathbf{a}$ is extreme: if $\mathbf{a} = \frac{1}{2}(\mathbf{y} + \mathbf{z})$ with $\mathbf{y}, \mathbf{z}$ at parameters $r, r' \in [0, 1]$, then comparing coefficients along the line gives $\frac{1}{2}(r + r') = 1$, which forces $r = r' = 1$ and $\mathbf{y} = \mathbf{z} = \mathbf{a}$. (The coefficient comparison is legitimate because $t \mapsto t\mathbf{a} + (1-t)\mathbf{b} = \mathbf{b} + t(\mathbf{a} - \mathbf{b})$ is injective, as $\mathbf{a} - \mathbf{b} \neq \mathbf{0}$.)
3. **The closed half-plane** $H = \{(x_1, x_2) \in \mathbb{R}^2 : x_2 \ge 0\}$ has **no** extreme points. Every $\mathbf{x} \in H$ is the midpoint of $\mathbf{x} + \mathbf{e}_1$ and $\mathbf{x} - \mathbf{e}_1$, both in H, and they differ.
4. **The empty set** is convex and compact with no extreme points. It satisfies the main theorem below only because $\operatorname{conv} \emptyset = \emptyset$, which is why the theorem's last sentence says "non-empty".

The closed disk $B_2 \subseteq \mathbb{R}^2$ is a richer example: its extreme points are the whole unit circle. The

section on unit balls below proves this for every n.

A non-example by minimal change. Take the closed triangle $T = \operatorname{conv}\{(0,0),(2,0),(0,2)\}$ and slide from the corner $(2,0)$ along the edge to its midpoint $(1,1)$. The point $(1,1)$ is still in T, still on its boundary, and still on a line with all of T on one side ($x_1 + x_2 \le 2$ on T). What fails is the one clause of Definition 17.8.1: $(1,1) = \frac{1}{2}\big((2,0)+(0,2)\big)$ with $(2,0) \neq (0,2)$.

> *Warning.* **Extreme is not the same as "on the boundary".** The point $(1,1)$ just used lies on the boundary of the triangle T, and every open disk around it contains points outside T; yet it is not extreme. The other direction does hold, for every convex set: an extreme point is never an interior point, since an interior point $\mathbf{x}$ is the midpoint of $\mathbf{x} \pm \varepsilon\mathbf{e}_1$ for small $\varepsilon > 0$.

> *Quick check.* Let $S = \{(0,0),(2,0),(0,2),(1,1),(1,0)\}$. Which points of S are extreme points of $\operatorname{conv} S$?

> *Solution.* Only $(0,0)$, $(2,0)$ and $(0,2)$. The hull is the triangle $T = \{x_1 \ge 0,\ x_2 \ge 0,\ x_1 + x_2 \le 2\}$ above, because $(1,1)$ and $(1,0) = \frac{1}{2}\big((0,0)+(2,0)\big)$ already lie in T. Each of those two points is the midpoint of two distinct points of T, so neither is extreme. The corners are extreme. For $(2,0)$: if $(2,0) = \frac{1}{2}(\mathbf{y}+\mathbf{z})$ with $\mathbf{y},\mathbf{z} \in T$, then $y_1, z_1 \le 2$ and $\frac{1}{2}(y_1 + z_1) = 2$ force $y_1 = z_1 = 2$, and the only point of T with first coordinate 2 is $(2,0)$, because $x_2 \ge 0$ and $x_1 + x_2 \le 2$. The other two corners are handled the same way, with x_2 and with $-x_1 - x_2$ in place of x_1.

Why this definition. It does not ask $\mathbf{x}$ to be far from the rest of C, or on a corner; on the disk, extreme points have extreme neighbors arbitrarily close. It asks only that $\mathbf{x}$ not be an average of other points of C, which is what "cannot be manufactured from the others" means for a convex hull. Exercise C1 shows that $\mathbf{x}$ is extreme exactly when $C \setminus \{\mathbf{x}\}$ is still convex.

The first result makes the indispensability precise: if a convex set is the hull of S, then S contains every extreme point.

Proposition 17.8.2 — Extreme Points of a Hull Come From the Generators

Let $S \subseteq V$ be any set. Then $\operatorname{ext}(\operatorname{conv} S) \subseteq S$.

> *Idea.* Split off one generator from a convex combination: what remains is again a point of the hull, and $\mathbf{x}$ lies strictly between the two.

> *Proof.* Let $\mathbf{x}$ be an extreme point of $\operatorname{conv} S$. By Theorem 17.1.3, $\mathbf{x} = \sum_{i=1}^{k} t_i \mathbf{s}_i$ with $\mathbf{s}_i \in S$, every $t_i > 0$ (drop the zero terms) and $\sum_i t_i = 1$. If $k = 1$ then $\mathbf{x} = \mathbf{s}_1 \in S$. If $k \ge 2$, then $0 < t_1 < 1$, and
>
> $$\mathbf{x} = t_1\mathbf{s}_1 + (1 - t_1)\mathbf{r}, \qquad \mathbf{r} = \sum_{i=2}^{k} \frac{t_i}{1 - t_1}\,\mathbf{s}_i.$$
>
> The coefficients of $\mathbf{r}$ are positive and add up to 1, so $\mathbf{r} \in \operatorname{conv} S$ by Theorem 17.1.3. Since $\mathbf{x}$ is extreme, $\mathbf{s}_1 = \mathbf{r} = \mathbf{x}$. In either case $\mathbf{x} \in S$.
>
> ■

In particular a **polytope**, the hull of finitely many points, has finitely many extreme points, all among the points one started from. Section 9 is built on this.

17.8.2 Faces

A single extreme point is too small an object for an induction on dimension. The right object is a piece of the set that behaves like an extreme point as a whole.

Definition 17.8.2 — Face

Let $C \subseteq V$ be convex. A **face** of C is a convex subset $F \subseteq C$ such that, **whenever** $t\mathbf{y} + (1-t)\mathbf{z} \in F$ with $\mathbf{y}, \mathbf{z} \in C$ and $0 < t < 1$, both $\mathbf{y}$ and $\mathbf{z}$ lie in F.

So a face swallows every segment of C that passes through it at an inner point. The empty set and C itself are faces, and a one-point set $\{\mathbf{x}\}$ is a face exactly when $\mathbf{x}$ is an extreme point: that is Definition 17.8.1 word for word. The edges of a triangle are faces. The segment joining the midpoints of two edges is convex but is not a face: if the triangle has corners $\mathbf{a}, \mathbf{b}, \mathbf{c}$ and the segment joins $\frac{1}{2}(\mathbf{a}+\mathbf{b})$ to $\frac{1}{2}(\mathbf{a}+\mathbf{c})$, its midpoint is $\frac{1}{2}\mathbf{a} + \frac{1}{2}\cdot\frac{1}{2}(\mathbf{b}+\mathbf{c})$, an inner point of a segment of the triangle whose ends $\mathbf{a}$ and $\frac{1}{2}(\mathbf{b}+\mathbf{c})$ do not lie on it.

What makes faces useful for an induction is that they pass extremeness upwards.

Lemma 17.8.3 — Extreme Points of a Face

Let $C \subseteq V$ be convex and F a face of C. Then $\operatorname{ext} F = F \cap \operatorname{ext} C$. In particular an extreme point of a face is an extreme point of C.

Proof. Let $\mathbf{x} \in \operatorname{ext} F$, and let $\mathbf{x} = t\mathbf{y} + (1-t)\mathbf{z}$ with $\mathbf{y}, \mathbf{z} \in C$ and $0 < t < 1$. Since F is a face, $\mathbf{y}, \mathbf{z} \in F$, and since $\mathbf{x}$ is extreme in F, $\mathbf{y} = \mathbf{z} = \mathbf{x}$. So $\mathbf{x} \in \operatorname{ext} C$. Conversely a point of F that is extreme in C is extreme in the smaller set F, because the definition then quantifies over fewer pairs $\mathbf{y}, \mathbf{z}$. ∎

The faces we can actually produce are the ones cut off by a hyperplane that has the whole set on one side. This is the situation of Theorem 17.3.6.

Proposition 17.8.4 — Supporting Slices Are Faces

Let $C \subseteq V$ be convex, let $\mathbf{w} \in V$ and $\alpha \in \mathbb{R}$, and suppose $\langle \mathbf{w}, \mathbf{x} \rangle \le \alpha$ for every $\mathbf{x} \in C$. Then:

(a) $F = \{\mathbf{x} \in C : \langle \mathbf{w}, \mathbf{x} \rangle = \alpha\}$ is a face of C;
(b) if F is a single point $\{\mathbf{c}\}$, then $\mathbf{c}$ is an extreme point of C.

Idea. A weighted average of numbers that are all at most α equals α only if each of them does.

Proof.

(a) F is convex, since if $\langle \mathbf{w}, \mathbf{y} \rangle = \langle \mathbf{w}, \mathbf{z} \rangle = \alpha$, the same holds for $t\mathbf{y} + (1-t)\mathbf{z}$ by linearity of the inner product in its second slot. Let $\mathbf{y}, \mathbf{z} \in C$, $0 < t < 1$, and $t\mathbf{y} + (1-t)\mathbf{z} \in F$. Then

$$\alpha = t\langle \mathbf{w}, \mathbf{y} \rangle + (1-t)\langle \mathbf{w}, \mathbf{z} \rangle,$$

with $\langle \mathbf{w}, \mathbf{y} \rangle \le \alpha$ and $\langle \mathbf{w}, \mathbf{z} \rangle \le \alpha$. If either inequality were strict, the right side would be strictly less than $t\alpha + (1-t)\alpha = \alpha$, because t and $1-t$ are positive. So both are equalities, and $\mathbf{y}, \mathbf{z} \in F$.

(b) By (a), $\{\mathbf{c}\}$ is a face, and its only point is extreme in it. By Lemma 17.8.3, $\mathbf{c} \in \operatorname{ext} C$.

■

A point $\mathbf{c}$ as in (b), the **unique** maximizer over C of some linear function $\mathbf{x} \mapsto \langle \mathbf{w}, \mathbf{x} \rangle$, is called an **exposed point**. Part (b) says that exposed points are extreme; it is the most convenient test for extremeness.

17.8.3 Minkowski's theorem

The main theorem is proved by induction on dimension. Recall from §01 that a non-empty convex set C has dimension $\dim C = \dim \operatorname{aff} C$; by Proposition 17.1.4, $\operatorname{aff} C = \mathbf{x}_0 + W_C$ with $W_C = \operatorname{span}\{\mathbf{y} - \mathbf{x}_0 : \mathbf{y} \in C\}$, independent of $\mathbf{x}_0 \in C$. So $\dim C = \dim W_C$ (Definition 17.1.5 (b)). A convex set has dimension 0 exactly when it is a single point, and for every $\mathbf{y} \in C$ the difference set $C - \mathbf{y} = \{\mathbf{x} - \mathbf{y} : \mathbf{x} \in C\}$ lies in W_C.

Theorem 17.8.5 — Minkowski's Theorem

Let V be a finite-dimensional real inner product space and let $K \subseteq V$ be a compact convex set. Then

$$K = \operatorname{conv}(\operatorname{ext} K).$$

In particular, a non-empty compact convex set has at least one extreme point.

Idea. The inclusion $\supseteq$ is free, since K is convex and contains its extreme points. For $\subseteq$, induct on $\dim K$. Take $\mathbf{x} \in K$ and a line through $\mathbf{x}$ in a direction of W_K. Compactness cuts the line down to a segment $[\mathbf{y}, \mathbf{z}]$ of K with $\mathbf{x}$ on it. An end $\mathbf{y}$ is not an interior point, and Theorem 17.3.6, applied **inside** W_K to the translate $K - \mathbf{y}$, gives a hyperplane through $\mathbf{y}$ with K on one side. The slice of K on that hyperplane is a face of smaller dimension, so by induction $\mathbf{y}$ is a convex combination of its extreme points, and those are extreme in K by Lemma 17.8.3. The same goes for $\mathbf{z}$, and $\mathbf{x}$ lies between $\mathbf{y}$ and $\mathbf{z}$. The space matters: in all of V, a hyperplane containing all of K would qualify, and would give nothing.

Proof. ($\supseteq$) K is convex and contains $\operatorname{ext} K$, so it contains $\operatorname{conv}(\operatorname{ext} K)$, the smallest convex set containing $\operatorname{ext} K$ (Definition 17.1.4).

($\subseteq$) If $K = \emptyset$ there is nothing to prove. For non-empty K we prove, by induction

on $d \geq 0$, the statement: *every non-empty compact convex set of dimension d, in any finite-dimensional real inner product space, is contained in the convex hull of its extreme points.*

If $d = 0$, then $K = \{\mathbf{x}_0\}$, and $\mathbf{x}_0$ is extreme, so $K = \operatorname{conv}(\operatorname{ext} K)$.

Let $d \geq 1$, assume the statement for all dimensions less than d, and let $\dim K = d$ and $\mathbf{x} \in K$. Write $W = W_K$, and choose $\mathbf{u} \in W$ with $\mathbf{u} \neq \mathbf{0}$, which is possible because $\dim W = d \geq 1$.

Step 1: a segment through x. Let $T = \{t \in \mathbb{R} : \mathbf{x} + t\mathbf{u} \in K\}$, which contains 0. It is bounded: if $\|\mathbf{k}\| \leq R$ for every $\mathbf{k} \in K$, then for $t \in T$, $|t|\|\mathbf{u}\| = \|(\mathbf{x} + t\mathbf{u}) - \mathbf{x}\| \leq 2R$. It is closed: if $t_j \in T$ and $t_j \to t$, then $\mathbf{x} + t_j\mathbf{u} \to \mathbf{x} + t\mathbf{u}$, which lies in K because K is closed. So T is a non-empty closed bounded subset of $\mathbb{R}$, which is compact by fact (A3) of Chapter 15's introduction. The function $t \mapsto t$ is continuous, so by fact (A4) (the extreme value theorem) it attains a minimum a and a maximum b on T, and $a \leq 0 \leq b$. Put $\mathbf{y} = \mathbf{x} + a\mathbf{u}$ and $\mathbf{z} = \mathbf{x} + b\mathbf{u}$, both in K. If $a < b$ then

$$\mathbf{x} = \frac{b}{b-a}\,\mathbf{y} + \frac{-a}{b-a}\,\mathbf{z},$$

a convex combination, since both coefficients are ≥ 0 and they add up to 1; if $a = b$ then $a = b = 0$ and $\mathbf{x} = \mathbf{y} = \mathbf{z}$. Either way $\mathbf{x} \in \operatorname{conv}\{\mathbf{y}, \mathbf{z}\}$.

Step 2: a supporting hyperplane at y, inside W. With the inner product of V restricted to it, $W \neq \{\mathbf{0}\}$ is a finite-dimensional real inner product space. The set $K - \mathbf{y}$ lies in W, is convex by Proposition 17.1.1 (c), and contains $\mathbf{0}$. But $\mathbf{0}$ is not an interior point of $K - \mathbf{y}$ in W (Definition 17.3.2): for every $\varepsilon > 0$, the vector $-\varepsilon\mathbf{u} \in W$, of norm $\varepsilon\|\mathbf{u}\|$, is **not** in $K - \mathbf{y}$, because $\mathbf{y} - \varepsilon\mathbf{u} = \mathbf{x} + (a - \varepsilon)\mathbf{u} \notin K$ by the choice of a. By Theorem 17.3.6, applied in W to $K - \mathbf{y}$ and $\mathbf{0}$, there is a non-zero $\mathbf{w} \in W$ with

$$\langle \mathbf{w}, \mathbf{k} - \mathbf{y} \rangle \leq \langle \mathbf{w}, \mathbf{0} \rangle = 0 \qquad \text{for every } \mathbf{k} \in K.$$

Step 3: the face through y has smaller dimension. So $\langle \mathbf{w}, \mathbf{k} \rangle \leq \alpha := \langle \mathbf{w}, \mathbf{y} \rangle$ on K, and by Proposition 17.8.4 (a), $F = \{\mathbf{k} \in K : \langle \mathbf{w}, \mathbf{k} \rangle = \alpha\}$ is a face of K. It is non-empty, as $\mathbf{y} \in F$, and convex. It is bounded, being inside K, and closed: if $\mathbf{k}_j \in F$ and $\mathbf{k}_j \to \mathbf{k}$, then $\mathbf{k} \in K$, and $|\langle \mathbf{w}, \mathbf{k}_j \rangle - \langle \mathbf{w}, \mathbf{k} \rangle| \leq \|\mathbf{w}\|\|\mathbf{k}_j - \mathbf{k}\| \to 0$ by Theorem 10.1.5, so $\langle \mathbf{w}, \mathbf{k} \rangle = \alpha$. So F is compact. Using $\mathbf{y} \in F$ as base point, W_F is spanned by vectors $\mathbf{k} - \mathbf{y}$ with $\mathbf{k} \in F$, each of which lies in

$$W' = \{\mathbf{v} \in W : \langle \mathbf{w}, \mathbf{v} \rangle = 0\},$$

the kernel of the linear functional $\mathbf{v} \mapsto \langle \mathbf{w}, \mathbf{v} \rangle$ on W. That functional is non-zero, since it sends $\mathbf{w}$ to $\|\mathbf{w}\|^2 > 0$, so its image is $\mathbb{R}$ and Theorem 3.3.1 gives $\dim W' = d - 1$. Hence $\dim F = \dim W_F \leq d - 1$ by Theorem 1.6.7.

Step 4: induction. By the induction hypothesis, $\mathbf{y} \in \operatorname{conv}(\operatorname{ext} F)$, and $\operatorname{ext} F \subseteq \operatorname{ext} K$ by Lemma 17.8.3. So $\mathbf{y} \in \operatorname{conv}(\operatorname{ext} K)$. Running Steps 2 to 4 with $-\mathbf{u}$ in place of $\mathbf{u}$, which exchanges the roles of a and b, gives $\mathbf{z} \in \operatorname{conv}(\operatorname{ext} K)$. Since $\operatorname{conv}(\operatorname{ext} K)$ is convex and contains $\mathbf{y}$ and $\mathbf{z}$, Step 1 gives $\mathbf{x} \in \operatorname{conv}(\operatorname{ext} K)$. As $\mathbf{x} \in K$ was arbitrary, this proves the inclusion and the theorem. The last sentence of the statement follows, since $\operatorname{conv} \emptyset = \emptyset$.

■

Warning. **Compactness cannot be dropped.** The quarter-plane $Q = \{x_1 \geq 0,\ x_2 \geq 0\}$ is closed and convex with exactly one extreme point, the origin, and $\operatorname{conv}\{\mathbf{0}\} = \{\mathbf{0}\} \neq Q$. The open disk, bounded but not closed, has no extreme points at all, since each of its points $\mathbf{x}$ is the midpoint of $\mathbf{x} \pm \varepsilon \mathbf{e}_1$ for small $\varepsilon > 0$.

Combined with Carathéodory's theorem (Theorem 17.2.2), Minkowski's theorem says more: every point of a compact convex K of dimension d is a convex combination of at most $d+1$ extreme points. To see this, pick $\mathbf{x}_0 \in K$ and apply Theorem 17.2.2 to the translate $\operatorname{ext} K - \mathbf{x}_0$, which lies in the d-dimensional space W_K; translating back preserves convex combinations, because their coefficients add up to 1.

The consequence used most often concerns linear functions. By the Riesz representation theorem (Theorem 10.5.1), every linear functional on V is $\mathbf{x} \mapsto \langle \mathbf{x}, \mathbf{a} \rangle$ for some $\mathbf{a} \in V$, and it is continuous by Theorem 10.1.5, since $|\langle \mathbf{x}, \mathbf{a} \rangle - \langle \mathbf{x}', \mathbf{a} \rangle| \leq \|\mathbf{a}\| \|\mathbf{x} - \mathbf{x}'\|$.

Corollary 17.8.6 — Linear Functions Peak at Extreme Points

Let $K \subseteq V$ be a non-empty compact convex set and $\mathbf{a} \in V$. Then the maximum of $\mathbf{x} \mapsto \langle \mathbf{x}, \mathbf{a} \rangle$ over K exists and is attained at an extreme point of K. The same holds for the minimum.

Idea. Minkowski's theorem writes a maximizer as an average of extreme points, and an average of values at most M equals M only if every value does.

Proof. By fact (A4) of Chapter 15's introduction, the continuous function $\mathbf{x} \mapsto \langle \mathbf{x}, \mathbf{a} \rangle$ attains a maximum M on K, at some $\mathbf{x}^* \in K$. By Theorem 17.8.5 and Theorem 17.1.3, $\mathbf{x}^* = \sum_{i=1}^{k} t_i \mathbf{v}_i$ with $\mathbf{v}_i \in \operatorname{ext} K$, $t_i > 0$ and $\sum_i t_i = 1$. Then

$$M = \langle \mathbf{x}^*, \mathbf{a} \rangle = \sum_{i=1}^{k} t_i \langle \mathbf{v}_i, \mathbf{a} \rangle,$$

while each $\langle \mathbf{v}_i, \mathbf{a} \rangle \leq M$. If some $\langle \mathbf{v}_i, \mathbf{a} \rangle < M$, the weighted average would be strictly less than M, because every $t_i > 0$. So $\langle \mathbf{v}_i, \mathbf{a} \rangle = M$ for every i, and $\mathbf{v}_1$ is an extreme point at which the maximum is attained. For the minimum, apply this to $-\mathbf{a}$.

■

This is why linear programs are solved at corners: when one of Section 6's feasible regions is bounded and non-empty, the corollary puts an optimum at an extreme point, and Section 9 shows that there are finitely many. The same corollary gives a new view of Chapter 16's variational formulas, as we will see after the density matrices.

17.8.4 Three unit balls

The unit balls of the three norms of Chapter 15 (Definition 15.1.2, Example (The 1-, 2- and ∞-norms on F^n)) are compact and convex. They are convex by the remark after Definition 15.1.2. They are bounded, and closed, because $\|\mathbf{x}_k\| \leq 1$ and $\mathbf{x}_k \to \mathbf{x}$ give $\|\mathbf{x}\| \leq \|\mathbf{x}_k\| + \|\mathbf{x} - \mathbf{x}_k\| \leq 1 + \|\mathbf{x} - \mathbf{x}_k\|$ for every k, hence $\|\mathbf{x}\| \leq 1$; so they are compact by Corollary 15.2.5.

Example. (The diamond, the cube and the sphere)

In $\mathbb{R}^n$ with $n \geq 1$, show that:

(a) $\operatorname{ext} B_1 = \{\pm\mathbf{e}_1, \dots, \pm\mathbf{e}_n\}$, $2n$ points;
(b) $\operatorname{ext} B_\infty = \{\mathbf{s} : \text{every } s_i = \pm 1\}$, the 2^n sign vectors;
(c) $\operatorname{ext} B_2 = \{\mathbf{x} : \|\mathbf{x}\|_2 = 1\}$, the whole unit sphere.

Solution. In each case we show that the listed points are extreme and that no other point is. The second half uses the same device each time: a point $\mathbf{x}$ of the ball is not extreme as soon as we find $\mathbf{v} \neq \mathbf{0}$ with $\mathbf{x} \pm \mathbf{v}$ both in the ball, because $\mathbf{x}$ is their midpoint.

(a) *The points $\pm\mathbf{e}_i$ are extreme.* Let $\mathbf{e}_i = \frac{1}{2}(\mathbf{y} + \mathbf{z})$ with $\|\mathbf{y}\|_1, \|\mathbf{z}\|_1 \leq 1$. Then

$$1 = \tfrac{1}{2}(y_i + z_i) \leq \tfrac{1}{2}(|y_i| + |z_i|) \leq \tfrac{1}{2}(\|\mathbf{y}\|_1 + \|\mathbf{z}\|_1) \leq 1,$$

so every inequality is an equality. The first forces $y_i = |y_i|$ and $z_i = |z_i|$. The second, since $|y_i| \leq \|\mathbf{y}\|_1$ and $|z_i| \leq \|\mathbf{z}\|_1$ separately, forces $|y_i| = \|\mathbf{y}\|_1$, so all other entries of $\mathbf{y}$ vanish, and the third forces $\|\mathbf{y}\|_1 = 1$. Hence $\mathbf{y} = \mathbf{e}_i$, and likewise $\mathbf{z} = \mathbf{e}_i$. By Lemma 17.8.1, $\mathbf{e}_i$ is extreme; for $-\mathbf{e}_i$ apply this to $-\mathbf{y}, -\mathbf{z}$.
No other point is extreme. Let $\mathbf{x} \in B_1$. If $\|\mathbf{x}\|_1 < 1$, put $\varepsilon = 1 - \|\mathbf{x}\|_1 > 0$ and $\mathbf{v} = \varepsilon\mathbf{e}_1$; then $\|\mathbf{x} \pm \mathbf{v}\|_1 \leq \|\mathbf{x}\|_1 + \varepsilon = 1$. If $\|\mathbf{x}\|_1 = 1$ and $\mathbf{x}$ is not some $\pm\mathbf{e}_i$, then $\mathbf{x}$ has two non-zero entries x_i, x_j with $i \neq j$. Let $\sigma_i, \sigma_j \in \{\pm 1\}$ be their signs, $\varepsilon = \min(|x_i|, |x_j|) > 0$, and $\mathbf{v} = \varepsilon(\sigma_i\mathbf{e}_i - \sigma_j\mathbf{e}_j)$. Adding $\mathbf{v}$ moves $|x_i|$ up by ε and $|x_j|$ down by ε, and subtracting $\mathbf{v}$ does the opposite; neither entry changes sign, because $\varepsilon \leq |x_i|, |x_j|$. So $\|\mathbf{x} \pm \mathbf{v}\|_1 = \|\mathbf{x}\|_1 = 1$.

(b) *Sign vectors are extreme.* Let $\mathbf{s} = \frac{1}{2}(\mathbf{y} + \mathbf{z})$ with $\|\mathbf{y}\|_\infty, \|\mathbf{z}\|_\infty \leq 1$. For each i, $s_i = \pm 1$ is the average of y_i and z_i, both in $[-1, 1]$. If $s_i = 1$, then $y_i + z_i = 2$ with $y_i, z_i \leq 1$ forces $y_i = z_i = 1$; if $s_i = -1$, then $y_i + z_i = -2$ with $y_i, z_i \geq -1$ forces $y_i = z_i = -1$. So $\mathbf{y} = \mathbf{z} = \mathbf{s}$.
No other point is extreme. If $\mathbf{x} \in B_\infty$ is not a sign vector, some $|x_i| < 1$. Put $\mathbf{v} = (1 - |x_i|)\mathbf{e}_i \neq \mathbf{0}$. Then the i-th entries of $\mathbf{x} \pm \mathbf{v}$ are $x_i \pm (1 - |x_i|)$, both in $[-1, 1]$, and the other entries are unchanged.

(c) *Unit vectors are extreme.* Let $\|\mathbf{x}\|_2 = 1$ and $\mathbf{x} = \frac{1}{2}(\mathbf{y} + \mathbf{z})$ with $\|\mathbf{y}\|_2, \|\mathbf{z}\|_2 \leq 1$. The parallelogram law of Chapter 10 §01, which comes from expanding with Theorem 10.1.2 (c), gives

$$\|\mathbf{y} - \mathbf{z}\|_2^2 = 2\|\mathbf{y}\|_2^2 + 2\|\mathbf{z}\|_2^2 - \|\mathbf{y} + \mathbf{z}\|_2^2 \leq 2 + 2 - \|2\mathbf{x}\|_2^2 = 0,$$

so $\mathbf{y} = \mathbf{z}$.

No other point is extreme. If $\|\mathbf{x}\|_2 < 1$, put $\mathbf{v} = (1 - \|\mathbf{x}\|_2)\mathbf{e}_1$; then $\|\mathbf{x} \pm \mathbf{v}\|_2 \leq \|\mathbf{x}\|_2 + (1 - \|\mathbf{x}\|_2) = 1$.

In (a) and (b), Minkowski's theorem now makes B_1 the hull of the $2n$ points $\pm\mathbf{e}_i$, and B_∞ the hull of the 2^n sign vectors. In (c) it says only that the ball is the hull of the sphere, and the infinitely many extreme points are why B_2 is not a polytope.

17.8.5 Density matrices

Sums and non-negative multiples of positive semidefinite matrices are positive semidefinite, because $\mathbf{x}^\top(s\mathbf{A}+t\mathbf{B})\mathbf{x} = s\,\mathbf{x}^\top\mathbf{A}\mathbf{x} + t\,\mathbf{x}^\top\mathbf{B}\mathbf{x}$; Chapter 12 §01 recorded this in Exercise (C2: The cone of positive matrices) (a). Cutting that cone with a single linear condition gives a compact convex set whose extreme points we can find exactly.

Definition 17.8.3 — Density Matrix

A **density matrix** of size n is a real symmetric matrix $\mathbf{X} \in M_n(\mathbb{R})$ with $\mathbf{X} \succeq 0$ and $\operatorname{tr}\mathbf{X} = 1$. We write $\mathcal{D}_n$ for the set of them.

The name comes from quantum mechanics, which uses the complex Hermitian version; the proofs below carry over, with $\mathbf{x}^*$ for $\mathbf{x}^\top$, $|\mathbf{x}^*\mathbf{y}|^2$ for $(\mathbf{x}^\top\mathbf{y})^2$, and Corollary 11.4.3 for Corollary 11.5.2. The set $\mathcal{D}_n$ is convex: if $\mathbf{X}, \mathbf{Y} \in \mathcal{D}_n$ and $0 \le t \le 1$, then $t\mathbf{X} + (1-t)\mathbf{Y}$ is symmetric, $\mathbf{x}^\top(t\mathbf{X} + (1-t)\mathbf{Y})\mathbf{x} = t\,\mathbf{x}^\top\mathbf{X}\mathbf{x} + (1-t)\,\mathbf{x}^\top\mathbf{Y}\mathbf{x} \ge 0$, and the trace is $t+(1-t) = 1$. It is compact in $M_n(\mathbb{R})$: the three conditions are preserved by entrywise limits, since symmetry and trace are linear and each inequality $\mathbf{x}^\top\mathbf{X}_j\mathbf{x} \ge 0$ survives the limit; and it is bounded, since by Corollary 11.5.2

$$\|\mathbf{X}\|_F^2 = \operatorname{tr}(\mathbf{X}^2) = \sum_{i=1}^{n} \lambda_i(\mathbf{X})^2 \le \Big(\sum_{i=1}^{n} \lambda_i(\mathbf{X})\Big)^2 = 1,$$

where the inequality uses $\lambda_i(\mathbf{X}) \ge 0$ (Theorem 12.1.4).

For a unit vector $\mathbf{x} \in \mathbb{R}^n$, the matrix $\mathbf{x}\mathbf{x}^\top$ is in $\mathcal{D}_n$: it is symmetric, $\mathbf{y}^\top\mathbf{x}\mathbf{x}^\top\mathbf{y} = (\mathbf{x}^\top\mathbf{y})^2 \ge 0$, and $\operatorname{tr}(\mathbf{x}\mathbf{x}^\top) = \mathbf{x}^\top\mathbf{x} = 1$. It is the orthogonal projection onto the line $\operatorname{span}\{\mathbf{x}\}$. One more fact about positive semidefinite matrices is needed: a zero value of the quadratic form pins down a null vector.

Lemma 17.8.7 — A Zero of the Form Is a Null Vector

Let $\mathbf{B} \in M_n(\mathbb{R})$ be symmetric with $\mathbf{B} \succeq 0$, and let $\mathbf{y} \in \mathbb{R}^n$ satisfy $\mathbf{y}^\top\mathbf{B}\mathbf{y} = 0$. Then $\mathbf{B}\mathbf{y} = \mathbf{0}$.

Proof. By Corollary 11.5.2, $\mathbf{B} = \sum_{i=1}^{n} \mu_i \mathbf{q}_i\mathbf{q}_i^\top$ for an orthonormal basis $(\mathbf{q}_1, \dots, \mathbf{q}_n)$ of eigenvectors, with eigenvalues $\mu_i \ge 0$ by Theorem 12.1.4. Then $0 = \mathbf{y}^\top\mathbf{B}\mathbf{y} = \sum_i \mu_i(\mathbf{q}_i^\top\mathbf{y})^2$, a sum of non-negative terms, so $\mu_i(\mathbf{q}_i^\top\mathbf{y})^2 = 0$ for every i. Hence $\mu_i(\mathbf{q}_i^\top\mathbf{y}) = 0$ for every i, and $\mathbf{B}\mathbf{y} = \sum_i \mu_i(\mathbf{q}_i^\top\mathbf{y})\mathbf{q}_i = \mathbf{0}$. ∎

Theorem 17.8.8 — Extreme Points of the Density Matrices

For $n \ge 1$,

$$\operatorname{ext}\mathcal{D}_n = \{\mathbf{x}\mathbf{x}^\top : \mathbf{x} \in \mathbb{R}^n,\ \|\mathbf{x}\| = 1\},$$

the orthogonal projections of rank one. Every $\mathbf{X} \in \mathcal{D}_n$ is a convex combination of at most n of them.

Idea. The spectral theorem writes $\mathbf{X}$ as $\sum_i \lambda_i \mathbf{q}_i \mathbf{q}_i^\top$, with weights $\lambda_i \geq 0$ adding up to $\operatorname{tr} \mathbf{X} = 1$. That is already a convex combination of rank-one projections, which gives the last sentence and shows at once that a matrix with two positive eigenvalues is not extreme. For the converse, suppose $\mathbf{x}\mathbf{x}^\top$ is an average of two density matrices. On every vector orthogonal to $\mathbf{x}$, the form of $\mathbf{x}\mathbf{x}^\top$ is zero, so the forms of both pieces are zero there too, and Lemma 17.8.7 turns that into "both pieces kill $\mathbf{x}^\perp$". A symmetric matrix that kills $\mathbf{x}^\perp$ is a multiple of $\mathbf{x}\mathbf{x}^\top$, and the trace fixes the multiple.

Proof. Let $\mathbf{X} \in \mathcal{D}_n$. By Corollary 11.5.2, $\mathbf{X} = \sum_{i=1}^n \lambda_i \mathbf{q}_i \mathbf{q}_i^\top$ with $(\mathbf{q}_1, \dots, \mathbf{q}_n)$ orthonormal and $\lambda_i = \lambda_i(\mathbf{X})$. Each $\lambda_i \geq 0$ by Theorem 12.1.4, and $\sum_i \lambda_i = \operatorname{tr} \mathbf{X} = 1$, the trace being the sum of the eigenvalues. Dropping the zero terms, this writes $\mathbf{X}$ as a convex combination of at most n matrices $\mathbf{q}_i \mathbf{q}_i^\top$, which proves the last sentence.

Only rank-one projections are extreme. At least one eigenvalue of $\mathbf{X}$ is positive, since the trace is 1. Suppose first that $\mathbf{X}$ has at least two positive eigenvalues. As they are listed decreasingly, $\lambda_1 \geq \lambda_2 > 0$, and then $0 < \lambda_1 < 1$, because the total is 1 and λ_2 is part of it. Put

$$\mathbf{Y} = \frac{1}{1 - \lambda_1} \sum_{i=2}^{n} \lambda_i \mathbf{q}_i \mathbf{q}_i^\top .$$

Its coefficients are non-negative and add up to 1, so $\mathbf{Y} \in \mathcal{D}_n$ by the convexity of $\mathcal{D}_n$, and $\mathbf{X} = \lambda_1 \mathbf{q}_1 \mathbf{q}_1^\top + (1 - \lambda_1)\mathbf{Y}$. The two ends differ, since $\mathbf{q}_1 \mathbf{q}_1^\top \mathbf{q}_1 = \mathbf{q}_1$ while $\mathbf{Y}\mathbf{q}_1 = \mathbf{0}$ by orthonormality. So $\mathbf{X}$ is not extreme. If instead $\mathbf{X}$ has exactly one positive eigenvalue, that eigenvalue is the whole trace, 1, and $\mathbf{X} = \mathbf{q}_1 \mathbf{q}_1^\top$. So every extreme point has the form $\mathbf{x}\mathbf{x}^\top$ with $\|\mathbf{x}\| = 1$.

Every rank-one projection is extreme. Let $\|\mathbf{x}\| = 1$ and $\mathbf{x}\mathbf{x}^\top = \frac{1}{2}(\mathbf{B} + \mathbf{C})$ with $\mathbf{B}, \mathbf{C} \in \mathcal{D}_n$. For every $\mathbf{y}$ with $\mathbf{x}^\top \mathbf{y} = 0$,

$$0 = (\mathbf{x}^\top \mathbf{y})^2 = \mathbf{y}^\top \mathbf{x}\mathbf{x}^\top \mathbf{y} = \tfrac{1}{2}\, \mathbf{y}^\top \mathbf{B}\mathbf{y} + \tfrac{1}{2}\, \mathbf{y}^\top \mathbf{C}\mathbf{y},$$

a sum of two non-negative numbers, so $\mathbf{y}^\top \mathbf{B}\mathbf{y} = 0$, and $\mathbf{B}\mathbf{y} = \mathbf{0}$ by Lemma 17.8.7. Now let $\mathbf{v} \in \mathbb{R}^n$ be arbitrary, and write $\mathbf{v} = (\mathbf{x}^\top \mathbf{v})\mathbf{x} + \mathbf{y}$ with $\mathbf{y} = \mathbf{v} - (\mathbf{x}^\top \mathbf{v})\mathbf{x}$, so that $\mathbf{x}^\top \mathbf{y} = \mathbf{x}^\top \mathbf{v} - \mathbf{x}^\top \mathbf{v} = 0$ because $\mathbf{x}^\top \mathbf{x} = 1$. Then $\mathbf{B}\mathbf{v} = (\mathbf{x}^\top \mathbf{v})\mathbf{B}\mathbf{x}$ for every $\mathbf{v}$, that is, $\mathbf{B} = (\mathbf{B}\mathbf{x})\mathbf{x}^\top$. Since $\mathbf{B}$ is symmetric, also $\mathbf{B} = \mathbf{B}^\top = \mathbf{x}(\mathbf{B}\mathbf{x})^\top$, and applying both expressions to $\mathbf{x}$ gives $\mathbf{B}\mathbf{x} = (\mathbf{x}^\top \mathbf{B}\mathbf{x})\, \mathbf{x}$. Hence $\mathbf{B} = c\, \mathbf{x}\mathbf{x}^\top$ with $c = \mathbf{x}^\top \mathbf{B}\mathbf{x}$, and $1 = \operatorname{tr} \mathbf{B} = c \operatorname{tr}(\mathbf{x}\mathbf{x}^\top) = c$. So $\mathbf{B} = \mathbf{x}\mathbf{x}^\top$, and by symmetry of the argument $\mathbf{C} = \mathbf{x}\mathbf{x}^\top$. By Lemma 17.8.1, $\mathbf{x}\mathbf{x}^\top$ is extreme. This proves the theorem. ∎

For instance, $\mathbf{X} = \frac{1}{15}\begin{pmatrix} 9 & 2 \\ 2 & 6 \end{pmatrix}$ is symmetric with trace 1, and $\mathbf{X}(2,1) = \frac{2}{3}(2,1)$, $\mathbf{X}(1,-2) = \frac{1}{3}(1,-2)$. With $\mathbf{q}_1 = \frac{1}{\sqrt{5}}(2,1)$ and $\mathbf{q}_2 = \frac{1}{\sqrt{5}}(1,-2)$, the proof's splitting is

$$\begin{aligned} \mathbf{X} &= \frac{2}{3}\, \mathbf{q}_1 \mathbf{q}_1^\top + \frac{1}{3}\, \mathbf{q}_2 \mathbf{q}_2^\top \\ &= \frac{2}{3} \cdot \frac{1}{5} \begin{pmatrix} 4 & 2 \\ 2 & 1 \end{pmatrix} + \frac{1}{3} \cdot \frac{1}{5} \begin{pmatrix} 1 & -2 \\ -2 & 4 \end{pmatrix}, \end{aligned}$$

and the entries check: $\frac{8+1}{15} = \frac{9}{15}$, $\frac{4-2}{15} = \frac{2}{15}$, $\frac{2+4}{15} = \frac{6}{15}$.

Here the spectral theorem handed us the decomposition promised by Minkowski's theorem,

with at most n terms. Carathéodory's theorem, in the coset of symmetric matrices of trace 1, of dimension $n(n+1)/2 - 1$, would only have promised $n(n+1)/2$. Structure beats counting.

Now the promised instance of Corollary 17.8.6. For a real symmetric $\mathbf{A}$, the function $\mathbf{X} \mapsto \operatorname{tr}(\mathbf{AX}) = \langle \mathbf{X}, \mathbf{A} \rangle$ is linear on $M_n(\mathbb{R})$, with $\langle \cdot, \cdot \rangle$ the Frobenius inner product.

Example. (The largest eigenvalue as a linear maximum)

Let $\mathbf{A} \in M_n(\mathbb{R})$ be symmetric. Show that $\lambda_1(\mathbf{A}) = \max\{\operatorname{tr}(\mathbf{AX}) : \mathbf{X} \in \mathcal{D}_n\}$, and find the maximum for $\mathbf{A} = \begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix}$.

Solution. The set $\mathcal{D}_n$ is non-empty, compact and convex, so by Corollary 17.8.6 the maximum exists and is attained at an extreme point, which by Theorem 17.8.8 is $\mathbf{xx}^\top$ with $\|\mathbf{x}\| = 1$. There,

$$\operatorname{tr}(\mathbf{Axx}^\top) = \operatorname{tr}(\mathbf{x}^\top \mathbf{Ax}) = \mathbf{x}^\top \mathbf{Ax} \leq \lambda_1(\mathbf{A})$$

by the cyclic property of the trace and Lemma 12.5.2. The bound is attained when $\mathbf{x}$ is a unit eigenvector for $\lambda_1(\mathbf{A})$, by the same lemma, so the maximum is $\lambda_1(\mathbf{A})$.

For the given $\mathbf{A}$, $\mathbf{A}(1,1) = (3,3)$ and $\mathbf{A}(1,-1) = (1,-1)$, so $\lambda_1(\mathbf{A}) = 3$, and the maximizer is $\mathbf{xx}^\top$ with $\mathbf{x} = \frac{1}{\sqrt{2}}(1,1)$:

$$\mathbf{X} = \frac{1}{2}\begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix}, \qquad \mathbf{AX} = \frac{1}{2}\begin{pmatrix} 3 & 3 \\ 3 & 3 \end{pmatrix}, \qquad \operatorname{tr}(\mathbf{AX}) = 3.$$

This is the case $k = 1$ of Ky Fan's maximum principle (Theorem 16.6.2); for $k > 1$, $\operatorname{tr}(\mathbf{Q}^\top \mathbf{AQ}) = \operatorname{tr}(\mathbf{AQQ}^\top)$ is again linear in the projection $\mathbf{QQ}^\top$, but this section does not show that the rank-k projections are the extreme points of any convex set.

17.8.6 Doubly stochastic matrices

Chapter 8 met **stochastic** matrices, whose entries are non-negative and whose columns add up to 1 (Definition 8.11.1). Asking the rows to add up to 1 as well gives a set with remarkable corners.

Definition 17.8.4 — Doubly Stochastic Matrix

A matrix $\mathbf{M} \in M_n(\mathbb{R})$ is **doubly stochastic** if all its entries are non-negative and **every** row and **every** column adds up to 1. We write Ω_n for the set of doubly stochastic $n \times n$ matrices.

Every permutation matrix $\mathbf{P}_\sigma$ is doubly stochastic, since it has exactly one 1 in each row and each column and zeros elsewhere (the remark after Definition 2.6.2). So is $\frac{1}{n}\mathbf{J}$, the matrix with every entry $\frac{1}{n}$. The set Ω_n is convex, since non-negativity and the $2n$ linear conditions on sums survive convex combinations. It is compact in $M_n(\mathbb{R})$: its entries lie in $[0,1]$, so it is bounded, and each defining condition, being a non-strict inequality or a linear equation in the entries, survives limits. By Minkowski's theorem, Ω_n is the hull of its extreme points, and the natural

candidates are the permutation matrices.

Proposition 17.8.9 — Permutation Matrices Are Extreme

Every permutation matrix is an extreme point of Ω_n.

Idea. Non-negative entries cannot cancel, so a zero of $\mathbf{P}$ forces zeros in both pieces, and the row sums then leave no freedom.

Proof. Let $\mathbf{P} = \mathbf{P}_\sigma$ and $\mathbf{P} = t\mathbf{A} + (1-t)\mathbf{B}$ with $\mathbf{A}, \mathbf{B} \in \Omega_n$ and $0 < t < 1$. Wherever $\mathbf{P}$ has a zero entry, $0 = t\,a_{ij} + (1-t)\,b_{ij}$ with both terms non-negative, so $a_{ij} = b_{ij} = 0$. Each row of $\mathbf{A}$ therefore has at most one non-zero entry, in the position where $\mathbf{P}$ has its 1, and since the row adds up to 1, that entry is 1. So $\mathbf{A} = \mathbf{P}$, and likewise $\mathbf{B} = \mathbf{P}$. ∎

The proof never used the column sums. The converse is much deeper.

Birkhoff's theorem. *The extreme points of Ω_n are exactly the $n!$ permutation matrices. Equivalently, every doubly stochastic matrix is a convex combination of permutation matrices.*

The two forms are equivalent by what we have. If the permutation matrices are all the extreme points, Minkowski's theorem (Theorem 17.8.5) makes Ω_n their hull. Conversely, if Ω_n is the hull of the permutation matrices, Proposition 17.8.2 puts every extreme point among them, and Proposition 17.8.9 shows that each of them is one. We do not prove Birkhoff's theorem here; Chapter 18 does. For $n = 2$ it can be checked by hand, as the next Quick check shows.

Quick check. Show that every $\mathbf{M} \in \Omega_2$ has the form $\begin{pmatrix} t & 1-t \\ 1-t & t \end{pmatrix}$ with $0 \le t \le 1$, and deduce Birkhoff's theorem for $n = 2$.

Solution. Let $t = m_{11}$. The first row sum gives $m_{12} = 1 - t$, the first column sum gives $m_{21} = 1 - t$, and the second row sum gives $m_{22} = 1 - (1-t) = t$. Non-negativity gives $0 \le t \le 1$. So

$$\mathbf{M} = t\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} + (1-t)\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix},$$

a convex combination of the two 2×2 permutation matrices. Hence Ω_2 is the segment between them, and its extreme points are its two ends.

Birkhoff's theorem would also give a second route to Schur's theorem, Theorem 16.8.2, which Chapter 16 §08 proved without it. If $\mathbf{A} = \mathbf{Q}\mathbf{D}\mathbf{Q}^\top$ with $\mathbf{Q}$ orthogonal and $\mathbf{D} = \operatorname{diag}(\lambda_1(\mathbf{A}), \dots, \lambda_n(\mathbf{A}))$ (Corollary 11.5.2, after reordering), then $\mathbf{d}(\mathbf{A}) = \mathbf{S}\boldsymbol{\lambda}(\mathbf{A})$ with $\mathbf{S} = (q_{ij}^2)$, doubly stochastic because the rows and columns of $\mathbf{Q}$ are unit vectors, so $\mathbf{d}(\mathbf{A})$ would be an average of rearrangements of $\boldsymbol{\lambda}(\mathbf{A})$, each majorized by $\boldsymbol{\lambda}(\mathbf{A})$, hence majorized by $\boldsymbol{\lambda}(\mathbf{A})$ itself by Example (The vectors majorized by a fixed vector).

17.8.7 When the extreme points are not closed

In every example so far, the extreme points have formed a closed set: finitely many points, a sphere, or the rank-one projections. That is not always so.

Example. (A double cone over a circle)

In $\mathbb{R}^3$, let $\Gamma = \{(1,0,0) + (\mathbf{u}, 0) : \mathbf{u} \in \mathbb{R}^2,\ \|\mathbf{u}\| = 1\}$ be the circle of radius 1 centered at $(1,0,0)$ in the plane $x_3 = 0$, where $(\mathbf{u}, 0) = (u_1, u_2, 0)$; it passes through the origin, at $\mathbf{u} = (-1, 0)$. Let $\mathbf{p} = (0,0,1)$, $\mathbf{q} = (0,0,-1)$, $S = \Gamma \cup \{\mathbf{p}, \mathbf{q}\}$ and $K = \operatorname{conv} S$. Show that K is compact and convex, that

$$\operatorname{ext} K = (\Gamma \setminus \{\mathbf{0}\}) \cup \{\mathbf{p}, \mathbf{q}\},$$

and that this set is not closed.

Solution. Compact and convex. K is convex as a convex hull. The set S is bounded and closed: a limit of points of Γ satisfies the closed conditions $(x_1 - 1)^2 + x_2^2 = 1$ and $x_3 = 0$, which describe Γ, and adding two points keeps it closed. So S is compact, and K is compact by Corollary 17.2.3.

The candidates. By Proposition 17.8.2, $\operatorname{ext} K \subseteq S$.

The origin is not extreme. $\mathbf{0} \in \Gamma \subseteq K$, and $\mathbf{0} = \frac{1}{2}(\mathbf{p} + \mathbf{q})$ with $\mathbf{p} \neq \mathbf{q}$.

The points $\mathbf{p}$ *and* $\mathbf{q}$ *are extreme.* Let $\varphi(\mathbf{x}) = x_3$. On S, $\varphi(\mathbf{p}) = 1$, $\varphi(\mathbf{q}) = -1$ and $\varphi = 0$ on Γ. A point $\mathbf{x} = \sum_i t_i \mathbf{s}_i$ of K, written as a convex combination with every $t_i > 0$ (Theorem 17.1.3), has $\varphi(\mathbf{x}) = \sum_i t_i \varphi(\mathbf{s}_i) \leq 1$, with equality only if every $\mathbf{s}_i = \mathbf{p}$, that is, only if $\mathbf{x} = \mathbf{p}$. So $\varphi \leq 1$ on K with equality exactly at $\mathbf{p}$, and $\mathbf{p}$ is extreme by Proposition 17.8.4 (b). The same argument with $-\varphi$ handles $\mathbf{q}$.

The other points of Γ *are extreme.* Fix $\mathbf{c} = (1,0,0) + (\mathbf{u}, 0)$ with $\mathbf{c} \neq \mathbf{0}$, that is, $\mathbf{u} \neq (-1, 0)$; then $u_1 > -1$, because a unit vector with $u_1 = -1$ is $(-1, 0)$. Let $\varphi(\mathbf{x}) = \langle \mathbf{u}, (x_1, x_2) \rangle = u_1 x_1 + u_2 x_2$, so that $\varphi(\mathbf{c}) = u_1 + \|\mathbf{u}\|^2 = u_1 + 1$. For a point $\mathbf{s} = (1,0,0) + (\mathbf{u}', 0)$ of Γ,

$$\varphi(\mathbf{s}) = u_1 + \langle \mathbf{u}, \mathbf{u}' \rangle \leq u_1 + \|\mathbf{u}\| \|\mathbf{u}'\| = u_1 + 1$$

by Theorem 10.1.5. Equality forces $(\mathbf{u}, \mathbf{u}')$ to be linearly dependent, so $\mathbf{u}' = \pm \mathbf{u}$, and $\mathbf{u}' = -\mathbf{u}$ would give $\langle \mathbf{u}, \mathbf{u}' \rangle = -1$; so equality holds only at $\mathbf{u}' = \mathbf{u}$, that is, at $\mathbf{s} = \mathbf{c}$. Also $\varphi(\mathbf{p}) = \varphi(\mathbf{q}) = 0 < 1 + u_1 = \varphi(\mathbf{c})$. So $\varphi(\mathbf{s}) < \varphi(\mathbf{c})$ for every $\mathbf{s} \in S$ other than $\mathbf{c}$. As before, a convex combination $\mathbf{x} = \sum_i t_i \mathbf{s}_i$ with all $t_i > 0$ has $\varphi(\mathbf{x}) \leq \varphi(\mathbf{c})$, with equality only if every $\mathbf{s}_i = \mathbf{c}$. By Proposition 17.8.4 (b), $\mathbf{c}$ is extreme.

Not closed. For $k \geq 1$ let $\mathbf{c}_k = \big(1 - \sqrt{1 - 1/k^2},\ 1/k,\ 0\big)$. It is $(1,0,0) + (\mathbf{u}_k, 0)$ with $\mathbf{u}_k = \big(-\sqrt{1 - 1/k^2}, 1/k\big)$, a unit vector, so $\mathbf{c}_k \in \Gamma$; and $\mathbf{c}_k \neq \mathbf{0}$, as its second entry is $1/k$. So every $\mathbf{c}_k$ is extreme. For $0 \leq h \leq 1$ we have $(1-h)^2 \leq 1 - h$, hence $1 - h \leq \sqrt{1-h} \leq 1$ and $0 \leq 1 - \sqrt{1-h} \leq h$. With $h = 1/k^2$, the first entry of $\mathbf{c}_k$ lies in $[0, 1/k^2]$, so $\mathbf{c}_k \to \mathbf{0}$, which is not extreme. So $\operatorname{ext} K$ contains a sequence converging to a point outside it, and it is not closed (Definition 17.1.6).

Geometrically, K is a double cone over the disk bounded by Γ, with apexes $\mathbf{p}$ and $\mathbf{q}$. The segment from $\mathbf{p}$ to $\mathbf{q}$ touches the rim of the disk at the origin, which robs the origin of its extremeness while leaving its neighbors on the circle intact. So the set of extreme points of a compact convex set need not be closed, and hence need not be compact.

17.8.8 Exercises

17.8.8.1 A. Check your understanding

Exercise A1.

(a) State the definition of an extreme point of a convex set $C \subseteq V$.

(b) True or false: every boundary point of a compact convex set in $\mathbb{R}^2$ is an extreme point. Justify your answer.

(c) True or false: there is a non-empty closed convex subset of $\mathbb{R}^2$ with no extreme points. Justify your answer.

(d) State Theorem 17.8.5, and name the two facts from Chapter 15's introduction that its proof uses.

(e) True or false: if $K = \operatorname{conv} S$ with S finite, then every point of S is an extreme point of K. Justify your answer.

Solution.

(a) A point $\mathbf{x} \in C$ is extreme if $\mathbf{x} = t\mathbf{y} + (1-t)\mathbf{z}$ with $\mathbf{y}, \mathbf{z} \in C$ and $0 < t < 1$ forces $\mathbf{y} = \mathbf{z} = \mathbf{x}$.

(b) False. In the square $[-1,1]^2$, the point $(1,0)$ is on the boundary, since $(1+\varepsilon, 0)$ lies outside for every $\varepsilon > 0$, but it is the midpoint of $(1,1)$ and $(1,-1)$, both in the square.

(c) True. The closed half-plane $\{x_2 \geq 0\}$ is one: each of its points $\mathbf{x}$ is the midpoint of $\mathbf{x} \pm \mathbf{e}_1$, which lie in it. A line is another.

(d) A compact convex subset K of a finite-dimensional real inner product space is the convex hull of its extreme points. The proof uses (A3), to see that the set of t with $\mathbf{x} + t\mathbf{u} \in K$ is compact, and (A4), the extreme value theorem, to find its smallest and largest elements.

(e) False. Take $S = \{0,1,2\} \subseteq \mathbb{R}$. Then $K = [0,2]$, whose extreme points are 0 and 2; the point $1 = \frac{1}{2}(0+2)$ of S is not extreme. What is true is the reverse inclusion $\operatorname{ext} K \subseteq S$ (Proposition 17.8.2).

17.8.8.2 B. Practice

Exercise B1: Finding extreme points.

Determine the extreme points of each of the following convex subsets of $\mathbb{R}^2$. Justify your answer.

(a) $\operatorname{conv}\{(0,0),(4,0),(0,2),(2,1),(1,1)\}$.

(b) $P = \{(x,y) : x^2 \leq y \leq 1\}$.

(c) The strip $\{(x,y) : 0 \leq y \leq 1\}$.

Hint: for (b), use Proposition 17.8.4 (b) with a tangent line.

Solution.

(a) By Proposition 17.8.2, every extreme point is one of the five listed points. The point $(2,1) = \frac{1}{2}\big((4,0)+(0,2)\big)$ is not extreme. Neither is $(1,1) = \frac{1}{2}\big((2,1)+(0,1)\big)$, since $(0,1) = \frac{1}{2}\big((0,0)+(0,2)\big)$ lies in the hull, and $(2,1) \neq (0,1)$. The three corners are extreme: each is the unique maximizer over the five points of a linear function, namely $-x-y$, x and y respectively, hence the unique maximizer over the hull by the convex-combination argument of Example (A double cone over a circle), and Proposition 17.8.4 (b) applies. So the extreme points are $(0,0)$, $(4,0)$ and $(0,2)$.

(b) *Points (a,a^2) with $-1 \le a \le 1$ are extreme.* Let $\varphi(x,y) = 2ax - y$. For $(x,y) \in P$,

$$\varphi(x,y) \le 2ax - x^2 = a^2 - (x-a)^2 \le a^2,$$

with equality only if $x = a$ and $y = x^2 = a^2$. So (a,a^2) is the unique maximizer of φ over P, and it lies in P because $a^2 \le 1$. By Proposition 17.8.4 (b) it is extreme. *No other point is extreme.* Let $(x,y) \in P$ with $y \neq x^2$, so $x^2 < y \le 1$. If $y < 1$, let $\varepsilon = \min(y - x^2, 1 - y) > 0$; then $(x, y \pm \varepsilon) \in P$ and (x,y) is their midpoint. If $y = 1$, then $|x| < 1$; let $\varepsilon = 1 - |x| > 0$; then $(x \pm \varepsilon)^2 \le (|x| + \varepsilon)^2 = 1$, so $(x \pm \varepsilon, 1) \in P$, and $(x,1)$ is their midpoint. So $\operatorname{ext} P = \{(a,a^2) : -1 \le a \le 1\}$.

(c) None: every point $\mathbf{x}$ of the strip is the midpoint of $\mathbf{x} \pm \mathbf{e}_1$, which lie in the strip. The strip is closed and convex but not bounded, so Minkowski's theorem does not apply.

Exercise B2: A density matrix split into pure pieces.

Let

$$\mathbf{X} = \begin{pmatrix} 1/2 & 1/4 \\ 1/4 & 1/2 \end{pmatrix}, \qquad \mathbf{Y} = \frac{1}{2}\begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix}, \qquad \mathbf{Z} = \begin{pmatrix} 1/2 & 1 \\ 1 & 1/2 \end{pmatrix}.$$

(a) For each of the three matrices, decide whether it lies in $\mathcal{D}_2$, and if so whether it is an extreme point.

(b) Write $\mathbf{X}$ as a convex combination of two extreme points of $\mathcal{D}_2$.

Solution.

(a) All three are symmetric with trace 1. For $\mathbf{X}$: $\mathbf{X}(1,1) = \frac{3}{4}(1,1)$ and $\mathbf{X}(1,-1) = \frac{1}{4}(1,-1)$, so its eigenvalues are $\frac{3}{4}$ and $\frac{1}{4}$, both non-negative. Hence $\mathbf{X} \in \mathcal{D}_2$ (Theorem 12.1.4), and it has two positive eigenvalues, so it is **not** extreme by Theorem 17.8.8. For $\mathbf{Y}$: $\mathbf{Y} = \mathbf{x}\mathbf{x}^\top$ with $\mathbf{x} = \frac{1}{\sqrt{2}}(1,1)$, a unit vector, so $\mathbf{Y} \in \mathcal{D}_2$ and it **is** extreme. For $\mathbf{Z}$: $\det \mathbf{Z} = \frac{1}{4} - 1 = -\frac{3}{4} < 0$, so the product of its eigenvalues is negative and one of them is negative. Hence $\mathbf{Z}$ is not positive semidefinite, and $\mathbf{Z} \notin \mathcal{D}_2$.

(b) With the unit eigenvectors $\mathbf{q}_1 = \frac{1}{\sqrt{2}}(1,1)$ and $\mathbf{q}_2 = \frac{1}{\sqrt{2}}(1,-1)$,

$$\begin{aligned} \mathbf{X} &= \frac{3}{4}\,\mathbf{q}_1\mathbf{q}_1^\top + \frac{1}{4}\,\mathbf{q}_2\mathbf{q}_2^\top \\ &= \frac{3}{4}\cdot\frac{1}{2}\begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix} + \frac{1}{4}\cdot\frac{1}{2}\begin{pmatrix} 1 & -1 \\ -1 & 1 \end{pmatrix}. \end{aligned}$$

The entries check: the diagonal is $\frac{3}{8} + \frac{1}{8} = \frac{1}{2}$ and the off-diagonal is $\frac{3}{8} - \frac{1}{8} = \frac{1}{4}$. The weights $\frac{3}{4}, \frac{1}{4}$ are non-negative and add up to 1, and both matrices are extreme points by Theorem 17.8.8.

Exercise B3: A doubly stochastic matrix from permutations.

Let

$$\mathbf{M} = \frac{1}{6}\begin{pmatrix} 3 & 2 & 1 \\ 1 & 3 & 2 \\ 2 & 1 & 3 \end{pmatrix}.$$

(a) Check that $\mathbf{M} \in \Omega_3$.

(b) Write $\mathbf{M}$ as a convex combination of three permutation matrices. Hence explain why $\mathbf{M}$ is not an extreme point of Ω_3.

Solution.

(a) The entries are non-negative. Each row of $6\mathbf{M}$ is a rearrangement of $3, 2, 1$, and so is each column (the columns are $(3,1,2)$, $(2,3,1)$, $(1,2,3)$), so every row and column of $\mathbf{M}$ adds up to $6/6 = 1$.

(b) The entries equal to 3 sit on the diagonal, the entries equal to 2 in positions $(1,2), (2,3), (3,1)$, and the entries equal to 1 in positions $(1,3), (2,1), (3,2)$. Each of these three patterns has exactly one position in each row and each column, so each is a permutation matrix:

$$\mathbf{P} = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 0 & 0 \end{pmatrix}, \qquad \mathbf{P}^2 = \begin{pmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix},$$

and $\mathbf{I}$. Hence

$$\mathbf{M} = \frac{1}{2}\mathbf{I} + \frac{1}{3}\mathbf{P} + \frac{1}{6}\mathbf{P}^2,$$

with weights non-negative and adding up to 1. Since $\mathbf{M} = \frac{1}{2}\mathbf{I} + \frac{1}{2}\left(\frac{2}{3}\mathbf{P} + \frac{1}{3}\mathbf{P}^2\right)$, with $\frac{2}{3}\mathbf{P} + \frac{1}{3}\mathbf{P}^2 \in \Omega_3$ by convexity and different from $\mathbf{I}$ (its diagonal is zero), $\mathbf{M}$ is the midpoint of two distinct points of Ω_3 and is not extreme.

17.8.8.3 C. Going deeper

Exercise C1: Deleting an extreme point.

Let $C \subseteq V$ be convex and $\mathbf{x} \in C$.

(a) Prove that $\mathbf{x}$ is an extreme point of C if and only if $C \setminus \{\mathbf{x}\}$ is convex.

(b) Deduce that $\mathbf{x}$ is an extreme point of C if and only if $\mathbf{x} \notin \operatorname{conv}(C \setminus \{\mathbf{x}\})$.

Solution.

(a) ($\Rightarrow$) Let $\mathbf{y}, \mathbf{z} \in C \setminus \{\mathbf{x}\}$ and $0 \le t \le 1$. The point $\mathbf{w} = t\mathbf{y} + (1-t)\mathbf{z}$ lies in C by convexity. If $t = 0$ or $t = 1$, $\mathbf{w}$ is $\mathbf{z}$ or $\mathbf{y}$, which is not $\mathbf{x}$. If $0 < t < 1$ and $\mathbf{w} = \mathbf{x}$, extremality would give $\mathbf{y} = \mathbf{x}$, which is false. So $\mathbf{w} \neq \mathbf{x}$, and $\mathbf{w} \in C \setminus \{\mathbf{x}\}$.
($\Leftarrow$) Suppose $\mathbf{x} = t\mathbf{y} + (1-t)\mathbf{z}$ with $\mathbf{y}, \mathbf{z} \in C$, $0 < t < 1$, and not both equal to $\mathbf{x}$. If exactly one of them, say $\mathbf{z}$, equals $\mathbf{x}$, then $\mathbf{x} = t\mathbf{y} + (1-t)\mathbf{x}$, so $t(\mathbf{y} - \mathbf{x}) = \mathbf{0}$ and $\mathbf{y} = \mathbf{x}$, a contradiction. So neither equals $\mathbf{x}$, both lie in $C \setminus \{\mathbf{x}\}$, and their combination $\mathbf{x}$ does not: $C \setminus \{\mathbf{x}\}$ is not convex.

(b) If $\mathbf{x}$ is extreme, $C \setminus \{\mathbf{x}\}$ is convex by (a), so it is its own hull (Definition 17.1.4),

which does not contain $\mathbf{x}$. If $\mathbf{x}$ is not extreme, (a) gives $\mathbf{y}, \mathbf{z} \in C \setminus \{\mathbf{x}\}$ and $t \in [0,1]$ with $t\mathbf{y} + (1-t)\mathbf{z} \notin C \setminus \{\mathbf{x}\}$; this point lies in C, so it is $\mathbf{x}$, and $\mathbf{x} \in \operatorname{conv}(C \setminus \{\mathbf{x}\})$.

Exercise C2: Every contraction is an average of orthogonal matrices.

Let $\mathcal{B} = \{\mathbf{A} \in M_n(\mathbb{R}) : \|\mathbf{A}\|_2 \le 1\}$, the unit ball of the operator 2-norm (Definition 15.3.2), so that $\mathbf{A} \in \mathcal{B}$ exactly when $\|\mathbf{A}\mathbf{x}\| \le \|\mathbf{x}\|$ for every $\mathbf{x} \in \mathbb{R}^n$.

(a) Prove that every orthogonal matrix is an extreme point of $\mathcal{B}$.

(b) Prove that every $\mathbf{A} \in \mathcal{B}$ that is not orthogonal is **not** an extreme point of $\mathcal{B}$.

(c) Deduce that every $\mathbf{A} \in \mathcal{B}$ is a convex combination of orthogonal matrices.

Hint for (b): use the singular value decomposition (Theorem 12.8.1) and change only the smallest singular value.

Solution.

(a) Let $\mathbf{Q}$ be orthogonal and $\mathbf{Q} = \frac{1}{2}(\mathbf{B} + \mathbf{C})$ with $\mathbf{B}, \mathbf{C} \in \mathcal{B}$. Let $\mathbf{x}$ be a unit vector. Then $\mathbf{Q}\mathbf{x}$ is a unit vector, $\mathbf{B}\mathbf{x}$ and $\mathbf{C}\mathbf{x}$ lie in the Euclidean unit ball B_2, and $\mathbf{Q}\mathbf{x} = \frac{1}{2}(\mathbf{B}\mathbf{x} + \mathbf{C}\mathbf{x})$. By Example (The diamond, the cube and the sphere) (c), $\mathbf{Q}\mathbf{x}$ is an extreme point of B_2, so $\mathbf{B}\mathbf{x} = \mathbf{C}\mathbf{x}$ by Lemma 17.8.1. This holds for every unit $\mathbf{x}$, hence for every $\mathbf{x}$ by scaling, so $\mathbf{B} = \mathbf{C}$. By Lemma 17.8.1 again, $\mathbf{Q}$ is extreme.

(b) By Theorem 12.8.1, $\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^{\top}$ with $\mathbf{U}, \mathbf{V}$ orthogonal and $\mathbf{\Sigma} = \operatorname{diag}(\sigma_1, \dots, \sigma_n)$, $\sigma_1 \ge \cdots \ge \sigma_n \ge 0$, and $\sigma_1 = \|\mathbf{A}\|_2 \le 1$ by Theorem 15.3.3 (c). If $\sigma_n = 1$, then every $\sigma_i = 1$ and $\mathbf{A} = \mathbf{U}\mathbf{V}^{\top}$ is orthogonal. So $\sigma_n < 1$. Put $\varepsilon = 1 - \sigma_n > 0$, let $\mathbf{u}_n, \mathbf{v}_n$ be the last columns of $\mathbf{U}, \mathbf{V}$, and $\mathbf{A}_{\pm} = \mathbf{A} \pm \varepsilon\, \mathbf{u}_n \mathbf{v}_n^{\top} = \mathbf{U}\mathbf{D}_{\pm}\mathbf{V}^{\top}$ with $\mathbf{D}_{\pm} = \operatorname{diag}(\sigma_1, \dots, \sigma_{n-1}, \sigma_n \pm \varepsilon)$. The last diagonal entries are 1 and $2\sigma_n - 1 \in [-1, 1)$, so every diagonal entry d_i of $\mathbf{D}_{\pm}$ has $|d_i| \le 1$. Since $\mathbf{U}$ and $\mathbf{V}^{\top}$ preserve Euclidean length,

$$\|\mathbf{A}_{\pm}\mathbf{x}\| = \|\mathbf{D}_{\pm}\mathbf{V}^{\top}\mathbf{x}\| \le \|\mathbf{V}^{\top}\mathbf{x}\| = \|\mathbf{x}\|,$$

the inequality because $\mathbf{D}_{\pm}$ multiplies each coordinate by a number of absolute value at most 1. So $\mathbf{A}_{\pm} \in \mathcal{B}$, $\mathbf{A} = \frac{1}{2}(\mathbf{A}_+ + \mathbf{A}_-)$, and $\mathbf{A}_+ \ne \mathbf{A}_-$ because $\mathbf{u}_n \mathbf{v}_n^{\top} \ne \mathbf{0}$. Hence $\mathbf{A}$ is not extreme.

(c) $\mathcal{B}$ is convex, being the unit ball of a norm (the remark after Definition 15.1.2). It is closed and bounded for $\|\cdot\|_2$: if $\|\mathbf{A}_j - \mathbf{A}\|_2 \to 0$ with $\|\mathbf{A}_j\|_2 \le 1$, then $\|\mathbf{A}\|_2 \le \|\mathbf{A}_j\|_2 + \|\mathbf{A} - \mathbf{A}_j\|_2 \le 1 + \|\mathbf{A} - \mathbf{A}_j\|_2$ for every j, and letting $j \to \infty$ gives $\|\mathbf{A}\|_2 \le 1$. By Corollary 15.2.5 it is compact for the Frobenius norm as well. By (a) and (b), $\operatorname{ext}\mathcal{B}$ is the set of orthogonal matrices, and Theorem 17.8.5 gives $\mathcal{B} = \operatorname{conv}(\mathrm{O}(n))$.

Exercise C3: The corners of the Loewner interval.

Let $\mathcal{E} = \{\mathbf{X} \in M_n(\mathbb{R}) : \mathbf{X}^{\top} = \mathbf{X},\ 0 \preceq \mathbf{X} \preceq \mathbf{I}\}$, where $\mathbf{X} \preceq \mathbf{I}$ means $\mathbf{I} - \mathbf{X} \succeq 0$ (Definition 12.5.1).

(a) Prove that every symmetric $\mathbf{P}$ with $\mathbf{P}^2 = \mathbf{P}$, that is, every orthogonal projection, is an extreme point of $\mathcal{E}$.

(b) Prove that no other point of $\mathcal{E}$ is extreme.

(c) Deduce that every $\mathbf{X} \in \mathcal{E}$ is a convex combination of orthogonal projections, and give such a combination for $\mathbf{X} = \operatorname{diag}(\frac{1}{2}, \frac{1}{4})$.

Hint for (a): use Lemma 17.8.7 twice, once on $\ker \mathbf{P}$ *and once on* $\operatorname{im} \mathbf{P}$.

Solution.

(a) First, $\mathbf{P} \in \mathcal{E}$: its eigenvalues satisfy $\lambda^2 = \lambda$, so each is 0 or 1, and $\mathbf{P}$ and $\mathbf{I} - \mathbf{P}$ have eigenvalues in $\{0, 1\}$, hence are positive semidefinite (Theorem 12.1.4). Let $\mathbf{P} = \frac{1}{2}(\mathbf{A} + \mathbf{B})$ with $\mathbf{A}, \mathbf{B} \in \mathcal{E}$. If $\mathbf{Px} = \mathbf{0}$, then $0 = \mathbf{x}^\top \mathbf{Px} = \frac{1}{2}\mathbf{x}^\top \mathbf{Ax} + \frac{1}{2}\mathbf{x}^\top \mathbf{Bx}$ with both terms ≥ 0, so $\mathbf{x}^\top \mathbf{Ax} = 0$ and $\mathbf{Ax} = \mathbf{0}$ by Lemma 17.8.7. If $\mathbf{Px} = \mathbf{x}$, then $0 = \mathbf{x}^\top(\mathbf{I} - \mathbf{P})\mathbf{x} = \frac{1}{2}\mathbf{x}^\top(\mathbf{I} - \mathbf{A})\mathbf{x} + \frac{1}{2}\mathbf{x}^\top(\mathbf{I} - \mathbf{B})\mathbf{x}$, so $\mathbf{x}^\top(\mathbf{I} - \mathbf{A})\mathbf{x} = 0$ and, since $\mathbf{I} - \mathbf{A} \succeq 0$, $(\mathbf{I} - \mathbf{A})\mathbf{x} = \mathbf{0}$, that is, $\mathbf{Ax} = \mathbf{x}$. Every $\mathbf{v} \in \mathbb{R}^n$ is $(\mathbf{v} - \mathbf{Pv}) + \mathbf{Pv}$, where $\mathbf{P}(\mathbf{v} - \mathbf{Pv}) = \mathbf{0}$ and $\mathbf{P}(\mathbf{Pv}) = \mathbf{Pv}$. So $\mathbf{Av} = \mathbf{0} + \mathbf{Pv} = \mathbf{Pv}$ for every $\mathbf{v}$, and $\mathbf{A} = \mathbf{P}$; then $\mathbf{B} = 2\mathbf{P} - \mathbf{A} = \mathbf{P}$. By Lemma 17.8.1, $\mathbf{P}$ is extreme.

(b) Let $\mathbf{X} \in \mathcal{E}$ not be idempotent. By Corollary 11.5.2, $\mathbf{X} = \sum_i \lambda_i \mathbf{q}_i \mathbf{q}_i^\top$ with $\mathbf{q}_i$ orthonormal, and every $\lambda_i \in [0, 1]$ because $\mathbf{X} \succeq 0$ and $\mathbf{I} - \mathbf{X} \succeq 0$ have eigenvalues λ_i and $1 - \lambda_i$. If every λ_i were 0 or 1, $\mathbf{X}^2 = \sum_i \lambda_i^2 \mathbf{q}_i \mathbf{q}_i^\top = \mathbf{X}$; so some λ_1, say, lies strictly between 0 and 1. Put $\varepsilon = \min(\lambda_1, 1 - \lambda_1) > 0$ and $\mathbf{X}_\pm = \mathbf{X} \pm \varepsilon \mathbf{q}_1 \mathbf{q}_1^\top$. These have the same eigenvectors, with λ_1 replaced by $\lambda_1 \pm \varepsilon \in [0, 1]$, so $\mathbf{X}_\pm \in \mathcal{E}$; they differ, and $\mathbf{X}$ is their midpoint.

(c) $\mathcal{E}$ is convex (both conditions survive convex combinations, as for $\mathcal{D}_n$), closed (each condition survives limits), and bounded (its eigenvalues lie in $[0, 1]$, so $\|\mathbf{X}\|_F^2 = \sum_i \lambda_i^2 \leq n$). By (a), (b) and Theorem 17.8.5, $\mathcal{E}$ is the convex hull of the orthogonal projections. For $\mathbf{X} = \operatorname{diag}(\frac{1}{2}, \frac{1}{4})$, reading off the eigenvalues in layers,

$$\mathbf{X} = \frac{1}{4}\,\mathbf{I} + \frac{1}{4}\operatorname{diag}(1, 0) + \frac{1}{2}\,\mathbf{0},$$

a convex combination of the projections $\mathbf{I}$, $\operatorname{diag}(1, 0)$ and $\mathbf{0}$ with weights $\frac{1}{4}, \frac{1}{4}, \frac{1}{2}$. The diagonal entries check: $\frac{1}{4} + \frac{1}{4} = \frac{1}{2}$ and $\frac{1}{4}$.

17.9 Polytopes

There are two ways to pin down a convex set with finitely many numbers. One lists finitely many points and takes their convex hull; the other lists finitely many linear inequalities and takes their common solutions. A triangle can be given either way, by its three corners or by its three sides. This section proves that for bounded sets the two descriptions always describe the same sets, which is the Minkowski–Weyl theorem. On the way it locates the optima of Section 6's linear programs over bounded regions: they occur at corners, and a corner of $\{\mathbf{x} : \mathbf{Ax} \leq \mathbf{b}\}$ can be recognized by a rank condition on the constraints that hold with equality there. The other direction of the theorem comes from Fourier–Motzkin elimination, an algorithm for projecting a system of inequalities that works the way Gaussian elimination does for equations.

Throughout, the field is $\mathbb{R}$ and the space is $\mathbb{R}^n$ with $n \geq 1$ and the dot product. An inequality between vectors is meant **entrywise**: $\mathbf{Ax} \leq \mathbf{b}$ says that $(\mathbf{Ax})_i \leq b_i$ for every i. For $\mathbf{A} \in M_{m \times n}(\mathbb{R})$ we write $\mathbf{a}_1^\top, \ldots, \mathbf{a}_m^\top$ for its rows, so that $\mathbf{Ax} \leq \mathbf{b}$ is the list of m inequalities $\mathbf{a}_i^\top \mathbf{x} \leq b_i$.

17.9.1 Two finite descriptions

The first description already appeared in Section 8, just after Proposition 17.8.2.

A polytope is the convex hull of finitely many points; a polyhedron is the solution set of finitely many linear inequalities.

Definition 17.9.1 — Polytope

A **polytope** in $\mathbb{R}^n$ is a set of the form $\operatorname{conv}\{\mathbf{v}_1, \dots, \mathbf{v}_k\}$ for **finitely many** points $\mathbf{v}_1, \dots, \mathbf{v}_k \in \mathbb{R}^n$, $k \geq 0$.

Definition 17.9.2 — Polyhedron

A **polyhedron** in $\mathbb{R}^n$ is a set of the form

$$P = \{\mathbf{x} \in \mathbb{R}^n : \mathbf{A}\mathbf{x} \leq \mathbf{b}\}$$

for some $m \geq 0$, $\mathbf{A} \in M_{m\times n}(\mathbb{R})$ and $\mathbf{b} \in \mathbb{R}^m$; that is, the intersection of **finitely many** sets $\{\mathbf{x} : \mathbf{a}_i^\top \mathbf{x} \leq b_i\}$. An extreme point of a polyhedron or of a polytope (Definition 17.8.1) is called a **vertex**.

In words: a polytope is built from the inside, by mixing finitely many given points; a polyhedron is carved from the outside, by finitely many cuts. When $\mathbf{a}_i \neq \mathbf{0}$, the set $\{\mathbf{x} : \mathbf{a}_i^\top \mathbf{x} \leq b_i\}$ is a closed half-space, bounded by the hyperplane $\mathbf{a}_i^\top \mathbf{x} = b_i$ (Definition 4.5.2). A zero row $\mathbf{a}_i = \mathbf{0}$ is allowed and harmless: the condition $0 \leq b_i$ either holds for every $\mathbf{x}$ or for none. An **equation** $\mathbf{a}^\top \mathbf{x} = \beta$ is allowed too, as the two inequalities $\mathbf{a}^\top \mathbf{x} \leq \beta$ and $-\mathbf{a}^\top \mathbf{x} \leq -\beta$. By Theorem 17.1.3, the polytope $\operatorname{conv}\{\mathbf{v}_1, \dots, \mathbf{v}_k\}$ is the set of all $\sum_j t_j \mathbf{v}_j$ with every $t_j \geq 0$ and $\sum_j t_j = 1$.

Some examples, simplest first.

1. **The empty set and a point** are both. $\emptyset = \operatorname{conv} \emptyset$, and $\emptyset = \{\mathbf{x} : 0 \leq -1\}$ with the single zero row. A point $\mathbf{v} = \operatorname{conv}\{\mathbf{v}\}$ is the solution set of the $2n$ inequalities $x_i \leq v_i$ and $-x_i \leq -v_i$.
2. **All of** $\mathbb{R}^n$ is a polyhedron, with $m = 0$ (or with the one row $0 \leq 0$). So is a closed half-space. Neither is a polytope, because a polytope is bounded: if $\|\mathbf{v}_j\| \leq R$ for every j, then $\|\sum_j t_j \mathbf{v}_j\| \leq \sum_j t_j \|\mathbf{v}_j\| \leq R$.
3. **The triangle** $T \subseteq \mathbb{R}^2$ with corners $(0,0), (3,0), (0,3)$ is $\operatorname{conv}\{(0,0), (3,0), (0,3)\}$, and it is the polyhedron $\{x_1 \geq 0,\ x_2 \geq 0,\ x_1 + x_2 \leq 3\}$. That the two descriptions agree is not a definition but a fact; the worked example in the section on Fourier–Motzkin elimination below derives each from the other.
4. **The cube** $B_\infty = [-1, 1]^n$ is the polyhedron given by the $2n$ inequalities $\pm x_i \leq 1$, and by Section 8 it is the hull of its 2^n sign vectors (Example (The diamond, the cube and the sphere) and Theorem 17.8.5). So it is both.

A non-example by minimal change. Replace the cube's square $B_\infty \subseteq \mathbb{R}^2$ by the disk B_2. It is still compact and convex, still the unit ball of a norm, and still the solution set of inequalities $\mathbf{a}^\top \mathbf{x} \leq 1$, one for **every** unit vector $\mathbf{a}$: by Theorem 10.1.5, $\mathbf{a}^\top \mathbf{x} \leq \|\mathbf{x}\| \leq 1$ on the disk, and a point with $\|\mathbf{x}\| > 1$ violates the inequality for $\mathbf{a} = \mathbf{x}/\|\mathbf{x}\|$. What fails is the word **finitely**. The disk is not a polytope: by Proposition 17.8.2 a polytope has finitely many extreme points,

while the disk has a whole circle of them (Example (The diamond, the cube and the sphere)). We will see after the Minkowski–Weyl theorem that it is not a polyhedron either.

Why these definitions. Both allow only finite data, and that is the point: finitely many inequalities can be checked, finitely many points can be listed, and the whole theory of this section is about moving between two finite lists. An infinite family of inequalities describes every closed convex set, by the separation theorem (Theorem 17.3.2), so dropping "finitely many" would make the second definition say nothing new.

Section 1 already showed that every polyhedron is convex and closed; we record it for citation.

Proposition 17.9.1 — Polyhedra Are Closed and Convex

Every polyhedron $P = \{\mathbf{x} : \mathbf{A}\mathbf{x} \le \mathbf{b}\}$ is convex and closed.

Proof. With the linear functional $\varphi_i(\mathbf{x}) = \mathbf{a}_i^\top \mathbf{x}$, each set $\{\mathbf{x} : \mathbf{a}_i^\top \mathbf{x} \le b_i\} = \{\varphi_i \le b_i\}$ is closed by Proposition 17.1.6 (c), and convex by Proposition 17.1.1 (b), as the preimage of the interval $(-\infty, b_i]$ under φ_i. So their intersection P is closed by Proposition 17.1.6 (b) and convex by Proposition 17.1.1 (a). ∎

Warning. **A polyhedron need not have any vertices, even when it is not empty.** The strip $\{\mathbf{x} \in \mathbb{R}^2 : -1 \le x_1 + x_2 \le 1\}$ is a closed convex set with no extreme points at all: every point $\mathbf{x}$ of it is the midpoint of $\mathbf{x} \pm (1, -1)$, which lie in it. Minkowski's theorem does not apply because the strip is unbounded, and in the language of the next theorem, its constraint rows $\pm(1, 1)$ have rank $1 < 2$.

17.9.2 Vertices are basic feasible points

Section 8 showed that a linear function on a non-empty compact convex set attains its maximum at an extreme point (Corollary 17.8.6). For a linear program over a bounded region $\{\mathbf{x} : \mathbf{A}\mathbf{x} \le \mathbf{b}\}$, that shrinks the search to the vertices. To make it a finite search we need a way to recognize a vertex from the data $\mathbf{A}, \mathbf{b}$, and a proof that there are finitely many.

Stand at a point $\mathbf{x}$ of P and look at the inequalities that are tight there. Each tight inequality $\mathbf{a}_i^\top \mathbf{x} = b_i$ confines $\mathbf{x}$ to a hyperplane. If the tight rows are rich enough to pin $\mathbf{x}$ down, there is no room to move in any direction, and $\mathbf{x}$ should be a corner. If not, there should be a direction along which one can move both ways without leaving P.

Definition 17.9.3 — Active Set, Basic Feasible Point

Let $P = \{\mathbf{x} \in \mathbb{R}^n : \mathbf{A}\mathbf{x} \le \mathbf{b}\}$ and $\mathbf{x} \in P$. The **active set** of $\mathbf{x}$ is $I(\mathbf{x}) = \{i : \mathbf{a}_i^\top \mathbf{x} = b_i\}$, the indices of the inequalities that hold with equality at $\mathbf{x}$. The point $\mathbf{x}$ is a **basic feasible point** of the system if among the active rows $\{\mathbf{a}_i : i \in I(\mathbf{x})\}$ there are n **linearly independent** ones.

Equivalently, the matrix $\mathbf{A}_{I(\mathbf{x})}$ formed by the active rows has a row space of dimension n, that is, rank n (Theorem 2.5.5); by Theorem 2.5.7 this says that its null space is $\{\mathbf{0}\}$, which means

that $\mathbf{x}$ is the **only** solution of the equations $\mathbf{a}_i^\top \mathbf{y} = b_i$, $i \in I(\mathbf{x})$. The word "feasible" records that $\mathbf{x}$ lies in P; a solution of n independent equations $\mathbf{a}_i^\top \mathbf{y} = b_i$ that violates some other inequality is a **basic point** but not a basic feasible one. Note that the definition depends on the system $\mathbf{A}\mathbf{x} \le \mathbf{b}$, not only on the set P; the theorem shows that the resulting notion depends only on P.

Theorem 17.9.2 — Vertices Are Basic Feasible Points

Let $P = \{\mathbf{x} \in \mathbb{R}^n : \mathbf{A}\mathbf{x} \le \mathbf{b}\}$ and $\mathbf{x} \in P$. Then $\mathbf{x}$ is a vertex of P if and only if $\mathbf{x}$ is a basic feasible point.

Idea. Both directions are about the directions $\mathbf{u}$ with $\mathbf{a}_i^\top \mathbf{u} = 0$ for every active i, the directions along which every tight constraint stays tight. If the active rows have rank n, the only such direction is $\mathbf{0}$, and an averaging argument pins down any segment through $\mathbf{x}$. If their rank is less than n, a non-zero such $\mathbf{u}$ exists by rank–nullity, and a short step $\pm\varepsilon\mathbf{u}$ keeps the tight constraints tight and, because there are finitely many, keeps the slack ones slack.

Proof. Write $I = I(\mathbf{x})$ and let $\mathbf{A}_I$ be the matrix of active rows (empty if $I = \emptyset$).

($\Leftarrow$) Suppose $\mathbf{A}_I$ has rank n, and let $\mathbf{x} = \frac{1}{2}(\mathbf{y} + \mathbf{z})$ with $\mathbf{y}, \mathbf{z} \in P$. For $i \in I$,

$$b_i = \mathbf{a}_i^\top \mathbf{x} = \tfrac{1}{2}\mathbf{a}_i^\top \mathbf{y} + \tfrac{1}{2}\mathbf{a}_i^\top \mathbf{z},$$

with $\mathbf{a}_i^\top \mathbf{y} \le b_i$ and $\mathbf{a}_i^\top \mathbf{z} \le b_i$; if either were strict, the average would be less than b_i. So $\mathbf{a}_i^\top \mathbf{y} = b_i = \mathbf{a}_i^\top \mathbf{x}$, that is, $\mathbf{A}_I(\mathbf{y} - \mathbf{x}) = \mathbf{0}$. Since $\mathbf{A}_I$ has n columns and rank n, its null space is $\{\mathbf{0}\}$ by Theorem 2.5.7, so $\mathbf{y} = \mathbf{x}$, and then $\mathbf{z} = 2\mathbf{x} - \mathbf{y} = \mathbf{x}$. By Lemma 17.8.1, $\mathbf{x}$ is a vertex.

($\Rightarrow$) Suppose $\mathbf{A}_I$ has rank less than n (this includes $I = \emptyset$). By Theorem 2.5.7 its null space is non-zero; choose $\mathbf{u} \neq \mathbf{0}$ with $\mathbf{a}_i^\top \mathbf{u} = 0$ for every $i \in I$. For $i \notin I$, the slack $b_i - \mathbf{a}_i^\top \mathbf{x}$ is positive. Let $\varepsilon > 0$ be smaller than $(b_i - \mathbf{a}_i^\top \mathbf{x})/|\mathbf{a}_i^\top \mathbf{u}|$ for every $i \notin I$ with $\mathbf{a}_i^\top \mathbf{u} \neq 0$; there are finitely many such i, so such an ε exists, and if there are none, take $\varepsilon = 1$. Then for $i \in I$, $\mathbf{a}_i^\top(\mathbf{x} \pm \varepsilon\mathbf{u}) = b_i$, and for $i \notin I$,

$$\mathbf{a}_i^\top(\mathbf{x} \pm \varepsilon\mathbf{u}) \le \mathbf{a}_i^\top \mathbf{x} + \varepsilon|\mathbf{a}_i^\top \mathbf{u}| \le b_i.$$

So $\mathbf{x} \pm \varepsilon\mathbf{u} \in P$, they differ because $\mathbf{u} \neq \mathbf{0}$, and $\mathbf{x}$ is their midpoint. Hence $\mathbf{x}$ is not a vertex. This proves the theorem.

■

The payoff is finiteness.

Corollary 17.9.3 — A Polyhedron Has Finitely Many Vertices

Let $P = \{\mathbf{x} \in \mathbb{R}^n : \mathbf{A}\mathbf{x} \le \mathbf{b}\}$ with $\mathbf{A} \in M_{m\times n}(\mathbb{R})$. Every vertex of P is the unique solution of $\mathbf{A}_J\mathbf{x} = \mathbf{b}_J$ for some set J of n row indices with $\mathbf{A}_J$ invertible. In particular P has at most $\binom{m}{n}$ vertices.

Idea. By the theorem, n independent active rows pin a vertex down, so a vertex is determined by which n rows those are.

Proof. Let $\mathbf{x}$ be a vertex. By Theorem 17.9.2, some n active rows, with index set $J \subseteq I(\mathbf{x})$, are linearly independent. The $n \times n$ matrix $\mathbf{A}_J$ then has independent rows, so its rank is n (Theorem 2.5.5), its null space is $\{\mathbf{0}\}$ (Theorem 2.5.7), and it is invertible (Theorem 2.4.4 (b)). As $J \subseteq I(\mathbf{x})$, $\mathbf{A}_J\mathbf{x} = \mathbf{b}_J$, so $\mathbf{x} = \mathbf{A}_J^{-1}\mathbf{b}_J$ is determined by J. Different vertices therefore come from different sets J, and there are $\binom{m}{n}$ sets of n indices.

■

This gives the finite recipe for a vertex list: for each choice of n rows with $\mathbf{A}_J$ invertible, solve $\mathbf{A}_J\mathbf{x} = \mathbf{b}_J$ and keep the solution if it satisfies the remaining inequalities.

Example. (The vertices of a quadrilateral)

Find the vertices of

$$P = \{\mathbf{x} \in \mathbb{R}^2 : x_1 \geq 0,\ x_2 \geq 0,\ x_1 + 2x_2 \leq 4,\ 3x_1 + x_2 \leq 6\},$$

and the maximum of $\varphi(\mathbf{x}) = x_1 + x_2$ over P.

Solution. Number the constraints (1) $-x_1 \leq 0$, (2) $-x_2 \leq 0$, (3) $x_1 + 2x_2 \leq 4$, (4) $3x_1 + x_2 \leq 6$. Any two of the four rows are linearly independent, so each of the $\binom{4}{2} = 6$ pairs gives one basic point. We solve each pair as equations and test the other two inequalities.

pair	basic point	other constraints
(1), (2)	$(0, 0)$	$0 \leq 4,\ 0 \leq 6$: feasible
(1), (3)	$(0, 2)$	$-2 \leq 0,\ 2 \leq 6$: feasible
(1), (4)	$(0, 6)$	$12 \leq 4$ fails
(2), (3)	$(4, 0)$	$12 \leq 6$ fails
(2), (4)	$(2, 0)$	$-2 \leq 0,\ 2 \leq 4$: feasible
(3), (4)	$(\frac{8}{5}, \frac{6}{5})$	$-\frac{8}{5} \leq 0,\ -\frac{6}{5} \leq 0$: feasible

For the last pair, subtracting (3) from twice (4) gives $5x_1 = 8$, so $x_1 = \frac{8}{5}$ and $x_2 = 6 - 3x_1 = \frac{6}{5}$; check $\frac{8}{5} + \frac{12}{5} = 4$. By Theorem 17.9.2 the vertices are the four feasible basic points $(0, 0)$, $(0, 2)$, $(2, 0)$ and $(\frac{8}{5}, \frac{6}{5})$, and P is a quadrilateral. The two infeasible basic points are where two of the lines cross outside P.

P is bounded, since $0 \leq x_1 \leq 2$ and $0 \leq x_2 \leq 2$ on it, so it is compact (Proposition 17.9.1, Corollary 15.2.5) and non-empty. By Corollary 17.8.6 the maximum of φ is attained at a vertex. The values are $0, 2, 2, \frac{14}{5}$, so the maximum is $\frac{14}{5}$, at $(\frac{8}{5}, \frac{6}{5})$.

Quick check. A polyhedron in $\mathbb{R}^2$ is given by $m = 5$ inequalities. What is the largest number of vertices the corollary allows? Could a polyhedron in $\mathbb{R}^3$ given by $m = 2$ inequalities have a vertex?

Solution. At most $\binom{5}{2} = 10$. In $\mathbb{R}^3$ a vertex needs 3 linearly independent active rows, and there are only 2 rows in all, so no: the rank of the active rows is at most $2 < 3$, and by Theorem 17.9.2 such a polyhedron has no vertices. Geometrically, the intersection of

two half-spaces in $\mathbb{R}^3$ always contains a whole line through each of its points.

The recipe is honest but slow: $\binom{m}{n}$ grows very fast. The **simplex method**, the classical algorithm for linear programs, uses the same theorem more cleverly. It moves from a vertex to a neighboring vertex, one sharing $n-1$ of its independent active constraints, along an edge on which the objective improves, and stops at a vertex where no edge improves it.

17.9.3 Fourier–Motzkin elimination

Now the other direction. Given a polytope $\operatorname{conv}\{\mathbf{v}_1,\dots,\mathbf{v}_k\}$, how do we find inequalities for it? The hull is the set of $\mathbf{x}$ for which **there exist** weights $\mathbf{t}\ge\mathbf{0}$ with $\sum_j t_j = 1$ and $\mathbf{x}=\sum_j t_j\mathbf{v}_j$. The conditions on the pair $(\mathbf{x},\mathbf{t})$ are linear inequalities, so the set of pairs is a polyhedron in $\mathbb{R}^{n+k}$, and the polytope is its image under the projection that forgets $\mathbf{t}$. So we need to know that a projection of a polyhedron is a polyhedron, and a way to compute it. For equations, eliminating a variable is Gaussian elimination. For inequalities the device is to pair every upper bound on the variable with every lower bound.

Write a point of $\mathbb{R}^{n+1}$ as $(\mathbf{x},s)$ with $\mathbf{x}\in\mathbb{R}^n$ and $s\in\mathbb{R}$, and let $\pi(\mathbf{x},s)=\mathbf{x}$.

Lemma 17.9.4 — Fourier–Motzkin Elimination

Let $P=\{(\mathbf{x},s)\in\mathbb{R}^n\times\mathbb{R} : \mathbf{a}_i^{\top}\mathbf{x}+c_i s\le b_i \text{ for } i=1,\dots,m\}$. Split the indices by the sign of the coefficient of s: $I_+=\{i:c_i>0\}$, $I_-=\{i:c_i<0\}$, $I_0=\{i:c_i=0\}$. Then $\pi(P)$ is the set of $\mathbf{x}\in\mathbb{R}^n$ satisfying

$$\begin{aligned} \mathbf{a}_i^{\top}\mathbf{x} &\le b_i && \text{for } i\in I_0,\\ (c_i\mathbf{a}_j - c_j\mathbf{a}_i)^{\top}\mathbf{x} &\le c_i b_j - c_j b_i && \text{for } i\in I_+,\ j\in I_-. \end{aligned}$$

In particular $\pi(P)$ is a polyhedron, and if every $b_i=0$, every right-hand side above is 0.

Idea. For fixed $\mathbf{x}$, each row with $c_i>0$ is an upper bound on s, each row with $c_i<0$ is a lower bound, and a row with $c_i=0$ does not mention s. A number s satisfying all of them exists exactly when every lower bound is at most every upper bound, and those comparisons are the new rows. Each new row is the combination $c_i\cdot(\text{row } j)+(-c_j)\cdot(\text{row } i)$, with both multipliers positive and chosen to cancel s.

Proof. Let Q be the set described by the new rows. For $i\in I_+$ and $j\in I_-$, put

$$U_i(\mathbf{x})=\frac{b_i-\mathbf{a}_i^{\top}\mathbf{x}}{c_i},\qquad L_j(\mathbf{x})=\frac{b_j-\mathbf{a}_j^{\top}\mathbf{x}}{c_j}.$$

Dividing row i by $c_i>0$ shows that it says $s\le U_i(\mathbf{x})$, and dividing row j by $c_j<0$, which reverses the inequality, shows that it says $s\ge L_j(\mathbf{x})$. Multiplying $L_j(\mathbf{x})\le U_i(\mathbf{x})$ by the positive number $-c_ic_j$ and rearranging gives exactly the new row for the pair (i,j):

$$L_j(\mathbf{x})\le U_i(\mathbf{x}) \iff (c_i\mathbf{a}_j-c_j\mathbf{a}_i)^{\top}\mathbf{x}\le c_ib_j-c_jb_i.$$

($\subseteq$) If $(\mathbf{x},s)\in P$, then $L_j(\mathbf{x})\le s\le U_i(\mathbf{x})$ for every pair, and the rows in I_0 hold since they do not involve s. So $\mathbf{x}\in Q$.

($\supseteq$) Let $\mathbf{x} \in Q$. If $I_- \neq \emptyset$, let $s = \max_{j \in I_-} L_j(\mathbf{x})$; if $I_- = \emptyset$ and $I_+ \neq \emptyset$, let $s = \min_{i \in I_+} U_i(\mathbf{x})$; if both are empty, let $s = 0$. In each case $L_j(\mathbf{x}) \le s \le U_i(\mathbf{x})$ for all $j \in I_-$ and $i \in I_+$: in the first case because every $L_j(\mathbf{x}) \le s$ by the choice of s, and $s = L_{j_0}(\mathbf{x}) \le U_i(\mathbf{x})$ for every i since $\mathbf{x} \in Q$; the second case is the same with the roles exchanged. The rows in I_0 hold because $\mathbf{x} \in Q$. So $(\mathbf{x}, s) \in P$ and $\mathbf{x} \in \pi(P)$.

The last sentence is visible: the new right-hand sides are b_i and $c_i b_j - c_j b_i$.

■

As an algorithm:

Algorithm. **Fourier–Motzkin elimination of one variable.** Input: a system of m inequalities $\mathbf{a}_i^{\top}\mathbf{x} + c_i s \le b_i$ in the unknowns $\mathbf{x} \in \mathbb{R}^n$ and $s \in \mathbb{R}$.

1. Sort the rows into I_+ ($c_i > 0$), I_- ($c_i < 0$) and I_0 ($c_i = 0$).
2. Copy every row of I_0, without its s term.
3. For every pair $i \in I_+$, $j \in I_-$, write down the row $c_i \cdot (\text{row } j) + (-c_j) \cdot (\text{row } i)$, which is $(c_i\mathbf{a}_j - c_j\mathbf{a}_i)^{\top}\mathbf{x} \le c_i b_j - c_j b_i$.
4. (Optional.) Delete every new row of the form $0 \le \beta$ with $\beta \ge 0$, which every $\mathbf{x}$ satisfies. A row $0 \le \beta$ with $\beta < 0$ means the projection is empty.

Output: $|I_0| + |I_+|\,|I_-|$ inequalities in $\mathbf{x}$ alone, at most, whose solution set is the projection of the input's solution set. To eliminate several variables, repeat.

When the variable to be eliminated appears in an **equation** with a non-zero coefficient, there is a shortcut: solve the equation for it and substitute into the other rows. The projection is unchanged, since the equation determines the eliminated variable from the others, and substitution is exactly Gaussian elimination.

Example. (A triangle, both ways)

Let $Q = \operatorname{conv}\{(0,0),(3,0),(0,3),(1,1)\} \subseteq \mathbb{R}^2$. Find a system of inequalities describing Q, and then recover the vertices of Q from it.

Solution. From points to inequalities. By Theorem 17.1.3, $\mathbf{x} \in Q$ if and only if there are $t_1, \dots, t_4 \ge 0$ with $\sum_j t_j = 1$ and

$$\mathbf{x} = t_1(0,0) + t_2(3,0) + t_3(0,3) + t_4(1,1),$$

that is,

$$x_1 = 3t_2 + t_4, \qquad x_2 = 3t_3 + t_4.$$

Three equations involve the weights, so we substitute three of them away and keep $s = t_4$: $t_2 = \frac{1}{3}(x_1 - s)$, $t_3 = \frac{1}{3}(x_2 - s)$, and

$$t_1 = 1 - t_2 - t_3 - s = 1 - \tfrac{1}{3}(x_1 + x_2 + s).$$

The four conditions $t_j \ge 0$, each multiplied by 3 where needed, become a system in (x_1, x_2, s):

$$\begin{aligned} &(1)\quad x_1 + x_2 + s \le 3, && (2)\quad -x_1 + s \le 0,\\ &(3)\quad -x_2 + s \le 0, && (4)\quad -s \le 0. \end{aligned}$$

Run the algorithm on s. The coefficients of s are $1, 1, 1, -1$, so $I_+ = \{1, 2, 3\}$, $I_- = \{4\}$ and $I_0 = \emptyset$. Each pair $(i, 4)$ has $c_i = 1$ and $-c_4 = 1$, so the new row is row i plus row 4, which just deletes the s:

$$x_1 + x_2 \le 3, \qquad -x_1 \le 0, \qquad -x_2 \le 0.$$

By Lemma 17.9.4, $Q = \{x_1 \ge 0,\ x_2 \ge 0,\ x_1 + x_2 \le 3\}$, the triangle T of the examples above. The generator $(1, 1)$ left no trace, as it should: it lies inside the triangle.

From inequalities to vertices. The three rows $(-1, 0)$, $(0, -1)$, $(1, 1)$ are pairwise independent, so each of the $\binom{3}{2} = 3$ pairs gives a basic point: $(0, 0)$, $(0, 3)$ and $(3, 0)$. Each satisfies the third inequality, so all three are vertices by Theorem 17.9.2. At $(1, 1)$ no constraint is active, so $I = \emptyset$ and it is not a vertex, which matches Proposition 17.8.2: the extreme points of the hull are among the four generators, and $(1, 1)$ is not one of them.

Warning. **Fourier–Motzkin does not return a minimal description.** Eliminating s from $-x_1 + s \le 0$, $s \le 1$, $-s \le 0$ and $x_1 - s \le 1$ pairs two upper bounds with two lower bounds, and gives $-x_1 \le 0$, $x_1 \le 2$, and twice the useless row $0 \le 1$. Even without trivial rows, the output can contain inequalities implied by the others. A single step can turn m rows into as many as $(m/2)^2$, and eliminating many variables compounds this, so the method is a proof device and a hand tool for small systems, not an efficient algorithm.

17.9.4 The Minkowski–Weyl theorem

Cones get the same treatment. Section 5 wrote $\mathrm{cone}(\mathbf{v}_1, \dots, \mathbf{v}_k)$ for the set of all non-negative combinations $\sum_j c_j \mathbf{v}_j$, $c_j \ge 0$, a convex cone (Definition 17.5.1), and called such cones **finitely generated**; we allow $k = 0$, with $\mathrm{cone}() = \{\mathbf{0}\}$. The inequality side is a homogeneous system.

Definition 17.9.4 — Polyhedral Cone

A **polyhedral cone** in $\mathbb{R}^n$ is a set of the form $C = \{\mathbf{x} \in \mathbb{R}^n : \mathbf{A}\mathbf{x} \le \mathbf{0}\}$ for some $m \ge 0$ and $\mathbf{A} \in M_{m \times n}(\mathbb{R})$.

A polyhedral cone is a polyhedron, and it is a convex cone: it contains $\mathbf{0}$, and if $\mathbf{A}\mathbf{u} \le \mathbf{0}$, $\mathbf{A}\mathbf{v} \le \mathbf{0}$ and $a, b \ge 0$, then $\mathbf{A}(a\mathbf{u} + b\mathbf{v}) = a\mathbf{A}\mathbf{u} + b\mathbf{A}\mathbf{v} \le \mathbf{0}$. By Proposition 17.9.1 it is closed, while for finitely generated cones closedness took the work of Theorem 17.5.4.

Theorem 17.9.5 — Minkowski–Weyl Theorem

(a) A subset of $\mathbb{R}^n$ is a polytope if and only if it is a bounded polyhedron.

(b) A subset of $\mathbb{R}^n$ is a finitely generated cone if and only if it is a polyhedral cone.

Idea. Four implications, two tools.

① *Bounded polyhedron ⇒ polytope.* This is Section 8 plus the vertex theorem: a bounded polyhedron is compact, so it is the hull of its vertices by Minkowski's theorem, and it has finitely many vertices.

② *Polyhedral cone ⇒ finitely generated.* Cut the cone with the cube $[-1,1]^n$. The result is a bounded polyhedron, hence by ① the hull of finitely many points, and scaling those points generates the cone.

③ *Polytope ⇒ polyhedron*, and ④ *finitely generated ⇒ polyhedral.* Write the set as the projection of a polyhedron in a bigger space, with the weights as extra coordinates, and eliminate the weights one at a time by Fourier–Motzkin. For a cone all right-hand sides are 0 and stay 0.

Proof. ① **A bounded polyhedron is a polytope.** Let $P = \{\mathbf{x} : \mathbf{A}\mathbf{x} \le \mathbf{b}\}$ be bounded. If $P = \emptyset$, then $P = \operatorname{conv}\emptyset$. Otherwise P is closed and convex by Proposition 17.9.1, and bounded, so it is compact by Corollary 15.2.5. By Theorem 17.8.5, $P = \operatorname{conv}(\operatorname{ext} P)$, and $\operatorname{ext} P$ is finite by Corollary 17.9.3. So P is a polytope.

② **A polyhedral cone is finitely generated.** Let $C = \{\mathbf{x} : \mathbf{A}\mathbf{x} \le \mathbf{0}\}$, and let $P = C \cap [-1,1]^n$, the polyhedron given by the rows of $\mathbf{A}$ together with the $2n$ rows $\pm x_i \le 1$. It is bounded and contains $\mathbf{0}$, so by ① $P = \operatorname{conv}\{\mathbf{v}_1, \dots, \mathbf{v}_k\}$, where $\mathbf{v}_1, \dots, \mathbf{v}_k$ are its vertices; in particular every $\mathbf{v}_j \in P \subseteq C$. We claim $C = \operatorname{cone}(\mathbf{v}_1, \dots, \mathbf{v}_k)$. If $\mathbf{c} \ge \mathbf{0}$, then $\mathbf{A}\sum_j c_j\mathbf{v}_j = \sum_j c_j\mathbf{A}\mathbf{v}_j \le \mathbf{0}$, since each $\mathbf{A}\mathbf{v}_j \le \mathbf{0}$ and each $c_j \ge 0$; so every such combination lies in C. Conversely let $\mathbf{x} \in C$. If $\mathbf{x} = \mathbf{0}$, take all $c_j = 0$. Otherwise put $r = \|\mathbf{x}\|_\infty > 0$. Then $\mathbf{A}(\mathbf{x}/r) = \frac{1}{r}\mathbf{A}\mathbf{x} \le \mathbf{0}$ and every entry of $\mathbf{x}/r$ lies in $[-1,1]$, so $\mathbf{x}/r \in P$, say $\mathbf{x}/r = \sum_j t_j\mathbf{v}_j$ with $t_j \ge 0$. Then $\mathbf{x} = \sum_j (rt_j)\mathbf{v}_j$ with $rt_j \ge 0$.

③ **A polytope is a bounded polyhedron.** Let $Q = \operatorname{conv}\{\mathbf{v}_1, \dots, \mathbf{v}_k\}$, and let $\mathbf{V}$ have columns $\mathbf{v}_j$. It is bounded, as in example 2 after Definition 17.9.2. By Theorem 17.1.3, Q is the image, under the map $(\mathbf{x}, \mathbf{t}) \mapsto \mathbf{x}$ that forgets the last k coordinates, of

$$\widehat{P} = \big\{(\mathbf{x},\mathbf{t}) \in \mathbb{R}^n \times \mathbb{R}^k : \mathbf{x} - \mathbf{V}\mathbf{t} \le \mathbf{0},\ \ -\mathbf{x} + \mathbf{V}\mathbf{t} \le \mathbf{0},\\ -\mathbf{t} \le \mathbf{0},\ \ \mathbf{1}^\top\mathbf{t} \le 1,\ \ -\mathbf{1}^\top\mathbf{t} \le -1\big\},$$

a polyhedron in $\mathbb{R}^{n+k}$. Forgetting the last k coordinates is forgetting one coordinate k times in a row, and by Lemma 17.9.4 each step takes a polyhedron to a polyhedron. So Q is a polyhedron.

④ **A finitely generated cone is polyhedral.** Let $C = \operatorname{cone}(\mathbf{v}_1, \dots, \mathbf{v}_k) = \{\mathbf{V}\mathbf{c} : \mathbf{c} \ge \mathbf{0}\}$, where $\mathbf{V}$ has columns $\mathbf{v}_j$. It is the image under the same map of $\{(\mathbf{x},\mathbf{c}) : \mathbf{x} - \mathbf{V}\mathbf{c} \le \mathbf{0},\ -\mathbf{x} + \mathbf{V}\mathbf{c} \le \mathbf{0},\ -\mathbf{c} \le \mathbf{0}\}$, whose right-hand sides are all 0. By the last sentence of Lemma 17.9.4, eliminating the k coordinates of $\mathbf{c}$ one at a time keeps every right-hand side 0, and the rows copied from I_0 keep theirs as well. So $C = \{\mathbf{x} : \mathbf{B}\mathbf{x} \le \mathbf{0}\}$ for the matrix $\mathbf{B}$ of the final rows (if no rows remain, $C = \mathbb{R}^n = \{\mathbf{x} : 0 \le 0\}$). This completes the proof.

■

Two consequences show what the theorem is for. First, **the intersection of two polytopes is a polytope**. By (a) each is a bounded polyhedron; putting the two systems of inequalities together describes the intersection, which is therefore a bounded polyhedron, hence a polytope by (a) again. From the point description alone this is not obvious at all: the corners of the intersection are, in general, new points found nowhere in the two lists. Second, (b) gives a new proof of Theorem 17.5.4, since every polyhedral cone is closed. In that proof the difficulty of Section 5 has moved into Fourier–Motzkin elimination. The same elimination shows that a linear image $\mathbf{M}(C)$ of a polyhedral cone $C = \{\mathbf{x} : \mathbf{A}\mathbf{x} \le \mathbf{0}\}$ is polyhedral: it is the image, under

the map forgetting $\mathbf{x}$, of $\{(\mathbf{y},\mathbf{x}) : \mathbf{y} - \mathbf{M}\mathbf{x} \le \mathbf{0},\ -\mathbf{y} + \mathbf{M}\mathbf{x} \le \mathbf{0},\ \mathbf{A}\mathbf{x} \le \mathbf{0}\}$, and the argument of ④ applies. So a linear image of a polyhedral cone is closed, and a closed convex cone with a non-closed linear image, like the one in Section 5, can never be polyhedral.

The disk B_2 is not a polyhedron. If it were, it would be a bounded polyhedron, hence a polytope by (a), and it is not one.

17.9.5 The cube and the cross-polytope

The two unit balls with corners from Section 8 are the standard example of the theorem, and they illustrate a duality between the two descriptions.

Example. (The cube and the cross-polytope)

For $n \ge 1$, describe B_∞ and B_1 both as polytopes and as polyhedra, and find their vertices from the inequalities by Theorem 17.9.2.

Solution. The cube. B_∞ is the polyhedron given by the $2n$ rows $\mathbf{e}_i^\top \mathbf{x} \le 1$ and $-\mathbf{e}_i^\top \mathbf{x} \le 1$. At a point $\mathbf{x}$ of it, the active rows are $\mathbf{e}_i$ for each i with $x_i = 1$ and $-\mathbf{e}_i$ for each i with $x_i = -1$; they are distinct standard vectors up to sign, so they are linearly independent, and their number is the rank. The rank is n exactly when every $|x_i| = 1$. So the vertices are the 2^n sign vectors, as Example (The diamond, the cube and the sphere) found directly, and B_∞ is their hull.

The cross-polytope. By Example (The diamond, the cube and the sphere) and Theorem 17.8.5, $B_1 = \operatorname{conv}\{\pm\mathbf{e}_1, \dots, \pm\mathbf{e}_n\}$. For its inequalities, let $\mathbf{s}$ run over the 2^n sign vectors. For every $\mathbf{s}$, $\mathbf{s}^\top \mathbf{x} = \sum_i s_i x_i \le \sum_i |x_i| = \|\mathbf{x}\|_1$, with equality when $s_i = 1$ for $x_i \ge 0$ and $s_i = -1$ for $x_i < 0$. So $\|\mathbf{x}\|_1 = \max_{\mathbf{s}} \mathbf{s}^\top \mathbf{x}$, and

$$B_1 = \{\mathbf{x} \in \mathbb{R}^n : \mathbf{s}^\top \mathbf{x} \le 1 \text{ for every sign vector } \mathbf{s}\},$$

a polyhedron with 2^n rows. At $\mathbf{e}_1$, the active rows are the $\mathbf{s}$ with $s_1 = 1$. They have rank n: they include $\mathbf{1}$, and for each $j \ge 2$ the vector $\mathbf{1} - 2\mathbf{e}_j$, so their span contains $\frac{1}{2}(\mathbf{1} - (\mathbf{1} - 2\mathbf{e}_j)) = \mathbf{e}_j$ for $j \ge 2$ and then $\mathbf{e}_1 = \mathbf{1} - \sum_{j \ge 2} \mathbf{e}_j$. The same holds at every $\pm\mathbf{e}_i$. Every other point $\mathbf{x}$ of B_1 has active rows of rank less than n. If $\|\mathbf{x}\|_1 < 1$, no row is active. If $\|\mathbf{x}\|_1 = 1$, then $\mathbf{x}$ has two non-zero entries x_i, x_j with $i \ne j$, since a point with one non-zero entry and $\|\mathbf{x}\|_1 = 1$ is some $\pm\mathbf{e}_i$; let $\sigma_i, \sigma_j \in \{\pm 1\}$ be their signs. An active $\mathbf{s}$ has $\sum_k s_k x_k = \sum_k |x_k|$ with each $s_k x_k \le |x_k|$, so $s_k x_k = |x_k|$ for every k, and in particular $s_i = \sigma_i$, $s_j = \sigma_j$. Hence $\mathbf{u} = \sigma_i \mathbf{e}_i - \sigma_j \mathbf{e}_j \ne \mathbf{0}$ has $\mathbf{s}^\top \mathbf{u} = \sigma_i^2 - \sigma_j^2 = 0$ for every active $\mathbf{s}$, and the matrix of active rows has rank less than n by Theorem 2.5.7. By Theorem 17.9.2, the vertices are exactly the $2n$ points $\pm\mathbf{e}_i$.

Duality. The rows of the cube are $\pm\mathbf{e}_i$, which are the vertices of the cross-polytope; the rows of the cross-polytope are the sign vectors, which are the vertices of the cube. In $\mathbb{R}^3$, the cube has 8 vertices and 6 inequalities, the octahedron 6 vertices and 8 inequalities. This exchange is the polytope form of the fact that $\|\cdot\|_1$ and $\|\cdot\|_\infty$ are dual norms (Definition 17.4.4): the maximum of $\mathbf{y}^\top \mathbf{x}$ over $\mathbf{x} \in B_1$ is $\|\mathbf{y}\|_\infty$, and over $\mathbf{x} \in B_\infty$ it is $\|\mathbf{y}\|_1$.

17.9.6 Exercises

17.9.6.1 A. Check your understanding

Exercise A1.

(a) State the definitions of a polytope and of a polyhedron in $\mathbb{R}^n$.

(b) True or false: every polyhedron is a polytope. Justify your answer.

(c) True or false: the intersection of two polytopes in $\mathbb{R}^n$ is a polytope. Justify your answer.

(d) State the criterion of Theorem 17.9.2 for a point of $\{\mathbf{x} : \mathbf{A}\mathbf{x} \le \mathbf{b}\}$ to be a vertex.

(e) True or false: every inequality produced by Fourier–Motzkin elimination is needed to describe the projection. Justify your answer.

Solution.

(a) A polytope is the convex hull of finitely many points of $\mathbb{R}^n$. A polyhedron is a set $\{\mathbf{x} \in \mathbb{R}^n : \mathbf{A}\mathbf{x} \le \mathbf{b}\}$ for some $\mathbf{A} \in M_{m\times n}(\mathbb{R})$ and $\mathbf{b} \in \mathbb{R}^m$, that is, an intersection of finitely many sets $\{\mathbf{x} : \mathbf{a}_i^{\top}\mathbf{x} \le b_i\}$.

(b) False. The half-plane $\{x_2 \ge 0\} \subseteq \mathbb{R}^2$ is a polyhedron, with one row, but it is unbounded, while every polytope is bounded.

(c) True. By Theorem 17.9.5 (a), each is a bounded polyhedron. Listing both systems of inequalities together describes the intersection, which is therefore a polyhedron, and it is bounded because it lies inside one of the two. By Theorem 17.9.5 (a) again, it is a polytope.

(d) A point $\mathbf{x}$ with $\mathbf{A}\mathbf{x} \le \mathbf{b}$ is a vertex if and only if the rows $\mathbf{a}_i$ with $\mathbf{a}_i^{\top}\mathbf{x} = b_i$ include n linearly independent ones.

(e) False. In the warning after Example (A triangle, both ways), two of the four output rows are $0 \le 1$, which every point satisfies.

17.9.6.2 B. Practice

Exercise B1: Vertices of a pentagon.

Find all vertices of

$$P = \{\mathbf{x} \in \mathbb{R}^2 : x_1 \ge 0,\ x_2 \ge 0,\ x_1 + x_2 \le 4,\ x_1 - x_2 \le 2,\ -x_1 + 2x_2 \le 5\},$$

and the maximum of $2x_1 + 3x_2$ over P. Hence write P as a polytope.

Solution. Number the rows (1) $-x_1 \le 0$, (2) $-x_2 \le 0$, (3) $x_1 + x_2 \le 4$, (4) $x_1 - x_2 \le 2$, (5) $-x_1 + 2x_2 \le 5$. Any two rows are independent (no two are multiples of each other),

so each of the $\binom{5}{2} = 10$ pairs gives one basic point.

pair	point	verdict
(1), (2)	$(0,0)$	feasible
(1), (3)	$(0,4)$	(5): $8 \le 5$ fails
(1), (4)	$(0,-2)$	(2) fails
(1), (5)	$(0,\frac{5}{2})$	feasible
(2), (3)	$(4,0)$	(4): $4 \le 2$ fails
(2), (4)	$(2,0)$	feasible
(2), (5)	$(-5,0)$	(1) fails
(3), (4)	$(3,1)$	feasible
(3), (5)	$(1,3)$	feasible
(4), (5)	$(9,7)$	(3): $16 \le 4$ fails

For instance, (3) and (4) added give $2x_1 = 6$, so $\mathbf{x} = (3,1)$; (3) and (5) added give $3x_2 = 9$, so $\mathbf{x} = (1,3)$; (4) and (5) added give $x_2 = 7$, then $x_1 = 9$. For the feasible points, the checks are routine: at $(0,\frac{5}{2})$, $0 + \frac{5}{2} \le 4$ and $-\frac{5}{2} \le 2$; at $(2,0)$, $2 \le 4$ and $-2 \le 5$; at $(3,1)$, $-3 + 2 \le 5$; at $(1,3)$, $1 - 3 \le 2$. By Theorem 17.9.2 the vertices are $(0,0)$, $(2,0)$, $(3,1)$, $(1,3)$, $(0,\frac{5}{2})$.

P is bounded, since $0 \le x_1, x_2 \le 4$ on it by rows (1) to (3), and non-empty. So by Corollary 17.8.6 the maximum of $2x_1 + 3x_2$ is attained at a vertex. The values are $0, 4, 9, 11, \frac{15}{2}$, so the maximum is 11, at $(1,3)$. By the proof of Theorem 17.9.5 (a), $P = \operatorname{conv}\{(0,0),(2,0),(3,1),(1,3),(0,\frac{5}{2})\}$.

Exercise B2: Inequalities for a quadrilateral.

Use Fourier–Motzkin elimination to find a system of inequalities describing the quadrilateral

$$Q = \operatorname{conv}\{(0,0),(2,0),(2,1),(0,2)\}.$$

Hence find the vertices of Q.

Hint: substitute away t_1, t_2, t_4 and keep $s = t_3$, the weight of $(2,1)$.

Solution. $\mathbf{x} \in Q$ if and only if there are $t_1, \dots, t_4 \ge 0$ with $\sum t_j = 1$, $x_1 = 2t_2 + 2t_3$ and $x_2 = t_3 + 2t_4$. With $s = t_3$: $t_2 = \frac{1}{2}(x_1 - 2s)$, $t_4 = \frac{1}{2}(x_2 - s)$, and

$$t_1 = 1 - t_2 - s - t_4 = 1 - \tfrac{1}{2}x_1 - \tfrac{1}{2}x_2 + \tfrac{1}{2}s.$$

The conditions $2t_1 \ge 0$, $2t_2 \ge 0$, $2t_4 \ge 0$, $t_3 \ge 0$ read

$$\begin{aligned} &(1)\quad x_1 + x_2 - s \le 2, && (2)\quad -x_1 + 2s \le 0,\\ &(3)\quad -x_2 + s \le 0, && (4)\quad -s \le 0. \end{aligned}$$

The coefficients of s are $-1, 2, 1, -1$, so $I_+ = \{2,3\}$ and $I_- = \{1,4\}$. The four pairs give:

$$\begin{aligned} (2),(1):&\ 2\cdot(1) + 1\cdot(2) = && x_1 + 2x_2 \le 4,\\ (2),(4):&\ 2\cdot(4) + 1\cdot(2) = && -x_1 \le 0,\\ (3),(1):&\ 1\cdot(1) + 1\cdot(3) = && x_1 \le 2,\\ (3),(4):&\ 1\cdot(4) + 1\cdot(3) = && -x_2 \le 0. \end{aligned}$$

So $Q = \{0 \le x_1 \le 2,\ x_2 \ge 0,\ x_1 + 2x_2 \le 4\}$ by Lemma 17.9.4. Its rows are $(-1,0),(1,0),(0,-1),(1,2)$. The pair $\pm(1,0)$ is dependent; the other five pairs give the basic points $(0,0)$, $(0,2)$, $(2,0)$, $(2,1)$ and $(4,0)$ (from $x_2 = 0$, $x_1 + 2x_2 = 4$), and the last violates $x_1 \le 2$. So by Theorem 17.9.2 the vertices are the four given points, and none of them was redundant.

Exercise B3: Which of these are vertices?.

Let $P = \{\mathbf{x} \in \mathbb{R}^3 : \mathbf{x} \ge \mathbf{0},\ x_1 + x_2 + x_3 \le 3,\ x_1 + x_2 \le 2\}$. Determine which of the following points are vertices of P. Justify your answer.

(a) $(0,2,1)$
(b) $(1,1,1)$
(c) $(0,0,3)$
(d) $(3,0,0)$
(e) $(1,0,0)$

Solution. We use Theorem 17.9.2: check that the point lies in P, list its active rows, and compute their rank. The rows are $-\mathbf{e}_1, -\mathbf{e}_2, -\mathbf{e}_3$, $(1,1,1)$ and $(1,1,0)$.

(a) $(0,2,1) \in P$: the entries are ≥ 0, $0+2+1 = 3 \le 3$, $0+2 \le 2$. Active: $-\mathbf{e}_1$, $(1,1,1)$, $(1,1,0)$. Their span contains $(1,1,1) - (1,1,0) = \mathbf{e}_3$, $\mathbf{e}_1$, and $(1,1,0) - \mathbf{e}_1 = \mathbf{e}_2$, so it is $\mathbb{R}^3$. Rank 3: **a vertex**.

(b) $(1,1,1) \in P$, with active rows $(1,1,1)$ and $(1,1,0)$ only. Rank $2 < 3$: **not a vertex**. Indeed it is the midpoint of $(0,2,1)$ and $(2,0,1)$, both in P.

(c) $(0,0,3) \in P$, with active rows $-\mathbf{e}_1$, $-\mathbf{e}_2$, $(1,1,1)$, which are independent (the third has a non-zero third entry, the first two do not). Rank 3: **a vertex**.

(d) $(3,0,0) \notin P$, since $3+0 = 3 > 2$. It is a basic point, the solution of $x_2 = 0$, $x_3 = 0$, $x_1 + x_2 + x_3 = 3$, but not a feasible one: **not a vertex**.

(e) $(1,0,0) \in P$, with active rows $-\mathbf{e}_2$ and $-\mathbf{e}_3$ only. Rank $2 < 3$: **not a vertex**. It is the midpoint of $(0,0,0)$ and $(2,0,0)$.

17.9.6.3 C. Going deeper

Exercise C1: Unbounded polyhedra.

Let $P = \{\mathbf{x} \in \mathbb{R}^n : \mathbf{A}\mathbf{x} \le \mathbf{b}\}$ be a **non-empty** polyhedron, and let $C = \{(\mathbf{x}, t) \in \mathbb{R}^n \times \mathbb{R} : \mathbf{A}\mathbf{x} - t\mathbf{b} \le \mathbf{0},\ -t \le 0\}$.

(a) Prove that $\mathbf{x} \in P$ if and only if $(\mathbf{x}, 1) \in C$.

(b) By Theorem 17.9.5 (b), C is generated by finitely many vectors $(\mathbf{w}_j, t_j)$, $j = 1, \dots, k$. Prove that every $t_j \ge 0$, and that

$$P = \operatorname{conv}\{\mathbf{w}_j / t_j : t_j > 0\} + \Big\{ \sum_{t_j = 0} c_j \mathbf{w}_j : c_j \ge 0 \Big\},$$

the set of sums of a point of the polytope and a point of the cone. So every non-empty polyhedron is a polytope plus a finitely generated cone.

(c) Check the statement for $P = \{\mathbf{x} \in \mathbb{R}^2 : x_1 \geq 0,\ 0 \leq x_2 \leq 1\}$, with the polytope $\mathrm{conv}\{(0,0),(0,1)\}$ and the cone generated by $\mathbf{e}_1$.

Solution.

(a) $(\mathbf{x}, 1) \in C$ says $\mathbf{A}\mathbf{x} - \mathbf{b} \leq \mathbf{0}$ and $-1 \leq 0$, which is $\mathbf{x} \in P$.

(b) Each generator lies in C, so $-t_j \leq 0$. Split the indices into $J_+ = \{j : t_j > 0\}$ and $J_0 = \{j : t_j = 0\}$.
($\subseteq$) Let $\mathbf{x} \in P$. By (a), $(\mathbf{x}, 1) = \sum_j c_j(\mathbf{w}_j, t_j)$ with $c_j \geq 0$. The last coordinate gives $1 = \sum_{j \in J_+} c_j t_j$, so $J_+ \neq \emptyset$, and

$$\mathbf{x} = \sum_{j \in J_+} (c_j t_j) \frac{\mathbf{w}_j}{t_j} + \sum_{j \in J_0} c_j \mathbf{w}_j,$$

where the weights $c_j t_j$ are non-negative and add up to 1. So $\mathbf{x}$ lies in the right-hand side.
($\supseteq$) Let $\mathbf{x} = \sum_{j \in J_+} s_j \mathbf{w}_j / t_j + \sum_{j \in J_0} c_j \mathbf{w}_j$ with $s_j \geq 0$, $\sum s_j = 1$ and $c_j \geq 0$. Then

$$(\mathbf{x}, 1) = \sum_{j \in J_+} \frac{s_j}{t_j}(\mathbf{w}_j, t_j) + \sum_{j \in J_0} c_j(\mathbf{w}_j, 0),$$

a non-negative combination of generators, so $(\mathbf{x}, 1) \in C$ and $\mathbf{x} \in P$ by (a).

(c) A point $(0, u) + c\mathbf{e}_1$ with $0 \leq u \leq 1$ and $c \geq 0$ is (c, u), which satisfies $x_1 \geq 0$ and $0 \leq x_2 \leq 1$. Conversely $(x_1, x_2) \in P$ is $(0, x_2) + x_1 \mathbf{e}_1$ with $(0, x_2) \in \mathrm{conv}\{(0,0),(0,1)\}$ and $x_1 \geq 0$. So $P = \mathrm{conv}\{(0,0),(0,1)\} + \{c\mathbf{e}_1 : c \geq 0\}$.

Exercise C2: Linear images of polyhedra.

Let $\mathbf{M} \in M_{p \times n}(\mathbb{R})$.

(a) Prove that if $P \subseteq \mathbb{R}^n$ is a polyhedron, then $\mathbf{M}(P) = \{\mathbf{M}\mathbf{x} : \mathbf{x} \in P\}$ is a polyhedron in $\mathbb{R}^p$, and that if P is a polyhedral cone, so is $\mathbf{M}(P)$.

(b) Prove that if Q is a polytope, then $\mathbf{M}(Q)$ is a polytope, directly from Definition 17.9.1.

(c) Deduce that a linear image of a polyhedral cone is closed. Why does this not contradict the existence of a closed convex cone with a non-closed linear image?

Solution.

(a) Let $P = \{\mathbf{x} : \mathbf{A}\mathbf{x} \leq \mathbf{b}\}$. Then $\mathbf{y} \in \mathbf{M}(P)$ if and only if there is $\mathbf{x}$ with $(\mathbf{y}, \mathbf{x})$ in

$$\widehat{P} = \{(\mathbf{y}, \mathbf{x}) \in \mathbb{R}^p \times \mathbb{R}^n : \mathbf{y} - \mathbf{M}\mathbf{x} \leq \mathbf{0},\ -\mathbf{y} + \mathbf{M}\mathbf{x} \leq \mathbf{0},\ \mathbf{A}\mathbf{x} \leq \mathbf{b}\},$$

a polyhedron in $\mathbb{R}^{p+n}$. So $\mathbf{M}(P)$ is the image of $\widehat{P}$ under the map forgetting the last n coordinates, and n applications of Lemma 17.9.4 show that it is a polyhedron. If $\mathbf{b} = \mathbf{0}$, every right-hand side in $\widehat{P}$ is 0, and stays 0 under elimination, so $\mathbf{M}(P)$ is a polyhedral cone.

(b) If $Q = \operatorname{conv}\{\mathbf{v}_1, \dots, \mathbf{v}_k\}$, then by Theorem 17.1.3 and linearity,

$$\mathbf{M}\Big(\sum_j t_j \mathbf{v}_j\Big) = \sum_j t_j \mathbf{M}\mathbf{v}_j,$$

so $\mathbf{M}(Q) = \operatorname{conv}\{\mathbf{M}\mathbf{v}_1, \dots, \mathbf{M}\mathbf{v}_k\}$, a polytope.

(c) By (a), the image of a polyhedral cone is a polyhedral cone, which is closed by Proposition 17.9.1. So a closed convex cone whose linear image is not closed cannot be polyhedral; by Theorem 17.9.5 (b), it cannot be finitely generated either. This is consistent with Section 5, where closedness was proved only for finitely generated cones.

Exercise C3: Vertices in standard form.

Let $\mathbf{A} \in M_{m\times n}(\mathbb{R})$ have columns $\mathbf{c}_1, \dots, \mathbf{c}_n$, let $\mathbf{b} \in \mathbb{R}^m$, and let $P = \{\mathbf{x} \in \mathbb{R}^n : \mathbf{A}\mathbf{x} = \mathbf{b},\ \mathbf{x} \geq \mathbf{0}\}$, the feasible region of a linear program in standard form.

(a) Prove that $\mathbf{x} \in P$ is a vertex of P if and only if the columns $\mathbf{c}_j$ with $x_j > 0$ are linearly independent.

(b) Deduce that a vertex of P has at most $\operatorname{rank}\mathbf{A}$ positive entries.

(c) Find the vertices of $P = \{\mathbf{x} \in \mathbb{R}^3 : x_1 + x_2 + x_3 = 1,\ \mathbf{x} \geq \mathbf{0}\}$, the standard triangle.

Solution.

(a) Write P as a polyhedron with the rows $\mathbf{A}\mathbf{x} \leq \mathbf{b}$, $-\mathbf{A}\mathbf{x} \leq -\mathbf{b}$ and $-\mathbf{e}_j^{\top}\mathbf{x} \leq 0$. At $\mathbf{x} \in P$, every row of $\pm\mathbf{A}$ is active, and $-\mathbf{e}_j$ is active exactly when $x_j = 0$. Let $S = \{j : x_j > 0\}$. By Theorem 17.9.2, $\mathbf{x}$ is a vertex if and only if the active rows have rank n, that is (Theorem 2.5.7), if and only if the only $\mathbf{u}$ with $\mathbf{A}\mathbf{u} = \mathbf{0}$ and $u_j = 0$ for all $j \notin S$ is $\mathbf{u} = \mathbf{0}$. For such $\mathbf{u}$, $\mathbf{A}\mathbf{u} = \sum_{j\in S} u_j \mathbf{c}_j$. So the condition says that $\sum_{j\in S} u_j \mathbf{c}_j = \mathbf{0}$ forces every $u_j = 0$, which is the linear independence of $\{\mathbf{c}_j : j \in S\}$.

(b) The columns $\mathbf{c}_j$ lie in $\operatorname{col}(\mathbf{A})$, of dimension $\operatorname{rank}\mathbf{A}$, and an independent list in it has at most $\operatorname{rank}\mathbf{A}$ vectors by Theorem 1.6.3 (a). By (a), a vertex has at most that many positive entries.

(c) Here $\mathbf{A} = (1\ 1\ 1)$, of rank 1. By (b) a vertex has at most one positive entry, and since the entries add up to 1, exactly one, equal to 1. Conversely $\mathbf{e}_j \in P$, and its one positive entry corresponds to the column $(1) \neq \mathbf{0}$, an independent list. So the vertices are $\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3$.

17.10 Convex Functions

The chapter so far has studied convex **sets**. Convex **functions** have been in the book for longer, as the first subsection recalls, and every finite support function of §04 is one too. This section defines the notion, ties it to convex sets through the epigraph, and proves its basic theorems: Jensen's inequality, the convexity of a supremum of affine functions, which pays a promise of Chapter 16 §06, a second-derivative test, and continuity. §11 then spends them on three classical inequalities.

Throughout, the field is $\mathbb{R}$. V is a real vector space, and a set $C \subseteq V$ called convex is convex in the sense of Definition 17.1.1. From the second-derivative test onward we work in $\mathbb{R}^n$, with the standard inner product and its norm $\|\cdot\| = \|\cdot\|_2$. A function g on an interval of $\mathbb{R}$ is **increasing** when $s \le t$ implies $g(s) \le g(t)$, as in Chapter 16 §11, and **strictly increasing** when $s < t$ implies $g(s) < g(t)$.

17.10.1 Convex functions and their epigraphs

Look again at three inequalities the book has already proved. For a norm, (N2) and (N3) of Definition 15.1.1 give $\|t\mathbf{x} + (1-t)\mathbf{y}\| \le t\|\mathbf{x}\| + (1-t)\|\mathbf{y}\|$ for $0 \le t \le 1$. For the top partial sum $s_k(\mathbf{A}) = \sum_{i \le k} \lambda_i(\mathbf{A})$ of a Hermitian matrix, Chapter 16 §06 derived $s_k(t\mathbf{A} + (1-t)\mathbf{B}) \le t s_k(\mathbf{A}) + (1-t) s_k(\mathbf{B})$ from Corollary 16.6.5. And the case $n = 1$ of operator convexity in Definition 16.11.1 (b) reads $f(ta + (1-t)b) \le tf(a) + (1-t)f(b)$ for numbers a, b. It is the same inequality three times, and it deserves a name.

A function is convex when, on every segment of its domain, its graph lies on or below the chord.

Definition 17.10.1 — Convex Function

Let C be a **non-empty convex** subset of a real vector space V, and let $f\colon C \to \mathbb{R}$. Then f is **convex** if

$$f\big(t\mathbf{x} + (1-t)\mathbf{y}\big) \;\le\; tf(\mathbf{x}) + (1-t)f(\mathbf{y})$$

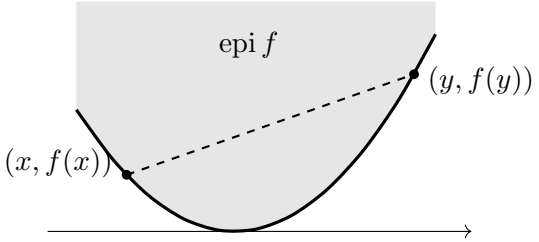
for **all** $\mathbf{x}, \mathbf{y} \in C$ and **all** real t with $0 \le t \le 1$. It is **strictly convex** if the inequality is **strict** whenever $\mathbf{x} \neq \mathbf{y}$ and $0 < t < 1$. It is **concave**, or **strictly concave**, if $-f$ is convex, or strictly convex.

The **epigraph** of f is the subset of the real vector space $V \times \mathbb{R}$, with componentwise operations,

$$\operatorname{epi} f = \{(\mathbf{x}, s) \in V \times \mathbb{R} : \mathbf{x} \in C,\ s \ge f(\mathbf{x})\}.$$

In words: take any two points $\mathbf{x}$ and $\mathbf{y}$ of the domain and any point $t\mathbf{x} + (1-t)\mathbf{y}$ between them. The left side is the value of f there. The right side is the value, at the same place, of the straight line through $(\mathbf{x}, f(\mathbf{x}))$ and $(\mathbf{y}, f(\mathbf{y}))$. So the condition says the chord is never below the graph. Strict convexity forbids the graph to touch the chord anywhere strictly between two distinct points. The epigraph is everything on or above the graph.

The domain must be convex, and this is the only thing to check. The point $t\mathbf{x}+(1-t)\mathbf{y}$ must lie in C, or f is not defined there. That is exactly what Definition 17.1.1 guarantees.



The picture shows $f(x) = 0.35x^2$ on $\mathbb{R}$: the dashed chord lies above the graph between its

endpoints, and the shaded region is the epigraph.

Example. (First convex functions)

Check each against Definition 17.10.1.

(a) An **affine function** $a(\mathbf{x}) = \varphi(\mathbf{x}) + c$, with φ a linear functional on V (Definition 4.1.1) and $c \in \mathbb{R}$.

(b) A norm $\|\cdot\|$ on $\mathbb{R}^n$.

(c) $f(x) = x^2$ on $\mathbb{R}$, and more generally $q(\mathbf{x}) = \mathbf{x}^\top \mathbf{A}\mathbf{x}$ on $\mathbb{R}^n$ for a symmetric $\mathbf{A} \succeq 0$.

Solution.

(a) Since φ is linear and $c = tc + (1-t)c$,

$$a\big(t\mathbf{x} + (1-t)\mathbf{y}\big) = t\varphi(\mathbf{x}) + (1-t)\varphi(\mathbf{y}) + tc + (1-t)c = ta(\mathbf{x}) + (1-t)a(\mathbf{y}).$$

Equality holds, so a is convex, and so is $-a$: an affine function is both convex and concave, and neither strictly. The constant functions are the degenerate case $\varphi = 0$. They matter because they show that convexity by itself forces no growth at all.

(b) By (N3) and then (N2) of Definition 15.1.1, with $|t| = t$ and $|1-t| = 1-t$ for $0 \le t \le 1$,

$$\|t\mathbf{x} + (1-t)\mathbf{y}\| \le \|t\mathbf{x}\| + \|(1-t)\mathbf{y}\| = t\|\mathbf{x}\| + (1-t)\|\mathbf{y}\|.$$

A norm is not strictly convex: on the ray through a non-zero $\mathbf{x}$, $\|s\mathbf{x}\| = s\|\mathbf{x}\|$ is linear in $s \ge 0$, so the chord between $\mathbf{x}$ and $2\mathbf{x}$ lies on the graph.

(c) Expanding and collecting terms,

$$tx^2 + (1-t)y^2 - \big(tx + (1-t)y\big)^2 = t(1-t)(x-y)^2 \;\ge\; 0,$$

and the right side is strictly positive when $x \ne y$ and $0 < t < 1$. So x^2 is strictly convex. The same expansion with $\mathbf{A}$ symmetric gives

$$tq(\mathbf{x}) + (1-t)q(\mathbf{y}) - q\big(t\mathbf{x} + (1-t)\mathbf{y}\big) = t(1-t)\, q(\mathbf{x}-\mathbf{y}),$$

and $q(\mathbf{x}-\mathbf{y}) = \langle \mathbf{A}(\mathbf{x}-\mathbf{y}), \mathbf{x}-\mathbf{y}\rangle \ge 0$ by (P2) of Definition 12.1.1. So q is convex. The case $n = 1$, $\mathbf{A} = (1)$, is x^2.

A non-example by minimal change. Replace x^2 by x^3 on $\mathbb{R}$. With $x = -2$, $y = 0$ and $t = \frac{1}{2}$, the left side is $(-1)^3 = -1$ and the right side is $\frac{1}{2}(-8) + \frac{1}{2}\cdot 0 = -4$, and $-1 \le -4$ is false. What fails is the inequality for this pair, on the negative half-line, where the graph bends downward. On the convex domain $(0, \infty)$ the same function is convex, as the one-variable test below shows. So convexity depends on the domain.

Why this definition. The inequality is non-strict so that affine functions and norms, the most important examples, qualify. Requiring it for every $t \in [0,1]$, not just $t = \frac{1}{2}$, is what makes Jensen's inequality below immediate. The name comes from the epigraph: a function is convex exactly when the set above its graph is convex.

Proposition 17.10.1 — Convex Function, Convex Epigraph

Let $C \subseteq V$ be non-empty and convex, and let $f\colon C \to \mathbb{R}$. Then f is convex if and only if $\operatorname{epi} f$ is a convex subset of $V \times \mathbb{R}$.

Idea. A point $(\mathbf{x}, s)$ lies in the epigraph exactly when $s \geq f(\mathbf{x})$. So the chord inequality for f and the statement that segments between points of the epigraph stay in it are one inequality, read in two directions.

Proof. ($\Rightarrow$) Let $(\mathbf{x}, s), (\mathbf{y}, u) \in \operatorname{epi} f$ and $0 \leq t \leq 1$. The point $t\mathbf{x} + (1-t)\mathbf{y}$ lies in C, since C is convex, and

$$f\big(t\mathbf{x} + (1-t)\mathbf{y}\big) \leq tf(\mathbf{x}) + (1-t)f(\mathbf{y}) \leq ts + (1-t)u,$$

the second step because $f(\mathbf{x}) \leq s$, $f(\mathbf{y}) \leq u$ and $t, 1-t \geq 0$. So $t(\mathbf{x}, s) + (1-t)(\mathbf{y}, u) \in \operatorname{epi} f$.

($\Leftarrow$) Let $\mathbf{x}, \mathbf{y} \in C$ and $0 \leq t \leq 1$. The points $(\mathbf{x}, f(\mathbf{x}))$ and $(\mathbf{y}, f(\mathbf{y}))$ lie in $\operatorname{epi} f$, so by convexity so does $\big(t\mathbf{x} + (1-t)\mathbf{y},\ tf(\mathbf{x}) + (1-t)f(\mathbf{y})\big)$. By the definition of the epigraph this says $f(t\mathbf{x} + (1-t)\mathbf{y}) \leq tf(\mathbf{x}) + (1-t)f(\mathbf{y})$. This proves the proposition. ∎

The same one-line argument shows that every **sublevel set** $\{\mathbf{x} \in C : f(\mathbf{x}) \leq c\}$ of a convex f is convex: if $f(\mathbf{x}) \leq c$ and $f(\mathbf{y}) \leq c$, then $f(t\mathbf{x} + (1-t)\mathbf{y}) \leq tc + (1-t)c = c$.

Quick check. Every sublevel set of a convex function is convex. Is the converse true? Is a function $f\colon \mathbb{R} \to \mathbb{R}$ whose sublevel sets are all convex necessarily convex?

Solution. No. Take $f(x) = x^3$. It is increasing: if $a < b$ then $b^3 - a^3 = (b-a)(a^2 + ab + b^2) > 0$, since $a^2 + ab + b^2 = (a + \frac{b}{2})^2 + \frac{3}{4}b^2$ vanishes only at $a = b = 0$. So if $x \leq z \leq y$ and $x^3, y^3 \leq c$, then $z^3 \leq y^3 \leq c$. Each sublevel set is therefore an interval, which is convex. But x^3 is not convex on $\mathbb{R}$, by the non-example above.

Warning. **A convex function need not be differentiable.** The function $|x|$ is a norm on $\mathbb{R}$, hence convex, and it has a corner at 0: its difference quotients $|h|/h$ are 1 for $h > 0$ and -1 for $h < 0$, so they have no limit. The same corner appears in linear algebra. The map $\mathbf{A} \mapsto \lambda_1(\mathbf{A})$ on Hermitian matrices is convex, as the next two subsections prove, and on the diagonal matrices $\operatorname{diag}(t, -t)$ it equals $|t|$. The corner sits at $t = 0$, where the top eigenvalue is repeated.

17.10.2 Jensen's inequality

The definition speaks of two points. Induction extends it to any finite convex combination (Definition 17.1.3), and that extension is the form in which convexity is most often used.

Theorem 17.10.2 — Jensen's Inequality

Let $C \subseteq V$ be non-empty and convex, and let $f\colon C \to \mathbb{R}$ be convex. Let $\mathbf{x}_1, \dots, \mathbf{x}_m \in C$, and let $w_1, \dots, w_m \geq 0$ with $w_1 + \cdots + w_m = 1$. Then $\sum_i w_i \mathbf{x}_i \in C$ and

$$f\Big(\sum_{i=1}^{m} w_i \mathbf{x}_i\Big) \;\leq\; \sum_{i=1}^{m} w_i f(\mathbf{x}_i).$$

If f is **strictly** convex and every $w_i > 0$, equality holds only when $\mathbf{x}_1 = \mathbf{x}_2 = \cdots = \mathbf{x}_m$.

Idea. Split off the last point. The remaining weights add up to $s = 1 - w_m$, and after dividing by s they are the weights of a convex combination $\mathbf{y}$ of $m-1$ points, to which induction applies. The whole combination is then $s\mathbf{y} + w_m\mathbf{x}_m$, a combination of **two** points, which is where the definition applies.

Proof. We prove both statements by induction on $m \geq 1$. For $m = 1$ the weight is $w_1 = 1$, both sides equal $f(\mathbf{x}_1)$, and the equality clause is empty.

Let $m \geq 2$ and assume both statements for $m-1$ points. If $w_m = 1$, every other weight is 0, both sides equal $f(\mathbf{x}_m)$, and the equality clause does not apply since $w_1 = 0$. Otherwise $s = 1 - w_m = w_1 + \cdots + w_{m-1} > 0$. The numbers w_i/s for $i < m$ are non-negative with sum 1, so by the inductive hypothesis $\mathbf{y} = \sum_{i<m}(w_i/s)\mathbf{x}_i$ lies in C and

$$f(\mathbf{y}) \leq \sum_{i<m} \frac{w_i}{s} f(\mathbf{x}_i). \tag{1}$$

Now $\sum_{i=1}^{m} w_i\mathbf{x}_i = s\mathbf{y} + w_m\mathbf{x}_m$ with $s + w_m = 1$, so this point lies in C because C is convex, and Definition 17.10.1 gives

$$\begin{aligned} f(s\mathbf{y} + w_m\mathbf{x}_m) &\leq s f(\mathbf{y}) + w_m f(\mathbf{x}_m) \\ &\leq \sum_{i<m} w_i f(\mathbf{x}_i) + w_m f(\mathbf{x}_m), \end{aligned} \tag{2}$$

where the second step multiplies (1) by $s > 0$. This proves the inequality.

For the equality clause, let f be strictly convex and every $w_i > 0$, so that $0 < w_m < 1$ and $0 < s < 1$. If equality holds in the theorem, both inequalities in (2) are equalities. The second is s times (1), so (1) is an equality, and the inductive hypothesis gives $\mathbf{x}_1 = \cdots = \mathbf{x}_{m-1}$; then $\mathbf{y}$ equals this common point. The first is the two-point inequality with weights strictly between 0 and 1, so strict convexity forces $\mathbf{y} = \mathbf{x}_m$. Hence all m points are equal, as claimed.

■

In the language of §01, the points $(\mathbf{x}_i, f(\mathbf{x}_i))$ lie in the convex set $\operatorname{epi} f$, and Jensen's inequality says that their convex combinations stay there. That is Theorem 17.1.3 read inside the epigraph.

17.10.3 Suprema of affine functions

Chapter 16 §06 showed that $s_k(\mathbf{A}) = \sum_{i \leq k} \lambda_i(\mathbf{A})$ is the largest of the linear functions $\mathbf{A} \mapsto \operatorname{tr}(\mathbf{Q}^*\mathbf{A}\mathbf{Q})$, deduced its convexity, and ended with a promise: "Chapter 17 studies convex functions in general, and the observation that a pointwise supremum of linear functions is convex is one of its basic facts." Here is that fact, stated for affine functions, which include the linear

ones.

Proposition 17.10.3 — A Supremum of Affine Functions Is Convex

Let $C \subseteq V$ be non-empty and convex, and let $(a_i)_{i\in I}$ be a non-empty family of affine functions on V. Suppose that for every $\mathbf{x} \in C$ the set $\{a_i(\mathbf{x}) : i \in I\}$ is bounded above, and put

$$g(\mathbf{x}) = \sup_{i\in I} a_i(\mathbf{x}) \qquad (\mathbf{x} \in C).$$

Then $g\colon C \to \mathbb{R}$ is convex.

Idea. Each a_i meets its own chord inequality with equality, and each lies below g. So at a point between $\mathbf{x}$ and $\mathbf{y}$, every a_i is at most the chord of g, and therefore so is their supremum.

Proof. The supremum exists for each $\mathbf{x} \in C$ by completeness, fact (A1) of Chapter 15's introduction. Let $\mathbf{x}, \mathbf{y} \in C$ and $0 \le t \le 1$. For each $i \in I$, by Example (First convex functions) (a) and then $a_i \le g$ at $\mathbf{x}$ and at $\mathbf{y}$,

$$a_i\big(t\mathbf{x} + (1-t)\mathbf{y}\big) = t a_i(\mathbf{x}) + (1-t) a_i(\mathbf{y}) \le t g(\mathbf{x}) + (1-t) g(\mathbf{y}),$$

where the inequality uses $t \ge 0$ and $1 - t \ge 0$. So the right side is an upper bound for the set $\{a_i(t\mathbf{x} + (1-t)\mathbf{y}) : i \in I\}$, and it is therefore at least that set's least upper bound, $g(t\mathbf{x} + (1-t)\mathbf{y})$. This proves the proposition.

■

The proof never used that the a_i are affine beyond the fact that each is convex. So the same argument shows that **a pointwise supremum of convex functions is convex**, whenever it is finite. In particular the maximum of two convex functions is convex. The minimum need not be: $\min(x, -x) = -|x|$ is concave and not convex.

Instances. Many convex functions of this chapter are suprema of linear functions, and this proposition proves their convexity at a stroke.

- $|x| = \max(x, -x)$; $\|\mathbf{x}\|_\infty = \max_i \max(x_i, -x_i)$; and $\|\mathbf{x}\|_1 = \max\{\langle \boldsymbol{\epsilon}, \mathbf{x}\rangle : \boldsymbol{\epsilon} \in \{\pm 1\}^n\}$, the maximum being attained at the vector of signs of $\mathbf{x}$.
- The support function $h_K(\mathbf{y})$ of Definition 17.4.2 is the supremum over $\mathbf{x} \in K$ of the linear functions $\mathbf{y} \mapsto \langle \mathbf{x}, \mathbf{y}\rangle$. So it is convex wherever it is finite, and in particular the dual norm of Definition 17.4.4 is convex.
- Every norm is the maximum of $\mathbf{x} \mapsto \langle \mathbf{x}, \mathbf{y}\rangle$ over $\|\mathbf{y}\|_* \le 1$ (Corollary 17.4.9). This describes the norm; it is not a new proof of its convexity, since §04 derived the corollary from the triangle inequality.
- The largest eigenvalue: by Lemma 12.5.2, $\lambda_1(\mathbf{A}) = \max_{\|\mathbf{x}\|=1} \langle \mathbf{A}\mathbf{x}, \mathbf{x}\rangle$, and each $\mathbf{A} \mapsto \langle \mathbf{A}\mathbf{x}, \mathbf{x}\rangle$ is linear.
- The Ky Fan sums s_k, the case that prompted the promise. They are the subject of the next subsection.

17.10.4 Convex functions of a Hermitian matrix

Let $F = \mathbb{R}$ or $F = \mathbb{C}$. The Hermitian $n \times n$ matrices over F form a **real** vector space: if $\mathbf{A}^* = \mathbf{A}$, $\mathbf{B}^* = \mathbf{B}$ and $s, t \in \mathbb{R}$, then $(s\mathbf{A} + t\mathbf{B})^* = s\mathbf{A} + t\mathbf{B}$. They do not form a complex one, since $(i\mathbf{I})^* = -i\mathbf{I}$. This is the space on which Chapter 16 §06 called s_k convex, and it is the setting here. When $F = \mathbb{C}$ it is an instance of the chapter's convention that a complex space is treated as a real one.

Corollary 17.10.4 — The Top Eigenvalue Sums Are Convex

Let $1 \le k \le n$. On the real vector space of Hermitian $n \times n$ matrices over F, the function

$$s_k(\mathbf{A}) = \lambda_1(\mathbf{A}) + \cdots + \lambda_k(\mathbf{A})$$

is convex. In particular $\mathbf{A} \mapsto \lambda_1(\mathbf{A})$ is convex, and $\mathbf{A} \mapsto \lambda_n(\mathbf{A})$ is concave.

Idea. Ky Fan's theorem writes s_k as a maximum of the functions $\mathbf{A} \mapsto \operatorname{tr}(\mathbf{Q}^*\mathbf{A}\mathbf{Q})$, each linear on the real space of Hermitian matrices, so Proposition 17.10.3 applies. For λ_n, change the sign of $\mathbf{A}$.

Proof. By Theorem 16.6.2, $s_k(\mathbf{A}) = \max\{\operatorname{tr}(\mathbf{Q}^*\mathbf{A}\mathbf{Q}) : \mathbf{Q} \in M_{n\times k}(F),\ \mathbf{Q}^*\mathbf{Q} = \mathbf{I}_k\}$. Fix such a $\mathbf{Q}$. The matrix $\mathbf{Q}^*\mathbf{A}\mathbf{Q}$ is Hermitian, so its diagonal entries, and hence its trace, are real. By Theorem 0.9.6 (1), $\mathbf{A} \mapsto \operatorname{tr}(\mathbf{Q}^*\mathbf{A}\mathbf{Q})$ respects sums and real multiples. So it is a linear functional on the real space of Hermitian matrices, and s_k is the maximum of this family. By Proposition 17.10.3, s_k is convex, and $k = 1$ gives λ_1.

For λ_n, the eigenvalues of $-\mathbf{A}$ are the negatives of those of $\mathbf{A}$, so $\lambda_n(\mathbf{A}) = -\lambda_1(-\mathbf{A})$, as in the proof of Corollary 16.6.6. The map $\mathbf{A} \mapsto \lambda_1(-\mathbf{A})$ is convex, because it is the convex λ_1 composed with the linear map $\mathbf{A} \mapsto -\mathbf{A}$, and a convex function composed with a linear map is convex, by substituting into Definition 17.10.1. So λ_n is the negative of a convex function, that is, concave.

■

This is the fact Chapter 16 §06 anticipated, and its promise is now paid. Chapter 16 reached convexity by a different path: Corollary 16.6.5 gives $s_k(\mathbf{A} + \mathbf{B}) \le s_k(\mathbf{A}) + s_k(\mathbf{B})$, and positive homogeneity $s_k(t\mathbf{A}) = t s_k(\mathbf{A})$, $t \ge 0$, turns subadditivity into convexity. Exercise C1 shows that the two paths are the same, and the warning at the end of Chapter 16 §06 still stands: a single λ_k with $1 < k < n$, the difference $s_k - s_{k-1}$ of two convex functions, is neither convex nor concave.

What is not proved here. For a convex f on an interval, $\mathbf{A} \mapsto \operatorname{tr} f(\mathbf{A}) = \sum_i f(\lambda_i(\mathbf{A}))$ is convex on the Hermitian matrices with spectrum in that interval, a statement about sums over the spectrum and far weaker than the operator convexity of Chapter 16 §11. It is proved in Chapter 20, and nothing in this chapter uses it.

17.10.5 A second-derivative test

For a function on an interval, convexity says the slope never decreases. The mean value theorem turns an increasing derivative into a chord inequality.

Lemma 17.10.5 — Increasing Derivative Gives Convexity

Let $I \subseteq \mathbb{R}$ be an open interval and let $g\colon I \to \mathbb{R}$ be differentiable. If g' is increasing on I, then g is convex; if g' is strictly increasing, then g is strictly convex. In particular, if g is twice differentiable with $g'' \geq 0$ on I, then g is convex, and if $g'' > 0$ on I, then g is strictly convex.

Idea. Split the chord at the intermediate point z into two sub-chords, over $[x, z]$ and over $[z, y]$. By the mean value theorem, each slope is a value of g' inside its interval, so an increasing g' makes the left slope at most the right one. A graph whose chord slopes increase in this way lies below the long chord.

Proof. Let $x, y \in I$ and $0 < t < 1$; the cases $t = 0$, $t = 1$ and $x = y$ are equalities. Exchanging x with y and t with $1 - t$ if necessary, we may assume $x < y$. Put $z = tx + (1 - t)y$, so that $x < z < y$, with

$$z - x = (1 - t)(y - x), \qquad y - z = t(y - x).$$

By the mean value theorem, fact (A6) of Chapter 15's introduction, applied on $[x, z]$ and on $[z, y]$, there are $c_1 \in (x, z)$ and $c_2 \in (z, y)$ with

$$g(z) - g(x) = (1 - t)(y - x)\, g'(c_1), \qquad g(y) - g(z) = t(y - x)\, g'(c_2).$$

Since $c_1 < c_2$ and g' is increasing, $g'(c_1) \leq g'(c_2)$. Multiplying by $t(1 - t)(y - x) > 0$,

$$\begin{aligned} t\big(g(z) - g(x)\big) &= t(1 - t)(y - x)\, g'(c_1) \\ &\leq t(1 - t)(y - x)\, g'(c_2) = (1 - t)\big(g(y) - g(z)\big). \end{aligned}$$

Rearranged, this is $g(z) \leq tg(x) + (1 - t)g(y)$. If g' is strictly increasing, then $g'(c_1) < g'(c_2)$, and every inequality is strict.

For the last sentence, let $a < b$ in I. Fact (A6) applied to g' gives $g'(b) - g'(a) = g''(c)(b - a)$ for some $c \in (a, b)$. This is ≥ 0 when $g'' \geq 0$, and > 0 when $g'' > 0$. So g' is increasing, or strictly increasing, and the first part applies.

■

Derivatives of polynomials, here and below, come from Chapter 9 §09: a polynomial is a power series with finitely many non-zero coefficients, so it converges for every real argument and that section's fact (A2) differentiates it term by term, while its fact (A3), the linearity of differentiation, handles sums and constant multiples; a partial derivative is such a derivative with the other variables fixed. For instance, $g(x) = x^4$ has $g'(x) = 4x^3$, which is strictly increasing (the Quick check after Proposition 17.10.1), so x^4 is strictly convex on $\mathbb{R}$. Likewise x^3, with $g'' = 6x \geq 0$ on $(0, \infty)$, is convex there, which is the claim made after the non-example.

In several variables the second derivative is the Hessian $\mathbf{H}_f(\mathbf{a})$ of Definition 13.6.2, and "$g'' \geq 0$" becomes "positive semidefinite". Chapter 13 §06 read the Hessian at a single critical point, where its definiteness decides a local extremum (Theorem 13.6.4). Here the Hessian is asked to be positive semidefinite at **every** point, and what it decides is global. Restricting f to lines would need a chain rule the book has not imported, so the proof below uses only Chapter 13 §06's (A1), that $\mathbf{H}_f(\mathbf{a})$ is symmetric, and its (A2), Taylor's theorem with a remainder $r(\mathbf{h})$ satisfying $r(\mathbf{h})/\|\mathbf{h}\|^2 \to 0$. It works with **second differences**, which (A2) controls directly.

Theorem 17.10.6 — Convexity from the Hessian

Let $U \subseteq \mathbb{R}^n$ be a non-empty open convex set, and let $f\colon U \to \mathbb{R}$ be twice continuously differentiable.

(a) f is convex on U if and only if $\mathbf{H}_f(\mathbf{a}) \succeq 0$ for every $\mathbf{a} \in U$.
(b) If $\mathbf{H}_f(\mathbf{a}) \succ 0$ for every $\mathbf{a} \in U$, then f is strictly convex on U.

Idea. Taylor's theorem at $\mathbf{z}$, applied at $\mathbf{z}+s\mathbf{v}$ and at $\mathbf{z}-s\mathbf{v}$ and added, kills the gradient term:

$$\frac{f(\mathbf{z}+s\mathbf{v}) + f(\mathbf{z}-s\mathbf{v}) - 2f(\mathbf{z})}{s^2} \longrightarrow \mathbf{v}^{\top}\mathbf{H}_f(\mathbf{z})\mathbf{v}.$$

For ($\Rightarrow$), convexity makes the left side ≥ 0, so the limit is too. For the other direction, restrict f to a segment and subtract the chord. If the difference were positive somewhere, it would have an interior maximum, and at a maximum every second difference is ≤ 0. That contradicts a **strictly** positive limit. So the argument handles $\mathbf{H}_f \succ 0$ first, and reaches $\mathbf{H}_f \succeq 0$ by adding $\varepsilon\|\mathbf{x}\|^2$ and letting $\varepsilon \to 0$.

Proof. Write $\mathbf{H}(\mathbf{z}) = \mathbf{H}_f(\mathbf{z})$. For $\mathbf{z} \in U$, $\mathbf{v} \in \mathbb{R}^n$ and real $s \neq 0$ small enough that $\mathbf{z} \pm s\mathbf{v} \in U$, put

$$\Delta(\mathbf{z}, \mathbf{v}, s) = f(\mathbf{z}+s\mathbf{v}) + f(\mathbf{z}-s\mathbf{v}) - 2f(\mathbf{z}).$$

Step 1: the second difference. We claim $\Delta(\mathbf{z}, \mathbf{v}, s)/s^2 \to \mathbf{v}^{\top}\mathbf{H}(\mathbf{z})\mathbf{v}$ as $s \to 0$. If $\mathbf{v} = \mathbf{0}$ both sides are 0. Otherwise Chapter 13 §06's (A2) at $\mathbf{z}$, with $\mathbf{h} = s\mathbf{v}$ and with $\mathbf{h} = -s\mathbf{v}$, gives

$$f(\mathbf{z} \pm s\mathbf{v}) = f(\mathbf{z}) \pm s\,\nabla f(\mathbf{z}) \cdot \mathbf{v} + \tfrac{1}{2}s^2\,\mathbf{v}^{\top}\mathbf{H}(\mathbf{z})\mathbf{v} + r(\pm s\mathbf{v}).$$

Adding the two and subtracting $2f(\mathbf{z})$,

$$\frac{\Delta(\mathbf{z}, \mathbf{v}, s)}{s^2} = \mathbf{v}^{\top}\mathbf{H}(\mathbf{z})\mathbf{v} + \|\mathbf{v}\|^2\Big(\frac{r(s\mathbf{v})}{\|s\mathbf{v}\|^2} + \frac{r(-s\mathbf{v})}{\|s\mathbf{v}\|^2}\Big),$$

and the bracket tends to 0 because $\|\pm s\mathbf{v}\| \to 0$. The same expansion shows that f is continuous: $f(\mathbf{z}+\mathbf{h}) - f(\mathbf{z}) = \nabla f(\mathbf{z}) \cdot \mathbf{h} + \tfrac{1}{2}\mathbf{h}^{\top}\mathbf{H}(\mathbf{z})\mathbf{h} + \|\mathbf{h}\|^2 \cdot r(\mathbf{h})/\|\mathbf{h}\|^2$, and each term tends to 0 as $\mathbf{h} \to \mathbf{0}$.

Step 2: (a), ($\Rightarrow$). Let f be convex, $\mathbf{a} \in U$ and $\mathbf{v} \in \mathbb{R}^n$. For small $s \neq 0$, $\mathbf{a} = \frac{1}{2}(\mathbf{a}+s\mathbf{v}) + \frac{1}{2}(\mathbf{a}-s\mathbf{v})$, so $f(\mathbf{a}) \leq \frac{1}{2}f(\mathbf{a}+s\mathbf{v}) + \frac{1}{2}f(\mathbf{a}-s\mathbf{v})$, that is, $\Delta(\mathbf{a}, \mathbf{v}, s) \geq 0$. Dividing by $s^2 > 0$ and letting $s \to 0$, Step 1 gives $\mathbf{v}^{\top}\mathbf{H}(\mathbf{a})\mathbf{v} \geq 0$, since a non-strict inequality survives a limit. The matrix $\mathbf{H}(\mathbf{a})$ is symmetric by Chapter 13 §06's (A1), so $\mathbf{H}(\mathbf{a}) \succeq 0$ by Definition 12.1.1.

Step 3: a maximum principle. Let $\mathbf{x} \neq \mathbf{y}$ in U, put $\mathbf{v} = \mathbf{y} - \mathbf{x}$, and let $\phi\colon U \to \mathbb{R}$ be continuous with the following property: for every point $\mathbf{z} = \mathbf{x} + t\mathbf{v}$ with $0 < t < 1$, the limit $L(\mathbf{z}) = \lim_{s\to 0}\big(\phi(\mathbf{z}+s\mathbf{v}) + \phi(\mathbf{z}-s\mathbf{v}) - 2\phi(\mathbf{z})\big)/s^2$ exists and is **strictly positive**. We claim

$$\phi\big(\mathbf{x}+t\mathbf{v}\big) < (1-t)\phi(\mathbf{x}) + t\phi(\mathbf{y}) \qquad (0 < t < 1).$$

Define $h(t) = \phi(\mathbf{x} + t\mathbf{v}) - (1-t)\phi(\mathbf{x}) - t\phi(\mathbf{y})$ on $[0,1]$. Every point of the segment lies in U, since U is convex. So h is continuous, and $h(0) = h(1) = 0$. The subtracted part is affine in t, so its second differences vanish, and $h(t+s) + h(t-s) - 2h(t) = \phi(\mathbf{z} + s\mathbf{v}) + \phi(\mathbf{z} - s\mathbf{v}) - 2\phi(\mathbf{z})$ with $\mathbf{z} = \mathbf{x} + t\mathbf{v}$.

Suppose $h(t_1) \geq 0$ for some $t_1 \in (0,1)$. The interval $[0,1]$ is closed and bounded, hence compact by fact (A3) of Chapter 15's introduction, so by the extreme value theorem, fact (A4), h attains a maximum value M at some point. Then $M \geq h(t_1) \geq 0$. If the maximum is attained only at 0 or 1, then $M = 0 \leq h(t_1)$, so t_1 attains it too. Either way, $M = h(t^*)$ for some $t^* \in (0,1)$. For $0 < s < \min(t^*, 1-t^*)$, both $h(t^* \pm s) \leq h(t^*)$, so the second difference of h at t^* is ≤ 0, and so is its limit $L(\mathbf{x} + t^*\mathbf{v})$. This contradicts $L > 0$. Hence $h < 0$ on $(0,1)$, which is the claim.

Step 4: (b). Let $\mathbf{H}(\mathbf{z}) \succ 0$ for every $\mathbf{z} \in U$. By Step 1, $\phi = f$ has $L(\mathbf{z}) = \mathbf{v}^\top \mathbf{H}(\mathbf{z})\mathbf{v} > 0$ whenever $\mathbf{v} \neq \mathbf{0}$, and it is continuous. So Step 3 gives $f((1-t)\mathbf{x} + t\mathbf{y}) < (1-t)f(\mathbf{x}) + tf(\mathbf{y})$ for all $\mathbf{x} \neq \mathbf{y}$ in U and $0 < t < 1$. Renaming t as $1-t$, this is strict convexity.

Step 5: (a), ($\Leftarrow$). Let $\mathbf{H}(\mathbf{z}) \succeq 0$ for every $\mathbf{z} \in U$. Let $\mathbf{x} \neq \mathbf{y}$ in U, $\mathbf{v} = \mathbf{y} - \mathbf{x}$, $0 < t < 1$, and $\varepsilon > 0$. Put $\phi(\mathbf{z}) = f(\mathbf{z}) + \varepsilon\|\mathbf{z}\|^2$, which is continuous. Expanding the norms,

$$\|\mathbf{z} + s\mathbf{v}\|^2 + \|\mathbf{z} - s\mathbf{v}\|^2 - 2\|\mathbf{z}\|^2 = 2s^2\|\mathbf{v}\|^2,$$

so by Step 1 the limit for ϕ is $L(\mathbf{z}) = \mathbf{v}^\top \mathbf{H}(\mathbf{z})\mathbf{v} + 2\varepsilon\|\mathbf{v}\|^2 \geq 2\varepsilon\|\mathbf{v}\|^2 > 0$. Step 3 applies. With $\mathbf{w} = (1-t)\mathbf{x} + t\mathbf{y}$, it gives

$$f(\mathbf{w}) + \varepsilon\|\mathbf{w}\|^2 < (1-t)\big(f(\mathbf{x}) + \varepsilon\|\mathbf{x}\|^2\big) + t\big(f(\mathbf{y}) + \varepsilon\|\mathbf{y}\|^2\big).$$

Let $\varepsilon \to 0$ through $\varepsilon = 1/k$. The inequality survives as a non-strict one, and gives $f(\mathbf{w}) \leq (1-t)f(\mathbf{x}) + tf(\mathbf{y})$. The cases $\mathbf{x} = \mathbf{y}$, $t = 0$ and $t = 1$ are equalities. So f is convex. This proves the theorem.

■

For $n = 1$, part (a) says that a twice continuously differentiable g on an open interval is convex exactly when $g'' \geq 0$, and its "if" half is Lemma 17.10.5 again.

Quick check. The function $f(x) = x^4$ is strictly convex on $\mathbb{R}$. Is its Hessian, the 1×1 matrix $(f''(x))$, positive definite at every point? What does this say about part (b)?

Solution. No. $f''(x) = 12x^2$ vanishes at $x = 0$, so the 1×1 matrix (0) is positive semidefinite but not positive definite. Yet f is strictly convex, as shown after Lemma 17.10.5. So the converse of part (b) fails: strict convexity does not force a positive definite Hessian.

Convexity is tested segment by segment, so f is convex exactly when its restriction $t \mapsto f(\mathbf{x} + t\mathbf{v})$ to every line is convex. The phrase *every line* matters.

Warning. **Convex along every line through one point is not enough.** Let $f(x,y) = x^2y^2$ on $\mathbb{R}^2$. On each line through the origin, $f(t\mathbf{v}) = t^4 v_1^2 v_2^2$, a non-negative multiple of the convex t^4, so each such restriction is convex. But f is not convex. On the segment from $(1,0)$ to $(0,1)$, a line that misses the origin, $f(1-t,t) = t^2(1-t)^2$ is 0 at both ends and $\frac{1}{16}$ at the midpoint. So the value at the midpoint exceeds the average 0 of the end values.

The Hessian test sees the same failure without guessing the segment. Here

$$\mathbf{H}_f(x,y) = \begin{pmatrix} 2y^2 & 4xy \\ 4xy & 2x^2 \end{pmatrix}, \qquad \det \mathbf{H}_f(x,y) = -12x^2y^2,$$

so at $(1,1)$ the determinant is $-12 < 0$. The two eigenvalues of this symmetric matrix have product -12, so one is negative, and $\mathbf{H}_f(1,1) \not\geq 0$. Part (a) confirms that f is not convex.

17.10.6 Continuity

The warning about $|x|$ shows that convexity does not buy differentiability. It does buy continuity on an open set, and in finite dimension the proof is short: a bound from above near a point is enough, and Jensen's inequality supplies one.

Theorem 17.10.7 — Convex Functions Are Continuous

Let $U \subseteq \mathbb{R}^n$ be a non-empty open convex set and let $f\colon U \to \mathbb{R}$ be convex. Then f is continuous on U. More precisely, for every $\mathbf{a} \in U$ there are $\delta > 0$ and $L \geq 0$ with

$$|f(\mathbf{a}+\mathbf{h}) - f(\mathbf{a})| \leq L\|\mathbf{h}\| \qquad \text{whenever } \|\mathbf{h}\| \leq \delta.$$

Idea. ① Bound f above on a small ball around $\mathbf{a}$. The ball sits inside the "diamond" spanned by the $2n$ points $\mathbf{a} \pm \rho\mathbf{e}_i$, and Jensen bounds f on the diamond by its largest value at those points. ② Turn an upper bound into a two-sided linear bound. Walk from $\mathbf{a}$ toward $\mathbf{a}+\mathbf{h}$ and on to the edge of the ball: convexity makes the rise over the short step at most a fraction of the rise over the whole way. Then walk the other way for the lower bound.

Proof. Fix $\mathbf{a} \in U$. Since U is open, Proposition 17.1.6 (a) gives $r > 0$ such that every point within distance r of $\mathbf{a}$ lies in U. Put $\rho = r/2$. The $2n+1$ points $\mathbf{a}$ and $\mathbf{a} \pm \rho\mathbf{e}_i$ lie in U, so let M be the largest value of f at them.

Step 1: an upper bound. Let $\mathbf{h} = \sum_i h_i\mathbf{e}_i$ with $\|\mathbf{h}\|_1 \leq \rho$, and let $\sigma_i = 1$ if $h_i \geq 0$ and $\sigma_i = -1$ otherwise, so that $|h_i|\sigma_i = h_i$. Then

$$\mathbf{a}+\mathbf{h} = \sum_{i=1}^{n} \frac{|h_i|}{\rho}\,(\mathbf{a} + \rho\sigma_i\mathbf{e}_i) + \Bigl(1 - \frac{\|\mathbf{h}\|_1}{\rho}\Bigr)\mathbf{a},$$

a convex combination: the weights are non-negative and add up to 1. By Theorem 17.10.2, $f(\mathbf{a}+\mathbf{h}) \leq M$. Put $\delta = \rho/\sqrt{n}$. If $\|\mathbf{h}\| \leq \delta$, then $\|\mathbf{h}\|_1 \leq \sqrt{n}\|\mathbf{h}\| \leq \rho$ by Proposition 15.1.2, so $f(\mathbf{a}+\mathbf{h}) \leq M$.

Step 2: the linear bound. Put $L = (M - f(\mathbf{a}))/\delta$, which is ≥ 0 because $\mathbf{a}$ is one of the points defining M. Let $0 < \|\mathbf{h}\| \leq \delta$; for $\mathbf{h} = \mathbf{0}$ there is nothing to prove. Put $s = \|\mathbf{h}\|/\delta \in (0,1]$ and $\mathbf{u} = \mathbf{h}/s$, so that $\|\mathbf{u}\| = \delta$ and $s\mathbf{u} = \mathbf{h}$. First,

$$\mathbf{a}+\mathbf{h} = (1-s)\mathbf{a} + s(\mathbf{a}+\mathbf{u}),$$

so convexity gives $f(\mathbf{a}+\mathbf{h}) \leq (1-s)f(\mathbf{a}) + sf(\mathbf{a}+\mathbf{u})$, that is,

$$f(\mathbf{a}+\mathbf{h}) - f(\mathbf{a}) \leq s\bigl(f(\mathbf{a}+\mathbf{u}) - f(\mathbf{a})\bigr) \leq s\bigl(M - f(\mathbf{a})\bigr),$$

using Step 1 at $\mathbf{u}$. Second,

$$\mathbf{a} = \frac{1}{1+s}(\mathbf{a}+\mathbf{h}) + \frac{s}{1+s}(\mathbf{a}-\mathbf{u}),$$

as one checks by multiplying out and using $s\mathbf{u} = \mathbf{h}$. Here $\mathbf{a}-\mathbf{u}$ lies in U, and convexity gives $(1+s)f(\mathbf{a}) \le f(\mathbf{a}+\mathbf{h}) + sf(\mathbf{a}-\mathbf{u})$, that is,

$$f(\mathbf{a}) - f(\mathbf{a}+\mathbf{h}) \le s\big(f(\mathbf{a}-\mathbf{u}) - f(\mathbf{a})\big) \le s\big(M - f(\mathbf{a})\big),$$

using Step 1 at $-\mathbf{u}$. Together, $|f(\mathbf{a}+\mathbf{h}) - f(\mathbf{a})| \le s(M - f(\mathbf{a})) = L\|\mathbf{h}\|$.

Step 3: continuity. If $\mathbf{x}_k \to \mathbf{a}$, then $\|\mathbf{x}_k - \mathbf{a}\| \le \delta$ for all large k, and for those k Step 2 gives $|f(\mathbf{x}_k) - f(\mathbf{a})| \le L\|\mathbf{x}_k - \mathbf{a}\| \to 0$. So f is continuous at $\mathbf{a}$, in the sequential sense of Chapter 15's introduction. As $\mathbf{a}$ was arbitrary, this proves the theorem.

■

By Theorem 15.2.2 the choice of the Euclidean norm is immaterial: every norm on $\mathbb{R}^n$ gives the same continuous functions. Both hypotheses of the theorem are needed.

Warning. **The domain must be open.** On the closed interval $[0,1]$, let $f = 0$ on $[0,1)$ and $f(1) = 1$. It is convex: the right side $tf(x) + (1-t)f(y)$ is never negative, and the left side is 0 unless $tx + (1-t)y = 1$, which for $0 < t < 1$ forces $x = y = 1$, where both sides equal 1. But $f(1 - 1/k) = 0 \not\to 1 = f(1)$. A convex function can jump at a boundary point of its domain.

Remark. **Finite dimension is needed too.** On the polynomials in $C[0,1]$, with the sup norm $\|p\|_\infty = \max_{t\in[0,1]}|p(t)|$ of Chapter 15 §01 restricted to them, the functional $\varphi(p) = p'(1)$ is linear, hence convex, on the whole space. The polynomials $p_k = x^{k^2}/k$ have $\|p_k\|_\infty = 1/k \to 0$ and $\varphi(p_k) = k \to \infty$, so φ is not continuous at 0. Step 1 is what fails: there is no finite set of points whose convex hull contains a ball.

The basic theory is now in place. A convex function is one with a convex epigraph; Jensen's inequality extends its defining inequality to every finite average; every supremum of affine functions is one, which accounts for the Ky Fan sums; the Hessian tests for it; and on an open set it is continuous. What it has not yet done is prove an inequality the book did not already know. §11 does that: with a logarithm constructed from the exponential, Jensen's inequality for $-\log$ gives the weighted arithmetic–geometric mean inequality, and from it come Young's and Hölder's inequalities, the triangle inequality for every p-norm, and the dual norms that §04 left open.

17.10.7 Exercises

17.10.7.1 A. Check your understanding

Exercise A1.

(a) Define "f is convex on C", and explain why C is required to be convex.

(b) Decide whether the following is correct, and justify your answer: if f and g are convex on C, then so are $f+g$ and $\max(f,g)$.

(c) Decide whether the following is correct, and justify your answer: if f and g are convex on $\mathbb{R}$, then so is their product fg.

(d) Decide whether the following is correct, and justify your answer: a convex function on $\mathbb{R}$ is differentiable.

(e) Decide whether the following is correct, and justify your answer: if $f\colon \mathbb{R}^2 \to \mathbb{R}$ is convex along every line through the origin, then f is convex.

(f) Name the facts of analysis that the proof of Theorem 17.10.6 uses.

Solution.

(a) Let C be a non-empty convex subset of a real vector space. Then $f\colon C \to \mathbb{R}$ is convex if $f(t\mathbf{x} + (1-t)\mathbf{y}) \leq tf(\mathbf{x}) + (1-t)f(\mathbf{y})$ for all $\mathbf{x}, \mathbf{y} \in C$ and all $t \in [0,1]$ (Definition 17.10.1). The left side evaluates f at $t\mathbf{x} + (1-t)\mathbf{y}$, and this point is in the domain for every choice exactly when C is convex.

(b) Correct. Adding the inequalities for f and for g gives the inequality for $f+g$. For the maximum, the remark after Proposition 17.10.3 applies: its proof works for any family of convex functions, and here the family is $\{f, g\}$.

(c) Incorrect. $f(x) = x$ is affine and $g(x) = x^2$ is convex (Example (First convex functions)), but $fg = x^3$ is not convex on $\mathbb{R}$: at -2, 0 and their midpoint -1 the non-example after Example (First convex functions) gives $-1 > -4$.

(d) Incorrect. $|x|$ is convex and not differentiable at 0, as the first warning of the section shows.

(e) Incorrect. $f(x,y) = x^2y^2$ is convex along every line through the origin but not convex, since $f(\frac{1}{2}, \frac{1}{2}) = \frac{1}{16} > 0 = \frac{1}{2}f(1,0) + \frac{1}{2}f(0,1)$.

(f) Chapter 13 §06's assumptions (A1), the symmetry of the Hessian, and (A2), Taylor's theorem with a second-order remainder; facts (A3) and (A4) of Chapter 15's introduction, compactness of $[0,1]$ and the extreme value theorem, in the maximum principle; and the algebra of limits, in the form "a non-strict inequality survives a limit".

17.10.7.2 B. Practice

Exercise B1: Which are convex?.

Determine which of the following functions are convex on the given domain. Justify your answer.

(a) $f(x,y) = 2x^2 - 2xy + y^2$ on $\mathbb{R}^2$.

(b) $f(x,y) = x^2 + 4xy + y^2$ on $\mathbb{R}^2$.

(c) $f(x) = \max(2x+1,\ -x,\ 3)$ on $\mathbb{R}$.

(d) $g(x) = 1/x$ on $(0, \infty)$.

(e) $g(x) = 1/x$ on $\{x \in \mathbb{R} : x \neq 0\}$.

Solution.

(a) Convex, indeed strictly convex. f is a polynomial, so twice continuously differen-

tiable, with constant Hessian $\mathbf{H} = \left(\begin{smallmatrix} 4 & -2 \\ -2 & 2 \end{smallmatrix}\right)$, which is symmetric. For $\mathbf{v} = (v_1, v_2)$,

$$\mathbf{v}^\top \mathbf{H} \mathbf{v} = 4v_1^2 - 4v_1 v_2 + 2v_2^2 = 2\big(v_1^2 + (v_1 - v_2)^2\big),$$

which is positive unless $v_1 = 0$ and $v_1 = v_2$, that is, unless $\mathbf{v} = \mathbf{0}$. So $\mathbf{H} \succ 0$ at every point, and Theorem 17.10.6 (b) applies.

(b) Not convex. Take $\mathbf{x} = (1, -1)$ and $\mathbf{y} = (-1, 1)$, with midpoint $\mathbf{0}$. Then $f(\mathbf{x}) = 1 - 4 + 1 = -2 = f(\mathbf{y})$, while $f(\mathbf{0}) = 0 > \frac{1}{2}(-2) + \frac{1}{2}(-2) = -2$. The inequality of Definition 17.10.1 fails with $t = \frac{1}{2}$.

(c) Convex. The three functions $2x + 1$, $-x$ and the constant 3 are affine, and f is their maximum, so Proposition 17.10.3 applies.

(d) Strictly convex. For $x > 0$ and small $h \neq 0$,

$$\frac{1}{h}\Big(\frac{1}{x+h} - \frac{1}{x}\Big) = -\frac{1}{x(x+h)} \longrightarrow -\frac{1}{x^2},$$

so $g'(x) = -1/x^2$. If $0 < a < b$ then $1/a^2 > 1/b^2$, so $-1/a^2 < -1/b^2$: g' is strictly increasing on $(0, \infty)$, and Lemma 17.10.5 gives strict convexity.

(e) The question has no answer: Definition 17.10.1 requires a convex domain, and this one is not. It contains -1 and 1 but not their midpoint 0, so the defining inequality is undefined for $x = -1$, $y = 1$, $t = \frac{1}{2}$.

17.10.7.3 C. Going deeper

Exercise C1: Subadditive and homogeneous.

Let $g\colon V \to \mathbb{R}$ be **positively homogeneous**: $g(t\mathbf{x}) = tg(\mathbf{x})$ for every $\mathbf{x} \in V$ and every real $t \geq 0$.

(a) Prove that g is convex if and only if $g(\mathbf{x} + \mathbf{y}) \leq g(\mathbf{x}) + g(\mathbf{y})$ for all $\mathbf{x}, \mathbf{y} \in V$.

(b) Deduce that every norm on $\mathbb{R}^n$ is convex, and that Corollary 16.6.5 and Corollary 17.10.4 are equivalent statements about s_k.

Solution.

(a) ($\Rightarrow$) Let g be convex. By homogeneity with $t = 2$ and then convexity with $t = \frac{1}{2}$,

$$g(\mathbf{x} + \mathbf{y}) = 2g\big(\tfrac{1}{2}\mathbf{x} + \tfrac{1}{2}\mathbf{y}\big) \leq 2\big(\tfrac{1}{2}g(\mathbf{x}) + \tfrac{1}{2}g(\mathbf{y})\big) = g(\mathbf{x}) + g(\mathbf{y}).$$

($\Leftarrow$) Let g be subadditive, and let $0 \leq t \leq 1$. By subadditivity and then homogeneity with the non-negative numbers t and $1 - t$,

$$g\big(t\mathbf{x} + (1-t)\mathbf{y}\big) \leq g(t\mathbf{x}) + g\big((1-t)\mathbf{y}\big) = tg(\mathbf{x}) + (1-t)g(\mathbf{y}).$$

(b) A norm is positively homogeneous by (N2) of Definition 15.1.1, since $|t| = t$ for $t \geq 0$, and subadditive by (N3); so it is convex by (a). This is a second proof of Example (First convex functions) (b). The function s_k is positively homogeneous on the Hermitian matrices, since multiplying by $t \geq 0$ multiplies each eigenvalue by t and keeps their order. So by (a), subadditivity of s_k, which is Corollary 16.6.5, holds exactly when s_k is convex, which is Corollary 17.10.4.

Exercise C2: Tangent lines.

Let $I \subseteq \mathbb{R}$ be an open interval and let $g\colon I \to \mathbb{R}$ be differentiable and convex.

(a) Prove that $g(y) \geq g(x) + g'(x)(y-x)$ for all $x, y \in I$.

(b) Deduce that $g(y) = \max_{x \in I}\big(g(x) + g'(x)(y-x)\big)$ for every $y \in I$: a differentiable convex function is the maximum of its tangent lines.

Hint: in (a), apply the definition to the points x and y with weight s on y, and let $s \to 0$.

Solution.

(a) If $y = x$ both sides are equal. Let $y \neq x$ and $0 < s \leq 1$. Convexity with weight s on y gives $g(x + s(y-x)) \leq (1-s)g(x) + sg(y)$, that is,

$$(y-x) \cdot \frac{g\big(x + s(y-x)\big) - g(x)}{s(y-x)} \;\leq\; g(y) - g(x).$$

The fraction is a difference quotient of g at x with step $s(y-x) \neq 0$. Take $s = 1/k$; the step tends to 0, so the fraction tends to $g'(x)$. A non-strict inequality survives the limit, so $(y-x)g'(x) \leq g(y) - g(x)$, as claimed.

(b) For fixed y, each $\ell_x(y) = g(x) + g'(x)(y-x)$ is at most $g(y)$ by (a), and $\ell_y(y) = g(y)$. So the maximum over x exists, is attained at $x = y$, and equals $g(y)$. Each ℓ_x is an affine function of y, so this is the converse of Proposition 17.10.3, for differentiable functions.

Exercise C3: Where a convex function is largest.

(a) Let $f\colon \mathbb{R}^n \to \mathbb{R}$ be convex, and let P be the convex hull $\operatorname{conv}\{\mathbf{x}_1, \ldots, \mathbf{x}_m\}$. Prove that $\max_{\mathbf{x} \in P} f(\mathbf{x}) = \max_i f(\mathbf{x}_i)$.

(b) Let $f(x, y) = x^2 - xy + y^2$ and let P be the triangle $\operatorname{conv}\{(2,0), (0,2), (-2,-2)\}$. Find the maximum and the minimum of f on P, and say where each is attained.

Solution.

(a) Each $\mathbf{x}_i$ lies in P, so the maximum over P, if it exists, is at least $\max_i f(\mathbf{x}_i)$. Conversely, let $\mathbf{x} \in P$. By Theorem 17.1.3, $\mathbf{x} = \sum_i w_i \mathbf{x}_i$ for some weights $w_i \geq 0$ with sum 1, and Theorem 17.10.2 gives $f(\mathbf{x}) \leq \sum_i w_i f(\mathbf{x}_i) \leq \max_i f(\mathbf{x}_i)$. So $\max_i f(\mathbf{x}_i)$ is an upper bound for f on P that is attained, hence the maximum. Compare Corollary 17.8.6, which says the same for a linear function on any compact convex set, with extreme points in place of the $\mathbf{x}_i$.

(b) The Hessian is the constant symmetric matrix $\left(\begin{smallmatrix} 2 & -1 \\ -1 & 2 \end{smallmatrix}\right)$, and $2v_1^2 - 2v_1v_2 + 2v_2^2 = v_1^2 + v_2^2 + (v_1 - v_2)^2 \geq 0$, so it is positive semidefinite and f is convex by Theorem 17.10.6 (a). By (a) the maximum is the largest vertex value: $f(2,0) = 4$, $f(0,2) = 4$ and $f(-2,-2) = 4 - 4 + 4 = 4$. So the maximum is 4, attained at all three vertices. For the minimum, $f(x,y) = \frac{1}{2}\big(x^2 + y^2 + (x-y)^2\big) \geq 0$, with equality only at $(0,0)$. And $(0,0) = \frac{1}{3}(2,0) + \frac{1}{3}(0,2) + \frac{1}{3}(-2,-2)$ lies in P. So the minimum is 0, attained only at the interior point $(0,0)$. The maximum of a convex function sits at vertices; its minimum need not.

17.11 Three Classical Inequalities

§10 built the basic theory of convex functions. This section spends it on three classical inequalities, each obtained from the one before. Jensen's inequality for the logarithm is the weighted arithmetic–geometric mean inequality; with two weights it is Young's inequality; and Young's inequality, applied coordinate by coordinate, is Hölder's. Hölder's inequality then settles two questions the book left open: the triangle inequality for the p-norm, which Chapter 15 §01 recorded without proof, and the dual of the p-norm, which §04 computed only for $p = 1, 2, \infty$.

Throughout, the field is $\mathbb{R}$, and "increasing" and "strictly increasing" are meant as in §10.

17.11.1 The logarithm and real powers

The first inequality needs a logarithm, and the book has none. It has the exponential: by fact (A1) of Chapter 9 §09, for real s the series $\sum_i s^i/i!$ converges to a real number e^s, with $e^{s+u} = e^s e^u$, $e^0 = 1$ and $e^s \geq 1$ for $s \geq 0$; and $\frac{d}{dt}e^t = e^t$ is the 1×1 case of Theorem 9.9.4 (b). We construct the logarithm as its inverse.

Lemma 17.11.1 — Exponential and Logarithm (a) $e^s > 0$ for every real s, and $s \mapsto e^s$ is strictly increasing and strictly convex on $\mathbb{R}$.

(b) For every real $y > 0$ there is exactly one real s with $e^s = y$; write $s = \log y$.

(c) $\log\colon (0, \infty) \to \mathbb{R}$ is strictly increasing and **strictly concave**, with $\log(xy) = \log x + \log y$ and $\log 1 = 0$.

Idea. The exponential is positive and is its own derivative, so it is strictly increasing with a strictly increasing derivative, hence strictly convex. The intermediate value theorem makes it take every positive value, so it has an inverse. Applying that increasing inverse to the convexity inequality of exp turns it into concavity of log.

Proof.

(a) If $s \geq 0$ then $e^s \geq 1 > 0$. If $s < 0$ then $e^{-s} \geq 1$, and $e^s e^{-s} = e^0 = 1$, so $e^s = 1/e^{-s} > 0$. The derivative e^s is therefore positive everywhere, and by the linearity of differentiation, fact (A3) of Chapter 9 §09, $-\exp$ has the negative derivative $-\exp$. By fact (A6) of Chapter 15's introduction, $-\exp$ is strictly decreasing, so exp is strictly increasing. So $g = \exp$ has a strictly increasing derivative, and Lemma 17.10.5 makes it strictly convex.

(b) Uniqueness holds because exp is strictly increasing. For existence, note first that exp is continuous: $e^{t+h} - e^t = e^t\, h \cdot (e^h - 1)/h$, and $(e^h - 1)/h \to 1$ is the derivative at 0, so the right side tends to 0. Let $y \geq 1$. For $s \geq 0$ every partial sum of the series with at least two terms is at least $1 + s$, so $e^s \geq 1 + s$, since a non-strict inequality survives a limit. Hence $e^y \geq 1 + y > y$, while $e^0 = 1 \leq y$. The intermediate value theorem, fact (A5) of Chapter 15's introduction, gives $s \in [0, y]$ with $e^s = y$. If $0 < y < 1$, apply this to $1/y > 1$ to get $e^{s'} = 1/y$; then $e^{-s'} = y$.

(c) If $0 < x < y$ and $\log x \geq \log y$, then $x = e^{\log x} \geq e^{\log y} = y$, since exp is increasing, which is false. So log is strictly increasing. Next, $e^{\log x + \log y} = e^{\log x} e^{\log y} = xy$, so $\log(xy) = \log x + \log y$ by uniqueness in (b), and $e^0 = 1$ gives $\log 1 = 0$. For

concavity, let $x, y > 0$ and $0 \le t \le 1$, and put $a = \log x$, $b = \log y$. By (a),

$$e^{ta+(1-t)b} \le te^a + (1-t)e^b = tx + (1-t)y.$$

Applying the increasing function log to both sides gives $t\log x + (1-t)\log y \le \log\bigl(tx + (1-t)y\bigr)$. If $x \ne y$ and $0 < t < 1$, then $a \ne b$, the first inequality is strict by strict convexity, and log keeps it strict. So $-\log$ is strictly convex.

■

Real powers. For $t > 0$ and real r put $t^r = e^{r\log t}$, and $0^r = 0$ for $r > 0$. For a positive integer r this is the usual power, since $e^{r\log t} = (e^{\log t})^r = t^r$ by $e^{s+u} = e^s e^u$. For $t, a, b > 0$ and real r, u, the rules $e^{s+u} = e^s e^u$ and $\log(ab) = \log a + \log b$, with $\log(t^r) = r\log t$ from the uniqueness in (b), give

$$t^r t^u = t^{r+u}, \qquad (t^r)^u = t^{ru}, \qquad (ab)^r = a^r b^r, \qquad (a/b)^r = a^r/b^r.$$

The first three extend to $t, a, b \ge 0$, and the last to $a \ge 0$, when the exponents r and u are positive: then a zero base makes both sides 0. They do not extend further, since 0^r is not defined for $r \le 0$. Finally, for $r > 0$ the function $t \mapsto t^r$ is strictly increasing on $[0, \infty)$: on $(0, \infty)$ it is exp applied to the strictly increasing $r\log t$, and $0^r = 0 < t^r$ for $t > 0$. This is the meaning of $|x_i|^p$ and of the exponent $1/p$ in the p-norm $\|\mathbf{x}\|_p = (\sum_i |x_i|^p)^{1/p}$ of Chapter 15 §01.

17.11.2 Arithmetic and geometric means

Chapter 16 §08 proved Lemma 16.8.6, the arithmetic–geometric mean inequality, by pure algebra: an induction that merges a number above the mean with one below it. Concavity of the logarithm gives a second proof, and a stronger statement, with arbitrary weights.

Theorem 17.11.2 — Weighted Arithmetic–Geometric Mean Inequality

Let $t_1, \dots, t_m \ge 0$, and let $w_1, \dots, w_m > 0$ with $w_1 + \cdots + w_m = 1$. Then

$$t_1^{w_1} t_2^{w_2} \cdots t_m^{w_m} \;\le\; w_1 t_1 + w_2 t_2 + \cdots + w_m t_m,$$

with equality if and only if $t_1 = t_2 = \cdots = t_m$.

Idea. Take logarithms. The product becomes the weighted average $\sum_i w_i \log t_i$, and the inequality becomes Jensen's inequality for the concave log. Then exponentiate back.

Proof. If some $t_j = 0$, the left side is 0, since $0^{w_j} = 0$, and the right side is ≥ 0. Equality then means $\sum_i w_i t_i = 0$, which with every $w_i > 0$ and $t_i \ge 0$ forces every $t_i = 0$; conversely, if every $t_i = 0$, both sides are 0.

So let every $t_i > 0$. By Lemma 17.11.1 (c), $-\log$ is strictly convex on $(0, \infty)$, so Theorem 17.10.2 gives

$$\sum_{i=1}^{m} w_i \log t_i \;\le\; \log\Bigl(\sum_{i=1}^{m} w_i t_i\Bigr),$$

with equality only when all t_i are equal. Apply the strictly increasing function exp. The right side becomes $\sum_i w_i t_i$, and the left side becomes $\prod_i e^{w_i \log t_i} = \prod_i t_i^{w_i}$, by

$e^{s+u} = e^s e^u$ and the definition of real powers. A strictly increasing function preserves both the inequality and its strictness, so equality holds exactly when all t_i are equal.

■

The case of equal weights is Lemma 16.8.6. With $w_i = 1/n$, the rules for powers turn the theorem into $(t_1 \cdots t_n)^{1/n} \le \frac{1}{n}\sum_i t_i$. Since $u \mapsto u^n$ is strictly increasing on $[0,\infty)$, raising both sides to the n-th power gives $t_1 \cdots t_n \le (\frac{1}{n}\sum_i t_i)^n$, with the same equality case. That is Lemma 16.8.6, now with arbitrary weights and seen as Jensen's inequality for the logarithm.

With two weights, the theorem becomes an inequality about products that is exactly what Hölder's inequality needs.

Lemma 17.11.3 — Young's Inequality

Let $p, q > 1$ with $\frac{1}{p} + \frac{1}{q} = 1$. Then for all real $a, b \ge 0$,

$$ab \;\le\; \frac{a^p}{p} + \frac{b^q}{q},$$

with equality if and only if $a^p = b^q$.

Proof. Apply Theorem 17.11.2 with $m = 2$, $t_1 = a^p$, $t_2 = b^q$, $w_1 = 1/p$ and $w_2 = 1/q$. The weights are positive and add up to 1, and $(a^p)^{1/p} = a$, $(b^q)^{1/q} = b$ by the rules for powers. So the left side of the theorem is ab and the right side is $a^p/p + b^q/q$, with equality exactly when $a^p = b^q$.

■

17.11.3 Hölder's inequality and the dual p-norms

Two exponents $p, q \in (1,\infty)$ with $\frac{1}{p} + \frac{1}{q} = 1$ are called **conjugate**; equivalently $q = p/(p-1)$. The pair $p = q = 2$ is conjugate to itself. Hölder's inequality is the Cauchy–Schwarz inequality with the two factors measured in two different norms.

Theorem 17.11.4 — Hölder's Inequality

Let $p, q \in (1,\infty)$ be conjugate exponents. For all $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$,

$$|\langle \mathbf{x}, \mathbf{y} \rangle| \;\le\; \sum_{i=1}^{n} |x_i y_i| \;\le\; \|\mathbf{x}\|_p \|\mathbf{y}\|_q.$$

Idea. Both sides of the second inequality scale the same way when $\mathbf{x}$ or $\mathbf{y}$ is multiplied by a positive number. So normalize to $\|\mathbf{x}\|_p = \|\mathbf{y}\|_q = 1$. Then apply Young's inequality coordinate by coordinate and add: the right-hand sides add up to $\frac{1}{p} + \frac{1}{q} = 1$.

Proof. The first inequality is the triangle inequality for numbers (Theorem 0.6.4) applied to $\sum_i x_i y_i$. For the second, if $\mathbf{x} = \mathbf{0}$ or $\mathbf{y} = \mathbf{0}$ both sides are 0. Otherwise $\|\mathbf{x}\|_p > 0$ and

$\|\mathbf{y}\|_q > 0$; put $a_i = |x_i|/\|\mathbf{x}\|_p$ and $b_i = |y_i|/\|\mathbf{y}\|_q$. Then $\sum_i a_i^p = \sum_i |x_i|^p/\|\mathbf{x}\|_p^p = 1$, because $\|\mathbf{x}\|_p^p = \sum_i |x_i|^p$ by the rules for powers, and likewise $\sum_i b_i^q = 1$. By Lemma 17.11.3 for each i, and adding,

$$\sum_{i=1}^{n} a_i b_i \;\le\; \frac{1}{p}\sum_{i=1}^{n} a_i^p + \frac{1}{q}\sum_{i=1}^{n} b_i^q = \frac{1}{p} + \frac{1}{q} = 1.$$

Multiplying by $\|\mathbf{x}\|_p\|\mathbf{y}\|_q$ gives $\sum_i |x_i y_i| \le \|\mathbf{x}\|_p\|\mathbf{y}\|_q$, as claimed.

■

For $p = q = 2$ this is Theorem 10.1.5 for the standard inner product on $\mathbb{R}^n$, reached without the inner product's geometry. The limiting pair $p = 1$, $q = \infty$ holds too, and more simply: $\sum_i |x_i y_i| \le \sum_i |x_i| \|\mathbf{y}\|_\infty$.

Chapter 15 §01 recorded the p-norm for every $p \ge 1$, but verified only $p = 1, 2, \infty$, because the triangle inequality for general p had not been proved. Hölder's inequality proves it.

Corollary 17.11.5 — Minkowski's Inequality

Let $1 < p < \infty$. For all $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$, $\|\mathbf{x}+\mathbf{y}\|_p \le \|\mathbf{x}\|_p + \|\mathbf{y}\|_p$. Consequently $\|\cdot\|_p$ is a norm on $\mathbb{R}^n$.

Idea. Split $|z_i|^p = |z_i| \cdot |z_i|^{p-1}$ and use the triangle inequality on the first factor. That leaves two sums, and Hölder's inequality bounds each, with the same second factor $(|z_i|^{p-1})_i$. Dividing by that common factor's norm leaves the triangle inequality.

Proof. Let $q = p/(p-1)$ be the conjugate exponent, and put $\mathbf{z} = \mathbf{x}+\mathbf{y}$. If $\mathbf{z} = \mathbf{0}$ there is nothing to prove. Otherwise, by the triangle inequality for numbers in each coordinate (Theorem 0.6.4),

$$\begin{aligned}\sum_i |z_i|^p &= \sum_i |z_i|\,|z_i|^{p-1} \\ &\le \sum_i |x_i|\,|z_i|^{p-1} + \sum_i |y_i|\,|z_i|^{p-1}.\end{aligned}$$

Apply Theorem 17.11.4 to each sum, with the vector $\mathbf{w} = (|z_1|^{p-1}, \dots, |z_n|^{p-1})$ as the second factor. Since $(p-1)q = p$,

$$\|\mathbf{w}\|_q = \Big(\sum_i |z_i|^p\Big)^{1/q} = \|\mathbf{z}\|_p^{p/q}.$$

So $\|\mathbf{z}\|_p^p \le (\|\mathbf{x}\|_p + \|\mathbf{y}\|_p)\|\mathbf{z}\|_p^{p/q}$. Divide by $\|\mathbf{z}\|_p^{p/q} > 0$, and use $p - p/q = p(1-1/q) = 1$, to get $\|\mathbf{z}\|_p \le \|\mathbf{x}\|_p + \|\mathbf{y}\|_p$. This is (N3) of Definition 15.1.1. (N1) holds because $\|\mathbf{x}\|_p = 0$ forces every $|x_i|^p = 0$, and (N2) because $\big(\sum_i |c|^p |x_i|^p\big)^{1/p} = |c|\|\mathbf{x}\|_p$ by the rules for powers.

■

The proof uses the coordinates only through their moduli: the triangle inequality $|x_i + y_i| \le |x_i| + |y_i|$, which Theorem 0.6.4 proves for complex numbers as well, and Hölder's inequality for the real vectors $(|x_i|)_i$, $(|y_i|)_i$ and $\mathbf{w}$, whose p-norms are those of $\mathbf{x}$ and $\mathbf{y}$. So it works verbatim

on $\mathbb{C}^n$, and $\|\cdot\|_p$ is a norm on F^n for $F = \mathbb{R}$ and for $F = \mathbb{C}$, as Chapter 15 §01 recorded.

Now the dual norm. Recall from Definition 17.4.4 that the dual norm of $\|\cdot\|$ at $\mathbf{y}$ is the largest value of $\langle \mathbf{x}, \mathbf{y} \rangle$ over the unit ball $\|\mathbf{x}\| \le 1$. §04 computed it for $p = 1, 2, \infty$: the 1-norm and the ∞-norm are dual to each other, and the 2-norm is dual to itself. Hölder's inequality supplies an upper bound for every other p, and a matching vector shows it is attained.

Theorem 17.11.6 — The Dual of the p-Norm

Let $p, q \in (1, \infty)$ be conjugate exponents. On $\mathbb{R}^n$ with the standard inner product, the dual norm of $\|\cdot\|_p$ is $\|\cdot\|_q$:

$$\max\{\langle \mathbf{x}, \mathbf{y} \rangle : \|\mathbf{x}\|_p \le 1\} = \|\mathbf{y}\|_q \qquad (\mathbf{y} \in \mathbb{R}^n).$$

For $\mathbf{y} \neq \mathbf{0}$ the maximum is attained at $\mathbf{x}$ with $x_i = \sigma_i |y_i|^{q-1} / \|\mathbf{y}\|_q^{q-1}$, where $\sigma_i = 1$ if $y_i \ge 0$ and $\sigma_i = -1$ otherwise.

Idea. Hölder's inequality bounds $\langle \mathbf{x}, \mathbf{y} \rangle$ by $\|\mathbf{y}\|_q$ on the whole unit ball. To show the bound is attained, give x_i the sign of y_i and make $|x_i|^p$ proportional to $|y_i|^q$, which is when Young's inequality is an equality in each coordinate. That is the stated witness, and a direct computation checks it.

Proof. If $\|\mathbf{x}\|_p \le 1$, then $\langle \mathbf{x}, \mathbf{y} \rangle \le \|\mathbf{x}\|_p \|\mathbf{y}\|_q \le \|\mathbf{y}\|_q$ by Theorem 17.11.4. For $\mathbf{y} = \mathbf{0}$ the bound 0 is attained at $\mathbf{x} = \mathbf{0}$. For $\mathbf{y} \neq \mathbf{0}$, take $\mathbf{x}$ as in the statement. Since $(q-1)p = q$,

$$\sum_i |x_i|^p = \frac{\sum_i |y_i|^q}{\|\mathbf{y}\|_q^q} = 1,$$

so $\|\mathbf{x}\|_p = 1$; and since $\sigma_i y_i = |y_i|$,

$$\langle \mathbf{x}, \mathbf{y} \rangle = \frac{\sum_i |y_i|^q}{\|\mathbf{y}\|_q^{q-1}} = \frac{\|\mathbf{y}\|_q^q}{\|\mathbf{y}\|_q^{q-1}} = \|\mathbf{y}\|_q.$$

So the bound is attained, and the largest value is $\|\mathbf{y}\|_q$.

■

Example. (A dual norm by hand)

Let $\mathbf{y} = (3, -4, 5) \in \mathbb{R}^3$, and let $p = \frac{3}{2}$ and $q = 3$. Compute the dual norm of $\mathbf{y}$ with respect to $\|\cdot\|_{3/2}$, find a vector $\mathbf{x}$ with $\|\mathbf{x}\|_{3/2} = 1$ at which it is attained, and compare with the value at the unit vector $\mathbf{e}_3$.

Solution. The exponents are conjugate, since $\frac{1}{p} + \frac{1}{q} = \frac{2}{3} + \frac{1}{3} = 1$. Next, $|3|^3 + |-4|^3 + |5|^3 = 27 + 64 + 125 = 216 = 6^3$, so $\|\mathbf{y}\|_3 = 216^{1/3} = 6$, using $(6^3)^{1/3} = 6$. By Theorem 17.11.6 the dual norm is 6.

For the maximizer, $q - 1 = 2$, so $x_i = \sigma_i |y_i|^2 / 6^2$ with σ_i the sign of y_i:

$$\mathbf{x} = \left(\tfrac{9}{36}, -\tfrac{16}{36}, \tfrac{25}{36}\right) = \left(\tfrac{1}{4}, -\tfrac{4}{9}, \tfrac{25}{36}\right).$$

> Check: $|x_i|^{3/2} = (|y_i|^2/36)^{3/2} = |y_i|^3/216$, giving $\frac{1}{8} + \frac{8}{27} + \frac{125}{216} = \frac{27+64+125}{216} = 1$. So $\|\mathbf{x}\|_{3/2} = 1$. And $\langle \mathbf{x}, \mathbf{y} \rangle = \frac{3}{4} + \frac{16}{9} + \frac{125}{36} = \frac{27+64+125}{36} = 6$.
>
> The unit vector $\mathbf{e}_3$ has $\|\mathbf{e}_3\|_{3/2} = 1$ and gives $\langle \mathbf{e}_3, \mathbf{y} \rangle = 5 < 6$. Putting all the weight on the largest coordinate of $\mathbf{y}$ is not optimal; the maximizer spreads it in proportion to $|y_i|^2$.

Exchanging the roles of p and q shows that the dual of $\|\cdot\|_q$ is $\|\cdot\|_p$, just as Theorem 17.4.8 requires. Together with §04, the dual norm of $\|\cdot\|_p$ is now known for every $p \in [1, \infty]$: it is $\|\cdot\|_q$ with $\frac{1}{p} + \frac{1}{q} = 1$, reading $\frac{1}{\infty}$ as 0. This completes §04's computation. Chapter 15 measured vectors and matrices but never a linear functional; §04's dual norm filled that gap, and now it is computed for every p-norm.

Look back at the chain. One convexity fact, that $-\log$ is strictly convex, went through Jensen's inequality to the weighted arithmetic–geometric mean inequality, through two weights to Young's inequality, and through normalization to Hölder's. Hölder's inequality then did two jobs that earlier chapters could not: it proved that every $\|\cdot\|_p$ is a norm, so that its unit ball is one of the convex sets this chapter began with, and it computed the dual of every such norm.

17.11.4 Summary and transfer

The chapter began with a word the book had been using without studying it. Convexity turned up in the positive semidefinite cone of Chapter 12, in the unit balls of Chapter 15, and in the Ky Fan sums of Chapter 16. The chapter ends with convexity as a subject: convex sets, the hyperplanes that separate them, the duality between a cone and its dual, extreme points and polytopes, and convex functions. Six moves did the work, and each transfers beyond this chapter.

- **Nearest point, then the normal direction.** Project onto a closed convex set; the vector from the projection to the point is the normal of a separating hyperplane (§03, Separating Hyperplanes). This is Chapter 10's best approximation, with an inequality where the equation was. *Transfer:* to prove that a point lies outside a closed convex set, and to certify it, look for the nearest point.
- **Count, then drop a point.** Too many points in n dimensions are affinely dependent, and moving the weights along the dependence removes one of them without leaving the hull (§02, Carathéodory's Theorem). Among too many generators of a cone, a linear dependence does the same (§05, Cones and Farkas's Lemma). *Transfer:* when a representation uses more pieces than the dimension allows, the surplus is a dependence, and a dependence can be spent.
- **Dualize.** A closed convex cone is determined by its dual cone, and every statement about the one has a statement about the other. Farkas's lemma is this move made into a theorem, linear programming duality (§06, Linear Programming Duality) is Farkas applied to one combined system, and the minimax theorem (§07, Matrix Games and the Minimax Theorem) is a duality statement of the same kind. *Transfer:* when a feasibility question will not yield, ask for the certificate that it fails.
- **Lift, then eliminate.** A hull of finitely many points is the projection of a polyhedron in a bigger space, with the weights as extra coordinates, and Fourier–Motzkin elimination removes those coordinates one at a time while keeping a system of inequalities (§09, Polytopes, Theorem 17.9.5). *Transfer:* to describe the image of a set given by inequalities, add the hidden variables as coordinates and eliminate them.
- **A supremum of linear functions is convex.** Support functions, dual norms, λ_1 and

the Ky Fan sums are convex for this one reason (§04, Gauges, Support Functions and Dual Norms, and §10, Convex Functions, Proposition 17.10.3). Its companion: a linear function on a compact convex set peaks at an extreme point (§08, Extreme Points). *Transfer:* to prove a function convex, write it as a maximum of affine functions.

- **Compactness turns a supremum into a maximum.** Once a hull, a ball or a set of weights is known to be compact, facts (A3) and (A4) of Chapter 15's introduction produce a nearest point, a maximizer or an extreme point that can be named and used. *Transfer:* before optimizing, check that the set is compact; afterwards, feed the maximizer back into the argument.

§§10–11 added two moves of their own. **Second differences**: on a segment, convexity is read off from $f(\mathbf{z}+s\mathbf{v})+f(\mathbf{z}-s\mathbf{v})-2f(\mathbf{z})$ (§10, Theorem 17.10.6). **Normalize, then use a two-point inequality**: Hölder's inequality is Young's inequality after scaling both vectors to norm 1 (§11, Theorem 17.11.4). *Transfer:* if multiplying any one variable by $c>0$ multiplies both sides by the same power of c, check the cases with a zero variable directly, and then assume every variable has norm 1.

The chapter also paid promises made in earlier chapters.

The promise	Made in	Paid by
"Chapter 17 studies convex functions in general, and the observation that a pointwise supremum of linear functions is convex is one of its basic facts"	Chapter 16 §06	§10 (Convex Functions), Proposition 17.10.3, with λ_1 and the Ky Fan sums as its instances (Corollary 17.10.4)
Non-negativity and capacities turn traffic flow "into one about inequalities, which is the subject of linear programming"	Chapter 2 §07	§06 (Linear Programming Duality)
A way to measure a linear functional: Chapter 15 measured vectors and matrices, but never a functional	Chapter 15	§04 (Gauges, Support Functions and Dual Norms): the definition, the double dual, and $p=1,2,\infty$; §11 (Three Classical Inequalities): every $1<p<\infty$, Theorem 17.11.6
The triangle inequality for $\|\cdot\|_p$, recorded without proof, "which Chapter 17 proves from Hölder's inequality"	Chapter 15 §01	§11 (Three Classical Inequalities), Corollary 17.11.5

Some things the chapter did not do. It stated Birkhoff's theorem, that the extreme points of the doubly stochastic matrices are exactly the permutation matrices, and left its proof to Chapter 18. The convexity of $\mathbf{A}\mapsto \operatorname{tr} f(\mathbf{A})$ for convex f, and the consequences of a majorization for every convex function, belong to Chapter 20. Convex optimization beyond linear programs, where a duality gap can occur, lies outside this chapter.

17.11.5 Exercises

17.11.5.1 A. Check your understanding

Exercise A1.

(a) State Young's inequality, with its hypotheses and its equality case.

(b) Decide whether the following is correct, and justify your answer: the exponent conjugate to $p = 4$ is $q = \frac{4}{3}$.

(c) Decide whether the following is correct, and justify your answer: $(t^r)^u = t^{ru}$ for every real $t \geq 0$ and all real r, u.

(d) Decide whether the following is correct, and justify your answer: if p, q are conjugate and $\langle \mathbf{x}, \mathbf{y} \rangle = \|\mathbf{x}\|_p \|\mathbf{y}\|_q$ for $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$, then one of $\mathbf{x}, \mathbf{y}$ is a scalar multiple of the other.

(e) Name the convex function to which the proof of Theorem 17.11.2 applies Jensen's inequality, and say why the equality case needs it to be **strictly** convex.

Solution.

(a) Let $p, q > 1$ with $\frac{1}{p} + \frac{1}{q} = 1$. Then $ab \leq a^p/p + b^q/q$ for all real $a, b \geq 0$, with equality if and only if $a^p = b^q$ (Lemma 17.11.3).

(b) Correct. $\frac{1}{4} + \frac{3}{4} = 1$; equivalently $q = p/(p-1) = 4/3$.

(c) Incorrect. Take $t = 0$, $r = 1$ and $u = -1$. Then $t^r = 0$, and 0^{-1} is not defined, since 0^r is defined only for $r > 0$; neither side has a value. The rule holds for $t > 0$ and all real r, u, and for $t = 0$ when $r, u > 0$.

(d) Incorrect. Take $p = 3$, $q = \frac{3}{2}$, $\mathbf{x} = (1, 2)$ and $\mathbf{y} = (1, 4)$. Then $\langle \mathbf{x}, \mathbf{y} \rangle = 1 + 8 = 9$, $\|\mathbf{x}\|_3 = (1+8)^{1/3} = 9^{1/3}$ and $\|\mathbf{y}\|_{3/2} = (1 + 4^{3/2})^{2/3} = 9^{2/3}$, since $4^{3/2} = 8$; so $\|\mathbf{x}\|_3 \|\mathbf{y}\|_{3/2} = 9^{1/3+2/3} = 9$. But neither vector is a multiple of the other, since $1 \cdot 4 - 2 \cdot 1 \neq 0$. Equality asks for $|x_i|^p$ to be proportional to $|y_i|^q$, not $\mathbf{x}$ to $\mathbf{y}$ (exercise C2).

(e) It is $-\log$ on $(0, \infty)$, which is strictly convex by Lemma 17.11.1 (c). Theorem 17.10.2 proves its equality clause only for strictly convex functions, and the hypothesis is needed: an affine function makes Jensen's inequality an equality for every choice of points.

17.11.5.2 B. Practice

Exercise B1: A dual norm by hand.

Let $\mathbf{y} = (1, -6, 8) \in \mathbb{R}^3$, and let $p = \frac{3}{2}$ and $q = 3$.

(a) Check that p and q are conjugate, and compute $\|\mathbf{y}\|_3$.

(b) Find $\mathbf{x} \in \mathbb{R}^3$ with $\|\mathbf{x}\|_{3/2} = 1$ and $\langle \mathbf{x}, \mathbf{y} \rangle = \|\mathbf{y}\|_3$.

(c) Hence determine the dual norm of $\mathbf{y}$ with respect to $\|\cdot\|_{3/2}$, and compare it with the value $\langle \mathbf{e}_3, \mathbf{y} \rangle$ at the unit vector $\mathbf{e}_3$.

Solution.

(a) $\frac{1}{p}+\frac{1}{q}=\frac{2}{3}+\frac{1}{3}=1$. Next, $|1|^3+|-6|^3+|8|^3=1+216+512=729=9^3$, so $\|\mathbf{y}\|_3=729^{1/3}=9$, using $(9^3)^{1/3}=9$.

(b) Follow Theorem 17.11.6: $x_i=\sigma_i|y_i|^2/9^2$ with σ_i the sign of y_i, since $q-1=2$. So

$$\mathbf{x}=\left(\tfrac{1}{81},-\tfrac{36}{81},\tfrac{64}{81}\right)=\left(\tfrac{1}{81},-\tfrac{4}{9},\tfrac{64}{81}\right).$$

Check: $|x_i|^{3/2}=(|y_i|^2/81)^{3/2}=|y_i|^3/729$, giving $\frac{1}{729}+\frac{216}{729}+\frac{512}{729}=1$. So $\|\mathbf{x}\|_{3/2}=1$. And $\langle\mathbf{x},\mathbf{y}\rangle=\frac{1}{81}+\frac{216}{81}+\frac{512}{81}=\frac{729}{81}=9$.

(c) By Theorem 17.11.6 the dual norm is $\|\mathbf{y}\|_3=9$, attained at the $\mathbf{x}$ of (b). The unit vector $\mathbf{e}_3$ has $\|\mathbf{e}_3\|_{3/2}=1$ and gives $\langle\mathbf{e}_3,\mathbf{y}\rangle=8<9$: even when one coordinate of $\mathbf{y}$ dominates, putting all the weight on it is not optimal.

Exercise B2: Harmonic and arithmetic means.

Let $x_1,\dots,x_n>0$. Prove that

$$\frac{n}{\frac{1}{x_1}+\cdots+\frac{1}{x_n}}\le\frac{x_1+\cdots+x_n}{n},$$

with equality if and only if $x_1=\cdots=x_n$.

Solution. By Exercise (B1: Which are convex?) (d), $g(t)=1/t$ is strictly convex on $(0,\infty)$. Let $m=\frac{1}{n}(x_1+\cdots+x_n)>0$. Theorem 17.10.2 with the weights $w_i=1/n>0$ gives

$$\frac{1}{m}=g\Big(\sum_{i=1}^n\frac{1}{n}x_i\Big)\le\sum_{i=1}^n\frac{1}{n}\,g(x_i)=\frac{1}{n}\Big(\frac{1}{x_1}+\cdots+\frac{1}{x_n}\Big),$$

with equality only when all x_i are equal. Both sides are positive, and taking reciprocals reverses the inequality: $m\ge n/(\sum_i 1/x_i)$, which is the claim. If all x_i equal c, both sides equal c. So equality holds exactly when the x_i are all equal.

17.11.5.3 C. Going deeper

Exercise C1: The exponential above its tangent.

(a) Deduce from Exercise (C2: Tangent lines) (a) that $e^y\ge 1+y$ for every real y.

(b) Deduce that $\log x\le x-1$ for every real $x>0$.

Solution.

(a) By Lemma 17.11.1 (a), the function exp is convex and differentiable on the open interval $\mathbb{R}$, with derivative exp. So Exercise (C2: Tangent lines) (a) applies, and at $x=0$ it gives $e^y\ge e^0+e^0(y-0)=1+y$. For $y\ge 0$ this was visible from the series, as in the proof of Lemma 17.11.1 (b); for $y<0$ it is new.

(b) Let $x>0$ and put $y=\log x$, so that $e^y=x$ by Lemma 17.11.1 (b). Part (a) gives $x\ge 1+\log x$, that is, $\log x\le x-1$.

Exercise C2: When Hölder is an equality.

Let $p, q \in (1, \infty)$ be conjugate exponents, and let $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$ be non-zero.

(a) Prove that $\sum_i |x_i y_i| = \|\mathbf{x}\|_p \|\mathbf{y}\|_q$ if and only if $|x_i|^p / \|\mathbf{x}\|_p^p = |y_i|^q / \|\mathbf{y}\|_q^q$ for every i.

(b) Deduce that the maximizer in Theorem 17.11.6 is unique: if $\mathbf{y} \neq \mathbf{0}$, $\|\mathbf{x}\|_p \leq 1$ and $\langle \mathbf{x}, \mathbf{y} \rangle = \|\mathbf{y}\|_q$, then $\mathbf{x}$ is the vector given there.

Hint: in (a), look at where the proof of Theorem 17.11.4 adds up the inequalities of Lemma 17.11.3.

Solution.

(a) Put $a_i = |x_i| / \|\mathbf{x}\|_p$ and $b_i = |y_i| / \|\mathbf{y}\|_q$, as in the proof of Theorem 17.11.4, so that $\sum_i a_i^p = \sum_i b_i^q = 1$. Dividing by $\|\mathbf{x}\|_p \|\mathbf{y}\|_q > 0$, the equality $\sum_i |x_i y_i| = \|\mathbf{x}\|_p \|\mathbf{y}\|_q$ says $\sum_i a_i b_i = 1 = \sum_i (a_i^p/p + b_i^q/q)$. By Lemma 17.11.3, $a_i b_i \leq a_i^p/p + b_i^q/q$ for each i. A sum of non-negative differences $(a_i^p/p + b_i^q/q) - a_i b_i$ is 0 exactly when each difference is 0, so equality holds exactly when $a_i b_i = a_i^p/p + b_i^q/q$ for every i, that is, by the equality case of Lemma 17.11.3, when $a_i^p = b_i^q$ for every i. By the rule $(a/b)^p = a^p / b^p$ for real powers, $a_i^p = |x_i|^p / \|\mathbf{x}\|_p^p$ and $b_i^q = |y_i|^q / \|\mathbf{y}\|_q^q$.

(b) Let $\mathbf{y} \neq \mathbf{0}$, $\|\mathbf{x}\|_p \leq 1$ and $\langle \mathbf{x}, \mathbf{y} \rangle = \|\mathbf{y}\|_q$. By Theorem 17.11.4,

$$\|\mathbf{y}\|_q = \langle \mathbf{x}, \mathbf{y} \rangle \leq \sum_i |x_i y_i| \leq \|\mathbf{x}\|_p \|\mathbf{y}\|_q \leq \|\mathbf{y}\|_q,$$

so every inequality is an equality. First, $\|\mathbf{x}\|_p = 1$, since $\|\mathbf{y}\|_q > 0$; in particular $\mathbf{x} \neq \mathbf{0}$. Second, $\sum_i x_i y_i = \sum_i |x_i y_i|$, and since $x_i y_i \leq |x_i y_i|$ for each i, every $x_i y_i \geq 0$. Third, by (a), $|x_i|^p = |y_i|^q / \|\mathbf{y}\|_q^q$ for every i. Raising to the power $1/p$ and using $q/p = q - 1$, which follows from $\frac{1}{p} + \frac{1}{q} = 1$, gives $|x_i| = |y_i|^{q-1} / \|\mathbf{y}\|_q^{q-1}$. If $y_i = 0$, then $x_i = 0$, as in the formula. If $y_i \neq 0$, then $x_i \neq 0$ and $x_i y_i \geq 0$, so x_i has the sign σ_i of y_i. Hence $x_i = \sigma_i |y_i|^{q-1} / \|\mathbf{y}\|_q^{q-1}$ for every i, which is the vector of Theorem 17.11.6.

Chapter 18

Non-negative Matrices

Two chapters left debts that this one pays. Chapter 8 §11 found the long-run behavior of a Markov chain by diagonalizing its transition matrix, proved that the chain settles down under three hypotheses, that the transition matrix is diagonalizable, that 1 is a simple eigenvalue and that every other eigenvalue has modulus less than 1 (Theorem 8.11.4), and promised that "Chapter 18 proves the Perron–Frobenius theorem, which gives the conclusions of Theorem 8.11.4 for every stochastic matrix with some power having all entries positive, without assuming diagonalizability and without computing eigenvalues." Chapter 17 §08 stated Birkhoff's theorem, that the extreme points of the doubly stochastic matrices are exactly the permutation matrices, proved its two forms equivalent, and left the theorem itself to this chapter.

Both debts are about matrices whose entries are all ≥ 0, and the theory of such matrices is unlike anything earlier in the book. It depends on the **standard basis**: the hypothesis $\mathbf{A} \geq 0$ is destroyed by almost every change of basis, so the similarity invariants that organized Chapters 8 and 9 are joined by a new kind of information, the pattern of zero entries. What that pattern buys is striking. A matrix with every entry positive has a positive eigenvalue that is simple, strictly larger in modulus than every other eigenvalue, and equal to the spectral radius, with an eigenvector whose entries are all positive; this is Perron's theorem. When some entries are zero, most of this survives when the zeros do not split the indices into a part that the rest cannot reach, a condition read off a directed graph. From those two facts follow the convergence of Markov chains, the ranking of web pages, Birkhoff's theorem, and the theory of the matrices $s\mathbf{I} - \mathbf{B}$ with $\mathbf{B} \geq 0$ that arise in economics and in the discretization of differential equations.

The field is $\mathbb{R}$. Matrices and vectors have real entries, and a real matrix is read in $M_n(\mathbb{C})$ whenever its eigenvalues are wanted, as in Chapter 15 §04, so that its spectral radius $\rho(\mathbf{A})$ is defined (Definition 15.4.1). Two conventions hold throughout and are never switched.

- **Stochastic means column-stochastic.** As in Definition 8.11.1, a stochastic matrix has non-negative entries and every **column** adding up to 1, and a Markov chain is $\mathbf{x}_{k+1} = \mathbf{A}\mathbf{x}_k$. Many books use rows and multiply on the left; their stochastic matrices are the transposes of ours.
- **The order is entrywise.** $\mathbf{A} \geq 0$ means every entry of $\mathbf{A}$ is ≥ 0, and $\mathbf{A} > 0$ means every entry is > 0, as for vectors in Chapter 17 §05; §01 defines the matrix version (Definition 18.1.1). This is **not** the Loewner order of Chapter 12, which the book always writes $\mathbf{A} \succeq 0$. A positive matrix need not be positive definite, and a positive definite matrix need not be positive: §01 gives a 2×2 example of each.
- **The absolute value is entrywise.** In this chapter $|\mathbf{M}|$ is the matrix of the moduli $|m_{ij}|$ of the entries of $\mathbf{M}$ (Definition 18.1.1 (c)), **not** the absolute value $(\mathbf{A}^*\mathbf{A})^{1/2}$ of Chapter

12.

18.0.1 The analysis this chapter imports

The list is Chapter 15's, facts (A1)–(A6) of that chapter's introduction, cited by the same name at the point of use. Three of them carry the weight, together with the algebra of limits from the same introduction. In §01, **(A3)**, compactness of closed bounded sets, and **(A4)**, the extreme value theorem, produce the eigenvalue and positive eigenvector of Perron's theorem as a maximum that is attained rather than merely approached. The passage from positive to general non-negative matrices in §03 is a limit, and it uses **(A2)**, monotone convergence, together with (A3) again. Nothing else analytic is used, and a section that needs anything more says so where it uses it.

18.0.2 What you need

- **Chapter 0 §06** — the modulus of a complex number and the triangle inequality: Theorem 0.6.2, Theorem 0.6.4.
- **Chapter 2 §06** — permutation matrices, which relabel coordinates: Definition 2.6.2, Lemma 2.6.6.
- **Chapters 6 and 7** — the characteristic polynomial and block triangular matrices: Theorem 6.10.3, Theorem 6.8.4, Theorem 7.1.1.
- **Chapter 8** — eigenvalues and their multiplicities, invariant subspaces, left eigenvectors, the spectral mapping theorem, and the Markov chains this chapter returns to: Definition 8.3.1, Theorem 8.1.3, Definition 8.10.1, Proposition 8.10.5, Theorem 8.10.6, Theorem 8.10.1, Definition 8.11.1, Definition 8.11.2, Theorem 8.11.4.
- **Chapter 9** — generalized eigenspaces, and the convergence of matrix powers and of the Neumann series: Theorem 9.1.3, Theorem 9.10.4, Corollary 9.10.5, Theorem 9.10.6.
- **Chapter 12** — positive semidefinite and positive definite matrices, which the entrywise order must not be confused with: Definition 12.1.1.

18.0.3 Roadmap

- **Positive matrices and Perron's theorem.** The entrywise order, the monotonicity of the spectral radius, and Perron's theorem for matrices with every entry positive, proved by maximizing over the simplex.
- **Irreducibility and graphs.** The directed graph of a matrix, strong connectivity, irreducible matrices and the test $(\mathbf{I}+\mathbf{A})^{n-1}>0$, and the block triangular normal form of a

reducible matrix.

- **The Perron–Frobenius theorem.** Every non-negative matrix has its spectral radius as an eigenvalue with a non-negative eigenvector, and for an irreducible matrix that eigenvalue is simple with a positive eigenvector. The examples that show irreducibility cannot be dropped.
- **The Collatz–Wielandt formula.** The spectral radius of an irreducible matrix as a max–min and a min–max over test vectors, and the row-sum bounds that follow.
- **Primitive matrices.** Irreducible matrices with a positive power, the eigenvalues on the circle of radius ρ, and the convergence of $(\mathbf{A}/\rho)^k$ without any diagonalizability.
- **Markov chains.** Chapter 8's promise, paid in its own words; chains that are irreducible but not primitive, reducible chains, and absorbing chains.
- **Birkhoff's theorem.** Every extreme point of the doubly stochastic matrices is a permutation matrix, and a second proof of Schur's theorem.
- **PageRank.** The Google matrix is positive, so Perron's theorem ranks the pages, and the damping factor bounds the rate of convergence.
- **M-matrices.** The matrices $s\mathbf{I} - \mathbf{B}$ with $\mathbf{B} \geq 0$, their many equivalent characterizations, and two applications. The chapter's summary closes this section.

18.0.4 Named moves

- **Push up a slack.** If $\mathbf{Au} \geq r\mathbf{u}$ with r maximal, the slack $\mathbf{Au} - r\mathbf{u}$ must vanish: one more application of a positive matrix would make it strictly positive and leave room to increase r. Perron's proof makes this move once, in its push-up claim, and then uses the claim three times.
- **Pair a slack with a positive left eigenvector.** A non-negative vector whose product with a positive vector is zero is itself zero. This is how a positive left eigenvector rules out a second Jordan block, and a non-negative eigenvector for a smaller eigenvalue.
- **Read the powers as walks.** The non-zero entries of $\mathbf{A}^k$ record the walks of length k in a graph, so questions about positivity of powers become questions about reachability, answered by following arrows.
- **Relabel and rescale, nothing more.** The only changes of basis that respect the entry-wise order are the relabelings of the coordinates, possibly combined with positive rescalings, and every normal form in the chapter uses only these.
- **Perturb to positive, then take the limit.** To prove something for a non-negative matrix, prove it for $\mathbf{A} + \varepsilon\mathbf{J}$, which is positive, and let $\varepsilon \to 0$; what survives the limit is exactly the non-strict part of the conclusion.

18.1 Positive Matrices and Perron's Theorem

Chapter 8 §11 found the long-run behavior of a Markov chain by diagonalizing its transition matrix, and warned that nothing guaranteed the method would work. Chapter 15 §04 gave every square matrix a spectral radius, the largest modulus of an eigenvalue, but said nothing about whether that modulus is itself an eigenvalue. For a general matrix it need not be: the swap $\left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$ has spectral radius 1 and the eigenvalue -1 sitting on the circle beside it, and the rotation by a right angle has no real eigenvalue at all. This section shows that a single hypothesis on the **entries** removes every one of these difficulties: if every entry of $\mathbf{A}$ is positive, then $\rho(\mathbf{A})$ is an

eigenvalue, it is simple, it strictly dominates every other eigenvalue in modulus, and it has an eigenvector with positive entries. That is Perron's theorem, and the rest of the chapter extends it.

Throughout, matrices and vectors have real entries, except where complex eigenvectors appear. The eigenvalues of a real matrix are those of the same matrix read in $M_n(\mathbb{C})$, exactly as in Chapter 15 §04, so that $\rho(\mathbf{A})$ is defined (Definition 15.4.1) and eigenvectors may have complex entries.

18.1.1 The entrywise order

Chapter 17 §05 wrote $\mathbf{x} \geq \mathbf{0}$ for a real vector with every entry ≥ 0. The same comparison, made one entry at a time, makes sense for matrices of any shape, and it is the only order this chapter uses. Its hook is a recurring expression: every probability argument of Chapter 8 §11 began "the entries are non-negative, so each entry of the product is a sum of non-negative terms". We name the hypothesis once and prove its consequences once.

The entrywise order compares two matrices of the same shape position by position.

Definition 18.1.1 — Entrywise Order; Non-negative and Positive Matrices

Let $\mathbf{A} = (a_{ij})$ and $\mathbf{B} = (b_{ij})$ be real $m \times n$ matrices.

(a) $\mathbf{A} \geq \mathbf{B}$ means $a_{ij} \geq b_{ij}$ for **every** i, j, and $\mathbf{A} > \mathbf{B}$ means $a_{ij} > b_{ij}$ for **every** i, j. We write $\mathbf{B} \leq \mathbf{A}$ and $\mathbf{B} < \mathbf{A}$ for the same statements.

(b) $\mathbf{A}$ is **non-negative** if $\mathbf{A} \geq 0$, and **positive** if $\mathbf{A} > 0$, where 0 is the zero matrix of the same shape.

(c) For a complex $m \times n$ matrix $\mathbf{M} = (m_{ij})$, the **entrywise absolute value** is the real matrix $|\mathbf{M}| := (|m_{ij}|)$.

Vectors are the case $n = 1$, so $\mathbf{x} \geq \mathbf{0}$, $\mathbf{x} > \mathbf{0}$ and $|\mathbf{x}| = (|x_1|, \ldots, |x_n|)$ have the same meaning as in Chapter 17 §05.

In words: (a) compares every pair of corresponding entries, and asks for a strict inequality in **every** position in the strict version. So $\mathbf{A} > \mathbf{B}$ is much stronger than "$\mathbf{A} \geq \mathbf{B}$ and $\mathbf{A} \neq \mathbf{B}$", and the two must not be confused. Clause (b) is the special case $\mathbf{B} = 0$. Clause (c) takes the modulus of each entry separately; it has nothing to do with the absolute value $(\mathbf{A}^*\mathbf{A})^{1/2}$ of Chapter 12, and in this chapter $|\mathbf{M}|$ always means the entrywise one.

Some examples, simplest first.

- $\begin{pmatrix} 1 & 2 \\ 3 & 2 \end{pmatrix} > 0$: every entry is positive. This is the matrix of Example (Eigenvalues and Eigenspaces of a 2×2 Matrix).
- $\mathbf{I}_2 = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \geq 0$, but $\mathbf{I}_2$ is **not** positive, since its off-diagonal entries are 0. Every stochastic matrix (Definition 8.11.1) is non-negative, and so is every permutation matrix.
- **The degenerate cases.** The zero matrix is non-negative and not positive. A 1×1 matrix (a) is positive exactly when $a > 0$, and then everything this section proves reduces to the

statement that a is an eigenvalue of (a) with eigenvector (1). It is worth keeping in mind that every theorem below must survive $n = 1$.

- For $\mathbf{M} = \begin{pmatrix} 3 & -4i \\ 0 & -1 \end{pmatrix}$, $|\mathbf{M}| = \begin{pmatrix} 3 & 4 \\ 0 & 1 \end{pmatrix}$.

Non-example by minimal change. Take the positive matrix $\begin{pmatrix} 1 & 2 \\ 3 & 2 \end{pmatrix}$ and change its $(1,2)$ entry to 0. The result $\begin{pmatrix} 1 & 0 \\ 3 & 2 \end{pmatrix}$ is still non-negative and still $\geq \mathbf{I}_2$, but it is not positive: the clause "**every** entry > 0" fails in one position. That one zero is enough to lose a conclusion of this section. The new matrix is triangular, with eigenvalues 1 and 2. Its eigenvectors for 2 are the multiples of $\mathbf{e}_2$, and those for 1 the multiples of $(1, -3)$. So the dominant eigenvalue 2 has a non-negative eigenvector, but **no** positive one. Perron's theorem below says this cannot happen for a positive matrix.

> *Warning.* **Positive is not positive definite, and positive definite is not positive.** The two words sound alike and measure different things. The entrywise order looks at entries; positive definiteness (Definition 12.1.1) looks at the quadratic form. The matrix $\begin{pmatrix} 1 & 2 \\ 2 & 1 \end{pmatrix}$ is positive, and symmetric, but its eigenvalues are 3 and -1, so it is not positive definite: $\mathbf{x} = (1, -1)$ gives $\mathbf{x}^\top \mathbf{A}\mathbf{x} = -2$. The matrix $\begin{pmatrix} 2 & -1 \\ -1 & 2 \end{pmatrix}$ is positive definite, with eigenvalues 1 and 3, but it has negative entries, so it is not even non-negative. In this book $\mathbf{A} \geq 0$ and $\mathbf{A} > 0$ always mean the entrywise order, and the Loewner order is always written $\mathbf{A} \succeq 0$, $\mathbf{A} \succ 0$.

Why this definition. The order is entrywise because the only operations the theory needs are sums and products of entries, and a sum or product of non-negative numbers is non-negative. The hypothesis is not coordinate-free: a change of basis destroys it at once. That is also why this chapter, unlike most of the book, cares about the **standard** basis: the hypothesis $\mathbf{A} \geq 0$ is a statement about the matrix, not about the operator $T_{\mathbf{A}}$. The only changes of basis that preserve it are the ones that rearrange coordinates and rescale them by positive numbers, and §02 uses the first kind throughout.

The first facts are the ones used in every argument below. They are the three rules of arithmetic with non-negative numbers, carried to matrices.

Lemma 18.1.1 — Rules of the Entrywise Order

Let $\mathbf{A}, \mathbf{B} \in M_{m\times n}(\mathbb{R})$, $\mathbf{C}, \mathbf{D} \in M_{n\times p}(\mathbb{R})$ and $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$.

(a) If $0 \leq \mathbf{A} \leq \mathbf{B}$ and $\mathbf{0} \leq \mathbf{x} \leq \mathbf{y}$, then $\mathbf{0} \leq \mathbf{A}\mathbf{x} \leq \mathbf{B}\mathbf{y}$.

(b) If $\mathbf{A} > 0$, $\mathbf{x} \geq \mathbf{0}$ and $\mathbf{x} \neq \mathbf{0}$, then $\mathbf{A}\mathbf{x} > \mathbf{0}$.

(c) If $0 \leq \mathbf{A} \leq \mathbf{B}$ and $0 \leq \mathbf{C} \leq \mathbf{D}$, then $0 \leq \mathbf{A}\mathbf{C} \leq \mathbf{B}\mathbf{D}$. In particular, for square $0 \leq \mathbf{A} \leq \mathbf{B}$, $0 \leq \mathbf{A}^k \leq \mathbf{B}^k$ for every $k \geq 0$.

> *Idea.* Each entry of a product is a sum of products of entries, so every rule comes down to the arithmetic of non-negative numbers. For the comparison in (a), write $\mathbf{B}\mathbf{y} - \mathbf{A}\mathbf{x}$ as a sum of two products of non-negative factors; for (b), one positive term in a sum of non-negative terms is enough; and (c) is (a) applied one column at a time.

Proof.

(a) Each entry $(\mathbf{Ax})_i = \sum_j a_{ij}x_j$ is a sum of products of non-negative numbers, so $\mathbf{Ax} \geq \mathbf{0}$. Next, $\mathbf{By} - \mathbf{Ax} = \mathbf{B}(\mathbf{y}-\mathbf{x}) + (\mathbf{B}-\mathbf{A})\mathbf{x}$, and both terms are non-negative by what was just shown, because $\mathbf{B} \geq 0$, $\mathbf{y} - \mathbf{x} \geq \mathbf{0}$, $\mathbf{B} - \mathbf{A} \geq 0$ and $\mathbf{x} \geq \mathbf{0}$.

(b) Since $\mathbf{x} \neq \mathbf{0}$ and $\mathbf{x} \geq \mathbf{0}$, some entry x_k is positive. For every i, $(\mathbf{Ax})_i = \sum_j a_{ij}x_j \geq a_{ik}x_k > 0$, because the other terms are ≥ 0 and $a_{ik} > 0$.

(c) By Theorem 0.9.2, column l of $\mathbf{AC}$ is $\mathbf{Ac}_l$, where $\mathbf{c}_l$ is column l of $\mathbf{C}$, and likewise for $\mathbf{BD}$. Since $\mathbf{0} \leq \mathbf{c}_l \leq \mathbf{d}_l$, part (a) gives $\mathbf{0} \leq \mathbf{Ac}_l \leq \mathbf{Bd}_l$ for every l. The statement about powers follows by induction on k: $\mathbf{A}^0 = \mathbf{B}^0 = \mathbf{I}$, and $\mathbf{A}^{k+1} = \mathbf{A}^k\mathbf{A} \leq \mathbf{B}^k\mathbf{B} = \mathbf{B}^{k+1}$ by the case just proved.

■

The absolute value interacts with products through the triangle inequality, which is the second tool.

Lemma 18.1.2 — Absolute Value of a Product

Let $\mathbf{A} \in M_{m\times n}(\mathbb{C})$, $\mathbf{B} \in M_{n\times p}(\mathbb{C})$ and $\mathbf{x} \in \mathbb{C}^n$. Then

(a) $|\mathbf{Ax}| \leq |\mathbf{A}|\,|\mathbf{x}|$;

(b) $|\mathbf{AB}| \leq |\mathbf{A}|\,|\mathbf{B}|$;

(c) if $m = n$, then $|\mathbf{A}^k| \leq |\mathbf{A}|^k$ for every $k \geq 0$.

Idea. Each entry of $\mathbf{Ax}$ is a sum of products, and the triangle inequality bounds its modulus by the sum of the moduli of the products: that is (a). Then (b) is (a) one column at a time, and (c) follows from (b) by induction on k, with the order rules to replace $|\mathbf{A}^k|$ by the larger $|\mathbf{A}|^k$.

Proof.

(a) For each i, the triangle inequality (Theorem 0.6.4, extended to finitely many terms by induction) and the multiplicativity of the modulus (Theorem 0.6.2 (d)) give

$$|(\mathbf{Ax})_i| = \Big|\sum_j a_{ij}x_j\Big| \leq \sum_j |a_{ij}|\,|x_j| = \big(|\mathbf{A}|\,|\mathbf{x}|\big)_i.$$

(b) Apply (a) to each column of $\mathbf{B}$, using Theorem 0.9.2 as in the previous proof.

(c) Induction on k. For $k = 0$, $|\mathbf{I}| = \mathbf{I}$. If $|\mathbf{A}^k| \leq |\mathbf{A}|^k$, then by (b) and Lemma 18.1.1 (c),

$$|\mathbf{A}^{k+1}| = |\mathbf{A}^k\mathbf{A}| \leq |\mathbf{A}^k|\,|\mathbf{A}| \leq |\mathbf{A}|^k|\mathbf{A}| = |\mathbf{A}|^{k+1}.$$

This proves the lemma.

■

For a non-negative $\mathbf{A}$ we have $|\mathbf{A}| = \mathbf{A}$, and (a) reads $|\mathbf{Ax}| \leq \mathbf{A}|\mathbf{x}|$. That is the form used below: whatever cancellation happens inside $\mathbf{Ax}$ can only make it smaller.

The proof of Perron's theorem also needs to know when the triangle inequality is an equality, a case Chapter 0 did not record. The answer is the expected one: when all the terms point in the same direction.

Lemma 18.1.3 — Equality in the Triangle Inequality

Let $z_1, \dots, z_m \in \mathbb{C}$, put $s = z_1 + \cdots + z_m$, and suppose $|s| = |z_1| + \cdots + |z_m|$ and $s \neq 0$. Then $z_j = |z_j|\, c$ for every j, where $c = s/|s|$ has $|c| = 1$.

Idea. Rotate the sum onto the positive real axis: multiplying by $d = \overline{s}/|s|$ turns s into the real number $|s|$. Then $|s|$ is the real part of $\sum_j dz_j$, which is at most $\sum_j |z_j|$ term by term. Equality of the totals forces equality in every term, and a complex number whose real part equals its modulus is a real number ≥ 0.

Proof. Recall from the proof of Theorem 0.6.4 that $\operatorname{Re} u = x \leq |x| \leq \sqrt{x^2 + y^2} = |u|$ for $u = x + yi$. Equality $\operatorname{Re} u = |u|$ forces equality in both steps, that is $y^2 = 0$ and $x = |x|$, so u is a real number ≥ 0 and $u = |u|$.

Put $d = \overline{s}/|s|$. Then $|d| = 1$ and $ds = |s|^2/|s| = |s|$ by Theorem 0.6.2 (c), (d). Hence

$$\sum_j |z_j| = |s| = ds = \operatorname{Re} \sum_j dz_j = \sum_j \operatorname{Re}(dz_j) \leq \sum_j |dz_j| = \sum_j |z_j|.$$

So the inequality in the middle is an equality. It is a sum of the inequalities $\operatorname{Re}(dz_j) \leq |dz_j|$, so each of them is an equality, and by the first paragraph $dz_j = |dz_j| = |z_j|$. Multiplying by $c = s/|s|$, which satisfies $cd = s\overline{s}/|s|^2 = 1$, gives $z_j = |z_j|\, c$.

■

18.1.2 The spectral radius is monotone

A first payoff joins the entrywise order to Chapter 15. Enlarging the entries of a non-negative matrix should not shrink its eigenvalues, and for the spectral radius this is true.

Proposition 18.1.4 — Monotonicity of the Spectral Radius

(a) If $\mathbf{A}, \mathbf{B} \in M_n(\mathbb{R})$ and $0 \leq \mathbf{A} \leq \mathbf{B}$, then $\rho(\mathbf{A}) \leq \rho(\mathbf{B})$.

(b) More generally, if $\mathbf{A} \in M_n(\mathbb{C})$, $\mathbf{B} \in M_n(\mathbb{R})$ and $|\mathbf{A}| \leq \mathbf{B}$, then $\rho(\mathbf{A}) \leq \rho(|\mathbf{A}|) \leq \rho(\mathbf{B})$.

Idea. Eigenvalues do not see the entries directly, but Gelfand's formula (Theorem 15.4.4) expresses ρ through the norms of the powers, and the largest absolute row sum $\|\cdot\|_\infty$ is a norm that does see the entries, monotonically. So compare the powers entrywise, take norms, take k-th roots and pass to the limit.

Proof.

(b) First, $|\mathbf{A}^k| \leq |\mathbf{A}|^k \leq \mathbf{B}^k$ for every $k \geq 1$: the first inequality is Lemma 18.1.2 (c), and the second is Lemma 18.1.1 (c) applied to $0 \leq |\mathbf{A}| \leq \mathbf{B}$. By Theorem 15.3.3

(b), $\|\mathbf{M}\|_\infty$ is the largest absolute row sum of $\mathbf{M}$, so it depends only on $|\mathbf{M}|$ and does not decrease when the entries of $|\mathbf{M}|$ increase. Hence

$$\|\mathbf{A}^k\|_\infty \le \||\mathbf{A}|^k\|_\infty \le \|\mathbf{B}^k\|_\infty \qquad (k \ge 1).$$

The k-th root is increasing on the non-negative reals, so the same inequalities hold between the k-th roots. The operator norm $\|\cdot\|_\infty$ is a matrix norm (Theorem 15.3.2 (d)), so by Theorem 15.4.4 the three sequences of k-th roots converge to $\rho(\mathbf{A})$, $\rho(|\mathbf{A}|)$ and $\rho(\mathbf{B})$. A non-strict inequality survives a limit, which gives $\rho(\mathbf{A}) \le \rho(|\mathbf{A}|) \le \rho(\mathbf{B})$.

(c) If $0 \le \mathbf{A} \le \mathbf{B}$, then $|\mathbf{A}| = \mathbf{A}$, and (b) gives $\rho(\mathbf{A}) \le \rho(\mathbf{B})$.

■

The inequality need not be strict, even when $\mathbf{A} \ne \mathbf{B}$: $\operatorname{diag}(1,0) \le \mathbf{I}_2$ and both have spectral radius 1. For positive matrices it is strict, which is Exercise C3. The hypothesis $0 \le \mathbf{A}$ cannot be dropped from (a): $\operatorname{diag}(-3,0) \le 0$ entrywise, yet $\rho(\operatorname{diag}(-3,0)) = 3 > 0 = \rho(0)$.

Example. (Enlarging one entry)

Let $\mathbf{A} = \begin{pmatrix} 1 & 2 \\ 1 & 0 \end{pmatrix}$ and $\mathbf{B} = \begin{pmatrix} 1 & 2 \\ 1 & 1 \end{pmatrix}$. Compute both spectral radii and compare with Proposition 18.1.4.

Solution. $0 \le \mathbf{A} \le \mathbf{B}$, with a difference only in the $(2,2)$ entry. By the 2×2 formula $p(x) = x^2 - (\operatorname{tr})x + \det$, $p_{\mathbf{A}}(x) = x^2 - x - 2 = (x-2)(x+1)$, so $\rho(\mathbf{A}) = 2$, and $p_{\mathbf{B}}(x) = x^2 - 2x - 1$, with roots $1 \pm \sqrt{2}$, so $\rho(\mathbf{B}) = 1 + \sqrt{2} \approx 2.414$. Indeed $\rho(\mathbf{A}) \le \rho(\mathbf{B})$. In both cases the eigenvalue of largest modulus is positive, which Perron's theorem below guarantees for the positive $\mathbf{B}$.

18.1.3 Perron's theorem

Here is the theorem this section is built around.

Theorem 18.1.5 — Perron's Theorem

Let $n \ge 1$ and let $\mathbf{A} \in M_n(\mathbb{R})$ be **positive**, $\mathbf{A} > 0$. Write $r = \rho(\mathbf{A})$. Then:

(a) $r > 0$, and r is an eigenvalue of $\mathbf{A}$ with an eigenvector $\mathbf{v} > \mathbf{0}$;

(b) r is **algebraically simple**: $a_{\mathbf{A}}(r) = 1$. In particular $E_r(\mathbf{A}) = \operatorname{span}(\mathbf{v})$;

(c) every eigenvalue $\lambda \in \mathbb{C}$ of $\mathbf{A}$ with $\lambda \ne r$ satisfies $|\lambda| < r$;

(d) every non-negative eigenvector of $\mathbf{A}$ is a positive multiple of $\mathbf{v}$. In particular, no eigenvector of $\mathbf{A}$ for an eigenvalue other than r is non-negative;

(e) $\mathbf{A}^\top$ is positive with $\rho(\mathbf{A}^\top) = r$, so (a)–(d) hold for $\mathbf{A}^\top$: there is $\mathbf{w} > \mathbf{0}$ with $\mathbf{w}^\top \mathbf{A} = r\mathbf{w}^\top$.

The route. There are several proofs of Perron's theorem. We take the one that finds r

as the answer to an optimization problem: **how large can t be if $\mathbf{Ax} \geq t\mathbf{x}$ for some probability vector $\mathbf{x}$?** Its advantage is that it produces the positive eigenvector and the eigenvalue together, and that compactness is used exactly once. The quotient form of this question, maximizing $\min_i (\mathbf{Ax})_i / x_i$ over $\mathbf{x} \in \Delta_n$, is the Collatz–Wielandt formula, which §04 develops for all irreducible matrices.

The quotient itself is awkward on the boundary of the simplex. Where some $x_i = 0$, the i-th ratio is undefined, and the natural repair, taking the minimum over the indices with $x_i > 0$ only, gives a function that need not be continuous. For $\mathbf{D} = \operatorname{diag}(2, 1)$ that function takes the value 2 at the corner $\mathbf{e}_1$, where only the first ratio counts, but the value $\min(2, 1) = 1$ at every point $(1 - t, t)$ with $0 < t < 1$. So the extreme value theorem cannot be applied to it as it stands. (For positive $\mathbf{A}$ the repaired function is in fact continuous, but proving that costs more than the route below; for the non-negative matrices of §04 it can genuinely fail.) We avoid the quotient: instead of maximizing a function on Δ_n, we maximize the coordinate t over the set of pairs $(\mathbf{x}, t)$ with $\mathbf{Ax} \geq t\mathbf{x}$, which is closed, and on which t is continuous.

> *Idea.* **Step roadmap.** ① The set $S = \{(\mathbf{x}, t) : \mathbf{x} \in \Delta_n,\ t \geq 0,\ \mathbf{Ax} \geq t\mathbf{x}\}$ is compact, so t attains a maximum r on it: facts (A3) and (A4) of Chapter 15's introduction. ② **Push-up claim:** if $\mathbf{u} \geq \mathbf{0}$, $\mathbf{u} \neq \mathbf{0}$ and $\mathbf{Au} \geq r\mathbf{u}$, then $\mathbf{Au} = r\mathbf{u}$ and $\mathbf{u} > \mathbf{0}$. Otherwise one more application of the positive matrix $\mathbf{A}$ turns the slack $\mathbf{Au} - r\mathbf{u}$ into a **strict** inequality, and a strict inequality leaves room to increase r, contradicting maximality. The maximizer therefore gives the positive eigenvector. ③ For any eigenvalue λ with eigenvector $\mathbf{x}$, $|\lambda||\mathbf{x}| \leq \mathbf{A}|\mathbf{x}|$, so $|\lambda| \leq r$ by maximality; hence $r = \rho(\mathbf{A})$. ④ If $|\lambda| = r$, the push-up claim forces equality in the triangle inequality, which aligns all entries of $\mathbf{x}$ and gives $\lambda = r$. ⑤ Subtract a multiple of $\mathbf{v}$ until an entry vanishes: the push-up claim leaves nothing, so $E_r(\mathbf{A})$ is a line. ⑥ Steps ①–⑤ for $\mathbf{A}^\top$ give a positive $\mathbf{w}$ with $\mathbf{A}^\top\mathbf{w} = \rho(\mathbf{A}^\top)\mathbf{w}$, and pairing with $\mathbf{v}$ shows $\rho(\mathbf{A}^\top) = r$. A second vector in the generalized eigenspace would give $(\mathbf{A} - r\mathbf{I})\mathbf{y} = \mathbf{v}$, and pairing with $\mathbf{w}$ yields $0 = \mathbf{w}^\top\mathbf{v} > 0$. ⑦ A non-negative eigenvector for $\lambda \neq r$ would be orthogonal to $\mathbf{w} > \mathbf{0}$, which is impossible.

Here is the proof, following the roadmap.

> *Proof.* Let $\mathbf{A} > 0$ be $n \times n$. By Definition 17.1.2, Δ_n is the set of probability vectors in $\mathbb{R}^n$. Define
>
> $$S = \big\{(\mathbf{x}, t) \in \mathbb{R}^n \times \mathbb{R} : \mathbf{x} \in \Delta_n,\ t \geq 0,\ \mathbf{Ax} \geq t\mathbf{x}\big\}.$$
>
> **Step 1: a maximal t.** S is non-empty: it contains $(\mathbf{x}, 0)$ for every $\mathbf{x} \in \Delta_n$, by Lemma 18.1.1 (a).
>
> S is bounded for the Euclidean norm on $\mathbb{R}^{n+1}$, the norm with which (A3) is stated. Let M be the largest entry of $\mathbf{A}$. If $(\mathbf{x}, t) \in S$, then $0 \leq x_i \leq 1$ for every i, and since the n entries of $\mathbf{x}$ add up to 1, some $x_k \geq 1/n$. Then
>
> $$\frac{t}{n} \leq t\, x_k \leq (\mathbf{Ax})_k = \sum_j a_{kj} x_j \leq M \sum_j x_j = M,$$
>
> so $0 \leq t \leq nM$. Hence $\|(\mathbf{x}, t)\|_2^2 = \sum_i x_i^2 + t^2 \leq n + (nM)^2$, and $\|(\mathbf{x}, t)\|_2 \leq \sqrt{n} + nM$.
>
> S is closed in $\mathbb{R}^{n+1}$ (Definition 17.1.6). Let $(\mathbf{x}_k, t_k) \in S$ converge to $(\mathbf{x}, t)$ in the Euclidean norm. Then each coordinate converges, since $|u_i| \leq \|\mathbf{u}\|_2$ for every $\mathbf{u} \in \mathbb{R}^{n+1}$. Every condition defining S is a finite list of non-strict inequalities and one equation between expressions built from the entries by sums and products: $x_i \geq 0$, $\sum_i x_i = 1$, $t \geq 0$, and

$(\mathbf{Ax})_i - t\,x_i \geq 0$. Each holds for every $(\mathbf{x}_k, t_k)$, and by the algebra of limits of Chapter 15's introduction each survives the limit. So $(\mathbf{x}, t) \in S$.

By fact (A3) of Chapter 15's introduction, the closed bounded set $S \subseteq \mathbb{R}^{n+1}$ is compact, and the function $(\mathbf{x}, t) \mapsto t$ is continuous on it. By fact (A4), the extreme value theorem, it attains a maximum: there are $\mathbf{z} \in \Delta_n$ and a largest number r such that

$$\mathbf{Az} \geq r\mathbf{z}, \qquad \text{and } t \leq r \text{ for every } (\mathbf{x}, t) \in S.$$

Moreover $r > 0$. Indeed, let s be the smallest row sum of $\mathbf{A}$, which is positive as $\mathbf{A} > 0$. The vector $\mathbf{x} = \frac{1}{n}\mathbf{1} \in \Delta_n$ satisfies $(\mathbf{Ax})_i = \frac{1}{n}\sum_j a_{ij} \geq \frac{s}{n} = s\,x_i$, so $(\frac{1}{n}\mathbf{1}, s) \in S$ and $r \geq s > 0$.

Step 2: the push-up claim.

Claim. If $\mathbf{u} \in \mathbb{R}^n$, $\mathbf{u} \geq \mathbf{0}$, $\mathbf{u} \neq \mathbf{0}$ and $\mathbf{Au} \geq r\mathbf{u}$, then $\mathbf{Au} = r\mathbf{u}$ and $\mathbf{u} > \mathbf{0}$.

Proof. Suppose $\mathbf{Au} \neq r\mathbf{u}$. Then $\mathbf{y} = \mathbf{Au} - r\mathbf{u}$ satisfies $\mathbf{y} \geq \mathbf{0}$ and $\mathbf{y} \neq \mathbf{0}$, so $\mathbf{Ay} > \mathbf{0}$ by Lemma 18.1.1 (b). Put $\mathbf{q} = \mathbf{Au}$; by the same rule $\mathbf{q} > \mathbf{0}$, and

$$\mathbf{Aq} - r\mathbf{q} = \mathbf{A}(\mathbf{Au} - r\mathbf{u}) = \mathbf{Ay} > \mathbf{0}.$$

Every $q_i > 0$, so $\varepsilon = \min_i (\mathbf{Ay})_i / q_i$ is defined and positive, and $(\mathbf{Aq})_i - r\,q_i = (\mathbf{Ay})_i \geq \varepsilon q_i$ for every i, that is, $\mathbf{Aq} \geq (r+\varepsilon)\mathbf{q}$. Let $\sigma = q_1 + \cdots + q_n > 0$ and $\mathbf{x} = \mathbf{q}/\sigma$. Then $\mathbf{x} \in \Delta_n$, and dividing by $\sigma > 0$ preserves the inequality, so $\mathbf{Ax} \geq (r+\varepsilon)\mathbf{x}$. Hence $(\mathbf{x}, r+\varepsilon) \in S$, which contradicts the maximality of r. Therefore $\mathbf{Au} = r\mathbf{u}$. Finally $\mathbf{Au} > \mathbf{0}$ by Lemma 18.1.1 (b), and $r > 0$, so $\mathbf{u} = r^{-1}\mathbf{Au} > \mathbf{0}$. ∎

Apply the claim to $\mathbf{u} = \mathbf{z}$, which is non-negative and non-zero because its entries add up to 1. It gives $\mathbf{Az} = r\mathbf{z}$ with $\mathbf{z} > \mathbf{0}$. Put $\mathbf{v} = \mathbf{z}$. So r is an eigenvalue of $\mathbf{A}$ with a positive eigenvector.

Step 3: $r = \rho(\mathbf{A})$. Let $\lambda \in \mathbb{C}$ be an eigenvalue of $\mathbf{A}$ and $\mathbf{x} \in \mathbb{C}^n$ an eigenvector for it. By Theorem 0.6.2 (d) and Lemma 18.1.2 (a), with $|\mathbf{A}| = \mathbf{A}$,

$$|\lambda|\,|\mathbf{x}| = |\lambda\mathbf{x}| = |\mathbf{Ax}| \leq \mathbf{A}|\mathbf{x}|.$$

The vector $|\mathbf{x}|$ is non-negative and non-zero, since $\mathbf{x} \neq \mathbf{0}$. Dividing by the sum $\sigma > 0$ of its entries, $\mathbf{x}' = |\mathbf{x}|/\sigma \in \Delta_n$ satisfies $\mathbf{Ax}' \geq |\lambda|\mathbf{x}'$, so $(\mathbf{x}', |\lambda|) \in S$ and $|\lambda| \leq r$. Since r is itself an eigenvalue, $r = \max\{|\lambda| : \lambda \in \operatorname{spec}(\mathbf{A})\} = \rho(\mathbf{A})$ (Definition 15.4.1). This proves (a).

Step 4: eigenvalues of modulus r. Let λ be an eigenvalue with $|\lambda| = r$, and $\mathbf{x}$ an eigenvector. The display of Step 3 reads $\mathbf{A}|\mathbf{x}| \geq r|\mathbf{x}|$, so the push-up claim applies to $|\mathbf{x}|$ and gives

$$\mathbf{A}|\mathbf{x}| = r|\mathbf{x}| \quad \text{and} \quad |\mathbf{x}| > \mathbf{0}.$$

Hence $|\mathbf{Ax}| = |\lambda||\mathbf{x}| = r|\mathbf{x}| = \mathbf{A}|\mathbf{x}|$. Read the first entry: with $z_j = a_{1j}x_j$,

$$\Big|\sum_j z_j\Big| = |(\mathbf{Ax})_1| = (\mathbf{A}|\mathbf{x}|)_1 = \sum_j a_{1j}|x_j| = \sum_j |z_j|,$$

and $\sum_j z_j = (\mathbf{A}\mathbf{x})_1 = \lambda x_1 \neq 0$, because $|\lambda x_1| = r|x_1| > 0$. By Lemma 18.1.3 there is $c \in \mathbb{C}$ with $|c| = 1$ and $a_{1j}x_j = a_{1j}|x_j|\,c$ for every j. Since $a_{1j} > 0$, we may divide: $x_j = c|x_j|$, that is, $\mathbf{x} = c|\mathbf{x}|$. Therefore

$$\lambda\mathbf{x} = \mathbf{A}\mathbf{x} = c\,\mathbf{A}|\mathbf{x}| = c\,r|\mathbf{x}| = r\mathbf{x},$$

and as $\mathbf{x} \neq \mathbf{0}$, $\lambda = r$. So every eigenvalue other than r has modulus $< r$, by Step 3. This proves (c). We record what the step showed for $\lambda = r$ itself: **every eigenvector $\mathbf{x}$ for r has the form $c|\mathbf{x}|$ with $|c| = 1$, $|\mathbf{x}| > \mathbf{0}$ and $\mathbf{A}|\mathbf{x}| = r|\mathbf{x}|$.**

Step 5: $E_r(\mathbf{A}) = \operatorname{span}(\mathbf{v})$. Let $\mathbf{x}$ be an eigenvector for r, and write $\mathbf{x} = c\,\mathbf{u}$ with $\mathbf{u} = |\mathbf{x}| > \mathbf{0}$ and $\mathbf{A}\mathbf{u} = r\mathbf{u}$, as just recorded. Let $\theta = \min_i u_i/v_i$, which is positive, and put $\mathbf{y} = \mathbf{u} - \theta\mathbf{v}$. Then $\mathbf{y}$ is real, $\mathbf{y} \geq \mathbf{0}$ by the choice of θ, $y_i = 0$ for an index i attaining the minimum, and $\mathbf{A}\mathbf{y} = r\mathbf{y}$. If $\mathbf{y} \neq \mathbf{0}$, the push-up claim would give $\mathbf{y} > \mathbf{0}$, contradicting $y_i = 0$. So $\mathbf{y} = \mathbf{0}$, and $\mathbf{x} = c\theta\,\mathbf{v} \in \operatorname{span}(\mathbf{v})$. Hence $E_r(\mathbf{A}) = \operatorname{span}(\mathbf{v})$ and $g_{\mathbf{A}}(r) = 1$.

Step 6: $a_{\mathbf{A}}(r) = 1$. First a positive left eigenvector. $\mathbf{A}^\top$ is positive, since it has the same entries, and Steps 1–5 used nothing about $\mathbf{A}$ but its positivity. Applied to $\mathbf{A}^\top$, they give $\mathbf{w} > \mathbf{0}$ with $\mathbf{A}^\top\mathbf{w} = r'\mathbf{w}$, where $r' = \rho(\mathbf{A}^\top)$. By Theorem 0.9.5, $(\mathbf{A}^\top\mathbf{w})^\top = \mathbf{w}^\top\mathbf{A}$, so

$$r'\,\mathbf{w}^\top\mathbf{v} = (\mathbf{A}^\top\mathbf{w})^\top\mathbf{v} = \mathbf{w}^\top\mathbf{A}\mathbf{v} = r\,\mathbf{w}^\top\mathbf{v}.$$

Here $\mathbf{w}^\top\mathbf{v} = \sum_i w_i v_i > 0$, because every term is positive, so $r' = r$. Hence $\rho(\mathbf{A}^\top) = r$ and $\mathbf{w}^\top\mathbf{A} = r\mathbf{w}^\top$.

Now suppose $a_{\mathbf{A}}(r) \geq 2$. The characteristic polynomial splits over $\mathbb{C}$ (Corollary 5.5.5), so Theorem 9.1.3 (c) applies to $\mathbf{A} \in M_n(\mathbb{C})$ and gives $\dim G_r(\mathbf{A}) = a_{\mathbf{A}}(r) \geq 2 > 1 = \dim E_r(\mathbf{A})$. Choose $\mathbf{x} \in G_r(\mathbf{A})$ with $\mathbf{x} \notin E_r(\mathbf{A})$, put $\mathbf{N} = \mathbf{A} - r\mathbf{I}$, and let $k \geq 1$ be least with $\mathbf{N}^k\mathbf{x} = \mathbf{0}$, which exists by Definition 9.1.2 and Theorem 0.2.11. Since $\mathbf{N}\mathbf{x} \neq \mathbf{0}$, $k \geq 2$. Put $\mathbf{y} = \mathbf{N}^{k-2}\mathbf{x}$. Then $\mathbf{N}\mathbf{y} = \mathbf{N}^{k-1}\mathbf{x} \neq \mathbf{0}$ by the minimality of k, and $\mathbf{N}(\mathbf{N}\mathbf{y}) = \mathbf{N}^k\mathbf{x} = \mathbf{0}$. So $\mathbf{N}\mathbf{y}$ is an eigenvector for r, and by Step 5, $\mathbf{N}\mathbf{y} = b\mathbf{v}$ with $b \neq 0$. But $\mathbf{w}^\top\mathbf{N} = \mathbf{w}^\top\mathbf{A} - r\mathbf{w}^\top = \mathbf{0}^\top$, so

$$0 = (\mathbf{w}^\top\mathbf{N})\mathbf{y} = \mathbf{w}^\top(\mathbf{N}\mathbf{y}) = b\,\mathbf{w}^\top\mathbf{v}.$$

Since $\mathbf{w}^\top\mathbf{v} > 0$ and $b \neq 0$, this is a contradiction. Hence $a_{\mathbf{A}}(r) \leq 1$, and $a_{\mathbf{A}}(r) \geq 1$ because r is an eigenvalue. Together with Step 5 this proves (b).

Step 7: non-negative eigenvectors. Let $\mathbf{x} \geq \mathbf{0}$, $\mathbf{x} \neq \mathbf{0}$, be an eigenvector for an eigenvalue λ. If $\lambda \neq r$, then Theorem 8.10.6, applied over $\mathbb{C}$ to the left eigenvector $\mathbf{w}$ for r and the right eigenvector $\mathbf{x}$ for λ, gives $\mathbf{w}^\top\mathbf{x} = 0$. But $\mathbf{w}^\top\mathbf{x} > 0$ by Lemma 18.1.1 (b), applied to the positive $1 \times n$ matrix $\mathbf{w}^\top$. So $\lambda = r$, and by Step 5, $\mathbf{x} = \theta\mathbf{v}$ for a scalar θ. Comparing any entry, $\theta = x_i/v_i$ is real and ≥ 0, and it is not 0 because $\mathbf{x} \neq \mathbf{0}$. This proves (d).

Finally, (e): $\mathbf{A}^\top$ is positive, and Step 6 showed $\rho(\mathbf{A}^\top) = r$ by pairing with $\mathbf{v}$, so (a)–(d) hold for $\mathbf{A}^\top$ by what has been proved, with the positive eigenvector $\mathbf{w}$ of Step 6. This completes the proof.

■

Remark. **Which analysis was used.** Exactly two facts from Chapter 15's introduction, both in Step 1: (A3), that the closed bounded set S is compact, and (A4), that the

continuous function t attains its maximum on it, together with the algebra of limits from the same introduction, which showed that S is closed. Everything else is algebra: the order rules, the triangle inequality with its equality case, and the generalized eigenspaces of Chapter 9.

Two examples show what the theorem says.

Example. (Perron's theorem for Chapter 8's first example)

Check each part of Theorem 18.1.5 for $\mathbf{A} = \begin{pmatrix} 1 & 2 \\ 3 & 2 \end{pmatrix}$.

Solution. Example (Eigenvalues and Eigenspaces of a 2×2 Matrix) found $p_{\mathbf{A}}(x) = (x-4)(x+1)$, $E_4(\mathbf{A}) = \operatorname{span}((2,3))$ and $E_{-1}(\mathbf{A}) = \operatorname{span}((1,-1))$. So $r = \rho(\mathbf{A}) = 4 > 0$ is an eigenvalue, with the positive eigenvector $\mathbf{v} = (2,3)$: part (a). It is a simple root of $p_{\mathbf{A}}$: part (b). The other eigenvalue has $|-1| = 1 < 4$: part (c). Every eigenvector for -1 is $t(1,-1)$ with $t \neq 0$, which has entries of opposite signs, so none is non-negative: part (d). For (e), the columns of $\mathbf{A}$ both sum to 4, so $\mathbf{1}^{\top}\mathbf{A} = 4\,\mathbf{1}^{\top}$ and $\mathbf{w} = (1,1)$ is a positive left eigenvector for 4, as the text after Definition 8.10.1 already observed.

Example. (A positive 3×3 matrix)

Let $\mathbf{A} = \begin{pmatrix} 1 & 3 & 1 \\ 2 & 2 & 1 \\ 4 & 2 & 3 \end{pmatrix}$. Find its eigenvalues and eigenvectors, and its positive left eigenvector.

Solution. Try the three vectors $(1,1,2)$, $(-1,-1,3)$ and $(-5,2,4)$:

$$\mathbf{A}\begin{pmatrix} 1 \\ 1 \\ 2 \end{pmatrix} = \begin{pmatrix} 6 \\ 6 \\ 12 \end{pmatrix}, \qquad \mathbf{A}\begin{pmatrix} -1 \\ -1 \\ 3 \end{pmatrix} = \begin{pmatrix} -1 \\ -1 \\ 3 \end{pmatrix}, \qquad \mathbf{A}\begin{pmatrix} -5 \\ 2 \\ 4 \end{pmatrix} = \begin{pmatrix} 5 \\ -2 \\ -4 \end{pmatrix}.$$

So 6, 1 and -1 are eigenvalues. They are distinct, and a 3×3 matrix has at most three eigenvalues (Corollary 8.2.3), so these are all, each with algebraic multiplicity 1 because the multiplicities add up to 3 (Corollary 5.5.5 (a)). As checks, $\operatorname{tr}\mathbf{A} = 6 = 6 + 1 - 1$ and $\det\mathbf{A} = -6 = 6 \cdot 1 \cdot (-1)$. Hence $\rho(\mathbf{A}) = 6$, with the positive eigenvector $\mathbf{v} = (1,1,2)$, and the other two eigenvalues have modulus $1 < 6$. The eigenvectors for 1 and -1 are the non-zero multiples of $(-1,-1,3)$ and $(-5,2,4)$, and each has entries of both signs, as Theorem 18.1.5 (d) requires.

For the left eigenvector, solve $(\mathbf{A}^{\top} - 6\mathbf{I})\mathbf{w} = \mathbf{0}$. Row reduction gives $\mathbf{w} = (10,11,7)$, and indeed

$$\mathbf{w}^{\top}\mathbf{A} = \begin{pmatrix} 10+22+28 & 30+22+14 & 10+11+21 \end{pmatrix} = \begin{pmatrix} 60 & 66 & 42 \end{pmatrix} = 6\,\mathbf{w}^{\top}.$$

The left and right eigenvectors for $\rho(\mathbf{A})$ are unrelated in general; here $\mathbf{w}^{\top}\mathbf{v} = 10 + 11 + 14 = 35$ for $\mathbf{v} = (1,1,2)$. Definition 18.1.2 below scales them so that this pairing is 1.

Quick check. The swap $\mathbf{S} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$ is non-negative. Which conclusions of Theo-

rem 18.1.5 hold for $\mathbf{S}$, and which fail?

Solution. $\mathbf{S}$ has eigenvalues 1 and -1, with eigenvectors $(1,1)$ and $(1,-1)$. So $\rho(\mathbf{S}) = 1$ is an eigenvalue with a positive eigenvector, it is simple, and the only non-negative eigenvectors are the positive multiples of $(1,1)$: (a), (b), (d) and (e) hold. Part (c) fails, since $-1 \neq 1$ and $|-1| = 1 = \rho(\mathbf{S})$. The hypothesis that fails is $\mathbf{S} > 0$: two entries are 0. This is the matrix whose powers do not converge in the warning of Chapter 8 §11, and (c) is exactly what was missing there.

The positive eigenvector is so useful that it gets a name.

Definition 18.1.2 — Perron Root, Perron Vector

Let $\mathbf{A} \in M_n(\mathbb{R})$ be positive. The number $\rho(\mathbf{A})$ is the **Perron root** of $\mathbf{A}$. The **Perron vector** of $\mathbf{A}$ is the unique $\mathbf{v} > \mathbf{0}$ with $\mathbf{A}\mathbf{v} = \rho(\mathbf{A})\mathbf{v}$ and $v_1 + \cdots + v_n = 1$. The **left Perron vector** of $\mathbf{A}$ is the unique $\mathbf{w} > \mathbf{0}$ with $\mathbf{w}^\top \mathbf{A} = \rho(\mathbf{A})\mathbf{w}^\top$ and $\mathbf{w}^\top \mathbf{v} = 1$, where $\mathbf{v}$ is the Perron vector.

Existence and uniqueness are Theorem 18.1.5 (a) and (b): the eigenspace for $\rho(\mathbf{A})$ is a line through a positive vector, and it meets the hyperplane $\{\mathbf{1}^\top \mathbf{x} = 1\}$ in exactly one point, the vector $\mathbf{v}/(\mathbf{1}^\top \mathbf{v})$. By (d), the Perron vector is also the **only** eigenvector of $\mathbf{A}$ in Δ_n. Likewise, by (e) and (b) applied to $\mathbf{A}^\top$, the positive left eigenvectors for $\rho(\mathbf{A})$ are the positive multiples of one $\mathbf{w}_0 > \mathbf{0}$, and since $\mathbf{w}_0^\top \mathbf{v} > 0$, exactly one of them, $\mathbf{w}_0/(\mathbf{w}_0^\top \mathbf{v})$, pairs with the Perron vector to 1. The two normalizations differ on purpose: $\mathbf{v}$ is a probability vector, and $\mathbf{w}^\top \mathbf{v} = 1$ makes $\mathbf{v}\mathbf{w}^\top$ a projection, the limit of $(\mathbf{A}/\rho(\mathbf{A}))^k$ that §05 finds. For Example (Perron's theorem for Chapter 8's first example) the Perron vector is $\frac{1}{5}(2,3)$ and the left Perron vector is $(1,1)$, since $\mathbf{1}^\top \mathbf{v} = 1$. For Example (A positive 3×3 matrix) the Perron vector is $\frac{1}{4}(1,1,2)$, and the left Perron vector is $\frac{4}{35}(10,11,7)$, since $(10,11,7)$ pairs with $\frac{1}{4}(1,1,2)$ to $\frac{35}{4}$.

Warning. **Perron's theorem says nothing about the other eigenvalues except their size.** They may be negative, as -1 is in Example (Perron's theorem for Chapter 8's first example), or non-real: the positive matrix $\left(\begin{smallmatrix} 1 & 2 & 3 \\ 3 & 1 & 2 \\ 2 & 3 & 1 \end{smallmatrix}\right)$ has row sums 6, hence the eigenvector $\mathbf{1}$ for 6, and its other two eigenvalues are the roots of $x^2 + 3x + 3$, namely $\frac{-3 \pm i\sqrt{3}}{2}$, of modulus $\sqrt{3} < 6$. They may also be repeated, as the eigenvalue 1 of $\left(\begin{smallmatrix} 2 & 1 & 1 \\ 1 & 2 & 1 \\ 1 & 1 & 2 \end{smallmatrix}\right)$ is. Simplicity is claimed for $\rho(\mathbf{A})$ alone.

18.1.4 What positivity buys, and what it costs

Each hypothesis of Theorem 18.1.5 has a job, and it is instructive to see where it went. **Positivity** of $\mathbf{A}$ was used in the push-up claim, to turn a non-negative, non-zero slack into a strictly positive one; in Step 4, to divide by a_{1j}; and in Step 1, to make $r > 0$. For a matrix that is only non-negative, each of these uses fails, and so can each conclusion: Exercise C2 gives a non-negative 2×2 matrix for each of (a)–(d), and the swap of the Quick check is the one for (c).

§03 shows that one conclusion survives in general, that $\rho(\mathbf{A})$ is an eigenvalue with a non-negative eigenvector, and that most of the rest returns under a hypothesis much weaker than positivity. That hypothesis, **irreducibility**, is a condition on where the zero entries are, and §02 introduces

it.

Here is the payoff for Chapter 8. A stochastic matrix has $\mathbf{1}^\top \mathbf{A} = \mathbf{1}^\top$, so $\mathbf{1}$ is a positive left eigenvector for 1. If $\mathbf{A}$ is stochastic and positive, Theorem 18.1.5 (d) applied to $\mathbf{A}^\top$ says that $\mathbf{1}$ is a left eigenvector for $\rho(\mathbf{A})$ and for no other eigenvalue, so $\rho(\mathbf{A}) = 1$. Then (b) and (c) say that 1 is simple and every other eigenvalue has modulus less than 1: two of the three hypotheses of Theorem 8.11.4 hold automatically. The third, diagonalizability, is the one §06 removes.

18.1.5 Exercises

18.1.5.1 A. Check your understanding

Exercise A1.

(a) Define what it means for a real matrix to be **non-negative** and to be **positive**, and define $|\mathbf{M}|$ for a complex matrix $\mathbf{M}$.

(b) State Theorem 18.1.5.

(c) True or false: a positive symmetric matrix is positive definite. Justify your answer.

(d) True or false: a positive matrix has no negative eigenvalue. Justify your answer.

(e) True or false: if $0 \le \mathbf{A} \le \mathbf{B}$ and $\mathbf{A} \neq \mathbf{B}$, then $\rho(\mathbf{A}) < \rho(\mathbf{B})$. Justify your answer.

(f) In the proof of Theorem 18.1.5, which step uses compactness, and why is the quotient $\min_i (\mathbf{A}\mathbf{x})_i / x_i$ not maximized directly?

Solution.

(a) $\mathbf{A}$ is non-negative if every entry is ≥ 0, and positive if every entry is > 0 (Definition 18.1.1). $|\mathbf{M}|$ is the real matrix whose (i,j) entry is $|m_{ij}|$.

(b) If $\mathbf{A} \in M_n(\mathbb{R})$ and $\mathbf{A} > 0$, then $r = \rho(\mathbf{A}) > 0$ is an eigenvalue of $\mathbf{A}$ with a positive eigenvector $\mathbf{v}$; it is algebraically simple; every other eigenvalue has modulus less than r; every non-negative eigenvector is a positive multiple of $\mathbf{v}$; and the same holds for $\mathbf{A}^\top$, which gives a positive left eigenvector.

(c) False. $\begin{pmatrix} 1 & 2 \\ 2 & 1 \end{pmatrix}$ is positive and symmetric with the eigenvalue -1; the warning after Definition 18.1.1 computes $\mathbf{x}^\top \mathbf{A} \mathbf{x} = -2$ for $\mathbf{x} = (1, -1)$.

(d) False. $\begin{pmatrix} 1 & 2 \\ 3 & 2 \end{pmatrix}$ has the eigenvalue -1 (Example (Perron's theorem for Chapter 8's first example)). Perron's theorem controls only the modulus of the other eigenvalues.

(e) False. $\operatorname{diag}(1, 0) \le \mathbf{I}_2$, the two differ, and both have spectral radius 1.

(f) Step 1: the set S is closed and bounded, so by (A3) and (A4) the coordinate t attains a maximum on it. The quotient is undefined where some $x_i = 0$. For a non-negative matrix its natural repair can be discontinuous on the boundary of Δ_n (for $\operatorname{diag}(2, 1)$ it jumps at $\mathbf{e}_1$), so the extreme value theorem does not apply to it directly. For positive $\mathbf{A}$ the repair is in fact continuous, but proving that costs more than maximizing t over S.

18.1.5.2 B. Practice

Exercise B1: A Perron vector by hand.

Let $\mathbf{A} = \begin{pmatrix} 2 & 1 & 1 \\ 3 & 4 & 3 \\ 3 & 1 & 4 \end{pmatrix}$. Find the eigenvalues of $\mathbf{A}$, its Perron root, Perron vector and left Perron vector. Check that no eigenvector for the other eigenvalues is non-negative.

Solution. Expanding $\det(x\mathbf{I} - \mathbf{A})$ along the first row,

$$\begin{aligned} p_{\mathbf{A}}(x) &= (x-2)\big((x-4)^2 - 3\big) + \big(-3(x-4) - 9\big) - \big(3 + 3(x-4)\big) \\ &= x^3 - 10x^2 + 23x - 14 = (x-1)(x-2)(x-7). \end{aligned}$$

(Check: $\operatorname{tr}\mathbf{A} = 10$ and $\det\mathbf{A} = 14$.) So the eigenvalues are $7, 2, 1$, and $\rho(\mathbf{A}) = 7$. Solving $(\mathbf{A} - 7\mathbf{I})\mathbf{x} = \mathbf{0}$, whose first two rows are $-5x_1 + x_2 + x_3 = 0$ and $3x_1 - 3x_2 + 3x_3 = 0$, gives $\mathbf{x} = t(1,3,2)$; indeed $\mathbf{A}(1,3,2) = (7,21,14)$. The entries of $(1,3,2)$ add up to 6, so the Perron vector is $\frac{1}{6}(1,3,2)$.

For the left eigenvector, $(\mathbf{A}^\top - 7\mathbf{I})\mathbf{w} = \mathbf{0}$ gives the multiples of $(3,2,3)$, and $(3,2,3)\mathbf{A} = (21,14,21) = 7\,(3,2,3)$. Against the Perron vector, $(3,2,3)\cdot\frac{1}{6}(1,3,2) = \frac{15}{6} = \frac{5}{2}$, so by Definition 18.1.2 the left Perron vector is $\frac{2}{5}(3,2,3) = \left(\frac{6}{5}, \frac{4}{5}, \frac{6}{5}\right)$.

For 2: $(\mathbf{A} - 2\mathbf{I})\mathbf{x} = \mathbf{0}$ gives $\mathbf{x} = t(1,3,-3)$, since $\mathbf{A}(1,3,-3) = (2,6,-6)$. For 1: $\mathbf{x} = t(1,0,-1)$, since $\mathbf{A}(1,0,-1) = (1,0,-1)$. For $t \neq 0$ each has entries of both signs, so neither is non-negative, as Theorem 18.1.5 (d) predicts.

Exercise B2: Which order?.

For each matrix, decide whether it is non-negative, whether it is positive, and whether it is positive definite. Justify your answers, and say whether Theorem 18.1.5 applies.

(a) $\begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix}$

(b) $\begin{pmatrix} 1 & 3 \\ 3 & 1 \end{pmatrix}$

(c) $\begin{pmatrix} 2 & -1 \\ -1 & 2 \end{pmatrix}$

(d) $\begin{pmatrix} 1 & 0 \\ 2 & 3 \end{pmatrix}$

(e) $\begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix}$

Solution. For a real symmetric 2×2 matrix, positive definite means both eigenvalues are positive (Definition 12.1.1, with the spectral theorem).

(a) Positive, hence non-negative. Eigenvalues $3, 1$, both positive, so positive definite. Perron applies: $\rho = 3$ with eigenvector $(1,1)$.

(b) Positive, hence non-negative. Eigenvalues $4, -2$, so **not** positive definite. Perron applies: $\rho = 4$ with eigenvector $(1,1)$, and $|-2| < 4$.

(c) Not non-negative, since the off-diagonal entries are -1; so not positive, and Perron

does not apply. It is positive definite, with eigenvalues $1, 3$.

(d) Non-negative, not positive (the $(1,2)$ entry is 0), and not symmetric, so not positive definite by clause (P1). Perron does not apply, although here $\rho = 3$ is an eigenvalue with the eigenvector $\mathbf{e}_2 \geq \mathbf{0}$, which is not positive.

(e) Positive. Eigenvalues 2 and 0, so positive semidefinite but **not** positive definite, as $\mathbf{x} = (1, -1)$ gives $\mathbf{x}^\top \mathbf{A}\mathbf{x} = 0$. Perron applies: $\rho = 2$, eigenvector $(1, 1)$, and the eigenvalue 0 has modulus less than 2.

Exercise B3: Bounds from the smallest and largest entry.

(a) Show that $\rho(c\mathbf{J}) = nc$ for every real $c \geq 0$, where $\mathbf{J}$ is the $n \times n$ all-ones matrix.

(b) Let $\mathbf{A} \in M_n(\mathbb{R})$ with $a \leq a_{ij} \leq b$ for all i, j, where $0 \leq a \leq b$. Prove that $na \leq \rho(\mathbf{A}) \leq nb$.

(c) Hence bound $\rho(\mathbf{A})$ for $\mathbf{A} = \begin{pmatrix} 1 & 2 & 3 \\ 2 & 3 & 1 \\ 3 & 1 & 2 \end{pmatrix}$, and compare with its exact value.

Solution.

(a) $\mathbf{J}\mathbf{1} = n\mathbf{1}$, so n is an eigenvalue of $\mathbf{J}$. Also $\mathbf{J}^2 = n\mathbf{J}$, since every entry of $\mathbf{J}^2$ is a sum of n ones. If $\mathbf{J}\mathbf{x} = \lambda\mathbf{x}$ with $\mathbf{x} \neq \mathbf{0}$, then $\lambda^2\mathbf{x} = \mathbf{J}^2\mathbf{x} = n\mathbf{J}\mathbf{x} = n\lambda\mathbf{x}$, so $\lambda^2 = n\lambda$ and $\lambda \in \{0, n\}$. Hence $\rho(\mathbf{J}) = n$, and $\rho(c\mathbf{J}) = c\,\rho(\mathbf{J}) = nc$ because the eigenvalues of $c\mathbf{J}$ are c times those of $\mathbf{J}$.

(b) The hypothesis says $0 \leq a\mathbf{J} \leq \mathbf{A} \leq b\mathbf{J}$. By Proposition 18.1.4 (a), applied twice, $\rho(a\mathbf{J}) \leq \rho(\mathbf{A}) \leq \rho(b\mathbf{J})$, and by (a) this reads $na \leq \rho(\mathbf{A}) \leq nb$.

(c) The entries lie between 1 and 3 and $n = 3$, so $3 \leq \rho(\mathbf{A}) \leq 9$. In fact every row sums to 6, so $\mathbf{A}\mathbf{1} = 6\,\mathbf{1}$, and Theorem 18.1.5 (d) says the positive eigenvector $\mathbf{1}$ belongs to $\rho(\mathbf{A})$. Hence $\rho(\mathbf{A}) = 6$.

18.1.5.3 C. Going deeper

Exercise C1: Symmetry passes to the Perron vector.

Let $\mathbf{A} > 0$ be $n \times n$ with Perron vector $\mathbf{v}$, and let $\mathbf{P}$ be a permutation matrix with $\mathbf{P}^\top\mathbf{A}\mathbf{P} = \mathbf{A}$.

(a) Prove that $\mathbf{P}\mathbf{v} = \mathbf{v}$.

(b) Deduce that the Perron vector of $\mathbf{A} = \begin{pmatrix} 1 & 1 & 3 \\ 1 & 1 & 3 \\ 1 & 1 & 1 \end{pmatrix}$ has equal first and second entries, and find it.

(c) Deduce that if $\mathbf{A} > 0$ commutes with the cyclic permutation matrix of $1 \to 2 \to \cdots \to n \to 1$, then its Perron vector is $\frac{1}{n}\mathbf{1}$.

Hint: for (a), $\mathbf{P}\mathbf{v}$ *is a positive vector in* Δ_n.

Solution.

(a) By Lemma 2.6.6 (b), $\mathbf{P}\mathbf{P}^\top = \mathbf{I}$, so $\mathbf{A}\mathbf{P} = \mathbf{P}\mathbf{P}^\top\mathbf{A}\mathbf{P} = \mathbf{P}\mathbf{A}$. Hence $\mathbf{A}(\mathbf{P}\mathbf{v}) = \mathbf{P}\mathbf{A}\mathbf{v} = \rho(\mathbf{A})\,\mathbf{P}\mathbf{v}$. The entries of $\mathbf{P}\mathbf{v}$ are those of $\mathbf{v}$ in another order ($\mathbf{P} = \mathbf{P}_\sigma$ sends $\mathbf{e}_j$ to $\mathbf{e}_{\sigma(j)}$), so $\mathbf{P}\mathbf{v} > \mathbf{0}$ and its entries add up to 1. By Definition 18.1.2 and the uniqueness proved after it, $\mathbf{P}\mathbf{v} = \mathbf{v}$.

(b) Let $\mathbf{P}$ be the permutation matrix that swaps $\mathbf{e}_1$ and $\mathbf{e}_2$. Then $\mathbf{P}^\top\mathbf{A}\mathbf{P}$ is $\mathbf{A}$ with rows $1, 2$ swapped and columns $1, 2$ swapped, which is $\mathbf{A}$ again, because rows 1 and 2 of $\mathbf{A}$ are equal and so are columns 1 and 2. By (a), $\mathbf{P}\mathbf{v} = \mathbf{v}$, that is, $v_1 = v_2$. Now try $\mathbf{v} = (1, 1, c)$: $\mathbf{A}\mathbf{v} = (2+3c, 2+3c, 2+c)$, and $\mathbf{A}\mathbf{v} = \lambda\mathbf{v}$ requires $\lambda = 2+3c$ and $2 + c = (2 + 3c)c$, that is, $3c^2 + c - 2 = 0$, so $c = \frac{2}{3}$ or $c = -1$. The positive choice $c = \frac{2}{3}$ gives the eigenvector $(3, 3, 2)$ with eigenvalue 4, and by Theorem 18.1.5 (d) this is the Perron eigenvector, so $\rho(\mathbf{A}) = 4$ and the Perron vector is $\frac{1}{8}(3, 3, 2)$.

(c) Let $\mathbf{C}$ be the cyclic permutation matrix, $\mathbf{C}\mathbf{e}_j = \mathbf{e}_{j+1}$ for $j < n$ and $\mathbf{C}\mathbf{e}_n = \mathbf{e}_1$. If $\mathbf{A}\mathbf{C} = \mathbf{C}\mathbf{A}$, then $\mathbf{C}^\top\mathbf{A}\mathbf{C} = \mathbf{C}^\top\mathbf{C}\mathbf{A} = \mathbf{A}$ by Lemma 2.6.6 (b). By (a), $\mathbf{C}\mathbf{v} = \mathbf{v}$, which says $v_n = v_1$ and $v_j = v_{j+1}$ for $j < n$, so all entries are equal. As they add up to 1, $\mathbf{v} = \frac{1}{n}\mathbf{1}$.

Exercise C2: Every conclusion fails for some non-negative matrix.

For each part of Theorem 18.1.5, (a) to (d), give a non-negative 2×2 matrix for which that part fails, and name the step of the proof that breaks. Then give a non-negative matrix for which (a), (b) and (c) fail at the same time.

Solution.

(a) $\mathbf{J}_2(0) = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$ has $\rho = 0$, and its eigenvectors are the non-zero multiples of $\mathbf{e}_1$, none positive. In the proof, $r > 0$ came from the smallest row sum, which here is 0; and the push-up claim fails, since $\mathbf{u} = \mathbf{e}_1$ satisfies $\mathbf{A}\mathbf{u} = 0 \cdot \mathbf{u}$ without being positive.

(b) $\mathbf{I}_2$: $\rho = 1$ is a double eigenvalue and $E_1 = \mathbb{R}^2$. Step 5 fails: $\mathbf{u} - \theta\mathbf{v}$ can be non-zero and non-negative with a zero entry, since $\mathbf{A}\mathbf{y} > \mathbf{0}$ is no longer forced.

(c) $\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$: the eigenvalue -1 has modulus $\rho = 1$. Step 4 fails: equality in the triangle inequality is automatic when each row has a single non-zero term, so it aligns nothing.

(d) $\mathrm{diag}(2, 1)$: the eigenvector $\mathbf{e}_2 \geq \mathbf{0}$ belongs to $1 \neq 2 = \rho$. Step 7 fails, because the left eigenvector for 2 is $\mathbf{e}_1$, which is not positive, and $\mathbf{e}_1^\top\mathbf{e}_2 = 0$ is no contradiction.

For all three at once, take

$$\mathbf{A} = \begin{pmatrix} 0 & 1 & 1 \\ 1 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix}.$$

It is block upper triangular with diagonal blocks $\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$ and (1), so $p_{\mathbf{A}}(x) = (x^2 - 1)(x - 1) = (x - 1)^2(x + 1)$ by Theorem 6.8.4, applied to $x\mathbf{I} - \mathbf{A}$ over $F[x]$, as the paragraph after it notes. Hence $\rho(\mathbf{A}) = 1$ and $a_{\mathbf{A}}(1) = 2$, so (b) fails, and $|-1| = \rho(\mathbf{A})$, so (c) fails. The system $(\mathbf{A} - \mathbf{I})\mathbf{x} = \mathbf{0}$ reads $-x_1 + x_2 + x_3 = 0$ and $x_1 - x_2 = 0$, which

forces $x_3 = 0$; so every eigenvector for 1 is a multiple of $(1, 1, 0)$, none of them positive, and (a) fails.

Exercise C3: The Perron root is strictly monotone.

Let $\mathbf{A}, \mathbf{B} \in M_n(\mathbb{R})$ with $0 < \mathbf{A} \leq \mathbf{B}$ and $\mathbf{A} \neq \mathbf{B}$.

(a) Prove that $\rho(\mathbf{A}) < \rho(\mathbf{B})$.

(b) Show by an example that the conclusion fails if $\mathbf{A} > 0$ is weakened to $\mathbf{A} \geq 0$.

Hint: pair $\mathbf{Bv}$ *with a positive left eigenvector of* $\mathbf{B}$*, where* $\mathbf{v}$ *is the Perron vector of* $\mathbf{A}$*.*

Solution.

(a) $\mathbf{B} \geq \mathbf{A} > 0$, so $\mathbf{B}$ is positive too. Let $\mathbf{v} > \mathbf{0}$ be the Perron vector of $\mathbf{A}$, and by Theorem 18.1.5 (e) let $\mathbf{w} > \mathbf{0}$ satisfy $\mathbf{w}^{\top}\mathbf{B} = \rho(\mathbf{B})\mathbf{w}^{\top}$. Then

$$\rho(\mathbf{B})\,\mathbf{w}^{\top}\mathbf{v} = \mathbf{w}^{\top}\mathbf{B}\mathbf{v} = \mathbf{w}^{\top}\mathbf{A}\mathbf{v} + \mathbf{w}^{\top}(\mathbf{B}-\mathbf{A})\mathbf{v} = \rho(\mathbf{A})\,\mathbf{w}^{\top}\mathbf{v} + \mathbf{w}^{\top}(\mathbf{B}-\mathbf{A})\mathbf{v}.$$

The matrix $\mathbf{B}-\mathbf{A}$ is non-negative and non-zero, say $b_{kl}-a_{kl} > 0$, so $\mathbf{w}^{\top}(\mathbf{B}-\mathbf{A})\mathbf{v} \geq w_k(b_{kl}-a_{kl})v_l > 0$, every other term being ≥ 0. Since $\mathbf{w}^{\top}\mathbf{v} > 0$, dividing gives $\rho(\mathbf{B}) > \rho(\mathbf{A})$.

(b) $\mathbf{A} = \operatorname{diag}(1, 0)$ and $\mathbf{B} = \mathbf{I}_2$ satisfy $0 \leq \mathbf{A} \leq \mathbf{B}$ and $\mathbf{A} \neq \mathbf{B}$, with $\rho(\mathbf{A}) = \rho(\mathbf{B}) = 1$. In the argument of (a), the Perron vector of $\mathbf{A}$ is replaced by $\mathbf{e}_1$, and $(\mathbf{B}-\mathbf{A})\mathbf{e}_1 = \mathbf{0}$: the extra mass sits where the eigenvector does not look.

18.2 Irreducibility and Graphs

Perron's theorem (Theorem 18.1.5) asks for every entry to be positive, and most matrices that arise in practice do not oblige. The bicycle chain of Chapter 8 §11 has a zero entry, since a bicycle at station 3 never reaches station 1 in one night; the Leslie matrix of the same section is mostly zeros; the swap has only two non-zero entries. Some zeros are harmless and some are fatal: the swap keeps $\rho = 1$ as a simple eigenvalue with a positive eigenvector, while for $\mathbf{I}_2$ the eigenvalue 1 is double and its positive eigenvectors are no longer all multiples of one. This section finds the dividing line. It depends only on **where** the zero entries are, and the right way to read that pattern is as a map of one-step moves between the indices: a directed graph. The matrices on the good side of the line are the **irreducible** ones, and §03 proves that they enjoy nearly all of Perron's conclusions.

Throughout, F is $\mathbb{R}$ or $\mathbb{C}$. The definitions of this section use only whether an entry is zero, so they make sense for any matrix. The statements about powers and positivity need $\mathbf{A} \geq 0$, and say so.

18.2.1 The graph of a matrix

The question that recurs is this: which entries of $\mathbf{A}^k$ are non-zero? For a non-negative matrix, $(\mathbf{A}^2)_{ij} = \sum_l a_{il}a_{lj}$ is positive exactly when some a_{il} and a_{lj} are both positive, that is, when

one can go from j to some l and from l to i along non-zero entries. In a Markov chain (Definition 8.11.2), a_{lj} is the probability of moving from state j to state l in one step, and the sentence says that state i can be reached from j in two steps. So we draw an arrow from j to i for each non-zero entry a_{ij} and count routes.

The graph of a matrix has a vertex for each index and an arrow from j to i whenever the entry a_{ij} is not zero.

Definition 18.2.1 — Directed Graph of a Matrix; Walks and Paths

Let $n \geq 1$ and $\mathbf{A} = (a_{ij}) \in M_n(F)$.

(a) The **directed graph** $G(\mathbf{A})$ of $\mathbf{A}$ has **vertices** $1, 2, \ldots, n$, and an **edge from j to i**, written $j \to i$, for **each** pair (i, j) with $a_{ij} \neq 0$. An edge $j \to j$, from a non-zero diagonal entry, is a **loop**.

(b) A **walk of length $k \geq 0$ from j to i** is a list of vertices $j = i_0, i_1, \ldots, i_k = i$ such that $i_{t-1} \to i_t$ is an edge for **every** $t = 1, \ldots, k$.

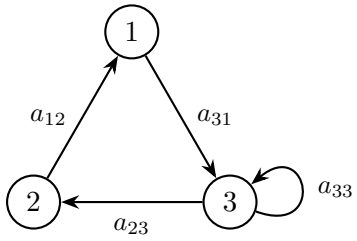
(c) A **path** is a walk whose vertices $i_0, \ldots, i_k$ are distinct.

In words: (a) turns each non-zero entry into an arrow, and the arrow for a_{ij} points **from the column index to the row index**. That is the direction in which $\mathbf{A}$ moves things: in $\mathbf{x} \mapsto \mathbf{Ax}$, entry j of $\mathbf{x}$ contributes $a_{ij}x_j$ to entry i of the image, and in a column-stochastic chain a_{ij} is the probability of the move from j to i. Clause (b) allows $k = 0$: the one-vertex list (j) is a walk of length 0 from j to itself, whatever the matrix. A walk may revisit vertices and use an edge several times; a path may not.

> *Remark.* Many books draw the arrow for $a_{ij} \neq 0$ from i to j. The two graphs differ by reversing every edge, and nothing below depends on the choice except the wording "from j to i". We take the direction that matches $\mathbf{x}_{k+1} = \mathbf{Ax}_k$ and the column-stochastic convention of Chapter 8 §11.

Examples, simplest first.

- $n = 1$. $G((a))$ has one vertex, with a loop if $a \neq 0$ and no edge if $a = 0$. In either case there is the walk of length 0 from 1 to 1.
- **The zero matrix** $0 \in M_n(F)$ has n vertices and no edges at all. **A positive matrix** has every possible edge, loops included.
- **A cycle.** The permutation matrix $\mathbf{C} = \left(\begin{smallmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{smallmatrix}\right)$ has $c_{21} = c_{32} = c_{13} = 1$, so its edges are $1 \to 2$, $2 \to 3$ and $3 \to 1$.
- **A path.** $\left(\begin{smallmatrix} 0 & 0 & 0 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{smallmatrix}\right)$ has the edges $1 \to 2$ and $2 \to 3$ only. There is a walk from 1 to 3, and none from 3 to anywhere but 3 itself.
- $\mathbf{A} = \left(\begin{smallmatrix} 0 & 2 & 0 \\ 0 & 0 & 1 \\ 3 & 0 & 1 \end{smallmatrix}\right)$ has the edges $2 \to 1$, $3 \to 2$, $1 \to 3$ and the loop $3 \to 3$, drawn below. The values of the entries play no part in the graph.



Non-example by minimal change. The graph records whether an entry is zero, not how large it is. Change the entry 3 of the last matrix to 10^{-9}: the graph is unchanged. Change it to 0: the edge $1 \to 3$ disappears, and with it every walk out of vertex 1 other than the one of length 0.

The graph was built to count routes, and it does, for non-negative matrices. The same lemma handles $\mathbf{I} + \mathbf{A}$, whose graph is that of $\mathbf{A}$ with a loop added at every vertex; a loop lets a walk wait, so walks of length **at most** k become walks of length exactly k.

Lemma 18.2.1 — Powers Count Walks

Let $\mathbf{A} \in M_n(\mathbb{R})$ be non-negative, and let $k \geq 0$ and $i, j \in \{1, \ldots, n\}$.

(a) $(\mathbf{A}^k)_{ij} > 0$ if and only if $G(\mathbf{A})$ has a walk of length k from j to i.
(b) $\big((\mathbf{I} + \mathbf{A})^k\big)_{ij} > 0$ if and only if $G(\mathbf{A})$ has a walk of length **at most** k from j to i.

Idea. Induction on k, peeling off the first step of a walk. Expanding $(\mathbf{A}^{k+1})_{ij} = \sum_l (\mathbf{A}^k)_{il} a_{lj}$ gives a sum of non-negative terms, so it is positive exactly when one term is: a first step $j \to l$ followed by a walk of length k from l to i. For $\mathbf{I} + \mathbf{A}$ the diagonal 1 adds the option of waiting at j instead of stepping.

Proof.

(a) Induction on k. For $k = 0$, $(\mathbf{I})_{ij} > 0$ exactly when $i = j$, which is exactly when there is a walk of length 0 from j to i. Suppose (a) holds for k. By Lemma 18.1.1 (c), $\mathbf{A}^k \geq 0$, so

$$(\mathbf{A}^{k+1})_{ij} = \sum_{l=1}^{n} (\mathbf{A}^k)_{il}\, a_{lj}$$

is a sum of non-negative terms. It is positive if and only if some term is, that is, if and only if there is an l with $a_{lj} > 0$ and $(\mathbf{A}^k)_{il} > 0$. By the definition of $G(\mathbf{A})$ and the induction hypothesis, this says: there is an edge $j \to l$ and a walk of length k from l to i. Putting j in front of that walk gives a walk of length $k + 1$ from j to i, and every such walk arises this way, with l its second vertex.

(b) Induction on k, with the same base case, since $(\mathbf{I} + \mathbf{A})^0 = \mathbf{I}$. Suppose (b) holds for k. As $(\mathbf{I} + \mathbf{A})^k \geq 0$ and $\mathbf{I} + \mathbf{A} \geq 0$,

$$\big((\mathbf{I} + \mathbf{A})^{k+1}\big)_{ij} = \sum_{l=1}^{n} \big((\mathbf{I} + \mathbf{A})^k\big)_{il} \,(\delta_{lj} + a_{lj})$$

is positive if and only if there is an l with $((\mathbf{I} + \mathbf{A})^k)_{il} > 0$ and either $l = j$ or $a_{lj} > 0$. By the induction hypothesis this says: there is a walk of length at most k

from l to i, where either $l = j$ or $j \to l$ is an edge. In the first case we have a walk of length at most k from j to i; in the second, putting j in front gives one of length at most $k+1$. Conversely, let a walk of length $m \le k+1$ from j to i be given. If $m \le k$, take $l = j$. If $m = k+1 \ge 1$, take l to be its second vertex, so that $j \to l$ is an edge and the rest of the walk has length k. This proves the lemma.

■

For the matrix drawn above, $\mathbf{A}^2 = \begin{pmatrix} 0 & 0 & 2 \\ 3 & 0 & 1 \\ 3 & 6 & 1 \end{pmatrix}$. Its $(1,1)$ entry is 0, and indeed the shortest walk from 1 back to 1 is $1 \to 3 \to 2 \to 1$, of length 3. Its $(1,3)$ entry is 2, from the walk $3 \to 2 \to 1$.

A long walk can always be shortened to a path, and a path is short.

Lemma 18.2.2 — Shortening a Walk to a Path

Let $\mathbf{A} \in M_n(F)$. If $G(\mathbf{A})$ has a walk from j to i, then it has a path from j to i, and every path has length at most $n-1$.

Idea. Take a shortest walk. If it visited some vertex twice, the loop between the two visits could be cut out, leaving a shorter walk; so a shortest walk is a path. A path visits distinct vertices, and there are only n of them.

Proof. Among the walks from j to i, choose one of least length k (Theorem 0.2.11), say $j = i_0, i_1, \dots, i_k = i$. Suppose two of its vertices coincide, $i_s = i_t$ with $s < t$. Deleting $i_{s+1}, \dots, i_t$ leaves the list $i_0, \dots, i_s, i_{t+1}, \dots, i_k$, which is still a walk, because the edge $i_t \to i_{t+1}$ (if $t < k$) is the edge $i_s \to i_{t+1}$. It has length $k - (t-s) < k$, contradicting the choice of k. So the vertices are distinct, and the walk is a path. A path of length k has $k+1$ distinct vertices among the n vertices of $G(\mathbf{A})$, so $k+1 \le n$.

■

18.2.2 Strong connectivity

Positivity of $\mathbf{A}$ says every vertex has an edge to every vertex. The useful weakening is to ask only for a **walk**.

A graph is strongly connected when every vertex can be reached from every vertex.

Definition 18.2.2 — Strongly Connected

Let $\mathbf{A} \in M_n(F)$. The graph $G(\mathbf{A})$ is **strongly connected** if, for **every** ordered pair (j, i) of vertices, there is a walk from j to i.

In words: whichever vertex we start from, every vertex can be reached, and the pair is **ordered**, so a walk from j to i and a walk from i back to j are both required. By Lemma 18.2.2, the walks may be taken to be paths of length at most $n-1$. For $n = 1$ the walk of length 0 suffices, so the graph of every 1×1 matrix, (0) included, is strongly connected.

The cycle $\mathbf{C}$ above is strongly connected: from any vertex, follow the arrows round. So is the graph drawn above, since it contains the cycle $1 \to 3 \to 2 \to 1$, and so is the graph of every positive matrix. The path is not: there is no walk from 3 to 1. Removing one edge from the cycle, by changing $c_{13} = 1$ to 0, gives exactly the path, so the clause that fails is the one for the pair $(3, 1)$; the walks from 1 to 2, from 1 to 3 and from 2 to 3 survive.

18.2.3 Irreducible matrices

Now the notion this chapter is built on. We want to single out the matrices whose eigenvalue problem cannot be split into two smaller ones. For a matrix with a zero block in the lower left, it can:

$$\mathbf{A} = \begin{pmatrix} \mathbf{B} & \mathbf{C} \\ 0 & \mathbf{D} \end{pmatrix} \quad \Longrightarrow \quad p_{\mathbf{A}} = p_{\mathbf{B}}\, p_{\mathbf{D}},$$

by Theorem 6.8.4 applied to $x\mathbf{I} - \mathbf{A}$, and the subspace spanned by the first few standard basis vectors is mapped into itself. For such a matrix Perron's conclusions fail in general: $\mathbf{I}_2$ and $\operatorname{diag}(2, 1)$ are of this shape. In this chapter a change of basis must preserve non-negativity, and the ones that do so while keeping the entries themselves are the relabelings of the coordinates. So the definition asks whether a relabeling produces the zero block.

A matrix is irreducible if no relabeling of the coordinates puts it in block upper triangular form.

Definition 18.2.3 — Irreducible Matrix

Let $\mathbf{A} \in M_n(F)$.

(a) For $n \geq 2$, $\mathbf{A}$ is **reducible** if there are a permutation matrix $\mathbf{P}$ and an integer k with $1 \leq k \leq n-1$ such that

$$\mathbf{P}^{\top}\mathbf{A}\mathbf{P} = \begin{pmatrix} \mathbf{B} & \mathbf{C} \\ 0 & \mathbf{D} \end{pmatrix}, \qquad \mathbf{B} \in M_k(F),\ \mathbf{D} \in M_{n-k}(F),$$

with 0 the $(n-k) \times k$ zero matrix. It is **irreducible** if it is **not** reducible.

(b) For $n = 1$, **every** matrix $(a) \in M_1(F)$ is irreducible, including (0).

In words: by Lemma 2.6.6 (b), $\mathbf{P}^{\top} = \mathbf{P}^{-1}$, so $\mathbf{P}^{\top}\mathbf{A}\mathbf{P}$ is similar to $\mathbf{A}$. It is the matrix of $T_{\mathbf{A}}$ in the standard basis taken in another order, and in (a) we ask whether some order has a zero block below the diagonal with **both** diagonal blocks non-empty, which is what $1 \leq k \leq n-1$ says. Irreducible means that **no** order does. Clause (b) is a convention, justified below.

To see what relabeling does to the entries, we compute it once.

Lemma 18.2.3 — Relabeling the Coordinates

Let $\sigma \in S_n$ and $\mathbf{A} \in M_n(F)$. Then $(\mathbf{P}_\sigma^{\top}\mathbf{A}\mathbf{P}_\sigma)_{st} = a_{\sigma(s)\sigma(t)}$ for all s, t. Consequently $t \to s$ is an edge of $G(\mathbf{P}_\sigma^{\top}\mathbf{A}\mathbf{P}_\sigma)$ if and only if $\sigma(t) \to \sigma(s)$ is an edge of $G(\mathbf{A})$.

Proof. By Definition 2.6.2, $\mathbf{P}_\sigma \mathbf{e}_t = \mathbf{e}_{\sigma(t)}$. The (s, t) entry of a matrix $\mathbf{M}$ is $\mathbf{e}_s^{\top}\mathbf{M}\mathbf{e}_t$, so

by Theorem 0.9.5,

$$(\mathbf{P}_\sigma^\top \mathbf{A}\mathbf{P}_\sigma)_{st} = \mathbf{e}_s^\top \mathbf{P}_\sigma^\top \mathbf{A}\mathbf{P}_\sigma \mathbf{e}_t = (\mathbf{P}_\sigma \mathbf{e}_s)^\top \mathbf{A}(\mathbf{P}_\sigma \mathbf{e}_t) = \mathbf{e}_{\sigma(s)}^\top \mathbf{A}\, \mathbf{e}_{\sigma(t)} = a_{\sigma(s)\sigma(t)}.$$

The statement about edges is the statement that one of these entries is non-zero exactly when the other is.

■

So the graph of $\mathbf{P}_\sigma^\top \mathbf{A}\mathbf{P}_\sigma$ is $G(\mathbf{A})$ with the vertex $\sigma(s)$ renamed s. In particular, Definition 18.2.2 holds for one exactly when it holds for the other. The zero block of Definition 18.2.3 becomes a statement about a set of vertices that no edge leaves.

Lemma 18.2.4 — Reducible Means a Set of Vertices With No Exit

Let $n \geq 2$ and $\mathbf{A} \in M_n(F)$. Then $\mathbf{A}$ is reducible if and only if there is a set $S \subseteq \{1, \ldots, n\}$ with $S \neq \emptyset$ and $S \neq \{1, \ldots, n\}$ such that

$$a_{ij} = 0 \qquad \text{whenever } j \in S \text{ and } i \notin S,$$

that is, such that no edge of $G(\mathbf{A})$ goes from a vertex in S to a vertex outside S.

Idea. The zero block of Definition 18.2.3 sits in the columns of the first k relabeled vertices and the rows of the others. So take S to be the first k vertices in the new order; conversely, given S, choose the order that lists S first. Lemma 18.2.3 translates between the entries and the vertices.

Proof. ($\Leftarrow$) Let k be the number of elements of S, so $1 \leq k \leq n-1$, and choose $\sigma \in S_n$ listing the elements of S first: $\sigma(1), \ldots, \sigma(k)$ are the elements of S and $\sigma(k+1), \ldots, \sigma(n)$ the others. For $t \leq k < s$ we have $\sigma(t) \in S$ and $\sigma(s) \notin S$, so by Lemma 18.2.3, $(\mathbf{P}_\sigma^\top \mathbf{A}\mathbf{P}_\sigma)_{st} = a_{\sigma(s)\sigma(t)} = 0$. That is, the lower-left $(n-k) \times k$ block of $\mathbf{P}_\sigma^\top \mathbf{A}\mathbf{P}_\sigma$ is zero, and $\mathbf{A}$ is reducible.

($\Rightarrow$) Let $\mathbf{P}$ and k be as in Definition 18.2.3 (a). By Definition 2.6.2, $\mathbf{P} = \mathbf{P}_\sigma$ for some $\sigma \in S_n$. Put $S = \{\sigma(1), \ldots, \sigma(k)\}$, which has k elements, so it is neither empty nor everything. If $j \in S$ and $i \notin S$, then $j = \sigma(t)$ with $t \leq k$ and $i = \sigma(s)$ with $s > k$, and $a_{ij} = (\mathbf{P}_\sigma^\top \mathbf{A}\mathbf{P}_\sigma)_{st} = 0$ because (s,t) lies in the zero block.

■

The condition says that the coordinate subspace $\operatorname{span}\{\mathbf{e}_j : j \in S\}$ is mapped into itself by $\mathbf{A}$, since column j of $\mathbf{A}$ is $\mathbf{A}\mathbf{e}_j$ and its entries outside S vanish. So a reducible matrix is one with an invariant subspace spanned by some of the standard basis vectors, other than $\{\mathbf{0}\}$ and F^n, and Theorem 8.1.3 is the source of the block form.

Now some examples, simplest first.

- $n = 1$**.** Irreducible by (b).
- **Positive matrices** are irreducible: no entry is 0, so no set S as in Lemma 18.2.4 exists.
- **The swap** $\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$ is irreducible. For $n = 2$, the candidates are $S = \{1\}$, which needs

$a_{21} = 0$, and $S = \{2\}$, which needs $a_{12} = 0$; both entries are 1. So a matrix may have zeros, even mostly zeros, and be irreducible.

- **Triangular matrices** with $n \geq 2$ are reducible. An upper triangular one already has the block form with $\mathbf{P} = \mathbf{I}$ and $k = 1$. A lower triangular one, such as the path matrix, is reducible too, by Lemma 18.2.4 with $S = \{n\}$: column n has its only possible non-zero entry on the diagonal. Reversing the order of the coordinates, $\sigma(s) = n + 1 - s$, turns the path matrix into $\mathbf{J}_3(0)$, which is upper triangular.
- **The zero matrix** of size $n \geq 2$ is reducible, and so is $\mathbf{I}_n$: any S will do.

Non-example by minimal change. The cycle $\mathbf{C}$ is irreducible, as the next theorem will show. Change its entry c_{13} from 1 to 0: the result is the path matrix, and $S = \{3\}$ now has no exit, because the only non-zero entry of column 3 outside row 3, the entry c_{13}, has become 0. That single clause of Lemma 18.2.4 is what changed.

Example. (A reducible matrix that does not look it)

Decide whether $\mathbf{A} = \begin{pmatrix} 1 & 0 & 2 \\ 3 & 4 & 5 \\ 6 & 0 & 7 \end{pmatrix}$ is irreducible, and if not, put it in block triangular form.

Solution. Column 2 has its only non-zero entry in row 2, so $S = \{2\}$ has no exit: $a_{12} = a_{32} = 0$. By Lemma 18.2.4, $\mathbf{A}$ is reducible. Following the proof, list 2 first: $\sigma(1) = 2$, $\sigma(2) = 1$, $\sigma(3) = 3$. By Lemma 18.2.3, the (s,t) entry of $\mathbf{P}_\sigma^\top \mathbf{A} \mathbf{P}_\sigma$ is $a_{\sigma(s)\sigma(t)}$, so

$$\mathbf{P}_\sigma^\top \mathbf{A} \mathbf{P}_\sigma = \begin{pmatrix} a_{22} & a_{21} & a_{23} \\ a_{12} & a_{11} & a_{13} \\ a_{32} & a_{31} & a_{33} \end{pmatrix} = \begin{pmatrix} 4 & 3 & 5 \\ 0 & 1 & 2 \\ 0 & 6 & 7 \end{pmatrix}.$$

Hence $p_{\mathbf{A}}(x) = (x - 4)(x^2 - 8x - 5)$, and the eigenvalues are 4 and $4 \pm \sqrt{21}$. In the graph, vertex 2 has only a loop leaving it: a chain that reaches state 2 stays there.

Why this definition, and why every 1×1 matrix is irreducible. The block form is the matrix picture of an invariant coordinate subspace, and it is exactly what splits $p_{\mathbf{A}}$ into two factors and lets the conclusions of Perron's theorem fail, as $\mathbf{I}_2$ shows. For $n = 1$ there is no room for two non-empty blocks, and a convention is needed. Some books call (0) reducible. We call every 1×1 matrix irreducible because that is the choice that makes the two theorems below true with no exception: the graph of a 1×1 matrix is always strongly connected, through the walk of length 0, and $(\mathbf{I} + \mathbf{A})^{1-1} = \mathbf{I} = (1)$ is always positive. The price is paid in §03: the irreducible matrix (0) has spectral radius 0, so the statement there that an irreducible non-negative matrix has $\rho(\mathbf{A}) > 0$ carries the hypothesis $n \geq 2$.

Warning. **Irreducibility depends only on which entries are zero, never on their size.** For every $t \neq 0$, however small, $\mathbf{A}_t = \begin{pmatrix} 1 & t \\ 1 & 1 \end{pmatrix}$ is irreducible, and for $t > 0$ its eigenvalues $1 \pm \sqrt{t}$ are distinct, with the positive eigenvector $(\sqrt{t}, 1)$ for $1 + \sqrt{t}$. At $t = 0$ it is lower triangular, hence reducible, and 1 becomes a double eigenvalue with the eigenvector $\mathbf{e}_2$ only. An entry of 10^{-9} and an entry of 10^9 count the same; an entry of 0 is different in kind. The property is not preserved by powers either: the swap is irreducible and its square is $\mathbf{I}_2$, which is not.

The first theorem says that irreducibility, defined through relabelings, is exactly strong connec-

tivity of the graph.

Theorem 18.2.5 — Irreducible If and Only If Strongly Connected

Let $n \geq 1$ and $\mathbf{A} \in M_n(F)$. Then $\mathbf{A}$ is irreducible if and only if $G(\mathbf{A})$ is strongly connected.

Idea. Both sides are about a set of vertices with no exit. If some vertex i cannot be reached from j, the set of vertices that **can** be reached from j contains j, misses i, and has no exit, since an exit would reach one more vertex. Conversely, a set with no exit traps every walk that starts inside it.

Proof. If $n = 1$, both sides hold, by Definition 18.2.3 (b) and the walk of length 0. Let $n \geq 2$. By Lemma 18.2.4 it suffices to show: $G(\mathbf{A})$ fails to be strongly connected if and only if there is a set S, neither empty nor all of $\{1, \ldots, n\}$, from which no edge leaves.

($\Rightarrow$) Suppose there are j and i with no walk from j to i. Let S be the set of vertices l such that there is a walk from j to l. Then $j \in S$, by the walk of length 0, and $i \notin S$. If $l \in S$ and $l \to m$ is an edge, then appending m to a walk from j to l gives a walk from j to m, so $m \in S$. Hence no edge leaves S.

($\Leftarrow$) Suppose no edge leaves S, and choose $j \in S$ and $i \notin S$. Let $j = i_0, i_1, \ldots, i_k$ be any walk from j. Then every i_t lies in S, by induction on t: $i_0 = j \in S$, and if $i_{t-1} \in S$, the edge $i_{t-1} \to i_t$ does not leave S, so $i_t \in S$. Hence no walk from j ends at i, and $G(\mathbf{A})$ is not strongly connected. This proves the theorem.

■

So the cycle $\mathbf{C}$ is irreducible, and so is the matrix drawn earlier: their graphs are strongly connected. Deciding irreducibility from the definition means looking at $n!$ relabelings; deciding it from the graph means following arrows.

Quick check. Is $\mathbf{M} = \begin{pmatrix} 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{pmatrix}$ irreducible? Every row and every column of $\mathbf{M}$ contains a non-zero entry off the diagonal.

Solution. No. The edges of $G(\mathbf{M})$ are $1 \to 2$, $2 \to 1$, $3 \to 4$ and $4 \to 3$, so there is no walk from 1 to 3, and $\mathbf{M}$ is reducible by Theorem 18.2.5. Directly, $S = \{1, 2\}$ has no exit, and indeed $\mathbf{M} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} \oplus \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$ is already block diagonal, with $\mathbf{P} = \mathbf{I}$ and $k = 2$. Having an off-diagonal entry in every row and column is necessary for irreducibility when $n \geq 2$ (Exercise C1), but it is not sufficient.

18.2.4 A test by one matrix power

For a non-negative matrix, Lemma 18.2.1 turns strong connectivity into positivity of a single matrix, and that is the bridge back to Perron's theorem.

Theorem 18.2.6 — Irreducibility Through a Power of $\mathbf{I}+\mathbf{A}$

Let $n \geq 1$ and let $\mathbf{A} \in M_n(\mathbb{R})$ be non-negative. Then $\mathbf{A}$ is irreducible if and only if

$$(\mathbf{I}+\mathbf{A})^{n-1} > 0.$$

Idea. Read both sides as statements about walks. Positivity of $(\mathbf{I}+\mathbf{A})^{n-1}$ asks for a walk of length **at most** $n-1$ between every ordered pair of vertices, and strong connectivity asks for a walk of any length. The two agree because a walk can always be shortened to a path, and a path has at most $n-1$ edges.

Proof. By Lemma 18.2.1 (b), $(\mathbf{I}+\mathbf{A})^{n-1} > 0$ if and only if, for every ordered pair (j,i), there is a walk of length at most $n-1$ from j to i. By Lemma 18.2.2, if there is any walk from j to i then there is one of length at most $n-1$, namely a path; so the condition is equivalent to asking for a walk of any length from j to i, for every ordered pair. That is Definition 18.2.2, and by Theorem 18.2.5 it is equivalent to irreducibility. ∎

Both sides always hold for $n = 1$, as the convention intends. The hypothesis $\mathbf{A} \geq 0$ cannot be dropped: $\begin{pmatrix} -1 & 1 \\ 1 & -1 \end{pmatrix}$ is irreducible, but adding $\mathbf{I}$ cancels its diagonal and leaves the swap, which is not positive. Cancellation is exactly what non-negativity rules out, since a sum of non-negative terms is zero only when every term is.

Example. (The cycle, by one power)

For the cycle $\mathbf{C} = \begin{pmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix}$, compute $(\mathbf{I}+\mathbf{C})^2$, and compare with the powers $\mathbf{C}^k$.

Solution. $\mathbf{C}$ is the permutation matrix of $1 \mapsto 2 \mapsto 3 \mapsto 1$, so $\mathbf{C}^2 = \left(\begin{smallmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 0 & 0 \end{smallmatrix}\right)$ and $\mathbf{C}^3 = \mathbf{I}$ by Lemma 2.6.6 (a). As $\mathbf{I}$ and $\mathbf{C}$ commute,

$$(\mathbf{I}+\mathbf{C})^2 = \mathbf{I} + 2\mathbf{C} + \mathbf{C}^2 = \begin{pmatrix} 1 & 1 & 2 \\ 2 & 1 & 1 \\ 1 & 2 & 1 \end{pmatrix} > 0,$$

so $\mathbf{C}$ is irreducible by Theorem 18.2.6, as the graph already showed. On the other hand every power $\mathbf{C}^k$ is $\mathbf{I}$, $\mathbf{C}$ or $\mathbf{C}^2$, each with six zero entries, so **no** power of $\mathbf{C}$ is positive. In the graph, the walks from j have lengths forced modulo 3 by where they end. The loops of $\mathbf{I}+\mathbf{C}$ let a walk wait, which is what $\mathbf{C}$ alone cannot do. §05 returns to this difference; it is the difference between irreducible and primitive.

The theorem is the reason irreducibility is enough for most of Perron's conclusions. If $\mathbf{A} \geq 0$ is irreducible, then $\mathbf{B} = (\mathbf{I}+\mathbf{A})^{n-1}$ is positive, so Theorem 18.1.5 applies to $\mathbf{B}$, and $\mathbf{B}$ is a polynomial in $\mathbf{A}$, so every eigenvector of $\mathbf{A}$ is an eigenvector of $\mathbf{B}$. §03 turns this observation into the Perron–Frobenius theorem.

18.2.5 The reducible normal form

A reducible matrix splits into two diagonal blocks, and each block may be reducible again. Splitting until nothing splits gives a normal form.

Theorem 18.2.7 — Reducible Normal Form

Let $n \geq 1$ and $\mathbf{A} \in M_n(F)$.

(a) There are a permutation matrix $\mathbf{P}$ and an integer $m \geq 1$ such that

$$\mathbf{P}^{\top}\mathbf{A}\mathbf{P} = \begin{pmatrix} \mathbf{A}_{11} & \mathbf{A}_{12} & \cdots & \mathbf{A}_{1m} \\ 0 & \mathbf{A}_{22} & \cdots & \mathbf{A}_{2m} \\ \vdots & & \ddots & \vdots \\ 0 & \cdots & 0 & \mathbf{A}_{mm} \end{pmatrix},$$

block upper triangular, with every diagonal block $\mathbf{A}_{ii}$ square and **irreducible**.

(b) In that case $p_{\mathbf{A}} = p_{\mathbf{A}_{11}}\, p_{\mathbf{A}_{22}} \cdots p_{\mathbf{A}_{mm}}$, so the eigenvalues of $\mathbf{A}$, with their algebraic multiplicities, are those of the diagonal blocks taken together.

(c) $\rho(\mathbf{A}) = \max_i \rho(\mathbf{A}_{ii})$; if $\mathbf{A} \geq 0$, every $\mathbf{A}_{ii} \geq 0$.

Idea. Strong induction on n: if $\mathbf{A}$ is irreducible there is nothing to do, and otherwise one relabeling gives two smaller diagonal blocks, which the induction hypothesis puts in normal form. The only work is to check that the two relabelings of the blocks combine into one relabeling of $\mathbf{A}$, and block multiplication does that.

Proof.

(a) Strong induction on n. If $\mathbf{A}$ is irreducible, which includes the case $n = 1$, take $\mathbf{P} = \mathbf{I}$ and $m = 1$. Otherwise $n \geq 2$, and there are a permutation matrix $\mathbf{P}_0$ and $1 \leq k \leq n-1$ with

$$\mathbf{P}_0^{\top}\mathbf{A}\mathbf{P}_0 = \begin{pmatrix} \mathbf{B} & \mathbf{C} \\ 0 & \mathbf{D} \end{pmatrix}, \qquad \mathbf{B} \in M_k(F),\ \mathbf{D} \in M_{n-k}(F).$$

Both sizes are less than n, so by the induction hypothesis there are permutation matrices $\mathbf{Q}_1 = \mathbf{P}_\alpha$ ($\alpha \in S_k$) and $\mathbf{Q}_2 = \mathbf{P}_\beta$ ($\beta \in S_{n-k}$) such that $\mathbf{Q}_1^{\top}\mathbf{B}\mathbf{Q}_1$ and $\mathbf{Q}_2^{\top}\mathbf{D}\mathbf{Q}_2$ are block upper triangular with square irreducible diagonal blocks. The direct sum $\mathbf{Q} = \mathbf{Q}_1 \oplus \mathbf{Q}_2$ (Definition 7.1.2) is the permutation matrix $\mathbf{P}_\gamma$ of the permutation γ with $\gamma(t) = \alpha(t)$ for $t \leq k$ and $\gamma(k+q) = k + \beta(q)$ for $q \leq n-k$, since its columns are $\mathbf{e}_{\gamma(1)}, \ldots, \mathbf{e}_{\gamma(n)}$. By Proposition 7.1.2, $\mathbf{Q}^{\top} = \mathbf{Q}_1^{\top} \oplus \mathbf{Q}_2^{\top}$, and by Theorem 7.1.1,

$$\mathbf{Q}^{\top}(\mathbf{P}_0^{\top}\mathbf{A}\mathbf{P}_0)\mathbf{Q} = \begin{pmatrix} \mathbf{Q}_1^{\top}\mathbf{B}\mathbf{Q}_1 & \mathbf{Q}_1^{\top}\mathbf{C}\mathbf{Q}_2 \\ 0 & \mathbf{Q}_2^{\top}\mathbf{D}\mathbf{Q}_2 \end{pmatrix}.$$

This is block upper triangular, and its diagonal blocks are those of $\mathbf{Q}_1^{\top}\mathbf{B}\mathbf{Q}_1$ followed by those of $\mathbf{Q}_2^{\top}\mathbf{D}\mathbf{Q}_2$, all square and irreducible. With $\mathbf{P} = \mathbf{P}_0\mathbf{Q}$, which is a permutation matrix by Lemma 2.6.6 (a), the left side is $\mathbf{P}^{\top}\mathbf{A}\mathbf{P}$ by Theorem 0.9.5. This proves (a).

(b) $\mathbf{P}^\top = \mathbf{P}^{-1}$ by Lemma 2.6.6 (b), so $\mathbf{P}^\top\mathbf{A}\mathbf{P}$ is similar to $\mathbf{A}$, and $p_{\mathbf{A}} = p_{\mathbf{P}^\top\mathbf{A}\mathbf{P}}$ by Theorem 6.10.3. The matrix $x\mathbf{I} - \mathbf{P}^\top\mathbf{A}\mathbf{P}$ is block upper triangular with diagonal blocks $x\mathbf{I} - \mathbf{A}_{ii}$. Applying Theorem 6.8.4 over $F[x]$, as the paragraph after it notes, to the first diagonal block and the rest, and then to the rest by induction on m, gives $p_{\mathbf{A}} = \prod_i p_{\mathbf{A}_{ii}}$. The roots of a product, with multiplicities, are those of the factors together.

(c) By (b), $\operatorname{spec}(\mathbf{A}) = \bigcup_i \operatorname{spec}(\mathbf{A}_{ii})$, and the largest modulus over a union is the largest of the largest moduli. If $\mathbf{A} \geq 0$, then by Lemma 18.2.3 the entries of $\mathbf{P}^\top\mathbf{A}\mathbf{P}$ are entries of $\mathbf{A}$, so they are ≥ 0, and so are those of each $\mathbf{A}_{ii}$.

■

The diagonal blocks of the normal form correspond to groups of vertices of $G(\mathbf{A})$ that can all reach one another. The first block is a group with no exit, and each later block can send edges only to the blocks before it. In a Markov chain the first block is therefore a set of states that the chain, once inside, never leaves; §06 uses exactly this. The blocks are unique up to their order and up to relabeling within each block, but we shall not need this and do not prove it.

Example. (A normal form with three blocks)

Put $\mathbf{A} = \begin{pmatrix} 0 & 0 & 1 & 0 \\ 1 & 2 & 0 & 1 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 3 \end{pmatrix}$ in reducible normal form, and find $\rho(\mathbf{A})$.

Solution. Read the edges column by column. Column 1 gives $1 \to 2$ and $1 \to 3$; column 2 gives the loop $2 \to 2$; column 3 gives $3 \to 1$ and $3 \to 4$; column 4 gives $4 \to 2$ and the loop $4 \to 4$. So 1 and 3 reach each other, and from them one can go to 4 and then to 2, but never back. The groups are $\{2\}$, $\{4\}$ and $\{1, 3\}$. Vertex 2 has no exit, so it comes first; the edges from 4 go only to 2 and 4, so 4 comes next; then $1, 3$. With $\sigma = (2, 4, 1, 3)$, that is $\sigma(1) = 2$, $\sigma(2) = 4$, $\sigma(3) = 1$, $\sigma(4) = 3$, Lemma 18.2.3 gives

$$\mathbf{P}_\sigma^\top \mathbf{A} \mathbf{P}_\sigma = \begin{pmatrix} 2 & 1 & 1 & 0 \\ 0 & 3 & 0 & 1 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{pmatrix},$$

with diagonal blocks (2), (3) and the swap $\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$, each irreducible. By Theorem 18.2.7 (b), $p_{\mathbf{A}}(x) = (x-2)(x-3)(x^2-1)$, so the eigenvalues are $2, 3, 1, -1$, and $\rho(\mathbf{A}) = 3$, the spectral radius of the second block.

18.2.6 Exercises

18.2.6.1 A. Check your understanding

Exercise A1.

(a) Define the directed graph $G(\mathbf{A})$, a walk, and strong connectivity. Which way does the edge for $a_{ij} \neq 0$ point?

(b) Define **irreducible**, including the case $n = 1$, and state Theorem 18.2.6.

(c) True or false: a matrix with a zero entry is reducible. Justify your answer.

(d) True or false: if $\mathbf{A} \geq 0$ is irreducible, then so is $\mathbf{A}^2$. Justify your answer.

(e) True or false: $\mathbf{A}$ is irreducible if and only if $\mathbf{A}^\top$ is. Justify your answer.

(f) True or false: the 2×2 zero matrix is irreducible. Justify your answer.

Solution.

(a) $G(\mathbf{A})$ has vertices $1, \dots, n$ and an edge $j \to i$ for each $a_{ij} \neq 0$, pointing from the column index to the row index. A walk of length k from j to i is a list $j = i_0, \dots, i_k = i$ with each $i_{t-1} \to i_t$ an edge. $G(\mathbf{A})$ is strongly connected if there is a walk from j to i for every ordered pair (j, i).

(b) For $n \geq 2$, $\mathbf{A}$ is reducible if $\mathbf{P}^\top \mathbf{A} \mathbf{P} = \left(\begin{smallmatrix} \mathbf{B} & \mathbf{C} \\ 0 & \mathbf{D} \end{smallmatrix}\right)$ for some permutation matrix $\mathbf{P}$ and square blocks $\mathbf{B}$, $\mathbf{D}$ of sizes k and $n - k$, $1 \leq k \leq n - 1$; irreducible means not reducible. Every 1×1 matrix is irreducible. The theorem: a non-negative $\mathbf{A} \in M_n(\mathbb{R})$ is irreducible if and only if $(\mathbf{I} + \mathbf{A})^{n-1} > 0$.

(c) False. The swap $\left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$ has two zero entries and is irreducible, since its graph $1 \to 2 \to 1$ is strongly connected (Theorem 18.2.5).

(d) False. The swap is irreducible and its square $\mathbf{I}_2$ is reducible, being triangular.

(e) True. $G(\mathbf{A}^\top)$ is $G(\mathbf{A})$ with every edge reversed, since $(\mathbf{A}^\top)_{ij} = a_{ji}$. Reversing a walk from j to i in $G(\mathbf{A})$ gives a walk from i to j in $G(\mathbf{A}^\top)$, so one graph is strongly connected exactly when the other is, and Theorem 18.2.5 finishes.

(f) False. With $n = 2$, the zero matrix is already upper triangular, so it is reducible with $\mathbf{P} = \mathbf{I}$, $k = 1$. Only the 1×1 zero matrix is irreducible, and that by convention.

18.2.6.2 B. Practice

Exercise B1: Deciding irreducibility.

Determine which of the following matrices are irreducible. Justify your answers, and for each reducible one give a permutation matrix that puts it in block upper triangular form.

(a) $\begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 0 & 0 \end{pmatrix}$

(b) $\begin{pmatrix} 1 & 2 & 0 \\ 0 & 3 & 0 \\ 4 & 5 & 6 \end{pmatrix}$

(c) $\begin{pmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 1 & 1 & 0 & 0 \end{pmatrix}$

(d) $\begin{pmatrix} 1 & 1 & 0 & 0 \\ 1 & 1 & 0 & 0 \\ 0 & 1 & 1 & 1 \\ 0 & 0 & 1 & 1 \end{pmatrix}$

Solution.

(a) The non-zero entries a_{12}, a_{23}, a_{31} give the edges $2 \to 1$, $3 \to 2$, $1 \to 3$: the cycle $1 \to 3 \to 2 \to 1$, which is strongly connected. Irreducible, by Theorem 18.2.5.

(b) Column 3 has its only non-zero entry in row 3, so $S = \{3\}$ has no exit, and the matrix is reducible by Lemma 18.2.4. With $\sigma(1) = 3$, $\sigma(2) = 1$, $\sigma(3) = 2$, Lemma 18.2.3 gives $\mathbf{P}_\sigma^\top \mathbf{A} \mathbf{P}_\sigma = \left(\begin{smallmatrix} 6 & 4 & 5 \\ 0 & 1 & 2 \\ 0 & 0 & 3 \end{smallmatrix}\right)$, which is even triangular.

(c) The edges are $1 \to 4$ (from a_{41}), $2 \to 1$ and $2 \to 4$ (from a_{12}, a_{42}), $3 \to 2$ (from a_{23}) and $4 \to 3$ (from a_{34}). The walk $1 \to 4 \to 3 \to 2 \to 1$ passes through every vertex and returns, so any vertex reaches any other by following it. Irreducible.

(d) Columns 3 and 4 have zeros in rows 1 and 2, so $S = \{3, 4\}$ has no exit: reducible. With $\sigma = (3, 4, 1, 2)$, $\mathbf{P}_\sigma^\top \mathbf{A} \mathbf{P}_\sigma = \left(\begin{smallmatrix} 1 & 1 & 0 & 1 \\ 1 & 1 & 0 & 0 \\ 0 & 0 & 1 & 1 \\ 0 & 0 & 1 & 1 \end{smallmatrix}\right)$. The edge $2 \to 3$ goes into S, which is allowed; only edges out of S are forbidden.

Exercise B2: One power decides.

For each matrix, compute $(\mathbf{I}+\mathbf{A})^2$ and decide whether $\mathbf{A}$ is irreducible. For the reducible one, read off from $(\mathbf{I}+\mathbf{A})^2$ a set of vertices with no exit.

(a) $\mathbf{A} = \begin{pmatrix} 0 & 1 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix}$

(b) $\mathbf{A} = \begin{pmatrix} 1 & 0 & 0 \\ 1 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix}$

Solution.

(a) $\mathbf{I} + \mathbf{A} = \left(\begin{smallmatrix} 1 & 1 & 1 \\ 1 & 1 & 0 \\ 0 & 1 & 1 \end{smallmatrix}\right)$, and multiplying out,

$$(\mathbf{I} + \mathbf{A})^2 = \begin{pmatrix} 2 & 3 & 2 \\ 2 & 2 & 1 \\ 1 & 2 & 1 \end{pmatrix} > 0.$$

Hence $\mathbf{A}$ is irreducible by Theorem 18.2.6.

(b) $\mathbf{I} + \mathbf{A} = \left(\begin{smallmatrix} 2 & 0 & 0 \\ 1 & 1 & 1 \\ 0 & 1 & 1 \end{smallmatrix}\right)$, and

$$(\mathbf{I} + \mathbf{A})^2 = \begin{pmatrix} 4 & 0 & 0 \\ 3 & 2 & 2 \\ 1 & 2 & 2 \end{pmatrix},$$

which has zero entries, so $\mathbf{A}$ is reducible. By Lemma 18.2.1 (b), column j of $(\mathbf{I}+\mathbf{A})^2$ is positive exactly in the rows i reachable from j. Column 2 is positive in

rows $2, 3$ only, so the vertices reachable from 2 form $S = \{2, 3\}$, and by the proof of Theorem 18.2.5 no edge leaves it. Indeed $a_{12} = a_{13} = 0$.

Exercise B3: Eigenvalues from the normal form.

Let $\mathbf{A} = \begin{pmatrix} 1 & 0 & 2 \\ 1 & 3 & 0 \\ 4 & 0 & 5 \end{pmatrix}$. Put $\mathbf{A}$ in reducible normal form, and hence find its eigenvalues and $\rho(\mathbf{A})$.

Solution. The edges are $1 \to 1$, $1 \to 2$, $1 \to 3$ (column 1), the loop $2 \to 2$ (column 2), and $3 \to 1$, $3 \to 3$ (column 3). Vertex 2 has no exit, and 1, 3 reach each other. List 2 first: $\sigma(1) = 2$, $\sigma(2) = 1$, $\sigma(3) = 3$. By Lemma 18.2.3,

$$\mathbf{P}_\sigma^{\top} \mathbf{A} \mathbf{P}_\sigma = \begin{pmatrix} 3 & 1 & 0 \\ 0 & 1 & 2 \\ 0 & 4 & 5 \end{pmatrix}.$$

The blocks (3) and $\left(\begin{smallmatrix} 1 & 2 \\ 4 & 5 \end{smallmatrix}\right)$ are irreducible, the second because both its off-diagonal entries are non-zero. By Theorem 18.2.7 (b), $p_{\mathbf{A}}(x) = (x - 3)(x^2 - 6x - 3)$, so the eigenvalues are 3 and $3 \pm 2\sqrt{3}$, and by (c), $\rho(\mathbf{A}) = 3 + 2\sqrt{3} \approx 6.46$, coming from the second block.

18.2.6.3 C. Going deeper

Exercise C1: A necessary condition that is not sufficient.

(a) Prove that if $n \geq 2$ and $\mathbf{A} \in M_n(F)$ is irreducible, then every row and every column of $\mathbf{A}$ contains a non-zero entry off the diagonal.

(b) Show that the converse fails for every even $n \geq 4$.

Solution.

(a) Suppose column j has no non-zero entry off the diagonal: $a_{ij} = 0$ for all $i \neq j$. Then $S = \{j\}$ has no exit, and S is neither empty nor everything because $n \geq 2$, so $\mathbf{A}$ is reducible by Lemma 18.2.4. Suppose instead row i has $a_{ij} = 0$ for all $j \neq i$. Then $S = \{1, \dots, n\} \setminus \{i\}$ has no exit, since the only entries $a_{i'j}$ with $j \in S$ and $i' \notin S$ are the a_{ij} with $j \neq i$; again $\mathbf{A}$ is reducible.

(b) Let $n = 2m$ with $m \geq 2$, and let $\mathbf{M}$ be the direct sum of m copies of the swap $\left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$. Every row and column has a 1 off the diagonal. But $S = \{1, 2\}$ has no exit, since column 1 and column 2 are zero outside rows $1, 2$, so $\mathbf{M}$ is reducible. The Quick check is the case $m = 2$.

Exercise C2: The exponent $n - 1$ is sharp.

Let $n \geq 2$ and let $\mathbf{C}_n$ be the cyclic permutation matrix with $\mathbf{C}_n \mathbf{e}_j = \mathbf{e}_{j+1}$ for $j < n$ and $\mathbf{C}_n \mathbf{e}_n = \mathbf{e}_1$.

(a) Prove that $\mathbf{C}_n$ is irreducible, but that $(\mathbf{I}+\mathbf{C}_n)^{n-2}$ is not positive.

(b) Prove that if $\mathbf{A} \geq 0$ is irreducible, then $(\mathbf{I}+\mathbf{A})^k > 0$ for every $k \geq n-1$.

Solution.

(a) The non-zero entries of $\mathbf{C}_n$ are $(\mathbf{C}_n)_{j+1,j} = 1$ for $j < n$ and $(\mathbf{C}_n)_{1n} = 1$, so the edges of $G(\mathbf{C}_n)$ are $j \to j+1$ and $n \to 1$, and there are no others. Following them from any vertex visits every vertex, so $G(\mathbf{C}_n)$ is strongly connected and $\mathbf{C}_n$ is irreducible (Theorem 18.2.5). Each vertex has exactly one outgoing edge, so the only walk from 1 of length $m \leq n-1$ is $1 \to 2 \to \cdots \to m+1$. In particular the shortest walk from 1 to n has length $n-1$, and there is no walk of length at most $n-2$ from 1 to n. By Lemma 18.2.1 (b), $\left((\mathbf{I}+\mathbf{C}_n)^{n-2}\right)_{n1} = 0$.

(b) By Lemma 18.2.1 (b), $((\mathbf{I}+\mathbf{A})^k)_{ij} > 0$ exactly when there is a walk of length at most k from j to i. For $k \geq n-1$, a walk of length at most $n-1$ is one of length at most k, and such walks exist for every pair by the proof of Theorem 18.2.6. Hence $(\mathbf{I}+\mathbf{A})^k > 0$.

Exercise C3: Irreducibility as growth of supports.

Let $n \geq 2$ and $\mathbf{A} \in M_n(\mathbb{R})$ with $\mathbf{A} \geq 0$. For $\mathbf{x} \geq \mathbf{0}$, call $\{i : x_i > 0\}$ the **support** of $\mathbf{x}$.

(a) Prove that the support of $(\mathbf{I}+\mathbf{A})\mathbf{x}$ is the support S of $\mathbf{x}$ together with every vertex i for which there is an edge $j \to i$ with $j \in S$.

(b) Prove that $\mathbf{A}$ is irreducible if and only if, for every $\mathbf{x} \geq \mathbf{0}$ with at least one zero entry and at least one positive entry, $(\mathbf{I}+\mathbf{A})\mathbf{x}$ has more positive entries than $\mathbf{x}$.

(c) Deduce, without using walks, that $(\mathbf{I}+\mathbf{A})^{n-1}\mathbf{x} > \mathbf{0}$ for every non-zero $\mathbf{x} \geq \mathbf{0}$ when $\mathbf{A}$ is irreducible, and hence that $(\mathbf{I}+\mathbf{A})^{n-1} > 0$.

Hint for (b): use Lemma 18.2.4.

Solution.

(a) $((\mathbf{I}+\mathbf{A})\mathbf{x})_i = x_i + \sum_j a_{ij}x_j$ is a sum of non-negative terms, so it is positive if and only if $x_i > 0$ or some $a_{ij}x_j > 0$, that is, $i \in S$ or there is $j \in S$ with $a_{ij} > 0$, which is an edge $j \to i$.

(b) Let $\mathbf{x}$ be as stated, with support S, which is neither empty nor everything. By (a), $(\mathbf{I}+\mathbf{A})\mathbf{x}$ has support containing S, and strictly larger exactly when some edge goes from S to a vertex outside S. ($\Rightarrow$) If $\mathbf{A}$ is irreducible, Lemma 18.2.4 says every such S has an exit, so the support grows. ($\Leftarrow$) If $\mathbf{A}$ were reducible, take S with no exit from Lemma 18.2.4, and let $\mathbf{x}$ have entry 1 on S and 0 elsewhere. Then $(\mathbf{I}+\mathbf{A})\mathbf{x}$ has support exactly S, with the same number of positive entries, contradicting the hypothesis.

(c) Let $\mathbf{x} \geq \mathbf{0}$, $\mathbf{x} \neq \mathbf{0}$, and put $\mathbf{x}_k = (\mathbf{I}+\mathbf{A})^k\mathbf{x} \geq \mathbf{0}$. By (a) the supports never shrink, and by (b) the support grows by at least one element at each step until it is everything. It starts with at least one element, so after at most $n-1$ steps it has n, and then stays so: $\mathbf{x}_{n-1} > \mathbf{0}$. Applying this to $\mathbf{x} = \mathbf{e}_j$ shows that column j of $(\mathbf{I}+\mathbf{A})^{n-1}$ is positive, for every j.

18.3 The Perron–Frobenius Theorem

Section 1 proved Perron's theorem (Theorem 18.1.5): a matrix with **every** entry positive has its spectral radius as a simple eigenvalue, with an eigenvector whose entries are all positive. That hypothesis is rarely met in practice. A Markov chain whose states can only step to their neighbors has a transition matrix full of zeros, and so does the matrix of almost any network. This section asks which of Perron's conclusions survive when zeros are allowed. There are two answers. For **every** non-negative matrix, the spectral radius is still an eigenvalue with a non-negative eigenvector, and of Perron's conclusions nothing more survives. For an **irreducible** matrix, in the sense of Section 2, every conclusion survives except one: other eigenvalues may reach the spectral radius in modulus. The positivity of the spectral radius also needs $n \geq 2$, because the 1×1 zero matrix counts as irreducible.

Throughout, matrices have real entries, and $\mathbf{A} \geq 0$, $\mathbf{A} > 0$, $\mathbf{x} \geq \mathbf{0}$ and $\mathbf{x} > \mathbf{0}$ are the entrywise order of Section 1. The spectrum is read in $\mathbb{C}$, as in Definition 15.4.1, so $\rho(\mathbf{A})$ is the largest modulus of a complex eigenvalue. We write $\mathbf{J}$ for the $n \times n$ matrix with every entry 1, and $\mathbf{1}$ for the all-ones vector.

18.3.1 What survives for every non-negative matrix

Start with the weakest hypothesis, $\mathbf{A} \geq 0$, and see what can be rescued. Three small matrices show at once that most of Perron's theorem is lost.

Example. (Three non-negative matrices that break Perron's theorem)

For each matrix, find ρ, its algebraic multiplicity, and all the non-negative eigenvectors, and say which conclusion of Theorem 18.1.5 fails:

$$\mathbf{N} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}, \qquad \mathbf{A}_c = \begin{pmatrix} 1 & 1 & 0 \\ 1 & 1 & 0 \\ 0 & 0 & c \end{pmatrix} \quad \text{with } c = 2 \text{ and with } c = 1.$$

Solution. The nilpotent matrix. $\mathbf{N}$ is upper triangular with zero diagonal, so its only eigenvalue is 0, with algebraic multiplicity 2 (Theorem 8.7.4 (b)), and $\rho(\mathbf{N}) = 0$. The eigenvectors are the non-zero solutions of $\mathbf{N}\mathbf{x} = \mathbf{0}$, that is, of $x_2 = 0$: the non-zero multiples of $\mathbf{e}_1$. So $\rho = 0$ is not positive, it is not simple, and no eigenvector is positive. What does survive is that $\rho(\mathbf{N}) = 0$ is an eigenvalue with the non-negative eigenvector $\mathbf{e}_1$.

The block matrix. $\mathbf{A}_c$ is block diagonal, with the 2×2 block $\left(\begin{smallmatrix} 1 & 1 \\ 1 & 1 \end{smallmatrix}\right)$ and the 1×1 block (c). The 2×2 block has trace 2 and determinant 0, so its eigenvalues are 2 and 0, with eigenvectors $(1, 1)$ and $(1, -1)$. Hence $p_{\mathbf{A}_c}(t) = t(t-2)(t-c)$, and the eigenvectors of $\mathbf{A}_c$ are built from those of the blocks: $(1, 1, 0)$ for 2, $(1, -1, 0)$ for 0, and $\mathbf{e}_3$ for c.

For $c = 2$: $\rho = 2$ has algebraic multiplicity 2. Its eigenspace is spanned by $(1, 1, 0)$ and $\mathbf{e}_3$, which are non-negative and not proportional, so the non-negative eigenvector is **not unique up to scale**. (It does contain the positive vector $(1, 1, 1)$, their sum.)

For $c = 1$: $\rho = 2$ is simple, but its eigenvectors are the multiples of $(1, 1, 0)$, none of them positive. And $\mathbf{e}_3 \geq \mathbf{0}$ is an eigenvector for the eigenvalue $1 < \rho$: a **non-negative eigenvector for a smaller eigenvalue**, which Theorem 18.1.5 rules out for positive matrices.

In each case ρ was still an eigenvalue with a non-negative eigenvector. That is the part that survives in general, and of Perron's conclusions it is all that survives. The proof is the first real use in the book of a *limiting auxiliary matrix* with a non-negative matrix in the limit. Perron's theorem applies to $\mathbf{A} + \varepsilon\mathbf{J}$, which is positive for every $\varepsilon > 0$; let $\varepsilon \to 0^+$ and keep whatever passes to the limit.

Theorem 18.3.1 — The Spectral Radius of a Non-negative Matrix Is an Eigenvalue

Let $\mathbf{A} \in M_n(\mathbb{R})$ with $n \geq 1$ and $\mathbf{A} \geq 0$. Then $\rho(\mathbf{A})$ is an eigenvalue of $\mathbf{A}$, and there is a vector $\mathbf{x} \in \mathbb{R}^n$ with $\mathbf{x} \geq \mathbf{0}$, $\mathbf{x} \neq \mathbf{0}$ and $\mathbf{A}\mathbf{x} = \rho(\mathbf{A})\mathbf{x}$.

Idea. ① Perturb: $\mathbf{A}_k = \mathbf{A} + \frac{1}{k}\mathbf{J}$ is positive, so Theorem 18.1.5 gives it an eigenvalue $\rho(\mathbf{A}_k)$ with a positive eigenvector $\mathbf{v}_k$, which we scale into the simplex Δ_n. ② The matrices $\mathbf{A}_k$ decrease as k grows, so by monotonicity the numbers $\rho(\mathbf{A}_k)$ decrease and stay $\geq \rho(\mathbf{A})$; by monotone convergence they have a limit $r \geq \rho(\mathbf{A})$. ③ The $\mathbf{v}_k$ need not converge, but they live in a closed bounded set, so a subsequence does. ④ Pass to the limit in $\mathbf{A}_k\mathbf{v}_k = \rho(\mathbf{A}_k)\mathbf{v}_k$: the limit equation makes r an eigenvalue of $\mathbf{A}$, so $r \leq \rho(\mathbf{A})$, and $r = \rho(\mathbf{A})$. The scaling into Δ_n is what stops the limit vector from being $\mathbf{0}$: its entries still add up to 1.

Proof. Let $\rho = \rho(\mathbf{A})$, and for each integer $k \geq 1$ put $\mathbf{A}_k = \mathbf{A} + \frac{1}{k}\mathbf{J}$. Every entry of $\mathbf{A}_k$ is at least $\frac{1}{k} > 0$, so $\mathbf{A}_k > 0$. By Theorem 18.1.5, $\rho_k := \rho(\mathbf{A}_k)$ is an eigenvalue of $\mathbf{A}_k$ with an eigenvector $\mathbf{v}_k > \mathbf{0}$. Dividing $\mathbf{v}_k$ by the sum of its entries, which is positive, we may assume $\mathbf{v}_k \in \Delta_n$ (Definition 17.1.2).

Step 1: ρ_k converges to some $r \geq \rho$. Since $\frac{1}{k+1} < \frac{1}{k}$ and $\mathbf{J} \geq 0$, we have $0 \leq \mathbf{A} \leq \mathbf{A}_{k+1} \leq \mathbf{A}_k$ entrywise for every k. By Proposition 18.1.4 (a), applied to each of these two inequalities, $\rho \leq \rho_{k+1} \leq \rho_k$. So the sequence $(-\rho_k)$ is increasing and bounded above by $-\rho$. By monotone convergence, fact (A2) of Chapter 15's introduction, it converges to its least upper bound, which is $\leq -\rho$ because $-\rho$ is an upper bound. Hence $\rho_k \to r$ for some real number $r \geq \rho$.

Step 2: a convergent subsequence. The set Δ_n is bounded, since every entry of a point of Δ_n lies in $[0, 1]$. It is closed: if points of Δ_n converge to $\mathbf{v}$, then each entry of $\mathbf{v}$ is a limit of numbers ≥ 0, hence ≥ 0, and the entries of $\mathbf{v}$ add up to a limit of sums equal to 1. By the compactness of closed bounded sets, fact (A3) of Chapter 15's introduction, the sequence $(\mathbf{v}_k)$ has a subsequence $(\mathbf{v}_{k_j})$ converging to some $\mathbf{v} \in \Delta_n$. In particular $\mathbf{v} \geq \mathbf{0}$, and $\mathbf{v} \neq \mathbf{0}$ because its entries add up to 1.

Step 3: the limit. For every j we have $\mathbf{A}_{k_j}\mathbf{v}_{k_j} = \rho_{k_j}\mathbf{v}_{k_j}$. Convergence in the Euclidean norm is entrywise convergence (Corollary 15.2.4), and $\mathbf{A}_{k_j} \to \mathbf{A}$ entrywise. Each entry of $\mathbf{A}_{k_j}\mathbf{v}_{k_j}$ is a sum of products of entries of $\mathbf{A}_{k_j}$ and of $\mathbf{v}_{k_j}$, so by the algebra of limits it converges to the corresponding entry of $\mathbf{A}\mathbf{v}$; likewise $\rho_{k_j} \to r$ by Step 1, since a subsequence of a convergent sequence has the same limit, and so $\rho_{k_j}\mathbf{v}_{k_j} \to r\mathbf{v}$. Limits are unique, so $\mathbf{A}\mathbf{v} = r\mathbf{v}$ with $\mathbf{v} \neq \mathbf{0}$; r is an eigenvalue of $\mathbf{A}$, hence $r \leq \rho$ by Definition 15.4.1;

with $r \geq \rho$, $r = \rho$. So $\mathbf{Av} = \rho\mathbf{v}$, and $\mathbf{v} \geq \mathbf{0}$ is the required eigenvector. This proves the theorem.

■

Two imported facts were used, both named where they act: (A2) in Step 1 and (A3) in Step 2. No statement about the roots of polynomials is needed.

Remark. Alternatively, $\rho_k \to \rho$ also follows from the continuity of eigenvalues proved in Chapter 15 §07, but that rests on a theorem about the roots of polynomials which Chapter 15 quotes without proof; the route above needs nothing of the kind.

The theorem is sharp, in the sense that each of Perron's further conclusions fails for some non-negative matrix. Example (Three non-negative matrices that break Perron's theorem) shows that ρ can be 0, it can be a repeated eigenvalue, the non-negative eigenvector can fail to be positive or unique, and another eigenvalue can have a non-negative eigenvector; and the swap matrix below shows that another eigenvalue can reach $|\lambda| = \rho$. The positive conclusions of Theorem 18.1.5 are *strict* statements — an entry is > 0, a multiplicity is 1, an inequality $|\lambda| < \rho$ is strict — and strict inequalities do not survive limits. Positive numbers can tend to 0; two simple eigenvalues can merge.

Warning. **A non-negative eigenvector does not identify ρ for a general non-negative matrix.** In $\mathbf{A}_1$ of Example (Three non-negative matrices that break Perron's theorem) the vector $\mathbf{e}_3 \geq \mathbf{0}$ is an eigenvector, but its eigenvalue is 1, while $\rho(\mathbf{A}_1) = 2$. To find ρ from an eigenvector, you need either irreducibility (next subsection) or a **positive** eigenvector, which Exercise C1 at the end of this section shows is enough.

18.3.2 The theorem for irreducible matrices

What goes wrong in Example (Three non-negative matrices that break Perron's theorem) is visible in the zero pattern: $\mathbf{A}_c$ splits into two blocks that do not talk to each other, and $\mathbf{N}$ passes mass from one coordinate to the other but never back. Section 2 made "every coordinate eventually talks to every other" precise. A non-negative matrix is **irreducible** (Definition 18.2.3) when no simultaneous permutation of its rows and columns brings it to block upper triangular form, and by Theorem 18.2.6 this happens exactly when $(\mathbf{I} + \mathbf{A})^{n-1} > 0$. That criterion is the bridge we need: it turns an irreducible matrix into a positive one, to which Theorem 18.1.5 applies.

Theorem 18.3.2 — Perron–Frobenius Theorem

Let $\mathbf{A} \in M_n(\mathbb{R})$ with $n \geq 1$ be non-negative and irreducible, and put $\rho = \rho(\mathbf{A})$. Then:

(a) ρ is an eigenvalue of $\mathbf{A}$ with an eigenvector $\mathbf{v} > \mathbf{0}$;

(b) ρ is **algebraically simple**: $a_{\mathbf{A}}(\rho) = 1$;

(c) every non-negative eigenvector of $\mathbf{A}$, for **any** eigenvalue, is a positive multiple of $\mathbf{v}$; in particular its eigenvalue is ρ, and the non-negative eigenvector is unique up to scale;

(d) if $n \geq 2$, then $\rho > 0$.

Idea. There are two ways to reach a positive matrix, and we take the one that keeps strict information. The perturbation $\mathbf{A} + \varepsilon\mathbf{J}$ of the last proof needs a limit, and a limit cannot certify strict conclusions; Exercise C2 at the end of this section shows them lost when the limit matrix is reducible. So instead we use $\mathbf{B} = (\mathbf{I} + \mathbf{A})^{n-1}$, which is positive by Theorem 18.2.6 and needs no limit. Step roadmap:

① Theorem 18.3.1 gives $\mathbf{Ax} = \rho\mathbf{x}$ with $\mathbf{x} \geq \mathbf{0}$, $\mathbf{x} \neq \mathbf{0}$.

② $\mathbf{Bx} = (1+\rho)^{n-1}\mathbf{x}$, and a positive matrix times a non-zero non-negative vector is positive; so $\mathbf{x} > \mathbf{0}$.

③ Every eigenvector of $\mathbf{A}$ is an eigenvector of $\mathbf{B} = q(\mathbf{A})$, and the Spectral Mapping Theorem transports multiplicities. So a non-negative eigenvector of $\mathbf{A}$, or a repeated ρ, would be a non-negative eigenvector of $\mathbf{B}$, or a repeated $\rho(\mathbf{B})$ — both of which Theorem 18.1.5 controls.

④ If $\rho = 0$, then $\mathbf{Ax} = \mathbf{0}$ with $\mathbf{x} > \mathbf{0}$ forces $\mathbf{A} = 0$, which is not irreducible for $n \geq 2$.

Proof. Let $q(t) = (1+t)^{n-1}$ and $\mathbf{B} = q(\mathbf{A}) = (\mathbf{I} + \mathbf{A})^{n-1}$. Since $\mathbf{A}$ is irreducible, $\mathbf{B} > 0$ by Theorem 18.2.6.

Step 1: an eigenvector $\mathbf{v} > \mathbf{0}$ for ρ. By Theorem 18.3.1 there is $\mathbf{x} \geq \mathbf{0}$, $\mathbf{x} \neq \mathbf{0}$, with $\mathbf{Ax} = \rho\mathbf{x}$. Then $(\mathbf{I}+\mathbf{A})\mathbf{x} = (1+\rho)\mathbf{x}$, and applying this $n-1$ times gives $\mathbf{Bx} = (1+\rho)^{n-1}\mathbf{x}$. Choose j_0 with $x_{j_0} > 0$, possible because $\mathbf{x} \geq \mathbf{0}$ and $\mathbf{x} \neq \mathbf{0}$. For every i,

$$(\mathbf{Bx})_i = \sum_{j=1}^{n} b_{ij}x_j \geq b_{ij_0}x_{j_0} > 0,$$

since every term is ≥ 0 and $b_{ij_0} > 0$. So $\mathbf{Bx} > \mathbf{0}$. As $1 + \rho \geq 1$, we may divide: $\mathbf{x} = (1+\rho)^{-(n-1)}\mathbf{Bx} > \mathbf{0}$. Put $\mathbf{v} = \mathbf{x}$. This proves (a).

Step 2: eigenvectors of A are eigenvectors of B. If $\mathbf{Ay} = \mu\mathbf{y}$ with $\mathbf{y} \neq \mathbf{0}$, then, exactly as in Step 1, $\mathbf{By} = q(\mu)\mathbf{y}$. In particular $\mathbf{Bv} = q(\rho)\mathbf{v}$ with $\mathbf{v} > \mathbf{0}$. By Theorem 18.1.5 (d), a non-negative eigenvector of the positive matrix $\mathbf{B}$ belongs to the eigenvalue $\rho(\mathbf{B})$; hence

$$q(\rho) = (1+\rho)^{n-1} = \rho(\mathbf{B}).$$

Step 3: simplicity. Over $\mathbb{C}$, write $p_{\mathbf{A}}(t) = (t-\lambda_1)\cdots(t-\lambda_n)$ with each eigenvalue repeated according to its algebraic multiplicity (Corollary 5.5.5). By the Spectral Mapping Theorem (Theorem 8.10.1),

$$p_{\mathbf{B}}(t) = \big(t - q(\lambda_1)\big)\cdots\big(t - q(\lambda_n)\big).$$

Suppose $a_{\mathbf{A}}(\rho) \geq 2$, say $\lambda_1 = \lambda_2 = \rho$. Then $q(\rho) = \rho(\mathbf{B})$ occurs at least twice in this factorization (other eigenvalues mapping to $\rho(\mathbf{B})$ could only increase this count), so $a_{\mathbf{B}}(\rho(\mathbf{B})) \geq 2$, contradicting the simplicity of $\rho(\mathbf{B})$ in Theorem 18.1.5. Hence $a_{\mathbf{A}}(\rho) = 1$, which is (b).

Step 4: non-negative eigenvectors. Let $\mathbf{y} \geq \mathbf{0}$, $\mathbf{y} \neq \mathbf{0}$, with $\mathbf{Ay} = \mu\mathbf{y}$ for some $\mu \in \mathbb{C}$. By Step 2, $\mathbf{y}$ is a non-negative eigenvector of $\mathbf{B}$, so by Theorem 18.1.5 (d) it belongs to $\rho(\mathbf{B})$. So $\mathbf{y}$ and $\mathbf{v}$ both lie in the eigenspace $E_{\rho(\mathbf{B})}(\mathbf{B})$. Since $\rho(\mathbf{B})$ is algebraically simple, Theorem 8.3.1 gives $\dim E_{\rho(\mathbf{B})}(\mathbf{B}) = 1$, so $\mathbf{y} = c\mathbf{v}$ for some scalar $c \neq 0$. Choosing i with $y_i > 0$ gives $c = y_i/v_i > 0$. Finally $\mathbf{Ay} = c\mathbf{Av} = \rho\, c\mathbf{v} = \rho\mathbf{y}$, so $\mu = \rho$. This proves (c).

Step 5: $\rho > 0$ when $n \geq 2$. Suppose $\rho = 0$. Then $\mathbf{A}\mathbf{v} = \mathbf{0}$, so for each i the sum $\sum_j a_{ij}v_j$ of non-negative terms is 0, which forces $a_{ij}v_j = 0$ and hence $a_{ij} = 0$ for every j, as $v_j > 0$. So $\mathbf{A} = 0$ and $\mathbf{B} = \mathbf{I}_n$. For $n \geq 2$ the matrix $\mathbf{I}_n$ has a zero entry off the diagonal, so it is not positive, contradicting $\mathbf{B} > 0$. This proves (d), and the theorem.

■

The first sentence of the proof is where irreducibility did its work, and irreducibility was used only there. Note also what the theorem does **not** claim. For positive matrices, Theorem 18.1.5 adds that every other eigenvalue has modulus strictly less than ρ. For irreducible matrices this is false.

Warning. **Irreducible does not make ρ strictly dominant.** The swap $\mathbf{P} = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$ is irreducible, since $\mathbf{I} + \mathbf{P} = \mathbf{J}$ is positive (Theorem 18.2.6 with $n = 2$). Its eigenvalues are 1 and -1, with eigenvectors $(1, 1)$ and $(1, -1)$. The theorem holds as stated: $\rho = 1$ is simple with the positive eigenvector $(1, 1)$, and $(1, -1)$ is not non-negative. But $|-1| = \rho$. Section 5 identifies the irreducible matrices for which ρ is strictly dominant.

The case $n = 1$ is worth one sentence. A 1×1 matrix (a) with $a \geq 0$ has $\rho = a$, simple, with the positive eigenvector (1), so clauses (a)–(c) hold for it outright; clause (d) must exclude $n = 1$, since (0) has $\rho = 0$. For $n \geq 2$ the zero matrix is the one thing (d) had to rule out, and irreducibility does.

Example. (The theorem on a matrix with zeros)

Let

$$\mathbf{A} = \begin{pmatrix} 0 & 1 & 0 \\ 2 & 0 & 1 \\ 2 & 1 & 0 \end{pmatrix}.$$

Show that $\mathbf{A}$ is irreducible, find $\rho(\mathbf{A})$ and a positive eigenvector, and check clause (c) of Theorem 18.3.2 against the other eigenvalue.

Solution. Irreducible. We have $\mathbf{I} + \mathbf{A} = \left(\begin{smallmatrix} 1 & 1 & 0 \\ 2 & 1 & 1 \\ 2 & 1 & 1 \end{smallmatrix}\right)$ and, multiplying out,

$$(\mathbf{I} + \mathbf{A})^2 = \begin{pmatrix} 3 & 2 & 1 \\ 6 & 4 & 2 \\ 6 & 4 & 2 \end{pmatrix} > 0,$$

so $\mathbf{A}$ is irreducible by Theorem 18.2.6 with $n = 3$. Note that $\mathbf{A}$ itself has four zero entries and is not positive, so Theorem 18.1.5 does not apply to it directly.

The spectrum. Expanding $\det(t\mathbf{I} - \mathbf{A})$ along the first row,

$$\begin{aligned} p_{\mathbf{A}}(t) &= t\,(t^2 - 1) + (-2t - 2) \\ &= t^3 - 3t - 2 = (t - 2)(t + 1)^2. \end{aligned}$$

So the eigenvalues are 2 and -1, the latter with algebraic multiplicity 2, and $\rho(\mathbf{A}) = 2$, algebraically simple as clause (b) says. A repeated eigenvalue elsewhere in the spectrum is no contradiction: the theorem speaks only about ρ.

The eigenvector. $(\mathbf{A} - 2\mathbf{I})\mathbf{x} = \mathbf{0}$ reads $-2x_1 + x_2 = 0$, $2x_1 - 2x_2 + x_3 = 0$, $2x_1 + x_2 - 2x_3 = 0$.

The first gives $x_2 = 2x_1$, the second then $x_3 = 2x_1$, and the third is satisfied: $2+2-4 = 0$. So $\mathbf{v} = (1,2,2) > \mathbf{0}$ and $\mathbf{A}\mathbf{v} = (2,4,4) = 2\mathbf{v}$.

The other eigenvalue. $\mathbf{A} + \mathbf{I} = \left(\begin{smallmatrix} 1 & 1 & 0 \\ 2 & 1 & 1 \\ 2 & 1 & 1 \end{smallmatrix}\right)$ has rank 2, and its null space is spanned by $(1,-1,-1)$: the first row gives $x_2 = -x_1$, the second $x_3 = -2x_1 - x_2 = -x_1$. Every eigenvector for -1 is a multiple of $(1,-1,-1)$ and has entries of both signs, as clause (c) predicts.

Quick check. For which values of $c \geq 0$ is the matrix $\mathbf{A}_c$ of Example (Three non-negative matrices that break Perron's theorem) irreducible? Is the answer consistent with what the example found?

Solution. For none. Whatever c is, $\mathbf{I} + \mathbf{A}_c$ is block diagonal with blocks of sizes 2 and 1, so every power of it is block diagonal too, and $(\mathbf{I} + \mathbf{A}_c)^2$ has zeros in positions $(1,3)$, $(2,3)$, $(3,1)$, $(3,2)$. By Theorem 18.2.6, $\mathbf{A}_c$ is reducible. This is consistent: the example found conclusions of Theorem 18.3.2 failing for $c = 1$ and $c = 2$, which is possible only for a reducible matrix.

18.3.3 The left Perron vector

Everything so far concerned the equation $\mathbf{A}\mathbf{v} = \rho\mathbf{v}$. A non-negative matrix acts on rows as well: in a Markov chain, the row $\mathbf{1}^\top$ is a left eigenvector of every stochastic matrix (Proposition 8.11.3 (c)). Left eigenvectors of $\mathbf{A}$ are eigenvectors of $\mathbf{A}^\top$ (Proposition 8.10.5 (a)), and irreducibility passes to the transpose, so the theorem applies to rows at no extra cost.

Corollary 18.3.3 — The Left Perron Vector

Let $\mathbf{A} \in M_n(\mathbb{R})$ be non-negative and irreducible, with $\rho = \rho(\mathbf{A})$ and $\mathbf{v} > \mathbf{0}$ as in Theorem 18.3.2. Then:

(a) $\mathbf{A}^\top$ is non-negative and irreducible, and $\rho(\mathbf{A}^\top) = \rho$;

(b) there is $\mathbf{w} > \mathbf{0}$ with $\mathbf{w}^\top\mathbf{A} = \rho\,\mathbf{w}^\top$, and every non-negative left eigenvector of $\mathbf{A}$ is a positive multiple of $\mathbf{w}$;

(c) $\mathbf{w}^\top\mathbf{v} > 0$, so $\mathbf{w}$ can be scaled to make $\mathbf{w}^\top\mathbf{v} = 1$.

Idea. Apply Theorem 18.3.2 to $\mathbf{A}^\top$ and read the answer back as rows. Two things must be checked first: that $\mathbf{A}^\top$ meets the hypotheses, which holds because the test $(\mathbf{I}+\mathbf{A})^{n-1} > 0$ survives transposition, and that $\mathbf{A}^\top$ has the same spectral radius, which holds because it has the same characteristic polynomial. Positivity of both vectors then makes $\mathbf{w}^\top\mathbf{v}$ a sum of positive terms.

Proof.

(a) The entries of $\mathbf{A}^\top$ are those of $\mathbf{A}$, so $\mathbf{A}^\top \geq 0$. Transposition reverses products and fixes $\mathbf{I}$ (Theorem 0.9.5), so $(\mathbf{I}+\mathbf{A}^\top)^{n-1} = \big((\mathbf{I}+\mathbf{A})^{n-1}\big)^\top$, which is positive because $(\mathbf{I}+\mathbf{A})^{n-1}$ is; hence $\mathbf{A}^\top$ is irreducible by Theorem 18.2.6. By Proposition 8.10.5 (b), $p_{\mathbf{A}^\top} = p_{\mathbf{A}}$, so $\mathbf{A}$ and $\mathbf{A}^\top$ have the same eigenvalues and $\rho(\mathbf{A}^\top) = \rho$.

(b) By (a) and Theorem 18.3.2 (a) applied to $\mathbf{A}^\top$, there is $\mathbf{w} > \mathbf{0}$ with $\mathbf{A}^\top \mathbf{w} = \rho \mathbf{w}$, which by Proposition 8.10.5 (a) says $\mathbf{w}^\top \mathbf{A} = \rho \mathbf{w}^\top$. A non-negative left eigenvector of $\mathbf{A}$ is a non-negative eigenvector of $\mathbf{A}^\top$, hence a positive multiple of $\mathbf{w}$ by Theorem 18.3.2 (c) applied to $\mathbf{A}^\top$.

(c) $\mathbf{w}^\top \mathbf{v} = \sum_i w_i v_i$ is a sum of positive numbers, so it is positive, and $\mathbf{w}/(\mathbf{w}^\top \mathbf{v})$ has the stated property.

■

This makes the following names well defined, since each vector is pinned down by (c) of the theorem or (b) of the corollary together with its normalization.

Definition 18.3.1 — Perron Root, Perron Vectors

This definition extends Definition 18.1.2 from positive matrices to irreducible ones. Let $\mathbf{A} \in M_n(\mathbb{R})$ be non-negative and irreducible. Its **Perron root** is $\rho(\mathbf{A})$. Its **(right) Perron vector** is the unique $\mathbf{v} > \mathbf{0}$ with $\mathbf{A}\mathbf{v} = \rho(\mathbf{A})\mathbf{v}$ and $\mathbf{1}^\top \mathbf{v} = 1$. Its **left Perron vector** is the unique $\mathbf{w} > \mathbf{0}$ with $\mathbf{w}^\top \mathbf{A} = \rho(\mathbf{A})\mathbf{w}^\top$ and $\mathbf{w}^\top \mathbf{v} = 1$.

The two normalizations are chosen for what they do. $\mathbf{1}^\top \mathbf{v} = 1$ makes $\mathbf{v}$ a probability vector, which is what a Markov chain wants; $\mathbf{w}^\top \mathbf{v} = 1$ makes the rank-one matrix $\mathbf{v}\mathbf{w}^\top$ idempotent, since

$$(\mathbf{v}\mathbf{w}^\top)(\mathbf{v}\mathbf{w}^\top) = \mathbf{v}\,(\mathbf{w}^\top \mathbf{v})\,\mathbf{w}^\top = \mathbf{v}\mathbf{w}^\top.$$

Section 5 shows that, for a large class of irreducible matrices, the powers $(\mathbf{A}/\rho)^k$ converge to exactly this matrix.

A positive matrix is irreducible, since then $(\mathbf{I}+\mathbf{A})^{n-1} \geq \mathbf{I}+\mathbf{A} > 0$ for $n \geq 2$: expand $(\mathbf{I}+\mathbf{A})^{n-1}$ by the binomial theorem, which applies because $\mathbf{I}$ and $\mathbf{A}$ commute, and note that every term is ≥ 0 and two of them are $\mathbf{I}$ and $(n-1)\mathbf{A} \geq \mathbf{A}$. So this definition covers the positive matrices of Section 1. For them the Perron root and both Perron vectors are those of Definition 18.1.2.

For the matrix of Example (The theorem on a matrix with zeros), the left eigenvector is $(3, 2, 1)$: indeed $(3,2,1)\mathbf{A} = (0+4+2,\ 3+0+1,\ 0+2+0) = (6,4,2)$. The right Perron vector is $\mathbf{v} = \frac{1}{5}(1,2,2)$, and $(3,2,1)\cdot\frac{1}{5}(1,2,2) = \frac{9}{5}$, so the left Perron vector is $\mathbf{w} = \frac{5}{9}(3,2,1)$.

Example. (An irreducible stochastic matrix)

Let

$$\mathbf{A} = \begin{pmatrix} 0 & 1/2 & 1 \\ 1 & 0 & 0 \\ 0 & 1/2 & 0 \end{pmatrix}.$$

Show that $\mathbf{A}$ is stochastic and irreducible, and find its Perron root and its right and left Perron vectors.

Solution. Each column is a probability vector, so $\mathbf{A}$ is stochastic (Definition 8.11.1). Multiplying out,

$$(\mathbf{I}+\mathbf{A})^2 = \begin{pmatrix} 3/2 & 3/2 & 2 \\ 2 & 3/2 & 1 \\ 1/2 & 1 & 1 \end{pmatrix} > 0,$$

so $\mathbf{A}$ is irreducible (Theorem 18.2.6).

Perron root. By Proposition 8.11.3 (c), 1 is an eigenvalue. Every column sum is 1, so $\|\mathbf{A}\|_1 = 1$ and $\rho(\mathbf{A}) \le 1$ by Corollary 15.4.2. Hence $\rho(\mathbf{A}) = 1$.

Left Perron vector. $\mathbf{1}^\top \mathbf{A} = \mathbf{1}^\top$ with $\mathbf{1} > \mathbf{0}$, so by Corollary 18.3.3 (b) the left Perron vector is a multiple of $\mathbf{1}$.

Right Perron vector. $\mathbf{A}\mathbf{x} = \mathbf{x}$ reads $\frac{1}{2}x_2 + x_3 = x_1$, $x_1 = x_2$, $\frac{1}{2}x_2 = x_3$. With $x_3 = 1$ this gives $x_2 = 2$, $x_1 = 2$, and the first equation holds: $1 + 1 = 2$. So $\mathbf{v} = \frac{1}{5}(2, 2, 1)$. Then $\mathbf{1}^\top \mathbf{v} = 1$, and the left Perron vector is $\mathbf{w} = \mathbf{1}$ itself.

By Theorem 18.3.2 (c), $\mathbf{v}$ is the **only** probability vector with $\mathbf{A}\mathbf{v} = \mathbf{v}$: this chain has exactly one steady state, and every state has positive probability in it. The other two eigenvalues are the roots of $2t^2 + 2t + 1$, namely $\frac{-1 \pm i}{2}$, of modulus $1/\sqrt{2} < 1$; the factorization is $p_{\mathbf{A}}(t) = (t - 1)(t^2 + t + \frac{1}{2})$, which the reader can confirm by expanding $\det(t\mathbf{I} - \mathbf{A})$ along the first column.

For every irreducible stochastic matrix the same three lines apply, and they show that the left Perron vector is always $\mathbf{1}$ and the steady state always unique and positive. Section 6 draws the consequences for Markov chains.

18.3.4 Exercises

18.3.4.1 A. Check your understanding

Exercise A1.

(a) State the Perron–Frobenius theorem for irreducible non-negative matrices.

(b) True or false: if $\mathbf{A} \ge 0$, then $\rho(\mathbf{A}) > 0$. Justify your answer.

(c) True or false: if $\mathbf{A} \ge 0$ is irreducible, then every eigenvalue $\lambda \ne \rho(\mathbf{A})$ has $|\lambda| < \rho(\mathbf{A})$. Justify your answer.

(d) True or false: if $\mathbf{A} \ge 0$ and $\mathbf{A}\mathbf{y} = \mu\mathbf{y}$ with $\mathbf{y} \ge \mathbf{0}$, $\mathbf{y} \ne \mathbf{0}$, then $\mu = \rho(\mathbf{A})$. Justify your answer.

(e) Which positive matrix does the proof of Theorem 18.3.2 apply Theorem 18.1.5 to, and why not to $\mathbf{A} + \varepsilon\mathbf{J}$?

Solution.

(a) See Theorem 18.3.2: for $\mathbf{A} \ge 0$ irreducible, $\rho(\mathbf{A})$ is an algebraically simple eigenvalue with a positive eigenvector, every non-negative eigenvector is a positive multiple of that one, and $\rho(\mathbf{A}) > 0$ when $n \ge 2$.

(b) False. $\mathbf{N} = \left(\begin{smallmatrix} 0 & 1 \\ 0 & 0 \end{smallmatrix}\right) \ge 0$ has $\rho(\mathbf{N}) = 0$ (Example (Three non-negative matrices that break Perron's theorem)). It is reducible, so this does not contradict Theorem 18.3.2 (d).

(c) False. The swap $\left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$ is irreducible with eigenvalues $1 = \rho$ and -1, and $|-1| = \rho$.

(d) False in general: $\mathbf{A}_1$ of Example (Three non-negative matrices that break Perron's theorem) has $\mathbf{A}_1\mathbf{e}_3 = \mathbf{e}_3$ but $\rho(\mathbf{A}_1) = 2$. It is true when $\mathbf{A}$ is irreducible, by Theorem 18.3.2 (c).

(e) To $\mathbf{B} = (\mathbf{I}+\mathbf{A})^{n-1}$, which is positive by Theorem 18.2.6. The perturbation $\mathbf{A}+\varepsilon\mathbf{J}$ requires a limit $\varepsilon \to 0^+$, and a limit cannot certify strict conclusions — positivity of the eigenvector and simplicity of ρ — which are exactly what the theorem asserts; Exercise C2 shows them lost when the limit matrix is reducible.

18.3.4.2 B. Practice

Exercise B1: Does the theorem apply?.

For each matrix, determine whether Theorem 18.3.2 applies. Where it does, find ρ and a positive eigenvector; where it does not, say which hypothesis fails and whether the conclusion fails too. Justify your answers.

(a) $\begin{pmatrix} 0 & 2 \\ 8 & 0 \end{pmatrix}$ (b) $\begin{pmatrix} 1 & 2 \\ 0 & 3 \end{pmatrix}$ (c) $\begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 0 & 0 \end{pmatrix}$ (d) $\begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$

Solution.

(a) Non-negative, and $\mathbf{I}+\mathbf{A} = \left(\begin{smallmatrix} 1 & 2 \\ 8 & 1 \end{smallmatrix}\right) > 0$, so irreducible by Theorem 18.2.6 with $n = 2$. The theorem applies. $p_{\mathbf{A}}(t) = t^2 - 16$, so the eigenvalues are ± 4 and $\rho = 4$. From $-4x_1 + 2x_2 = 0$, $\mathbf{v} = (1, 2) > \mathbf{0}$; check: $\mathbf{A}\mathbf{v} = (4, 8) = 4\mathbf{v}$. As with the swap, -4 has the same modulus as ρ.

(b) Non-negative, but $(\mathbf{I} + \mathbf{A})^1 = \left(\begin{smallmatrix} 2 & 2 \\ 0 & 4 \end{smallmatrix}\right)$ has a zero entry, so $\mathbf{A}$ is reducible and the theorem does not apply. The eigenvalues are 1 and 3 (Theorem 8.7.4 (b)), so $\rho = 3$. Here $(\mathbf{A} - 3\mathbf{I})\mathbf{x} = \mathbf{0}$ reads $-2x_1 + 2x_2 = 0$, so $(1, 1) > \mathbf{0}$ is an eigenvector for ρ: conclusions (a) and (b) happen to hold. Conclusion (c) fails: $\mathbf{e}_1 \geq \mathbf{0}$ is an eigenvector for $1 \neq \rho$.

(c) Non-negative. With $\mathbf{C}$ this matrix, $\mathbf{C}\mathbf{e}_1 = \mathbf{e}_3$, $\mathbf{C}\mathbf{e}_3 = \mathbf{e}_2$, $\mathbf{C}\mathbf{e}_2 = \mathbf{e}_1$, and $\mathbf{I} + \mathbf{C} + \mathbf{C}^2 = \mathbf{J}$; so $(\mathbf{I} + \mathbf{C})^2 = \mathbf{I} + 2\mathbf{C} + \mathbf{C}^2 \geq \mathbf{I} + \mathbf{C} + \mathbf{C}^2 = \mathbf{J} > 0$, and $\mathbf{C}$ is irreducible. The theorem applies. $\mathbf{C}^3 = \mathbf{I}$, and $p_{\mathbf{C}}(t) = t^3 - 1$ (expand along the first column), so the eigenvalues are the three cube roots of unity, all of modulus 1, and $\rho = 1$ with $\mathbf{v} = \mathbf{1}$, since every row of $\mathbf{C}$ has a single 1.

(d) Not non-negative, so the theorem does not apply, and its conclusion fails: $p(t) = t^2 + 1$, the eigenvalues are $\pm i$, and $\rho = 1$ is not an eigenvalue at all.

Exercise B2: Both Perron vectors.

Let

$$\mathbf{A} = \begin{pmatrix} 0 & 1 & 0 \\ 2 & 0 & 2 \\ 1 & 0 & 1 \end{pmatrix}.$$

Show that $\mathbf{A}$ is irreducible, and find its Perron root, its right Perron vector and its left Perron vector (Definition 18.3.1). Hence write down the matrix $\mathbf{v}\mathbf{w}^\top$ and check that it is idempotent.

Solution. Irreducible. $\mathbf{I}+\mathbf{A} = \left(\begin{smallmatrix} 1 & 1 & 0 \\ 2 & 1 & 2 \\ 1 & 0 & 2 \end{smallmatrix}\right)$, and

$$(\mathbf{I}+\mathbf{A})^2 = \begin{pmatrix} 3 & 2 & 2 \\ 6 & 3 & 6 \\ 3 & 1 & 4 \end{pmatrix} > 0,$$

so $\mathbf{A}$ is irreducible by Theorem 18.2.6.

Perron root. Expanding $\det(t\mathbf{I}-\mathbf{A})$ along the first row,

$$\begin{aligned} p_{\mathbf{A}}(t) &= t\big(t(t-1)-0\big) + \big(-2(t-1)-2\big) \\ &= t^3 - t^2 - 2t = t(t-2)(t+1), \end{aligned}$$

so the eigenvalues are $2, 0, -1$ and $\rho = 2$.

Right. $(\mathbf{A}-2\mathbf{I})\mathbf{x} = \mathbf{0}$: the first row gives $x_2 = 2x_1$, the third $x_1 - x_3 = 0$. So $\mathbf{x} = (1,2,1)$; check the second row: $2-4+2=0$. Normalizing, $\mathbf{v} = \frac{1}{4}(1,2,1)$.

Left. $(\mathbf{A}^\top - 2\mathbf{I})\mathbf{y} = \mathbf{0}$, with $\mathbf{A}^\top = \left(\begin{smallmatrix} 0 & 2 & 1 \\ 1 & 0 & 0 \\ 0 & 2 & 1 \end{smallmatrix}\right)$: the second row gives $y_1 = 2y_2$, the third $2y_2 - y_3 = 0$. So $\mathbf{y} = (2,1,2)$; check the first row: $-4+2+2=0$. Then $\mathbf{y}^\top\mathbf{v} = \frac{1}{4}(2+2+2) = \frac{3}{2}$, so $\mathbf{w} = \frac{2}{3}(2,1,2)$.

The product.

$$\mathbf{v}\mathbf{w}^\top = \frac{1}{4}\cdot\frac{2}{3}\begin{pmatrix} 2 & 1 & 2 \\ 4 & 2 & 4 \\ 2 & 1 & 2 \end{pmatrix} = \frac{1}{6}\begin{pmatrix} 2 & 1 & 2 \\ 4 & 2 & 4 \\ 2 & 1 & 2 \end{pmatrix}.$$

It is idempotent because $(\mathbf{v}\mathbf{w}^\top)^2 = \mathbf{v}(\mathbf{w}^\top\mathbf{v})\mathbf{w}^\top = \mathbf{v}\mathbf{w}^\top$, as $\mathbf{w}^\top\mathbf{v} = 1$. Directly: call the displayed integer matrix $\mathbf{M}$. Row i of $\mathbf{M}^2$ is row i of $\mathbf{M}$ times $\mathbf{M}$; the first row gives $2(2,1,2)+1(4,2,4)+2(2,1,2) = 6(2,1,2)$, and the other rows are multiples of the first, so $\mathbf{M}^2 = 6\mathbf{M}$. Hence $\left(\frac{1}{6}\mathbf{M}\right)^2 = \frac{1}{36}\cdot 6\mathbf{M} = \frac{1}{6}\mathbf{M}$.

Exercise B3: A reducible matrix, clause by clause.

Let

$$\mathbf{A} = \begin{pmatrix} 2 & 0 & 0 \\ 1 & 3 & 0 \\ 0 & 1 & 2 \end{pmatrix}.$$

Show that $\mathbf{A}$ is reducible. Find $\rho(\mathbf{A})$ and every non-negative eigenvector of $\mathbf{A}$. Hence decide which of the four conclusions of Theorem 18.3.2 hold for $\mathbf{A}$ and which fail.

Solution. Reducible. $\mathbf{I}+\mathbf{A}$ is lower triangular, so $(\mathbf{I}+\mathbf{A})^2$ is lower triangular and has zero entries above the diagonal; by Theorem 18.2.6, $\mathbf{A}$ is reducible.

Spectrum. $\mathbf{A}$ is lower triangular, so its eigenvalues are $2, 3, 2$ (Theorem 8.7.4 (b), applied to $\mathbf{A}^\top$, which has the same characteristic polynomial by Proposition 8.10.5 (b)). So $\rho = 3$, with $a_{\mathbf{A}}(3) = 1$.

Eigenvectors for 3. $(\mathbf{A}-3\mathbf{I})\mathbf{x} = \mathbf{0}$ reads $-x_1 = 0$, $x_1 = 0$, $x_2 - x_3 = 0$; the solutions are the multiples of $(0,1,1)$. *Eigenvectors for 2.* $(\mathbf{A}-2\mathbf{I})\mathbf{x} = \mathbf{0}$ reads $x_1 + x_2 = 0$, $x_2 = 0$; the solutions are the multiples of $(0,0,1)$. So the non-negative eigenvectors are the positive multiples of $(0,1,1)$ and of $\mathbf{e}_3$.

Verdict. Conclusion (b) holds and (d) holds ($\rho = 3 > 0$). Conclusion (a) fails in its strong form: ρ is an eigenvalue, as Theorem 18.3.1 guarantees, but no eigenvector for it is positive. Conclusion (c) fails: $\mathbf{e}_3 \geq \mathbf{0}$ is an eigenvector for $2 \neq \rho$.

18.3.4.3 C. Going deeper

Exercise C1: A positive eigenvector always belongs to the spectral radius.

Let $\mathbf{A} \in M_n(\mathbb{R})$ with $\mathbf{A} \geq 0$, **not** assumed irreducible.

(a) Prove that if $\mathbf{A}\mathbf{x} = \mu\mathbf{x}$ with $\mathbf{x} > \mathbf{0}$, then $\mu = \rho(\mathbf{A})$.

(b) Deduce that if every row of $\mathbf{A}$ has the same sum s, then $\rho(\mathbf{A}) = s$.

(c) Show by an example that (a) fails if $\mathbf{x} > \mathbf{0}$ is weakened to $\mathbf{x} \geq \mathbf{0}$, $\mathbf{x} \neq \mathbf{0}$.

Hint: apply Theorem 18.3.1 to $\mathbf{A}^\top$.

Solution.

(a) Since $\mathbf{A}$ and $\mathbf{x}$ are real and $\mathbf{x} \neq \mathbf{0}$, $\mu = (\mathbf{A}\mathbf{x})_i / x_i$ for any i is real, and it is ≥ 0 because $(\mathbf{A}\mathbf{x})_i \geq 0$ and $x_i > 0$. By Proposition 8.10.5 (b), $\rho(\mathbf{A}^\top) = \rho(\mathbf{A}) = \rho$, and $\mathbf{A}^\top \geq 0$, so Theorem 18.3.1 gives $\mathbf{y} \geq \mathbf{0}$, $\mathbf{y} \neq \mathbf{0}$, with $\mathbf{A}^\top\mathbf{y} = \rho\mathbf{y}$, that is, $\mathbf{y}^\top\mathbf{A} = \rho\mathbf{y}^\top$. Compute $\mathbf{y}^\top\mathbf{A}\mathbf{x}$ two ways:

$$\rho\,\mathbf{y}^\top\mathbf{x} = (\mathbf{y}^\top\mathbf{A})\mathbf{x} = \mathbf{y}^\top(\mathbf{A}\mathbf{x}) = \mu\,\mathbf{y}^\top\mathbf{x}.$$

Now $\mathbf{y}^\top\mathbf{x} = \sum_i y_i x_i > 0$, as every term is ≥ 0 and the terms with $y_i > 0$ are positive. Dividing, $\mu = \rho$.

(b) Equal row sums s say $\mathbf{A}\mathbf{1} = s\mathbf{1}$, and $\mathbf{1} > \mathbf{0}$, so $s = \rho(\mathbf{A})$ by (a).

(c) $\mathbf{A}_1$ of Example (Three non-negative matrices that break Perron's theorem) has $\mathbf{A}_1\mathbf{e}_3 = \mathbf{e}_3$ with $\mathbf{e}_3 \geq \mathbf{0}$, $\mathbf{e}_3 \neq \mathbf{0}$, but $\rho(\mathbf{A}_1) = 2 \neq 1$.

Exercise C2: What the limit loses.

This exercise shows why the proof of Theorem 18.3.2 does not take the limit $\mathbf{A}+\varepsilon\mathbf{J} \to \mathbf{A}$.

(a) For $\varepsilon > 0$, find the eigenvalues of $\mathbf{I}_2 + \varepsilon\mathbf{J}$. Show that ρ is simple for every $\varepsilon > 0$, but not at $\varepsilon = 0$.

(b) For $\varepsilon > 0$, let $\mathbf{N}_\varepsilon = \left(\begin{smallmatrix} \varepsilon & 1+\varepsilon \\ \varepsilon & \varepsilon \end{smallmatrix}\right)$, which is $\mathbf{N} + \varepsilon\mathbf{J}$ for the nilpotent $\mathbf{N}$ of Example (Three non-negative matrices that break Perron's theorem). Show that $\rho(\mathbf{N}_\varepsilon) = \varepsilon + \sqrt{\varepsilon(1+\varepsilon)}$ with eigenvector $\left(\sqrt{1+\varepsilon},\ \sqrt{\varepsilon}\right) > \mathbf{0}$, and find the limit of this eigenvector as $\varepsilon \to 0^+$.

(c) Which conclusions of Theorem 18.1.5 survive the limit in these two examples, and which do not? Explain in one sentence why this is to be expected.

Solution.

(a) $\mathbf{J}\mathbf{1} = 2\cdot\mathbf{1}$ and $\mathbf{J}(1,-1) = \mathbf{0}$, so $\mathbf{I}_2 + \varepsilon\mathbf{J}$ has the eigenvalue $1+2\varepsilon$ on $(1,1)$ and 1 on $(1,-1)$. For $\varepsilon > 0$ these are distinct, so $\rho = 1+2\varepsilon$ is simple. At $\varepsilon = 0$ the matrix is $\mathbf{I}_2$ and $\rho = 1$ has algebraic multiplicity 2.

(b) $\mathbf{N}_\varepsilon - \varepsilon\mathbf{I} = \left(\begin{smallmatrix} 0 & 1+\varepsilon \\ \varepsilon & 0 \end{smallmatrix}\right)$ has characteristic polynomial $t^2 - \varepsilon(1+\varepsilon)$, so the eigenvalues of $\mathbf{N}_\varepsilon$ are $\varepsilon \pm \sqrt{\varepsilon(1+\varepsilon)}$, and $\rho(\mathbf{N}_\varepsilon) = \varepsilon + \sqrt{\varepsilon(1+\varepsilon)}$, which exceeds the modulus of the other one since $\varepsilon > 0$. With $s = \sqrt{\varepsilon(1+\varepsilon)}$ and $\mathbf{u} = \left(\sqrt{1+\varepsilon}, \sqrt{\varepsilon}\right)$,

$$(\mathbf{N}_\varepsilon - \varepsilon\mathbf{I})\mathbf{u} = \left((1+\varepsilon)\sqrt{\varepsilon},\ \varepsilon\sqrt{1+\varepsilon}\right) = s\,\mathbf{u},$$

since $(1+\varepsilon)\sqrt{\varepsilon} = s\sqrt{1+\varepsilon}$ and $\varepsilon\sqrt{1+\varepsilon} = s\sqrt{\varepsilon}$. So $\mathbf{N}_\varepsilon\mathbf{u} = (\varepsilon + s)\mathbf{u}$ with $\mathbf{u} > \mathbf{0}$. As $\varepsilon \to 0^+$, $\mathbf{u} \to (1, 0) = \mathbf{e}_1$, which is non-negative but not positive.

(c) What survives is that ρ is an eigenvalue with a non-negative eigenvector, which is Theorem 18.3.1. Simplicity is lost in (a), and positivity of the eigenvector in (b). This is expected because those conclusions are strict — a multiplicity equal to 1, entries > 0 — and a limit of positive numbers need only be ≥ 0, while two distinct eigenvalues can converge to one.

Exercise C3: Uniqueness through the left Perron vector.

Let $\mathbf{A} \geq 0$ be irreducible, with left Perron vector $\mathbf{w}$ (Definition 18.3.1, Corollary 18.3.3).

(a) Using Theorem 8.10.6, give a second proof that if $\mathbf{A}\mathbf{y} = \mu\mathbf{y}$ with $\mathbf{y} \geq \mathbf{0}$, $\mathbf{y} \neq \mathbf{0}$, then $\mu = \rho(\mathbf{A})$.

(b) Deduce that an irreducible stochastic matrix has exactly one steady state (Definition 8.11.2), and that it is positive.

Solution.

(a) Suppose $\mu \neq \rho(\mathbf{A})$. The vector $\mathbf{w}$ is a left eigenvector for $\rho(\mathbf{A})$ and $\mathbf{y}$ a right eigenvector for μ, so Theorem 8.10.6 gives $\mathbf{w}^\top\mathbf{y} = 0$. But $\mathbf{w} > \mathbf{0}$, $\mathbf{y} \geq \mathbf{0}$ and $\mathbf{y} \neq \mathbf{0}$, so $\mathbf{w}^\top\mathbf{y} = \sum_i w_i y_i \geq w_i y_i > 0$ for an index i with $y_i > 0$. This contradiction shows $\mu = \rho(\mathbf{A})$.

(b) Let $\mathbf{A}$ be stochastic and irreducible. As in Example (An irreducible stochastic matrix), $\rho(\mathbf{A}) = 1$: 1 is an eigenvalue by Proposition 8.11.3 (c), and $\rho(\mathbf{A}) \leq \|\mathbf{A}\|_1 = 1$ by Corollary 15.4.2. A steady state is a probability vector $\mathbf{x}$ with $\mathbf{A}\mathbf{x} = \mathbf{x}$: a non-negative eigenvector for $1 = \rho(\mathbf{A})$, normalized by $\mathbf{1}^\top\mathbf{x} = 1$. By Theorem 18.3.2 (c), every such $\mathbf{x}$ is a positive multiple of the Perron vector $\mathbf{v}$, and the normalization forces $\mathbf{x} = \mathbf{v}$. So there is exactly one steady state, namely $\mathbf{v} > \mathbf{0}$.

18.4 The Collatz–Wielandt Formula

Section 3 proved that the spectral radius of a non-negative matrix is an eigenvalue, and that for an irreducible matrix it comes with a positive eigenvector. It did not say how to find the number. Finding it through the characteristic polynomial means finding the largest root of a polynomial of degree n, which in general has no formula in radicals once $n \geq 5$. This section gives a way to trap $\rho(\mathbf{A})$ between two numbers read off from a single test vector, with no eigenvalue computed. Each test vector gives a lower and an upper bound, and the bounds meet exactly at the Perron vector. That turns $\rho(\mathbf{A})$ into a maximum and a minimum over vectors, much as Chapter 16 turned the eigenvalues of a Hermitian matrix into extreme values of the Rayleigh

quotient (Definition 16.1.1).

Throughout, matrices have real entries, and $\geq$, $>$ between matrices or vectors are the entrywise order of Section 1. We use one elementary fact repeatedly. If $\mathbf{A} \geq 0$ and $\mathbf{u} \geq \mathbf{u}'$, then $\mathbf{A}\mathbf{u} \geq \mathbf{A}\mathbf{u}'$, because each entry of $\mathbf{A}(\mathbf{u} - \mathbf{u}')$ is a sum of products of non-negative numbers. In words, a non-negative matrix preserves the order.

18.4.1 Bounds from a single test vector

If $\mathbf{v} > \mathbf{0}$ is an eigenvector for ρ, then the ratios $(\mathbf{A}\mathbf{v})_i / v_i$ are all equal to ρ. For a vector that is not an eigenvector, the ratios spread out. The idea of this section is that ρ always lies somewhere in that spread.

Take $\mathbf{x} = \mathbf{1}$. Then $(\mathbf{A}\mathbf{1})_i$ is the i-th row sum, so the ratios are the row sums. For

$$\mathbf{A} = \begin{pmatrix} 0 & 1 & 1 \\ 0 & 1 & 2 \\ 1 & 0 & 3 \end{pmatrix}$$

they are $2, 3, 4$. The characteristic polynomial is $t^3 - 4t^2 + 2t - 1$, and $\rho(\mathbf{A}) \approx 3.51$, which indeed lies between 2 and 4. Two propositions make "lies in the spread" precise, one for each end. The upper end is the classical one.

Proposition 18.4.1 — Subinvariance

Let $\mathbf{A} \in M_n(\mathbb{R})$ with $\mathbf{A} \geq 0$, and let $s \in \mathbb{R}$.

(a) If $\mathbf{x} > \mathbf{0}$ and $\mathbf{A}\mathbf{x} \leq s\mathbf{x}$, then $\rho(\mathbf{A}) \leq s$.

(b) If $\mathbf{A}$ is irreducible, $\mathbf{x} \geq \mathbf{0}$, $\mathbf{x} \neq \mathbf{0}$ and $\mathbf{A}\mathbf{x} \leq s\mathbf{x}$, then $\rho(\mathbf{A}) \leq s$. If moreover $\mathbf{A}\mathbf{x} \neq s\mathbf{x}$, then $\rho(\mathbf{A}) < s$.

Idea. For (a), rescale the coordinates by the entries of $\mathbf{x}$. In the new coordinates, $\mathbf{x}$ becomes $\mathbf{1}$, the hypothesis says that every row sum is at most s, and Chapter 15's row-sum bound finishes the job. For (b), $\mathbf{x}$ may have zero entries, so no rescaling is possible. Instead, pair the inequality with the left Perron vector $\mathbf{w} > \mathbf{0}$, which turns $\mathbf{w}^{\top}\mathbf{A}\mathbf{x}$ into $\rho\,\mathbf{w}^{\top}\mathbf{x}$.

Proof.

(a) Let $\mathbf{D} = \operatorname{diag}(x_1, \dots, x_n)$, which is invertible because every $x_i > 0$, and put $\mathbf{C} = \mathbf{D}^{-1}\mathbf{A}\mathbf{D}$. Its entries are $c_{ij} = a_{ij}x_j / x_i \geq 0$, and its i-th row sum is

$$\sum_{j=1}^{n} \frac{a_{ij}x_j}{x_i} = \frac{(\mathbf{A}\mathbf{x})_i}{x_i} \leq s,$$

where the inequality divides $(\mathbf{A}\mathbf{x})_i \leq s x_i$ by $x_i > 0$. Since the entries of $\mathbf{C}$ are non-negative, its absolute row sums are its row sums, so $\|\mathbf{C}\|_\infty \leq s$ by Theorem 15.3.3 (b). The matrices $\mathbf{A}$ and $\mathbf{C}$ are similar, so they have the same characteristic polynomial (Theorem 6.10.3) and the same spectral radius. Hence $\rho(\mathbf{A}) = \rho(\mathbf{C}) \leq \|\mathbf{C}\|_\infty \leq s$ by Corollary 15.4.2.

(b) Let $\rho = \rho(\mathbf{A})$ and let $\mathbf{w} > \mathbf{0}$ be a left eigenvector for ρ (Corollary 18.3.3). Since $\mathbf{w} \geq \mathbf{0}$ and $s\mathbf{x} - \mathbf{A}\mathbf{x} \geq \mathbf{0}$, the number $\mathbf{w}^\top(s\mathbf{x} - \mathbf{A}\mathbf{x})$ is ≥ 0. But $\mathbf{w}^\top \mathbf{A}\mathbf{x} = \rho\, \mathbf{w}^\top \mathbf{x}$, so

$$\mathbf{w}^\top(s\mathbf{x} - \mathbf{A}\mathbf{x}) = (s - \rho)\, \mathbf{w}^\top \mathbf{x}.$$

Choose i with $x_i > 0$. Then $\mathbf{w}^\top \mathbf{x} \geq w_i x_i > 0$, so $s - \rho \geq 0$. If moreover $\mathbf{A}\mathbf{x} \neq s\mathbf{x}$, then $s\mathbf{x} - \mathbf{A}\mathbf{x}$ has some entry > 0, and pairing with $\mathbf{w} > \mathbf{0}$ gives $\mathbf{w}^\top(s\mathbf{x} - \mathbf{A}\mathbf{x}) > 0$, hence $s - \rho > 0$. This proves the proposition.

■

The name comes from the inequality $\mathbf{A}\mathbf{x} \leq s\mathbf{x}$: the vector $\mathbf{x}$ is carried into something no bigger than a multiple of itself, "sub-invariant" up to the factor s.

Warning. **In part (a), the test vector must be positive unless A is irreducible.** For $\mathbf{A} = \operatorname{diag}(1, 5)$ and $\mathbf{x} = \mathbf{e}_1$, we have $\mathbf{A}\mathbf{x} = \mathbf{e}_1 \leq 1 \cdot \mathbf{x}$, yet $\rho(\mathbf{A}) = 5$. The zero entry of $\mathbf{x}$ hides the second coordinate from the test entirely. Part (b) allows zero entries only because irreducibility guarantees that every coordinate is seen through $\mathbf{w} > \mathbf{0}$.

The lower end needs no positivity at all, and it holds for every non-negative matrix.

Proposition 18.4.2 — Superinvariance

Let $\mathbf{A} \in M_n(\mathbb{R})$ with $\mathbf{A} \geq 0$, let $s \in \mathbb{R}$, and let $\mathbf{x} \geq \mathbf{0}$, $\mathbf{x} \neq \mathbf{0}$, with $\mathbf{A}\mathbf{x} \geq s\mathbf{x}$.

(a) Then $\rho(\mathbf{A}) \geq s$.

(b) If $\mathbf{A}$ is irreducible and $\mathbf{A}\mathbf{x} \neq s\mathbf{x}$, then $\rho(\mathbf{A}) > s$.

Idea. For (a), the proof cannot use a similarity, because $\mathbf{x}$ may have zero entries. Instead it iterates the inequality to get $\mathbf{A}^k\mathbf{x} \geq s^k\mathbf{x}$, so the powers of $\mathbf{A}$ grow at least like s^k, and Gelfand's formula reads $\rho(\mathbf{A})$ off that growth. For (b), pair with the left Perron vector exactly as in Proposition 18.4.1 (b).

Proof.

(a) If $s \leq 0$, then $\rho(\mathbf{A}) \geq 0 \geq s$. Let $s > 0$. We claim that $\mathbf{A}^k\mathbf{x} \geq s^k\mathbf{x}$ for every $k \geq 0$. The case $k = 0$ is an equality. If it holds for k, then

$$\mathbf{A}^{k+1}\mathbf{x} = \mathbf{A}(\mathbf{A}^k\mathbf{x}) \geq \mathbf{A}(s^k\mathbf{x}) = s^k\mathbf{A}\mathbf{x} \geq s^{k+1}\mathbf{x},$$

where the first inequality holds because $\mathbf{A} \geq 0$ preserves the order, and the second multiplies $\mathbf{A}\mathbf{x} \geq s\mathbf{x}$ by $s^k > 0$. This proves the claim.
Choose i with $x_i = \|\mathbf{x}\|_\infty$, which is positive since $\mathbf{x} \geq \mathbf{0}$ and $\mathbf{x} \neq \mathbf{0}$. By the claim, and Theorem 15.3.2 (a),

$$s^k\|\mathbf{x}\|_\infty = s^k x_i \leq (\mathbf{A}^k\mathbf{x})_i \leq \|\mathbf{A}^k\mathbf{x}\|_\infty \leq \|\mathbf{A}^k\|_\infty \|\mathbf{x}\|_\infty.$$

Dividing by $\|\mathbf{x}\|_\infty > 0$ and taking k-th roots gives $\|\mathbf{A}^k\|_\infty^{1/k} \geq s$ for every $k \geq 1$. The operator norm $\|\cdot\|_\infty$ is a matrix norm (Theorem 15.3.2 (d)), so by Gelfand's formula (Theorem 15.4.4) the left side tends to $\rho(\mathbf{A})$ as $k \to \infty$. A non-strict inequality survives the limit, so $\rho(\mathbf{A}) \geq s$.

(b) Let $\mathbf{w} > \mathbf{0}$ be a left eigenvector of $\mathbf{A}$ for $\rho = \rho(\mathbf{A})$ (Corollary 18.3.3). As in the proof of Proposition 18.4.1 (b), $\mathbf{w}^\top(\mathbf{A}\mathbf{x} - s\mathbf{x}) = (\rho - s)\,\mathbf{w}^\top\mathbf{x}$ with $\mathbf{w}^\top\mathbf{x} > 0$. Now $\mathbf{A}\mathbf{x} - s\mathbf{x} \geq \mathbf{0}$ has a positive entry, so the left side is > 0 and $\rho > s$.

■

Remark. For an irreducible $\mathbf{A}$, part (a) also follows from the one-line pairing argument of part (b), exactly as in Proposition 18.4.1 (b). The detour through Gelfand's formula is what makes (a) hold for **every** non-negative matrix, where $\mathbf{w}$ may have zero entries and $\mathbf{w}^\top\mathbf{x}$ may vanish.

Quick check. Let $\mathbf{A} = \begin{pmatrix} 2 & 3 \\ 1 & 0 \end{pmatrix}$. Use $\mathbf{x} = \mathbf{1}$ and $\mathbf{x} = (3, 1)$ to bound $\rho(\mathbf{A})$ above and below. What do you conclude?

Solution. $\mathbf{A}\mathbf{1} = (5, 1)$, so $\mathbf{A}\mathbf{1} \geq 1 \cdot \mathbf{1}$ and $\mathbf{A}\mathbf{1} \leq 5 \cdot \mathbf{1}$; the two propositions give $1 \leq \rho(\mathbf{A}) \leq 5$. Next, $\mathbf{A}(3, 1) = (9, 3) = 3 \cdot (3, 1)$, so $3 \leq \rho(\mathbf{A}) \leq 3$, that is, $\rho(\mathbf{A}) = 3$. Indeed $p_{\mathbf{A}}(t) = t^2 - 2t - 3 = (t-3)(t+1)$. A test vector that happens to be an eigenvector closes the gap completely.

18.4.2 The two Collatz–Wielandt functions

The propositions ask for a number s with $\mathbf{A}\mathbf{x} \leq s\mathbf{x}$ or $\mathbf{A}\mathbf{x} \geq s\mathbf{x}$. The best such numbers for a given $\mathbf{x}$ deserve names, since they are the bounds a test vector actually delivers.

Definition 18.4.1 — Collatz–Wielandt Functions

Let $\mathbf{A} \in M_n(\mathbb{R})$ with $\mathbf{A} \geq 0$.

(a) For $\mathbf{x} \geq \mathbf{0}$ with $\mathbf{x} \neq \mathbf{0}$, the **lower Collatz–Wielandt function** is

$$r_{\mathbf{A}}(\mathbf{x}) := \min\left\{ \frac{(\mathbf{A}\mathbf{x})_i}{x_i} : 1 \leq i \leq n,\ x_i > 0 \right\}.$$

(b) For $\mathbf{x} > \mathbf{0}$, the **upper Collatz–Wielandt function** is

$$R_{\mathbf{A}}(\mathbf{x}) := \max\left\{ \frac{(\mathbf{A}\mathbf{x})_i}{x_i} : 1 \leq i \leq n \right\}.$$

In words: $r_{\mathbf{A}}(\mathbf{x})$ is the smallest of the ratios, taken only over the coordinates where $\mathbf{x}$ is positive, and $R_{\mathbf{A}}(\mathbf{x})$ is the largest of the ratios, for a vector with no zero coordinates. Both are well defined: the first set is non-empty because $\mathbf{x} \neq \mathbf{0}$, and both are finite sets of real numbers.

The definition is built so that

$$\mathbf{A}\mathbf{x} \geq r_{\mathbf{A}}(\mathbf{x})\,\mathbf{x} \quad (\mathbf{x} \geq \mathbf{0},\ \mathbf{x} \neq \mathbf{0}), \qquad \mathbf{A}\mathbf{x} \leq R_{\mathbf{A}}(\mathbf{x})\,\mathbf{x} \quad (\mathbf{x} > \mathbf{0}).$$

In the first, the coordinates with $x_i > 0$ satisfy $(\mathbf{A}\mathbf{x})_i \geq r_{\mathbf{A}}(\mathbf{x})x_i$ by the choice of the minimum, and the coordinates with $x_i = 0$ satisfy $(\mathbf{A}\mathbf{x})_i \geq 0 = r_{\mathbf{A}}(\mathbf{x})x_i$ because $\mathbf{A}\mathbf{x} \geq \mathbf{0}$. And $r_{\mathbf{A}}(\mathbf{x})$ is the **largest** s with $\mathbf{A}\mathbf{x} \geq s\mathbf{x}$, since any such s is at most each ratio; likewise $R_{\mathbf{A}}(\mathbf{x})$ is the

smallest s with $\mathbf{Ax} \leq s\mathbf{x}$.

Some examples, simplest first.

- **The all-ones vector.** $\underline{r}_{\mathbf{A}}(\mathbf{1})$ and $\overline{r}_{\mathbf{A}}(\mathbf{1})$ are the smallest and the largest row sum of $\mathbf{A}$.
- **An eigenvector.** If $\mathbf{x} > \mathbf{0}$ and $\mathbf{Ax} = \mu\mathbf{x}$, every ratio equals μ, so $\underline{r}_{\mathbf{A}}(\mathbf{x}) = \overline{r}_{\mathbf{A}}(\mathbf{x}) = \mu$.
- **A standard basis vector.** $\underline{r}_{\mathbf{A}}(\mathbf{e}_j) = a_{jj}$: only the coordinate j counts, and there the ratio is $(\mathbf{Ae}_j)_j/1 = a_{jj}$.
- **The 1×1 case.** For $\mathbf{A} = (a)$, both functions are the constant $a = \rho(\mathbf{A})$.

Non-example by minimal change. Try to define $\overline{r}_{\mathbf{A}}$ on vectors with zero entries in the same way as $\underline{r}_{\mathbf{A}}$, as the maximum over the coordinates with $x_i > 0$. For the swap $\mathbf{A} = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$ and $\mathbf{x} = \mathbf{e}_1$, we get $\mathbf{Ax} = \mathbf{e}_2$, and the only ratio is $0/1 = 0$. But $\rho(\mathbf{A}) = 1$, so this "upper bound" is $0 < \rho$. What fails is the inequality $\mathbf{Ax} \leq 0 \cdot \mathbf{x}$: in the ignored coordinate, $(\mathbf{Ax})_2 = 1 > 0$. The coordinates where $\mathbf{x}$ vanishes are harmless for a lower bound, where they contribute $(\mathbf{Ax})_i \geq 0$, and fatal for an upper bound.

> *Warning.* **The two functions are not mirror images.** The lower function accepts every non-zero $\mathbf{x} \geq \mathbf{0}$; the upper one accepts only $\mathbf{x} > \mathbf{0}$. The formula of the next subsection is therefore a maximum over the closed orthant and a minimum over the open one, and letting the minimum range over the closed orthant too would make it false, as the non-example shows.

18.4.3 The formula

With the two functions in hand, the propositions of the first subsection say that $\underline{r}_{\mathbf{A}}(\mathbf{x}) \leq \rho(\mathbf{A}) \leq \overline{r}_{\mathbf{A}}(\mathbf{x})$, and the second example shows both bounds attained at a positive eigenvector. For an irreducible matrix, such an eigenvector exists (Theorem 18.3.2), and more is true: nothing else attains either bound.

Theorem 18.4.3 — Collatz–Wielandt Formula

Let $\mathbf{A} \in M_n(\mathbb{R})$ be non-negative and irreducible, with Perron vector $\mathbf{v}$ (Definition 18.3.1). Then

$$\rho(\mathbf{A}) = \max_{\substack{\mathbf{x} \geq \mathbf{0} \\ \mathbf{x} \neq \mathbf{0}}} \underline{r}_{\mathbf{A}}(\mathbf{x}) = \min_{\mathbf{x} > \mathbf{0}} \overline{r}_{\mathbf{A}}(\mathbf{x}),$$

both extreme values are attained at $\mathbf{x} = \mathbf{v}$, and they are attained **only** at the positive multiples of $\mathbf{v}$: if $\mathbf{x} \geq \mathbf{0}$, $\mathbf{x} \neq \mathbf{0}$ and $\underline{r}_{\mathbf{A}}(\mathbf{x}) = \rho(\mathbf{A})$, or if $\mathbf{x} > \mathbf{0}$ and $\overline{r}_{\mathbf{A}}(\mathbf{x}) = \rho(\mathbf{A})$, then $\mathbf{x}$ is a positive multiple of $\mathbf{v}$.

> *Idea.* The inequalities are the two propositions, applied with the best constants $\underline{r}_{\mathbf{A}}(\mathbf{x})$ and $\overline{r}_{\mathbf{A}}(\mathbf{x})$. Attainment is the eigenvector example. For the "only" clause, use the strict halves of the propositions: if $\mathbf{x}$ attains a bound without being an eigenvector, the strict inequality would push ρ strictly past itself. The usual proofs of this formula start from the optimization problem and need a compactness argument, which is delicate for a matrix with zero entries: then $\underline{r}_{\mathbf{A}}$ can jump where a coordinate of $\mathbf{x}$ becomes 0, whereas for a positive matrix it is continuous. Here the compactness was spent once, in Sections 1 and 3, and it has already produced the maximizer.

Proof. Let $\rho = \rho(\mathbf{A})$.

The inequalities. Let $\mathbf{x} \geq \mathbf{0}$, $\mathbf{x} \neq \mathbf{0}$. Since $\mathbf{Ax} \geq \underline{r}_{\mathbf{A}}(\mathbf{x})\,\mathbf{x}$, Proposition 18.4.2 (a) gives $\underline{r}_{\mathbf{A}}(\mathbf{x}) \leq \rho$. Let $\mathbf{x} > \mathbf{0}$. Since $\mathbf{Ax} \leq \overline{r}_{\mathbf{A}}(\mathbf{x})\,\mathbf{x}$, Proposition 18.4.1 (a) gives $\rho \leq \overline{r}_{\mathbf{A}}(\mathbf{x})$.

Attainment. By Theorem 18.3.2 (a) and Definition 18.3.1, $\mathbf{v} > \mathbf{0}$ and $\mathbf{Av} = \rho\mathbf{v}$, so every ratio $(\mathbf{Av})_i/v_i$ equals ρ, and $\underline{r}_{\mathbf{A}}(\mathbf{v}) = \overline{r}_{\mathbf{A}}(\mathbf{v}) = \rho$. With the inequalities, this shows that ρ is the maximum of $\underline{r}_{\mathbf{A}}$ and the minimum of $\overline{r}_{\mathbf{A}}$.

Only at multiples of $\mathbf{v}$. Let $\mathbf{x} \geq \mathbf{0}$, $\mathbf{x} \neq \mathbf{0}$, with $\underline{r}_{\mathbf{A}}(\mathbf{x}) = \rho$, so that $\mathbf{Ax} \geq \rho\mathbf{x}$. If $\mathbf{Ax} \neq \rho\mathbf{x}$, then Proposition 18.4.2 (b) with $s = \rho$ gives $\rho > \rho$, which is absurd. Hence $\mathbf{Ax} = \rho\mathbf{x}$, and $\mathbf{x}$ is a positive multiple of $\mathbf{v}$ by Theorem 18.3.2 (c). If instead $\mathbf{x} > \mathbf{0}$ and $\overline{r}_{\mathbf{A}}(\mathbf{x}) = \rho$, then $\mathbf{Ax} \leq \rho\mathbf{x}$, and Proposition 18.4.1 (b) rules out $\mathbf{Ax} \neq \rho\mathbf{x}$ in the same way. Conversely, $\underline{r}_{\mathbf{A}}(c\mathbf{v}) = \overline{r}_{\mathbf{A}}(c\mathbf{v}) = \rho$ for $c > 0$, since the ratios do not change when $\mathbf{x}$ is scaled. This proves the theorem.

■

So $\rho(\mathbf{A})$ is characterized without eigenvalues: it is the largest growth factor that $\mathbf{A}$ guarantees in every coordinate of some non-negative vector, and the smallest growth factor that bounds every coordinate of some positive vector.

Remark. Irreducibility is used only for the attainment of the minimum and for the "only" clause. For **every** $\mathbf{A} \geq 0$, the inequalities hold by the same two propositions, and the maximum is still attained, at the non-negative eigenvector $\mathbf{x}$ of Theorem 18.3.1: every ratio over a coordinate with $x_i > 0$ equals ρ. The minimum can fail to be attained; Exercise C3 at the end of this section works out an example.

18.4.4 Row sums and column sums

The simplest test vector is $\mathbf{1}$, and the transpose supplies a second family of bounds for free. For a non-negative matrix, write $r_i = \sum_j a_{ij}$ for the i-th row sum and $c_j = \sum_i a_{ij}$ for the j-th column sum.

Corollary 18.4.4 — Row and Column Sums Bound the Spectral Radius

Let $\mathbf{A} \in M_n(\mathbb{R})$ with $\mathbf{A} \geq 0$.

(a) $\min_i r_i \leq \rho(\mathbf{A}) \leq \max_i r_i$ and $\min_j c_j \leq \rho(\mathbf{A}) \leq \max_j c_j$.

(b) If $\mathbf{A}$ is irreducible, then $\rho(\mathbf{A}) = \min_i r_i$ if and only if $\rho(\mathbf{A}) = \max_i r_i$, if and only if all the row sums are equal. The same holds for the column sums.

Idea. Use the test vector $\mathbf{1}$, whose ratios are the row sums: the two propositions give (a) for rows, and the "only" clause of Theorem 18.4.3 gives (b), since equality at $\mathbf{1}$ makes $\mathbf{1}$ an eigenvector. For columns, run the same argument on $\mathbf{A}^\top$, which has the same spectral radius.

Proof.

(a) $\mathbf{A1}$ is the vector of row sums, so $\mathbf{A1} \geq (\min_i r_i)\mathbf{1}$ and $\mathbf{A1} \leq (\max_i r_i)\mathbf{1}$, with $\mathbf{1} > \mathbf{0}$. Proposition 18.4.2 (a) and Proposition 18.4.1 (a) give the row bounds. The column sums of $\mathbf{A}$ are the row sums of $\mathbf{A}^\top \geq 0$, and $\rho(\mathbf{A}^\top) = \rho(\mathbf{A})$ because $p_{\mathbf{A}^\top} = p_{\mathbf{A}}$ (Proposition 8.10.5 (b)); so the row bounds for $\mathbf{A}^\top$ are the column bounds for $\mathbf{A}$.

(b) If all row sums equal r, then $\min_i r_i = \max_i r_i = r$, and (a) gives $\rho(\mathbf{A}) = r$. Conversely, suppose $\rho(\mathbf{A}) = \min_i r_i = \underline{r}_{\mathbf{A}}(\mathbf{1})$. By the "only" clause of Theorem 18.4.3, $\mathbf{1}$ is a positive multiple of the Perron vector, so $\mathbf{A1} = \rho(\mathbf{A})\mathbf{1}$, and every row sum equals $\rho(\mathbf{A})$. The same argument with $\overline{r}_{\mathbf{A}}(\mathbf{1}) = \max_i r_i$ handles the maximum. For the columns, apply this to $\mathbf{A}^\top$, which is irreducible with $\rho(\mathbf{A}^\top) = \rho(\mathbf{A})$ by Corollary 18.3.3 (a).

■

Compare this with Chapter 15. Corollary 15.4.2 gives $\rho(\mathbf{A}) \leq \|\mathbf{A}\|_\infty$ and $\rho(\mathbf{A}) \leq \|\mathbf{A}\|_1$ for **every** complex matrix, and for $\mathbf{A} \geq 0$ these are exactly the upper bounds in (a), since the absolute row and column sums are then the row and column sums. What non-negativity adds is the **lower** bound. For a matrix with entries of both signs there is none:

$$\mathbf{M} = \begin{pmatrix} 1 & -1 \\ 1 & -1 \end{pmatrix}$$

has absolute row sums $2, 2$, but $\mathbf{M}^2 = 0$, so every eigenvalue λ satisfies $\lambda^2 = 0$ and $\rho(\mathbf{M}) = 0$. Nor do the signed row sums help:

$$\mathbf{M}' = \begin{pmatrix} 7 & -3 \\ 19 & -7 \end{pmatrix}$$

has row sums 4 and 12, both larger than $\rho(\mathbf{M}') = 2\sqrt{2}$, since $p_{\mathbf{M}'}(t) = t^2 + 8$.

The equality clause (b) genuinely needs irreducibility. The reducible matrix $\operatorname{diag}(1, 2)$ has $\rho = 2 = \max_i r_i$ with unequal row sums, and $\left(\begin{smallmatrix} 1 & 0 \\ 1 & 1 \end{smallmatrix}\right)$ has $\rho = 1 = \min_i r_i$ with row sums 1 and 2.

Example. (Four bounds, and which one to keep)

Bound $\rho(\mathbf{A})$ above and below using row and column sums, for

$$\mathbf{A} = \begin{pmatrix} 0 & 1 & 1 \\ 0 & 1 & 2 \\ 1 & 0 & 3 \end{pmatrix}.$$

Solution. The row sums are $2, 3, 4$ and the column sums are $1, 2, 6$. By Corollary 18.4.4 (a), $2 \leq \rho(\mathbf{A}) \leq 4$ from the rows and $1 \leq \rho(\mathbf{A}) \leq 6$ from the columns. Keep the larger lower bound and the smaller upper bound: $2 \leq \rho(\mathbf{A}) \leq 4$. Chapter 15's Corollary 15.4.2 gives only the upper bound 4.

The matrix is irreducible: $(\mathbf{I} + \mathbf{A})^2 = \left(\begin{smallmatrix} 2 & 3 & 7 \\ 2 & 4 & 12 \\ 5 & 1 & 17 \end{smallmatrix}\right) > 0$ (Theorem 18.2.6). Its row sums are not all equal, so by Corollary 18.4.4 (b) both bounds are strict: $2 < \rho(\mathbf{A}) < 4$.

18.4.5 Estimating the spectral radius

A bracket of width 2 is crude. The Collatz–Wielandt formula says that a better test vector gives a better bracket, and a test vector close to the Perron vector gives a very narrow one. There is a cheap way to improve a test vector: multiply it by $\mathbf{A}$.

The improvement is guaranteed. Let $\mathbf{x} > \mathbf{0}$, and suppose $\mathbf{Ax} > \mathbf{0}$ too. Since $\mathbf{A}$ preserves the order,

$$\mathbf{A}(\mathbf{Ax}) \geq \mathbf{A}\big(\underline{r}_{\mathbf{A}}(\mathbf{x})\,\mathbf{x}\big) = \underline{r}_{\mathbf{A}}(\mathbf{x})\,\mathbf{Ax},$$

so $\underline{r}_{\mathbf{A}}(\mathbf{Ax}) \geq \underline{r}_{\mathbf{A}}(\mathbf{x})$, because $\underline{r}_{\mathbf{A}}(\mathbf{Ax})$ is the largest s with $\mathbf{A}(\mathbf{Ax}) \geq s\,\mathbf{Ax}$. In the same way $\overline{r}_{\mathbf{A}}(\mathbf{Ax}) \leq \overline{r}_{\mathbf{A}}(\mathbf{x})$. So the brackets from $\mathbf{x}, \mathbf{Ax}, \mathbf{A}^2\mathbf{x}, \ldots$ are nested, as long as each $\mathbf{A}^k\mathbf{x} > \mathbf{0}$: each lower bound is at least the previous one, and each upper bound is at most the previous one. The condition holds whenever $\mathbf{x} > \mathbf{0}$ and $\mathbf{A}$ is irreducible with $n \geq 2$, since no row of $\mathbf{A}$ is then zero (a zero row, moved to the bottom by a permutation, would give the block form of Definition 18.2.3 with $k = n - 1$), so every entry of $\mathbf{Ay}$ is positive when $\mathbf{y} > \mathbf{0}$.

Example. (Trapping the spectral radius)

For the matrix $\mathbf{A}$ of Example (Four bounds, and which one to keep), compute the brackets $[\underline{r}_{\mathbf{A}}(\mathbf{x}), \overline{r}_{\mathbf{A}}(\mathbf{x})]$ for $\mathbf{x} = \mathbf{1}, \mathbf{A1}, \mathbf{A}^2\mathbf{1}, \mathbf{A}^3\mathbf{1}, \mathbf{A}^4\mathbf{1}$. Hence give $\rho(\mathbf{A})$ to two decimal places, and check the answer against the characteristic polynomial.

Solution. Each step multiplies the previous vector by $\mathbf{A}$, whose rows are $(0,1,1)$, $(0,1,2)$, $(1,0,3)$. The ratios are taken coordinate by coordinate.

$\mathbf{x}$	$\mathbf{Ax}$	ratios $(\mathbf{Ax})_i/x_i$	bracket
$(1,1,1)$	$(2,3,4)$	$2,\ 3,\ 4$	$[2,\ 4]$
$(2,3,4)$	$(7,11,14)$	$\frac{7}{2},\ \frac{11}{3},\ \frac{7}{2}$	$[\frac{7}{2},\ \frac{11}{3}]$
$(7,11,14)$	$(25,39,49)$	$\frac{25}{7},\ \frac{39}{11},\ \frac{7}{2}$	$[\frac{7}{2},\ \frac{25}{7}]$
$(25,39,49)$	$(88,137,172)$	$\frac{88}{25},\ \frac{137}{39},\ \frac{172}{49}$	$[\frac{172}{49},\ \frac{88}{25}]$
$(88,137,172)$	$(309,481,604)$	$\frac{309}{88},\ \frac{481}{137},\ \frac{151}{43}$	$[\frac{481}{137},\ \frac{151}{43}]$

For instance, in the last row $\mathbf{A}(88,137,172) = (137+172,\ 137+344,\ 88+516) = (309,481,604)$, and $\frac{604}{172} = \frac{151}{43}$. All five test vectors are positive, so each bracket is valid by Theorem 18.4.3, and they are nested, as the argument before the example predicts. The five brackets have widths 2, $\frac{1}{6}$, $\frac{1}{14}$, $\frac{12}{1225}$ and $\frac{4}{5891}$. Since $\frac{481}{137} = 3.51094\ldots$ and $\frac{151}{43} = 3.51162\ldots$,

$$3.5109 < \rho(\mathbf{A}) < 3.5117,$$

and therefore $\rho(\mathbf{A}) = 3.51$ to two decimal places.

Check. Expanding $\det(t\mathbf{I} - \mathbf{A})$ along the first column gives

$$\begin{aligned} p_{\mathbf{A}}(t) &= t\big((t-1)(t-3)\big) - \big((-1)(-2) - (-1)(t-1)\big) \\ &= t^3 - 4t^2 + 2t - 1. \end{aligned}$$

Exactly, $p_{\mathbf{A}}(3.51) = -0.016849 < 0$ and $p_{\mathbf{A}}(3.512) = 0.004937728 > 0$. A real polynomial that changes sign on an interval has a root there, by the intermediate value theorem, fact (A5) of Chapter 15's introduction. So $p_{\mathbf{A}}$ has a real root between 3.51 and 3.512, consistent with the bracket.

Two things about this computation deserve a comment. First, every number in it is a certified bound, not an approximation whose error is unknown: $\rho(\mathbf{A}) \geq \frac{172}{49}$ is a theorem about this matrix, proved by one multiplication. Second, the iteration $\mathbf{x} \mapsto \mathbf{A}\mathbf{x}$ is the power method, and Chapter 23 studies how fast it converges. Nesting alone does not make the brackets shrink to a point, as the next warning shows.

Warning. **The brackets need not close up.** For the swap $\mathbf{A} = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$, which is irreducible with $\rho = 1$, start from $\mathbf{x} = (1, 2)$. Then $\mathbf{A}\mathbf{x} = (2, 1)$, with ratios 2 and $\frac{1}{2}$, and $\mathbf{A}^2\mathbf{x} = \mathbf{x}$. The bracket is $[\frac{1}{2}, 2]$ at every step and never improves. The iteration only swaps the two coordinates, because the eigenvalue -1 has the same modulus as ρ. Section 5 studies the irreducible matrices whose other eigenvalues all have modulus strictly less than ρ.

18.4.6 Exercises

18.4.6.1 A. Check your understanding

Exercise A1.

(a) Define $\underline{r}_{\mathbf{A}}(\mathbf{x})$ and $\overline{r}_{\mathbf{A}}(\mathbf{x})$, and state on which vectors each is defined.

(b) For $\mathbf{A} = \left(\begin{smallmatrix} 1 & 2 \\ 3 & 0 \end{smallmatrix}\right)$, compute $\underline{r}_{\mathbf{A}}(\mathbf{1})$ and $\overline{r}_{\mathbf{A}}(\mathbf{1})$. What do you conclude about $\rho(\mathbf{A})$?

(c) True or false: if $\mathbf{A} \geq 0$, $\mathbf{x} \geq \mathbf{0}$, $\mathbf{x} \neq \mathbf{0}$ and $\mathbf{A}\mathbf{x} \leq 2\mathbf{x}$, then $\rho(\mathbf{A}) \leq 2$. Justify your answer.

(d) True or false: for every $\mathbf{A} \geq 0$, $\rho(\mathbf{A})$ is at least the smallest row sum of $\mathbf{A}$. Justify your answer.

(e) Name the result from Chapter 15 that gives the upper bound in Corollary 18.4.4 (a), and say what that result does not give.

Solution.

(a) See Definition 18.4.1: $\underline{r}_{\mathbf{A}}(\mathbf{x})$ is the minimum of $(\mathbf{A}\mathbf{x})_i / x_i$ over the indices with $x_i > 0$, defined for $\mathbf{x} \geq \mathbf{0}$, $\mathbf{x} \neq \mathbf{0}$; $\overline{r}_{\mathbf{A}}(\mathbf{x})$ is the maximum of $(\mathbf{A}\mathbf{x})_i / x_i$ over all indices, defined only for $\mathbf{x} > \mathbf{0}$.

(b) $\mathbf{A}\mathbf{1} = (3, 3)$, so both equal 3, and $\rho(\mathbf{A}) = 3$ by Proposition 18.4.2 (a) and Proposition 18.4.1 (a). Indeed $p_{\mathbf{A}}(t) = t^2 - t - 6 = (t - 3)(t + 2)$.

(c) False: $\mathbf{A} = \operatorname{diag}(1, 5)$ and $\mathbf{x} = \mathbf{e}_1$ give $\mathbf{A}\mathbf{x} = \mathbf{x} \leq 2\mathbf{x}$, but $\rho(\mathbf{A}) = 5$. It becomes true if $\mathbf{x} > \mathbf{0}$ (Proposition 18.4.1 (a)) or if $\mathbf{A}$ is irreducible (Proposition 18.4.1 (b)).

(d) True, by Corollary 18.4.4 (a), which rests on Proposition 18.4.2 (a) with $\mathbf{x} = \mathbf{1}$. No irreducibility is needed.

(e) Corollary 15.4.2, which bounds ρ above by the largest absolute row sum and the largest absolute column sum of any complex matrix. It gives no lower bound, and none exists for matrices with entries of both signs: $\left(\begin{smallmatrix} 1 & -1 \\ 1 & -1 \end{smallmatrix}\right)$ has $\rho = 0$.

18.4.6.2 B. Practice

Exercise B1: A certified bracket.

Let

$$\mathbf{A} = \begin{pmatrix} 1 & 2 & 0 \\ 0 & 1 & 3 \\ 1 & 0 & 2 \end{pmatrix}.$$

Show that $\mathbf{A}$ is irreducible. Compute the brackets $[\underline{r}_{\mathbf{A}}(\mathbf{x}), \overline{r}_{\mathbf{A}}(\mathbf{x})]$ for $\mathbf{x} = \mathbf{1}$ and for $\mathbf{x} = (10, 11, 8)$. Hence show that $3.18 < \rho(\mathbf{A}) \le 3.25$, and check this against $p_{\mathbf{A}}$.

Solution. Irreducible. $\mathbf{I} + \mathbf{A} = \left(\begin{smallmatrix} 2 & 2 & 0 \\ 0 & 2 & 3 \\ 1 & 0 & 3 \end{smallmatrix}\right)$, and $(\mathbf{I} + \mathbf{A})^2 = \left(\begin{smallmatrix} 4 & 8 & 6 \\ 3 & 4 & 15 \\ 5 & 2 & 9 \end{smallmatrix}\right) > 0$, so $\mathbf{A}$ is irreducible by Theorem 18.2.6.

Brackets. $\mathbf{A1} = (3, 4, 3)$, giving $[3, 4]$. Next,

$$\mathbf{A}(10, 11, 8) = (10 + 22,\ 11 + 24,\ 10 + 16) = (32, 35, 26),$$

with ratios $\frac{32}{10} = 3.2$, $\frac{35}{11} = 3.1818\ldots$, $\frac{26}{8} = 3.25$. The bracket is $[\frac{35}{11}, \frac{13}{4}]$. By Theorem 18.4.3, $\frac{35}{11} \le \rho(\mathbf{A}) \le \frac{13}{4}$. Since $\frac{35}{11} > 3.18$, this gives $3.18 < \rho(\mathbf{A}) \le 3.25$.

Check. Expanding along the first row,

$$\begin{aligned} p_{\mathbf{A}}(t) &= (t-1)\big((t-1)(t-2)\big) + 2\big(0 - 3\big) \\ &= t^3 - 4t^2 + 5t - 8. \end{aligned}$$

Then $p_{\mathbf{A}}(\frac{35}{11}) = -\frac{498}{1331} < 0$ and $p_{\mathbf{A}}(\frac{13}{4}) = \frac{21}{64} > 0$, so by the intermediate value theorem (fact (A5) of Chapter 15's introduction) $p_{\mathbf{A}}$ has a root in the bracket, consistent with the estimate. (In fact $\rho(\mathbf{A}) \approx 3.219$.)

Exercise B2: When a sum bound is exact.

For each matrix, give the bounds of Corollary 18.4.4 (a) from rows and from columns, and decide whether they determine ρ. Justify your answers.

$$\text{(a)}\ \begin{pmatrix} 1 & 2 & 1 \\ 3 & 0 & 1 \\ 0 & 2 & 2 \end{pmatrix} \qquad \text{(b)}\ \begin{pmatrix} 1 & 3 \\ 2 & 0 \end{pmatrix} \qquad \text{(c)}\ \begin{pmatrix} 2 & 0 \\ 5 & 3 \end{pmatrix}$$

Solution.

(a) Row sums $4, 4, 4$; column sums $4, 4, 4$. Both bracket ρ in $[4, 4]$, so $\rho = 4$, with eigenvector $\mathbf{1}$.

(b) Row sums $4, 2$, giving $[2, 4]$; column sums $3, 3$, giving $[3, 3]$. So $\rho = 3$, with $\mathbf{1}$ as a left eigenvector: $\mathbf{1}^{\top}\mathbf{A} = (3, 3)$. Check: $p(t) = t^2 - t - 6 = (t-3)(t+2)$. The matrix is irreducible ($\mathbf{I} + \mathbf{A} > 0$), and the row sums are unequal, so by Corollary 18.4.4 (b) the row bracket is strict, $2 < 3 < 4$, as it is.

(c) Row sums $2, 8$, giving $[2, 8]$; column sums $7, 3$, giving $[3, 7]$. Together, $3 \le \rho \le 7$. The matrix is lower triangular, so its eigenvalues are 2 and 3 and $\rho = 3$, the smallest column sum, although the column sums are unequal. This does not contradict Corollary 18.4.4 (b): the matrix is reducible, since $\mathbf{I} + \mathbf{A}$ has a zero entry in position $(1, 2)$ and $n - 1 = 1$.

Exercise B3: A weighted test vector.

Let

$$\mathbf{A} = \frac{1}{10}\begin{pmatrix} 5 & 20 \\ 1 & 2 \end{pmatrix}.$$

Show that neither the row sums nor the column sums prove $\rho(\mathbf{A}) < 1$. Then use the test vector $\mathbf{x} = (5, 1)$ to prove $\rho(\mathbf{A}) \le \frac{9}{10}$. Hence deduce that $\mathbf{A}^k \to 0$ as $k \to \infty$.

Solution. The row sums are $\frac{25}{10}$ and $\frac{3}{10}$, and the column sums $\frac{6}{10}$ and $\frac{22}{10}$. Each upper bound in Corollary 18.4.4 (a) exceeds 1, so neither proves $\rho(\mathbf{A}) < 1$.

With $\mathbf{x} = (5, 1) > \mathbf{0}$,

$$\mathbf{A}\mathbf{x} = \tfrac{1}{10}(25 + 20,\ 5 + 2) = \left(\tfrac{45}{10},\ \tfrac{7}{10}\right),$$

and the ratios are $\frac{45}{50} = \frac{9}{10}$ and $\frac{7}{10}$. So $\mathbf{A}\mathbf{x} \le \frac{9}{10}\mathbf{x}$, and Proposition 18.4.1 (a) gives $\rho(\mathbf{A}) \le \frac{9}{10} < 1$. Hence $\mathbf{A}^k \to 0$ by Corollary 15.4.5 (a).

18.4.6.3 C. Going deeper

Exercise C1: Lower bounds from single entries.

Let $\mathbf{A} \in M_n(\mathbb{R})$ with $\mathbf{A} \ge 0$, not necessarily irreducible.

(a) Prove that $\rho(\mathbf{A}) \ge a_{ii}$ for every i.

(b) Prove that $\rho(\mathbf{A}) \ge \sqrt{a_{ij}a_{ji}}$ for every $i \ne j$.

(c) Hence show that $\left(\begin{smallmatrix} 1 & 4 & 0 \\ 9 & 2 & 0 \\ 0 & 0 & 5 \end{smallmatrix}\right)$ has $\rho \ge 6$, and check this exactly.

Hint: choose a test vector supported on $\{i\}$ or on $\{i, j\}$.

Solution.

(a) Take $\mathbf{x} = \mathbf{e}_i$. Then $(\mathbf{A}\mathbf{e}_i)_i = a_{ii}$ and every other coordinate of $\mathbf{A}\mathbf{e}_i$ is ≥ 0, so $\mathbf{A}\mathbf{e}_i \ge a_{ii}\mathbf{e}_i$, and Proposition 18.4.2 (a) gives $\rho(\mathbf{A}) \ge a_{ii}$.

(b) If $a_{ij}a_{ji} = 0$, the claim is $\rho(\mathbf{A}) \ge 0$, which holds. Otherwise put $s = \sqrt{a_{ij}a_{ji}} > 0$ and $\mathbf{x} = \sqrt{a_{ij}}\,\mathbf{e}_i + \sqrt{a_{ji}}\,\mathbf{e}_j \ge \mathbf{0}$, $\mathbf{x} \ne \mathbf{0}$. Dropping non-negative terms,

$$(\mathbf{A}\mathbf{x})_i \ge a_{ij}\sqrt{a_{ji}} = s\sqrt{a_{ij}} = sx_i, \qquad (\mathbf{A}\mathbf{x})_j \ge a_{ji}\sqrt{a_{ij}} = s\sqrt{a_{ji}} = sx_j,$$

and the other coordinates satisfy $(\mathbf{A}\mathbf{x})_k \ge 0 = sx_k$. So $\mathbf{A}\mathbf{x} \ge s\mathbf{x}$, and Proposition 18.4.2 (a) gives $\rho(\mathbf{A}) \ge s$.

(c) With $i = 1$, $j = 2$: $\sqrt{4 \cdot 9} = 6$, so $\rho \ge 6$. The diagonal bound of (a) gives only 5. Exactly: the matrix is block diagonal, the 2×2 block has $p(t) = t^2 - 3t - 34$ with roots $\frac{3 \pm \sqrt{145}}{2}$, and the 1×1 block contributes 5. So $\rho = \frac{3+\sqrt{145}}{2} \approx 7.52 \ge 6$.

Exercise C2: Strict monotonicity.

Let $\mathbf{A}, \mathbf{B} \in M_n(\mathbb{R})$ with $0 \le \mathbf{A} \le \mathbf{B}$ and $\mathbf{A} \ne \mathbf{B}$.

(a) Prove that if $\mathbf{A}$ is irreducible, then so is $\mathbf{B}$, and $\rho(\mathbf{A}) < \rho(\mathbf{B})$.

(b) Show by an example that the strict inequality can fail if $\mathbf{A}$ is reducible.

Solution.

(a) Since $\mathbf{I}+\mathbf{B} \geq \mathbf{I}+\mathbf{A} \geq 0$ and a non-negative matrix preserves the order, induction on k gives $(\mathbf{I}+\mathbf{B})^k \geq (\mathbf{I}+\mathbf{A})^k$: indeed $(\mathbf{I}+\mathbf{B})^{k+1} = (\mathbf{I}+\mathbf{B})(\mathbf{I}+\mathbf{B})^k \geq (\mathbf{I}+\mathbf{B})(\mathbf{I}+\mathbf{A})^k \geq (\mathbf{I}+\mathbf{A})^{k+1}$, column by column. With $k = n-1$, $(\mathbf{I}+\mathbf{B})^{n-1} \geq (\mathbf{I}+\mathbf{A})^{n-1} > 0$, so $\mathbf{B}$ is irreducible by Theorem 18.2.6.
Let $\mathbf{v} > \mathbf{0}$ be the Perron vector of $\mathbf{A}$. Then $\mathbf{B}\mathbf{v} = \mathbf{A}\mathbf{v} + (\mathbf{B}-\mathbf{A})\mathbf{v} \geq \mathbf{A}\mathbf{v} = \rho(\mathbf{A})\mathbf{v}$. Moreover $\mathbf{B}-\mathbf{A} \geq 0$ has some entry $b_{ij} - a_{ij} > 0$, and then $\big((\mathbf{B}-\mathbf{A})\mathbf{v}\big)_i \geq (b_{ij}-a_{ij})v_j > 0$, so $\mathbf{B}\mathbf{v} \neq \rho(\mathbf{A})\mathbf{v}$. By Proposition 18.4.2 (b) applied to the irreducible $\mathbf{B}$, $\rho(\mathbf{B}) > \rho(\mathbf{A})$.

(b) $\mathbf{A} = \operatorname{diag}(1,0)$ and $\mathbf{B} = \operatorname{diag}(1, \frac{1}{2})$ satisfy $0 \leq \mathbf{A} \leq \mathbf{B}$, $\mathbf{A} \neq \mathbf{B}$, and $\rho(\mathbf{A}) = \rho(\mathbf{B}) = 1$.

Exercise C3: The minimum need not be attained.

Let $\mathbf{A} = \left(\begin{smallmatrix} 1 & 1 \\ 0 & 1 \end{smallmatrix}\right)$.

(a) Show that $\mathbf{A}$ is reducible and $\rho(\mathbf{A}) = 1$.

(b) Show that $\overline{r}_{\mathbf{A}}(\mathbf{x}) > 1$ for every $\mathbf{x} > \mathbf{0}$, so that $\min_{\mathbf{x}>\mathbf{0}} \overline{r}_{\mathbf{A}}(\mathbf{x})$ does not exist.

(c) Show that nevertheless $\overline{r}_{\mathbf{A}}(\mathbf{x})$ takes values as close to 1 as we like, and that $\max_{\mathbf{x}\geq\mathbf{0},\mathbf{x}\neq\mathbf{0}} \underline{r}_{\mathbf{A}}(\mathbf{x}) = 1$ is attained.

Solution.

(a) $\mathbf{I}+\mathbf{A} = \left(\begin{smallmatrix} 2 & 1 \\ 0 & 2 \end{smallmatrix}\right)$ has a zero entry, so $\mathbf{A}$ is reducible (Theorem 18.2.6 with $n = 2$). It is triangular with diagonal $1, 1$, so $\rho(\mathbf{A}) = 1$ (Theorem 8.7.4 (b)).

(b) For $\mathbf{x} = (x_1, x_2) > \mathbf{0}$, $\mathbf{A}\mathbf{x} = (x_1 + x_2,\ x_2)$, with ratios $1 + x_2/x_1$ and 1. Hence $\overline{r}_{\mathbf{A}}(\mathbf{x}) = 1 + x_2/x_1 > 1$. Suppose some $\mathbf{x} > \mathbf{0}$ gave the smallest value $m = 1 + x_2/x_1$. Then $\mathbf{x}' = (x_1, x_2/2) > \mathbf{0}$ gives $\overline{r}_{\mathbf{A}}(\mathbf{x}') = 1 + x_2/(2x_1) < m$, a contradiction. So there is no minimum.

(c) For $\mathbf{x} = (1, t)$ with $t > 0$, $\overline{r}_{\mathbf{A}}(\mathbf{x}) = 1 + t$, which is as close to 1 as we like. For the lower function, $\mathbf{x} = \mathbf{e}_1$ gives $\mathbf{A}\mathbf{e}_1 = \mathbf{e}_1$, so $\underline{r}_{\mathbf{A}}(\mathbf{e}_1) = 1 = \rho(\mathbf{A})$; since every value of $\underline{r}_{\mathbf{A}}$ is $\leq \rho(\mathbf{A})$ by Proposition 18.4.2 (a), the maximum is attained at $\mathbf{e}_1$, which is the non-negative eigenvector of Theorem 18.3.1.

18.5 Primitive Matrices

The Perron–Frobenius theorem tells us what an irreducible non-negative matrix looks like at its spectral radius: $\rho(\mathbf{A})$ is an algebraically simple eigenvalue with a positive eigenvector. It says nothing about what the powers $\mathbf{A}^m$ do, and Chapter 8 §11 already met the obstacle. The swap $\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$ is irreducible, has a positive eigenvector for $\rho = 1$, and its powers alternate forever. This section finds the extra hypothesis that makes the powers settle down, proves that under it $(\mathbf{A}/\rho)^m$ converges to an explicit rank-one matrix, and explains what goes wrong without it: the eigenvalues of modulus ρ are then spread evenly around a circle, and their number is read

off the zero pattern of $\mathbf{A}$.

Throughout, matrices are real and $\mathbf{A} \geq 0$ is meant entrywise, as are $\mathbf{A} > 0$, $\mathbf{x} \geq \mathbf{0}$ and $\mathbf{x} > \mathbf{0}$. The spectrum is taken over $\mathbb{C}$, and $\rho(\mathbf{A})$ is the spectral radius (Definition 15.4.1).

18.5.1 Walks in a non-negative matrix

Whether a power $\mathbf{A}^m$ has a positive entry at position (i, j) depends only on which entries of $\mathbf{A}$ are zero. The bookkeeping device is the directed graph $G(\mathbf{A})$ of §02 (Definition 18.2.1): it has an edge $j \to i$ for each non-zero entry a_{ij}, and a walk of length m from j to i is a list $j = i_0, i_1, \ldots, i_m = i$ of vertices in which each $i_{t-1} \to i_t$ is an edge. The edge for a_{ij} points from the column index to the row index, the direction in which a column-stochastic chain moves. A walk is **closed** if $i_0 = i_m$ and $m \geq 1$.

By §02's count of walks (Lemma 18.2.1 (a)), for $\mathbf{A} \geq 0$ and $m \geq 0$, $(\mathbf{A}^m)_{ij} > 0$ if and only if $G(\mathbf{A})$ has a walk of length m from j to i. Everything in this section about zero patterns rests on that fact.

18.5.2 Primitive matrices

Here is the property the swap lacks. Its powers are $\mathbf{I}$ and the swap itself, and each of them has zero entries; no power ever mixes every state with every other.

A primitive matrix is one that, after enough steps, connects every index to every index at once.

Definition 18.5.1 — Primitive Matrix

A matrix $\mathbf{A} \in M_n(\mathbb{R})$, $n \geq 1$, with $\mathbf{A} \geq 0$ is **primitive** if $\mathbf{A}^k > 0$ for **some** integer $k \geq 1$, that is, if **every** entry of some power of $\mathbf{A}$ is **strictly** positive.

In words: we are allowed to wait, but only for a finite number k of steps, and after those k steps all n^2 entries must be positive together. By Lemma 18.2.1 (a), $\mathbf{A}$ is primitive exactly when there is one length k such that every vertex of $G(\mathbf{A})$ has a walk of length k to every vertex, including to itself.

Examples.

- **Positive matrices.** If $\mathbf{A} > 0$, take $k = 1$. Perron's theorem (Theorem 18.1.5) is about these.
- **A matrix with zeros.** $\mathbf{A} = \begin{pmatrix} 1 & 1 \\ 2 & 0 \end{pmatrix}$ has a zero entry, but $\mathbf{A}^2 = \begin{pmatrix} 3 & 1 \\ 2 & 2 \end{pmatrix} > 0$. So $\mathbf{A}$ is primitive with $k = 2$. In the graph: the edges are $1 \to 1$, $1 \to 2$ and $2 \to 1$, and $1 \to 1 \to 1$, $1 \to 1 \to 2$, $2 \to 1 \to 1$, $2 \to 1 \to 2$ are walks of length 2 between every ordered pair.
- **A slower one.** $\mathbf{W} = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 1 & 0 \end{pmatrix}$. Its edges are $2 \to 1$, $3 \to 2$, $1 \to 3$ and $2 \to 3$, so its closed walks include $1 \to 3 \to 2 \to 1$ of length 3 and $2 \to 3 \to 2$ of length 2. Multiplying out, $\mathbf{W}^4 = \begin{pmatrix} 0 & 1 & 1 \\ 1 & 1 & 1 \\ 1 & 2 & 1 \end{pmatrix}$ still has a zero, and $\mathbf{W}^5 = \begin{pmatrix} 1 & 1 & 1 \\ 1 & 2 & 1 \\ 1 & 2 & 2 \end{pmatrix} > 0$. So $\mathbf{W}$ is primitive,

and the smallest k is 5.

- **Degenerate case.** A 1×1 matrix (a) is primitive if and only if $a > 0$. The zero 1×1 matrix is not, which is why the statements below exclude it.

Non-example by minimal change. Change the $(1,1)$-entry of $\begin{pmatrix} 1 & 1 \\ 2 & 0 \end{pmatrix}$ to 0. The result $\mathbf{A}' = \begin{pmatrix} 0 & 1 \\ 2 & 0 \end{pmatrix}$ is still non-negative, and it is still irreducible, since $(\mathbf{I}+\mathbf{A}')^1 > 0$ (Theorem 18.2.6). But $\mathbf{A}'^2 = 2\mathbf{I}$, so the even powers of $\mathbf{A}'$ are multiples of $\mathbf{I}$ and the odd powers multiples of $\mathbf{A}'$, and every power has two zero entries: $\mathbf{A}'$ is not primitive. The clause that fails is "some power is positive"; what was lost is the loop $1 \to 1$; without it every edge joins 1 and 2, so every closed walk has even length. More generally, the powers of a permutation matrix are permutation matrices (Lemma 2.6.6), and for $n \geq 2$ a permutation matrix has zeros; so no permutation matrix of size $n \geq 2$ is primitive.

Why this definition. Asking for $\mathbf{A} > 0$ itself would be too strong: it excludes the matrices above, whose powers behave exactly like those of a positive matrix. Asking only that each position (i,j) be positive in **some** power, possibly a different power for each position, is too weak: that is irreducibility, and the swap satisfies it. Primitivity sits between the two. It asks for a **single** power that is positive everywhere.

> *Warning.* **Irreducible does not mean primitive.** Irreducibility asks that each j be reachable from each i by a walk of **some** length; primitivity asks for walks of **one common** length. For the swap, every walk from 1 to 2 has odd length and every walk from 1 to 1 has even length, so no single power is positive at both $(1,1)$ and $(1,2)$.

> *Quick check.* Is $\mathbf{A} = \begin{pmatrix} 0 & 1 \\ 1 & 1 \end{pmatrix}$ primitive? Is $\mathbf{B} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$?

> *Solution.* $\mathbf{A}^2 = \begin{pmatrix} 1 & 1 \\ 1 & 2 \end{pmatrix} > 0$, so $\mathbf{A}$ is primitive. For $\mathbf{B}$, every power is upper triangular, $\mathbf{B}^m = \begin{pmatrix} 1 & m \\ 0 & 1 \end{pmatrix}$, so the $(2,1)$-entry is always 0 and $\mathbf{B}$ is not primitive: $G(\mathbf{B})$ has no walk from 1 to 2 at all.

The first consequences of the definition come straight from the graph and from Perron's theorem applied to the positive power.

Proposition 18.5.1 — First Properties of Primitive Matrices

Let $\mathbf{A} \in M_n(\mathbb{R})$ be primitive, with $\mathbf{A}^k > 0$. Then:

(a) $\mathbf{A}^m > 0$ for **every** $m \geq k$;
(b) $\mathbf{A}$ is irreducible;
(c) $\rho(\mathbf{A}) > 0$, and $\rho(\mathbf{A})$ is the **only** eigenvalue of $\mathbf{A}$ of modulus $\rho(\mathbf{A})$.

> *Idea.*
>
> (a) Multiplying a positive matrix by a non-negative matrix with no zero column keeps it positive. (b) A positive power gives walks between all vertices, which is strong connectivity. (c) The eigenvalues of $\mathbf{A}^k$ are the k-th powers of those of $\mathbf{A}$. A

second eigenvalue of $\mathbf{A}$ on the circle of radius ρ would land, after raising to the k-th power, on the circle where Perron's theorem allows only the simple eigenvalue $\rho(\mathbf{A}^k)$.

Proof.

(a) Column j of $\mathbf{A}^k$ is $\mathbf{A}^{k-1}$ times column j of $\mathbf{A}$ (Theorem 0.9.2; for $k = 1$ read $\mathbf{A}^0 = \mathbf{I}$). Since $\mathbf{A}^k > 0$, no column of $\mathbf{A}$ is zero. Now suppose $\mathbf{A}^m > 0$ for some $m \geq k$. Then $(\mathbf{A}^{m+1})_{ij} = \sum_l (\mathbf{A}^m)_{il} a_{lj}$ is a sum of non-negative terms, and the term for an l with $a_{lj} > 0$ is positive. So $\mathbf{A}^{m+1} > 0$, and (a) follows by induction on m.

(b) For every ordered pair (j, i), $(\mathbf{A}^k)_{ij} > 0$, so Lemma 18.2.1 (a) gives a walk from j to i in $G(\mathbf{A})$. So $G(\mathbf{A})$ is strongly connected (Definition 18.2.2), and $\mathbf{A}$ is irreducible by Theorem 18.2.5.

(c) Over $\mathbb{C}$, write $p_{\mathbf{A}} = (x - \lambda_1) \cdots (x - \lambda_n)$, with each eigenvalue repeated according to its algebraic multiplicity. By the Spectral Mapping Theorem (Theorem 8.10.1) with $q = x^k$,

$$p_{\mathbf{A}^k} = (x - \lambda_1^k) \cdots (x - \lambda_n^k).$$

So $\rho(\mathbf{A}^k) = \max_i |\lambda_i|^k = \rho(\mathbf{A})^k$. By Theorem 18.1.5 applied to $\mathbf{A}^k > 0$, $\rho(\mathbf{A}^k) > 0$ is an algebraically simple eigenvalue of $\mathbf{A}^k$, and every other eigenvalue of $\mathbf{A}^k$ has modulus less than $\rho(\mathbf{A}^k)$. In particular $\rho(\mathbf{A})^k > 0$, so $\rho(\mathbf{A}) > 0$.

By (b) and Theorem 18.3.2, $\rho := \rho(\mathbf{A})$ is an eigenvalue of $\mathbf{A}$; say $\lambda_1 = \rho$. Suppose some λ_s with $s \geq 2$ had $|\lambda_s| = \rho$ but $\lambda_s \neq \rho$. Then λ_s^k is an eigenvalue of $\mathbf{A}^k$ of modulus $\rho^k = \rho(\mathbf{A}^k)$, so by Perron's theorem it is not an "other" eigenvalue: $\lambda_s^k = \rho^k$. Then ρ^k occurs at least twice in the list $\lambda_1^k, \ldots, \lambda_n^k$, at positions 1 and s, so $a_{\mathbf{A}^k}(\rho^k) \geq 2$, contradicting simplicity. Hence ρ is the only eigenvalue of modulus ρ.

■

Part (c) is the whole spectral content of primitivity, and the rest of the section shows that it is also enough. Part (a) says that once the powers become positive they stay positive, so the least such k, the **exponent** of $\mathbf{A}$, is well defined and marks a permanent change.

18.5.3 The limit theorem

For the swap, $\rho = 1$ and the powers do not converge. We now show that primitivity is exactly what makes $(\mathbf{A}/\rho)^m$ converge, and we identify the limit. The answer involves eigenvectors on both sides.

If $\mathbf{A} \geq 0$ is irreducible, then Theorem 18.3.2 (a) and Corollary 18.3.3 (a)–(c) provide $\mathbf{v} > \mathbf{0}$ and $\mathbf{w} > \mathbf{0}$ with $\mathbf{A}\mathbf{v} = \rho(\mathbf{A})\mathbf{v}$, $\mathbf{w}^\top \mathbf{A} = \rho(\mathbf{A})\mathbf{w}^\top$ and $\mathbf{w}^\top \mathbf{v} > 0$, and the right and left Perron vectors of Definition 18.3.1 are the pair scaled so that $\mathbf{1}^\top \mathbf{v} = 1$ and $\mathbf{w}^\top \mathbf{v} = 1$. Each of $\mathbf{v}, \mathbf{w}$ is determined up to a positive factor, because $\rho(\mathbf{A})$ is algebraically simple (Theorem 18.3.2 (b)), so its eigenspaces for $\mathbf{A}$ and $\mathbf{A}^\top$ are lines (Theorem 8.3.1, Proposition 8.10.5 (b)).

Theorem 18.5.2 — Limit Theorem for Primitive Matrices

Let $\mathbf{A} \in M_n(\mathbb{R})$ be primitive, $\rho = \rho(\mathbf{A})$, and let $\mathbf{v} > \mathbf{0}$ and $\mathbf{w} > \mathbf{0}$ satisfy $\mathbf{A}\mathbf{v} = \rho\mathbf{v}$ and $\mathbf{w}^{\top}\mathbf{A} = \rho\mathbf{w}^{\top}$, for instance the right and left Perron vectors of $\mathbf{A}$. Then, entrywise,

$$\left(\frac{1}{\rho}\mathbf{A}\right)^{m} \longrightarrow \frac{\mathbf{v}\mathbf{w}^{\top}}{\mathbf{w}^{\top}\mathbf{v}} \qquad (m \to \infty).$$

The limit is a positive matrix of rank one, and it does not depend on how $\mathbf{v}$ and $\mathbf{w}$ are scaled. The same conclusion holds for every irreducible $\mathbf{A} \geq 0$ with $\rho(\mathbf{A}) > 0$ whose only eigenvalue of modulus $\rho(\mathbf{A})$ is $\rho(\mathbf{A})$ itself.

Idea. Divide by ρ, so that the Perron eigenvalue becomes 1 and every other eigenvalue lies strictly inside the unit circle. Chapter 9 §10 then says the powers converge, with no diagonalizability needed, because it works with the Jordan form. It remains to name the limit Ł. Three identities pin it down: $\mathbf{B}Ł = Ł$ puts every column of Ł on the line through $\mathbf{v}$; $Ł\mathbf{B} = Ł$ puts every row on the line through $\mathbf{w}^{\top}$; and $Ł\mathbf{v} = \mathbf{v}$ fixes the scale.

Proof. It suffices to prove the last sentence, since a primitive matrix is irreducible with $\rho(\mathbf{A}) > 0$ and has $\rho(\mathbf{A})$ as its only eigenvalue of modulus $\rho(\mathbf{A})$, by Proposition 18.5.1 (b) and (c).

So let $\mathbf{A} \geq 0$ be irreducible with $\rho > 0$ the only eigenvalue of modulus ρ, and put $\mathbf{B} = \rho^{-1}\mathbf{A}$. By Theorem 8.10.1 with $q = x/\rho$, the eigenvalues of $\mathbf{B}$ are the numbers λ/ρ, $\lambda \in \operatorname{spec}(\mathbf{A})$, with the same algebraic multiplicities. So 1 is an eigenvalue of $\mathbf{B}$ with $a_{\mathbf{B}}(1) = a_{\mathbf{A}}(\rho) = 1$ by Theorem 18.3.2, and every other eigenvalue of $\mathbf{B}$ has modulus less than 1. Since the 1-blocks in a Jordan form of $\mathbf{B}$ have total size $a_{\mathbf{B}}(1) = 1$ (Corollary 9.3.2 (a)), there is a single 1-block, of size 1. By Theorem 9.10.4, $\mathbf{B}^m$ converges to some Ł $\in M_n(\mathbb{C})$.

Three identities. By the algebra of limits, (B3) of Chapter 9 §10, applied entry by entry, $\mathbf{B}^{m+1} = \mathbf{B}\,\mathbf{B}^m \to \mathbf{B}Ł$ and $\mathbf{B}^{m+1} = \mathbf{B}^m\mathbf{B} \to Ł\mathbf{B}$; but $(\mathbf{B}^{m+1})$ is a tail of $(\mathbf{B}^m)$, so it also tends to Ł. Hence $\mathbf{B}Ł = Ł = Ł\mathbf{B}$. Also $\mathbf{B}\mathbf{v} = \mathbf{v}$, so $\mathbf{B}^m\mathbf{v} = \mathbf{v}$ for every m, and letting $m \to \infty$ gives $Ł\mathbf{v} = \mathbf{v}$.

The columns. $\mathbf{B}Ł = Ł$ says that every column of Ł lies in $E_1(\mathbf{B}) = E_\rho(\mathbf{A})$, which is the line $\operatorname{span}(\mathbf{v})$, as noted before the theorem. So column j of Ł is $u_j\mathbf{v}$ for some $u_j \in \mathbb{C}$, that is, $Ł = \mathbf{v}\mathbf{u}^{\top}$ with $\mathbf{u} = (u_1, \dots, u_n)$.

The rows. $Ł\mathbf{B} = Ł$ reads $\mathbf{v}(\mathbf{u}^{\top}\mathbf{B}) = \mathbf{v}\mathbf{u}^{\top}$. Choose r with $v_r \neq 0$ and compare row r: $\mathbf{u}^{\top}\mathbf{B} = \mathbf{u}^{\top}$, so $\mathbf{B}^{\top}\mathbf{u} = \mathbf{u}$, and $\mathbf{u}$ lies in the eigenspace of $\mathbf{A}^{\top}$ for ρ. That eigenspace is the line through $\mathbf{w}$, so $\mathbf{u} = c\mathbf{w}$ for some $c \in \mathbb{C}$.

The scale. Now $\mathbf{v} = Ł\mathbf{v} = c\,\mathbf{v}(\mathbf{w}^{\top}\mathbf{v})$, and comparing entry r gives $c\,\mathbf{w}^{\top}\mathbf{v} = 1$. Since $\mathbf{w}^{\top}\mathbf{v} > 0$, $c = 1/(\mathbf{w}^{\top}\mathbf{v})$, and $Ł = \mathbf{v}\mathbf{w}^{\top}/(\mathbf{w}^{\top}\mathbf{v})$.

Finally, $\mathbf{v}\mathbf{w}^{\top}$ has (i,j)-entry $v_iw_j > 0$ and every column a multiple of $\mathbf{v}$, so the limit is positive of rank one; replacing $\mathbf{v}, \mathbf{w}$ by $s\mathbf{v}, t\mathbf{w}$ with $s, t > 0$ multiplies numerator and denominator by st. This proves the theorem.

■

Note what the proof did **not** use: no eigenvector basis, no computation of the other eigenvalues. Chapter 9's Jordan-form criterion did the analysis once and for all; Perron–Frobenius supplied the simple eigenvalue and the two positive eigenvectors. With the normalization $\mathbf{w}^{\top}\mathbf{v} = 1$ of

§03, the limit is simply the idempotent $\mathbf{v}\mathbf{w}^{\top}$. §06 turns the theorem into the long-run theorem for Markov chains.

Example. (A Limit Computed Two Ways)

Let $\mathbf{A} = \begin{pmatrix} 1 & 1 \\ 2 & 0 \end{pmatrix}$, which is primitive since $\mathbf{A}^2 > 0$. Find $\lim_m (\mathbf{A}/\rho)^m$ from Theorem 18.5.2, and confirm it with an exact formula for $\mathbf{A}^m$.

Solution. The theorem. $p_{\mathbf{A}} = x^2 - x - 2 = (x-2)(x+1)$, so $\rho = 2$. A positive right eigenvector solves $(\mathbf{A} - 2\mathbf{I})\mathbf{v} = \mathbf{0}$, that is, $-v_1 + v_2 = 0$: take $\mathbf{v} = (1,1)$. A positive left eigenvector solves $(\mathbf{A}^{\top} - 2\mathbf{I})\mathbf{w} = \mathbf{0}$, with $\mathbf{A}^{\top} - 2\mathbf{I} = \begin{pmatrix} -1 & 2 \\ 1 & -2 \end{pmatrix}$: take $\mathbf{w} = (2,1)$. Then $\mathbf{w}^{\top}\mathbf{v} = 3$, and

$$\left(\tfrac{1}{2}\mathbf{A}\right)^m \longrightarrow Ł = \frac{1}{3}\begin{pmatrix} 1 \\ 1 \end{pmatrix}\begin{pmatrix} 2 & 1 \end{pmatrix} = \frac{1}{3}\begin{pmatrix} 2 & 1 \\ 2 & 1 \end{pmatrix}.$$

The formula. $Ł^2 = Ł$, because $\mathbf{w}^{\top}\mathbf{v}/3 = 1$, and $Ł(\mathbf{I} - Ł) = \mathbf{0}$. A direct check gives $3Ł - \mathbf{I} = \begin{pmatrix} 1 & 1 \\ 2 & 0 \end{pmatrix} = \mathbf{A}$, so $\mathbf{A} = 2Ł - (\mathbf{I} - Ł)$. Since $Ł$ and $\mathbf{I} - Ł$ are complementary projections, induction on m gives

$$\mathbf{A}^m = 2^m Ł + (-1)^m(\mathbf{I} - Ł),$$
$$\left(\tfrac{1}{2}\mathbf{A}\right)^m = Ł + \left(-\tfrac{1}{2}\right)^m \frac{1}{3}\begin{pmatrix} 1 & -1 \\ -2 & 2 \end{pmatrix}.$$

For $m = 2$ this is $\frac{1}{3}\begin{pmatrix} 2 & 1 \\ 2 & 1 \end{pmatrix} + \frac{1}{12}\begin{pmatrix} 1 & -1 \\ -2 & 2 \end{pmatrix} = \frac{1}{4}\begin{pmatrix} 3 & 1 \\ 2 & 2 \end{pmatrix}$, which is $\mathbf{A}^2/4$. The error term is $(-\frac{1}{2})^m$ times a fixed matrix: it decays at the rate $|\lambda_2|/\rho = \frac{1}{2}$ and changes sign at every step.

Warning. **The limit uses the left eigenvector, not the transpose of the right one.** For the matrix above, $\mathbf{v}\mathbf{v}^{\top}/(\mathbf{v}^{\top}\mathbf{v}) = \frac{1}{2}\begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix}$, which is not the limit. The two agree when $\mathbf{A}$ is symmetric, since then $\mathbf{w} = \mathbf{v}$; in general $\mathbf{w}$ carries the information about how much each starting index contributes in the long run.

The limit theorem also gives the converse of Proposition 18.5.1 (c).

Theorem 18.5.3 — Primitivity from the Spectrum

Let $\mathbf{A} \in M_n(\mathbb{R})$, $\mathbf{A} \geq 0$, be irreducible with $\rho(\mathbf{A}) > 0$. Then $\mathbf{A}$ is primitive if and only if $\rho(\mathbf{A})$ is the only eigenvalue of $\mathbf{A}$ of modulus $\rho(\mathbf{A})$.

Idea. One direction is already proved. For the other, the limit theorem gives a **positive** limit, and a sequence that converges to a positive number is eventually positive. There are only n^2 entries to wait for, so some single power is positive everywhere.

Proof. ($\Rightarrow$) This is Proposition 18.5.1 (c).

($\Leftarrow$) By the last sentence of Theorem 18.5.2, $(\mathbf{A}/\rho)^m \to Ł$ with $Ł > 0$. Each of the n^2

entries of $(\mathbf{A}/\rho)^m$ converges to a positive number c_{ij}, so it is positive for all m beyond some m_{ij}: this is the definition of the limit with $\varepsilon = c_{ij}/2$. For m larger than the largest of these finitely many m_{ij}, $(\mathbf{A}/\rho)^m > 0$, and hence $\mathbf{A}^m = \rho^m(\mathbf{A}/\rho)^m > 0$. So $\mathbf{A}$ is primitive.

■

The hypothesis $\rho(\mathbf{A}) > 0$ excludes only the 1×1 zero matrix: for $n \geq 2$ it holds for every irreducible $\mathbf{A} \geq 0$ by Theorem 18.3.2 (d), and for $n = 1$, $\rho((a)) = a$.

18.5.4 The peripheral spectrum and the period

What does an irreducible, non-primitive matrix look like? The eigenvalues of modulus $\rho(\mathbf{A})$ are called the **peripheral eigenvalues** of $\mathbf{A}$, and the theorem just proved says that a non-primitive irreducible matrix, other than the 1×1 zero matrix, has more than one of them. For the swap they are ± 1. For the 3×3 cyclic permutation they are the three cube roots of unity, as we shall compute. The pattern is general, and it is controlled by a number read off the walks.

The period is the common step size of all round trips.

Definition 18.5.2 — Period

Let $\mathbf{A} \in M_n(\mathbb{R})$, $\mathbf{A} \geq 0$, be irreducible and not the 1×1 zero matrix. The **period** of $\mathbf{A}$ is the greatest common divisor of the lengths of all closed walks in $\mathbf{A}$.

There is at least one closed walk, so the definition makes sense. If $n = 1$, then $\mathbf{A} = (a)$ with $a > 0$, and the loop $1 \to 1$ is a closed walk of length 1. If $n \geq 2$, then $G(\mathbf{A})$ is strongly connected (Theorem 18.2.5), so there are walks from 1 to 2 and from 2 to 1, and one followed by the other is a closed walk. For the swap, every edge joins 1 and 2, so closed walks have even length, and $1 \to 2 \to 1$ has length 2: the period is 2. For $\mathbf{W}$ above, closed walks of lengths 3 and 2 give period 1. A single positive diagonal entry a_{ii} is a loop $i \to i$, a closed walk of length 1, and forces period 1.

The main theorem of this part says that the period counts the peripheral eigenvalues, and that they sit at the corners of a regular polygon. As in §01, $|\mathbf{z}| = (|z_1|, \dots, |z_n|)$ is the entrywise absolute value of $\mathbf{z} \in \mathbb{C}^n$.

Theorem 18.5.4 — The Peripheral Spectrum

Let $\mathbf{A} \in M_n(\mathbb{R})$, $\mathbf{A} \geq 0$, be irreducible and not the 1×1 zero matrix. Put $\rho = \rho(\mathbf{A})$, let h be the number of **distinct** eigenvalues of $\mathbf{A}$ of modulus ρ, and let $\omega = e^{2\pi i/h}$. Then:

(a) the eigenvalues of $\mathbf{A}$ of modulus ρ are exactly $\rho, \rho\omega, \rho\omega^2, \dots, \rho\omega^{h-1}$, and each is algebraically simple;

(b) $\mathbf{A}$ is similar to $\omega\mathbf{A}$; in particular $\operatorname{spec}(\mathbf{A})$ is unchanged by multiplication by ω, with algebraic multiplicities;

(c) h equals the period of $\mathbf{A}$.

Idea. **Step roadmap.** ① Take an eigenvector $\mathbf{z}$ for a peripheral eigenvalue $\rho e^{i\theta}$. The triangle inequality (Theorem 0.6.4) gives $\mathbf{A}|\mathbf{z}| \geq \rho|\mathbf{z}|$, and superinvariance (Proposition 18.4.2) forces equality, so $|\mathbf{z}|$ is a positive multiple of $\mathbf{v}$. Equality in the triangle inequality then says all terms of each row sum point in the same direction, and that is a similarity $\mathbf{D}^{-1}\mathbf{A}\mathbf{D} = e^{i\theta}\mathbf{A}$ with $\mathbf{D}$ diagonal. ② So the spectrum is invariant under rotation by every peripheral angle, the peripheral points form a finite group of rotations, and a finite group of h points on the unit circle must be the h-th roots of unity. ③ The diagonal matrix $\mathbf{D}$ records a phase at each vertex, and each edge advances the phase by one step; going round a closed walk returns the phase, which ties h to walk lengths.

Proof. Recall that $\rho > 0$ (the remark after Theorem 18.5.3), and let $\mathbf{v} > \mathbf{0}$ be an eigenvector of $\mathbf{A}$ for ρ (Theorem 18.3.2 (a)).

Step 1. *Let $\lambda = \rho e^{i\theta}$ be an eigenvalue. Then there are real numbers $\varphi_1, \dots, \varphi_n$ such that $e^{i\varphi_j} = e^{i\theta}e^{i\varphi_i}$ whenever $a_{ij} > 0$; consequently, with $\mathbf{D} = \operatorname{diag}(e^{i\varphi_1}, \dots, e^{i\varphi_n})$, we have $\mathbf{D}^{-1}\mathbf{A}\mathbf{D} = e^{i\theta}\mathbf{A}$.*

Let $\mathbf{A}\mathbf{z} = \lambda\mathbf{z}$ with $\mathbf{z} \neq \mathbf{0}$. By Lemma 18.1.2 (a), with $|\mathbf{A}| = \mathbf{A}$ since $\mathbf{A} \geq 0$, in each row

$$\rho\,|z_i| = |\lambda z_i| = \Big|\sum_j a_{ij} z_j\Big| \leq \sum_j a_{ij}|z_j| = (\mathbf{A}|\mathbf{z}|)_i.$$

So $\mathbf{A}|\mathbf{z}| \geq \rho|\mathbf{z}|$, where $|\mathbf{z}| \geq \mathbf{0}$ and $|\mathbf{z}| \neq \mathbf{0}$. If $\mathbf{A}|\mathbf{z}| \neq \rho|\mathbf{z}|$, then Proposition 18.4.2 (b) with $s = \rho$ would give $\rho > \rho$; hence $\mathbf{A}|\mathbf{z}| = \rho|\mathbf{z}|$. So $|\mathbf{z}|$ is a non-negative eigenvector of $\mathbf{A}$, and by Theorem 18.3.2 (c) it is a positive multiple of $\mathbf{v}$. Therefore $|\mathbf{z}| > \mathbf{0}$, and we may write $z_j = |z_j|e^{i\varphi_j}$ in polar form.

Now every inequality in the display is an equality. Fix i. The number $S = \sum_j a_{ij}z_j = \lambda z_i = \rho|z_i|e^{i(\theta+\varphi_i)}$ (Theorem 0.6.5) is non-zero, since $\rho > 0$ and $|z_i| > 0$, and $|S| = \sum_j |a_{ij}z_j|$. So Lemma 18.1.3, applied to the n numbers $a_{ij}z_j$, with $S/|S| = e^{i(\theta+\varphi_i)}$, gives $a_{ij}z_j = a_{ij}|z_j|e^{i(\theta+\varphi_i)}$ for every j. If $a_{ij} > 0$, dividing by $a_{ij}|z_j| > 0$ gives $e^{i\varphi_j} = e^{i(\theta+\varphi_i)} = e^{i\theta}e^{i\varphi_i}$. This is the first statement. For the second, the (i,j)-entry of $\mathbf{D}^{-1}\mathbf{A}\mathbf{D}$ is $e^{-i\varphi_i}a_{ij}e^{i\varphi_j}$, which is $e^{i\theta}a_{ij}$ when $a_{ij} > 0$ and $0 = e^{i\theta}a_{ij}$ when $a_{ij} = 0$.

Step 2. *Proof of (a) and (b).* Write $p_{\mathbf{A}} = (x-\lambda_1)\cdots(x-\lambda_n)$ over $\mathbb{C}$. For every peripheral $\lambda = \rho e^{i\theta}$, Step 1 and Theorem 6.10.3 give $p_{\mathbf{A}} = p_{e^{i\theta}\mathbf{A}}$, and by Theorem 8.10.1 with $q = e^{i\theta}x$,

$$\begin{aligned}(x-\lambda_1)\cdots(x-\lambda_n) = p_{\mathbf{A}} &= p_{e^{i\theta}\mathbf{A}} \\ &= (x - e^{i\theta}\lambda_1)\cdots(x - e^{i\theta}\lambda_n).\end{aligned}$$

So multiplication by $e^{i\theta}$ permutes the eigenvalues listed with multiplicity:

$$a_{\mathbf{A}}(e^{i\theta}\mu) = a_{\mathbf{A}}(\mu) \qquad \text{for every } \mu \in \mathbb{C}.$$

Let $G = \{\lambda/\rho : \lambda \in \operatorname{spec}(\mathbf{A}),\ |\lambda| = \rho\}$, a set of h complex numbers of modulus 1 containing 1, because $\rho \in \operatorname{spec}(\mathbf{A})$ by Theorem 18.3.2. If $g = e^{i\theta}$ and g' lie in G, then $\rho g' \in \operatorname{spec}(\mathbf{A})$, so $g\rho g' \in \operatorname{spec}(\mathbf{A})$ by the invariance just proved, and it has modulus ρ: thus $gg' \in G$. For fixed $g \in G$, the map $G \to G$, $x \mapsto gx$, is injective, since $g \neq 0$; as G is finite it is a bijection. Hence the product Π of all elements of G satisfies $\Pi = \prod_{x\in G} gx = g^h\,\Pi$, and $\Pi \neq 0$, so $g^h = 1$. So G is contained in the set of h-th roots of unity, which has exactly h elements $1, \omega, \dots, \omega^{h-1}$ (Example (Roots of Unity)). Both sets have h elements, so they are equal. This proves the first half of (a).

Each $\rho\omega^j$ has $a_{\mathbf{A}}(\rho\omega^j) = a_{\mathbf{A}}(\rho) = 1$, by the invariance with $e^{i\theta} = \omega^j$ and Theorem 18.3.2. This proves (a). Taking $\lambda = \rho\omega$ in Step 1 gives (b).

Step 3. *Proof of (c).* Let d be the period.

h divides d. Apply Step 1 to $\lambda = \rho\omega$, so $e^{i\theta} = \omega$. Along a closed walk $i_0 \to i_1 \to \cdots \to i_L = i_0$ each entry $a_{i_t i_{t-1}}$ is positive, so Step 1 gives $e^{i\varphi_{i_{t-1}}} = \omega e^{i\varphi_{i_t}}$ for each t, and chaining these L equations gives $e^{i\varphi_{i_0}} = \omega^L e^{i\varphi_{i_L}} = \omega^L e^{i\varphi_{i_0}}$. So $\omega^L = 1$, and h divides L (Example (Roots of Unity)). As this holds for every closed walk, h divides d.

d divides h. If $n = 1$ then $d = 1$. Let $n \geq 2$. Since $G(\mathbf{A})$ is strongly connected (Theorem 18.2.5), every vertex j is joined to vertex 1 by walks in both directions; for $j = 1$ this includes the walk of length 0. Choose for each j the length ℓ_j of some walk from 1 to j, with $\ell_1 = 0$. Any two walks from 1 to j, of lengths ℓ and ℓ', have lengths congruent modulo d: following either by a fixed walk from j back to 1, of length s, gives closed walks of lengths $\ell + s$ and $\ell' + s$ (or length 0, trivially a multiple of d), both multiples of d. Now if $a_{ij} > 0$, a walk from 1 to j followed by the edge $j \to i$ is a walk from 1 to i of length $\ell_j + 1$, so $\ell_i \equiv \ell_j + 1 \pmod{d}$. Put $\zeta = e^{2\pi i/d}$ and $\mathbf{E} = \operatorname{diag}(\zeta^{-\ell_1}, \dots, \zeta^{-\ell_n})$. Then the (i,j)-entry of $\mathbf{E}^{-1}\mathbf{A}\mathbf{E}$ is $\zeta^{\ell_i - \ell_j} a_{ij} = \zeta a_{ij}$ when $a_{ij} > 0$, since $\zeta^d = 1$, and 0 otherwise. So $\mathbf{E}^{-1}\mathbf{A}\mathbf{E} = \zeta\mathbf{A}$. As in Step 2, $\operatorname{spec}(\mathbf{A}) = \zeta \operatorname{spec}(\mathbf{A})$, so $\zeta\rho \in \operatorname{spec}(\mathbf{A})$, with modulus ρ. By (a), $\zeta = \omega^j$ for some j, so $\zeta^h = (\omega^h)^j = 1$, and d divides h: $e^{2\pi i h/d} = 1 = e^{2\pi i \cdot 0/d}$, and two integers k, l give the same number $e^{2\pi i k/d} = e^{2\pi i l/d}$ only when d divides $k - l$ (Example (Roots of Unity)).

Both h and d are positive, so $h = d$. This proves the theorem.

■

The two halves of Step 3 are mirror images. The diagonal similarity attached to a peripheral eigenvalue is a consistent labeling of the indices by h phases, with every positive entry advancing the phase by one; the walks of $\mathbf{A}$ build such a labeling with d phases.

Combining (c) with Theorem 18.5.3 gives a test that needs no eigenvalues at all.

Corollary 18.5.5 — Primitivity from Walks

Let $\mathbf{A} \in M_n(\mathbb{R})$, $\mathbf{A} \geq 0$, be irreducible and not the 1×1 zero matrix. Then $\mathbf{A}$ is primitive if and only if its period is 1. In particular, an irreducible $\mathbf{A} \geq 0$ with at least one positive diagonal entry is primitive.

Proof. Since $\mathbf{A}$ is not the 1×1 zero matrix, $\rho(\mathbf{A}) > 0$ by the remark after Theorem 18.5.3. So by that theorem, $\mathbf{A}$ is primitive if and only if $h = 1$, and h is the period by Theorem 18.5.4 (c). A positive diagonal entry is a closed walk of length 1, so the period divides 1.

■

18.5.5 The cyclic permutation

The standard irreducible matrix that is not primitive is the cyclic shift. It generalizes Chapter 8's swap, and it shows every part of Theorem 18.5.4 at once.

Example. (The Cyclic Permutation)

Let $n \geq 2$ and let $\sigma \in S_n$ send $j \mapsto j+1$ for $j < n$ and $n \mapsto 1$. Its permutation matrix $\mathbf{P} = \mathbf{P}_\sigma$ (Definition 2.6.2) has columns $\mathbf{e}_2, \mathbf{e}_3, \ldots, \mathbf{e}_n, \mathbf{e}_1$. Show that $\mathbf{P}$ is irreducible with period n, find its peripheral eigenvalues, and show that $\mathbf{P}^m$ does not converge.

Solution. Walks. The non-zero entries of $\mathbf{P}$ are $p_{j+1,\,j}$ for $j < n$ and p_{1n}, so the edges of $G(\mathbf{P})$ are $j \to j+1$ for $j < n$ and $n \to 1$: the graph is the cycle $1 \to 2 \to \cdots \to n \to 1$. Every walk runs round it, and a closed walk goes round a whole number of times, so its length is a multiple of n; the walk $1 \to 2 \to \cdots \to n \to 1$ has length n. So the period is n. Following the cycle, every vertex reaches every vertex, so $G(\mathbf{P})$ is strongly connected and $\mathbf{P}$ is irreducible (Theorem 18.2.5).

Eigenvalues. Since $\mathbf{P}\mathbf{e}_j = \mathbf{e}_{\sigma(j)}$ and σ^n is the identity, $\mathbf{P}^n\mathbf{e}_j = \mathbf{e}_j$ for every j, so $\mathbf{P}^n = \mathbf{I}$. If $\mathbf{P}\mathbf{z} = \lambda\mathbf{z}$ with $\mathbf{z} \neq \mathbf{0}$, then $\mathbf{z} = \mathbf{P}^n\mathbf{z} = \lambda^n\mathbf{z}$, so $\lambda^n = 1$ and $|\lambda| = 1$. Hence $\rho(\mathbf{P}) = 1$ and **every** eigenvalue is peripheral. By Theorem 18.5.4, $h = n$, so the peripheral eigenvalues are the n numbers $1, \omega, \ldots, \omega^{n-1}$, $\omega = e^{2\pi i/n}$, each algebraically simple. That accounts for all n eigenvalues, and $p_{\mathbf{P}} = (x-1)(x-\omega)\cdots(x-\omega^{n-1}) = x^n - 1$, the last equality because both sides are monic of degree n with the same n distinct roots.

Powers. $\mathbf{P}^n = \mathbf{I}$, so the sequence $\mathbf{P}, \mathbf{P}^2, \ldots$ repeats with period n, and $\mathbf{P}^m$ runs through n distinct permutation matrices. A sequence that returns to each of two different matrices infinitely often has no limit, so $\mathbf{P}^m$ does not converge. Starting a chain at $\mathbf{e}_1$, $\mathbf{P}^m\mathbf{e}_1$ runs round $\mathbf{e}_1, \mathbf{e}_2, \ldots, \mathbf{e}_n, \mathbf{e}_1, \ldots$ forever, although $\mathbf{P}$ has the steady state $\frac{1}{n}\mathbf{1}$.

For $n = 2$ this is exactly the warning in Chapter 8 §11: the swap has the eigenvalue $-1 = e^{2\pi i/2}$, and Chapter 9 §10 identified an eigenvalue of modulus 1 other than 1 as the only obstruction to convergence (Corollary 9.10.5). We now know where that eigenvalue comes from. It is forced by the period: every closed walk has even length. §06 shows that the chain still settles down **on average**.

18.5.6 How large a power is needed

The definition of primitivity asks for some $\mathbf{A}^k > 0$ but gives no bound on k, so a direct check might seem to require computing powers without end. By Lemma 18.2.1 (a), the zero pattern of $\mathbf{A}^m$ depends only on the zero pattern of $\mathbf{A}$, and there are finitely many patterns, so in principle the question is finite. The sharp answer is classical.

Theorem 18.5.6 — Wielandt's Bound

If $\mathbf{A} \in M_n(\mathbb{R})$ is primitive, then $\mathbf{A}^{(n-1)^2+1} > 0$. The bound cannot be improved: for $n \geq 2$ the matrix $\mathbf{W}_n$ with ones at the positions $(i, i+1)$ for $i < n$ and at $(n, 1)$ and $(n, 2)$, and zeros elsewhere, is primitive and $\mathbf{W}_n^{(n-1)^2}$ has a zero entry.

This theorem is due to H. Wielandt (1950). **We state it without proof**; the proof is a careful count of walk lengths, and nothing in this book depends on it. The matrix $\mathbf{W}_3$ is the matrix $\mathbf{W}$ of the examples, where we saw that $\mathbf{W}^4$ has a zero at position $(1,1)$ and $\mathbf{W}^5 > 0$; here $(n-1)^2+1 = 5$. In the walks: a closed walk at 1 must leave by $1 \to 3$ and return by $2 \to 1$, so it is made of 3-cycles $1 \to 3 \to 2 \to 1$ and detours round $3 \to 2 \to 3$, and its length $3 + 3a + 2b$, with $a, b \geq 0$, is never 4. For $n = 4$ the bound is 10, and $\mathbf{W}_4^9$ is not positive while $\mathbf{W}_4^{10}$ is.

> *Remark.* The bound is quadratic in n, not $n-1$ as for $(\mathbf{I}+\mathbf{A})^{n-1}$ in Theorem 18.2.6. Adding $\mathbf{I}$ puts a loop at every vertex, which lets walks wait; a primitive matrix may have no such loops, and then the walks must make up lengths from long cycles, as $\mathbf{W}_n$ does with its cycles of lengths n and $n-1$.

18.5.7 Exercises

18.5.7.1 A. Check your understanding

Exercise A1.

(a) Define a primitive matrix, and state the limit theorem for primitive matrices.

(b) True or false: every primitive matrix is irreducible. Justify your answer.

(c) True or false: every irreducible non-negative matrix is primitive. Justify your answer.

(d) True or false: if $\mathbf{A} \geq 0$ is irreducible and $a_{11} > 0$, then $\mathbf{A}$ is primitive. Justify your answer.

(e) An irreducible $\mathbf{A} \geq 0$ has $\rho(\mathbf{A}) = 2$ and period 4. Which of its eigenvalues can you name without further information?

(f) Name the two ingredients from earlier chapters that the proof of Theorem 18.5.2 combines.

Solution.

(a) $\mathbf{A} \in M_n(\mathbb{R})$, $\mathbf{A} \geq 0$, is primitive if $\mathbf{A}^k > 0$ for some $k \geq 1$ (Definition 18.5.1). Theorem 18.5.2: if $\mathbf{A}$ is primitive with $\rho = \rho(\mathbf{A})$, and $\mathbf{v} > \mathbf{0}$, $\mathbf{w} > \mathbf{0}$ satisfy $\mathbf{A}\mathbf{v} = \rho\mathbf{v}$ and $\mathbf{w}^{\top}\mathbf{A} = \rho\mathbf{w}^{\top}$, then $(\mathbf{A}/\rho)^m \to \mathbf{v}\mathbf{w}^{\top}/(\mathbf{w}^{\top}\mathbf{v})$ entrywise.

(b) True, by Proposition 18.5.1 (b).

(c) False. The swap $\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$ is irreducible, but each of its powers is $\mathbf{I}$ or the swap, and both have zero entries.

(d) True, by Corollary 18.5.5: the loop $1 \to 1$ is a closed walk of length 1, so the period is 1. (If $n = 1$, then $\mathbf{A} = (a_{11})$ with $a_{11} > 0$ is primitive directly.)

(e) By Theorem 18.5.4, $h = 4$, so the eigenvalues of modulus 2 are $2, 2i, -2, -2i$, each algebraically simple. The others cannot be named, but they come in orbits of multiplication by i, by part (b) of that theorem.

(f) The Jordan-form convergence criterion of Chapter 9 §10 (Theorem 9.10.4), which gives convergence of $(\mathbf{A}/\rho)^m$; and the Perron–Frobenius theorem (Theorem 18.3.2), which gives the simple eigenvalue ρ and the positive vectors $\mathbf{v}, \mathbf{w}$ that identify the limit.

18.5.7.2 B. Practice

Exercise B1: Which are primitive?.

Determine which of the following matrices are primitive. Justify your answer.

(a) $\begin{pmatrix} 0 & 1 \\ 1 & 1 \end{pmatrix}$.

(b) $\begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 0 & 0 \end{pmatrix}$.

(c) $\begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix}$.

(d) $\begin{pmatrix} 1 & 1 & 0 \\ 0 & 1 & 1 \\ 0 & 0 & 1 \end{pmatrix}$.

Solution.

(a) Primitive: its square is $\begin{pmatrix} 1 & 1 \\ 1 & 2 \end{pmatrix} > 0$.

(b) Not primitive. It is the cyclic permutation matrix of Example (The Cyclic Permutation) with $n = 3$ (columns $\mathbf{e}_3, \mathbf{e}_1, \mathbf{e}_2$, the same shift run the other way), and every power of a permutation matrix is a permutation matrix (Lemma 2.6.6), which has zero entries.

(c) Not primitive. The positive entries are at $(1,2), (2,1), (2,3), (3,2)$, so the edges of $G(\mathbf{A})$ are $1 \to 2$, $2 \to 1$, $2 \to 3$ and $3 \to 2$, and every edge joins vertex 2 to the set $\{1, 3\}$. A closed walk therefore has even length, and $1 \to 2 \to 1$ has length 2: the matrix has period 2. It is irreducible, since every vertex reaches every other through 2, so $G(\mathbf{A})$ is strongly connected (Theorem 18.2.5). By Corollary 18.5.5 it is not primitive. (Directly: $\mathbf{A}^m$ has zero $(1,2)$-entry for even m and zero $(1,1)$-entry for odd m.)

(d) Not primitive. The positive entries sit at positions (i, j) with $i \leq j$, so every edge $j \to i$ has $i \leq j$, vertex numbers never increase along a walk, and there is no walk from 1 to 2. By Lemma 18.2.1 (a), the $(2,1)$-entry of every power is 0.

Exercise B2: A limit without diagonalizing.

Let $\mathbf{A} = \begin{pmatrix} 0 & 0 & 1 \\ 2 & 0 & 1 \\ 2 & 1 & 0 \end{pmatrix}$.

(a) Show that $\mathbf{A}$ is primitive.

(b) Show that $p_{\mathbf{A}} = (x-2)(x+1)^2$, and that $\mathbf{A}$ is **not** diagonalizable.

(c) Find positive right and left eigenvectors for $\rho(\mathbf{A})$, and hence $\lim_m (\mathbf{A}/2)^m$.

Solution.

(a) Compute

$$\mathbf{A}^2 = \begin{pmatrix} 2 & 1 & 0 \\ 2 & 1 & 2 \\ 2 & 0 & 3 \end{pmatrix}, \qquad \mathbf{A}^4 = (\mathbf{A}^2)^2 = \begin{pmatrix} 6 & 3 & 2 \\ 10 & 3 & 8 \\ 10 & 2 & 9 \end{pmatrix} > 0.$$

So $\mathbf{A}$ is primitive.

(b) Here $x\mathbf{I} - \mathbf{A} = \begin{pmatrix} x & 0 & -1 \\ -2 & x & -1 \\ -2 & -1 & x \end{pmatrix}$, and expansion along the first row gives

$$\begin{aligned} p_{\mathbf{A}} &= x\big(x^2 - 1\big) + (-1)\big((-2)(-1) - x(-2)\big) \\ &= x^3 - x - 2 - 2x = x^3 - 3x - 2. \end{aligned}$$

Since $(x-2)(x+1)^2 = (x-2)(x^2+2x+1) = x^3 - 3x - 2$, this is the claimed factorization. For $\lambda = -1$, $\mathbf{A} + \mathbf{I} = \begin{pmatrix} 1 & 0 & 1 \\ 2 & 1 & 1 \\ 2 & 1 & 1 \end{pmatrix}$ has rank 2 (rows 2 and 3 agree, rows 1 and 2 are independent), so $g_{\mathbf{A}}(-1) = 1 < 2 = a_{\mathbf{A}}(-1)$, and $\mathbf{A}$ is not diagonalizable.

(c) $\mathbf{A} - 2\mathbf{I} = \begin{pmatrix} -2 & 0 & 1 \\ 2 & -2 & 1 \\ 2 & 1 & -2 \end{pmatrix}$: the first row gives $v_3 = 2v_1$, and then the second gives $2v_1 - 2v_2 + 2v_1 = 0$, so $v_2 = 2v_1$. Take $\mathbf{v} = (1, 2, 2)$; check: $\mathbf{A}\mathbf{v} = (2, 4, 4)$. For the left vector, $\mathbf{A}^\top - 2\mathbf{I} = \begin{pmatrix} -2 & 2 & 2 \\ 0 & -2 & 1 \\ 1 & 1 & -2 \end{pmatrix}$: the second row gives $w_3 = 2w_2$, and the first gives $w_1 = w_2 + w_3 = 3w_2$. Take $\mathbf{w} = (3, 1, 2)$; check: $\mathbf{w}^\top\mathbf{A} = (0+2+4,\ 0+0+2,\ 3+1+0) = (6, 2, 4) = 2\mathbf{w}^\top$. Then $\mathbf{w}^\top\mathbf{v} = 3+2+4 = 9$, and by Theorem 18.5.2

$$\Big(\frac{1}{2}\mathbf{A}\Big)^m \longrightarrow \frac{1}{9}\begin{pmatrix} 1 \\ 2 \\ 2 \end{pmatrix}\begin{pmatrix} 3 & 1 & 2 \end{pmatrix} = \frac{1}{9}\begin{pmatrix} 3 & 1 & 2 \\ 6 & 2 & 4 \\ 6 & 2 & 4 \end{pmatrix}.$$

Part (b) shows that Chapter 8's diagonalization method is unavailable here; the theorem does not need it.

Exercise B3: Period and peripheral eigenvalues.

Let $\mathbf{A} = \begin{pmatrix} 0 & 1 & 0 \\ 2 & 0 & 2 \\ 0 & 1 & 0 \end{pmatrix}$.

(a) Show that $\mathbf{A}$ is irreducible with period 2.

(b) Use Theorem 18.5.4 to predict the eigenvalues of modulus $\rho(\mathbf{A})$ in terms of $\rho(\mathbf{A})$, then compute $p_{\mathbf{A}}$ and confirm.

(c) Hence explain why $(\mathbf{A}/\rho(\mathbf{A}))^m$ does not converge.

Solution.

(a) The positive entries are at $(1,2),(2,1),(2,3),(3,2)$, the same pattern as in B1(c), so the argument there applies: $\mathbf{A}$ is irreducible with period 2.

(b) With $h=2$ and $\omega=-1$, the peripheral eigenvalues are ρ and $-\rho$, and the spectrum is symmetric under $\lambda \mapsto -\lambda$. Expanding along the first row,

$$p_{\mathbf{A}} = \det \begin{pmatrix} x & -1 & 0 \\ -2 & x & -2 \\ 0 & -1 & x \end{pmatrix} = x(x^2-2) + 1\cdot(-2x) = x(x-2)(x+2).$$

So $\rho = 2$, the peripheral eigenvalues are ± 2, and the remaining eigenvalue 0 is its own negative, as predicted.

(c) The vector $\mathbf{z} = (1,-2,1)$ satisfies $\mathbf{A}\mathbf{z} = (-2,4,-2) = -2\mathbf{z}$, so $\mathbf{A}/2$ has the eigenvalue -1. By Theorem 9.10.4, the powers of a matrix with an eigenvalue of modulus 1 other than 1 do not converge. Concretely, $(\mathbf{A}/2)^m\mathbf{z} = (-1)^m\mathbf{z}$ alternates in sign.

18.5.7.3 C. Going deeper

Exercise C1: Shifting by the identity.

Let $\mathbf{A} \in M_n(\mathbb{R})$, $\mathbf{A} \geq 0$, be irreducible, with right and left Perron vectors $\mathbf{v}, \mathbf{w}$, and let $t > 0$.

(a) Prove that $\mathbf{A} + t\mathbf{I}$ is primitive, with $\rho(\mathbf{A}+t\mathbf{I}) = \rho(\mathbf{A}) + t$ and the same Perron vectors $\mathbf{v}, \mathbf{w}$.

(b) Deduce that $\big((\mathbf{A}+t\mathbf{I})/(\rho(\mathbf{A})+t)\big)^m \to \mathbf{v}\mathbf{w}^\top/(\mathbf{w}^\top\mathbf{v})$, and apply this to the swap with $t=1$.

Solution.

(a) $\mathbf{A}+t\mathbf{I} \geq 0$ has the same off-diagonal pattern as $\mathbf{A}$, so $(\mathbf{I}+\mathbf{A}+t\mathbf{I})^{n-1} \geq (\mathbf{I}+\mathbf{A})^{n-1} > 0$ entrywise, since each product of non-negative matrices can only grow when an entry grows; so $\mathbf{A}+t\mathbf{I}$ is irreducible (Theorem 18.2.6). Its diagonal entries are $\geq t > 0$, so it is primitive by Corollary 18.5.5. By Theorem 8.10.1 with $q = x+t$, its eigenvalues are $\lambda+t$, $\lambda \in \operatorname{spec}(\mathbf{A})$, and $|\lambda+t| \leq |\lambda|+t \leq \rho(\mathbf{A})+t$ by Theorem 0.6.4, with $\rho(\mathbf{A})+t$ itself an eigenvalue, since $\rho(\mathbf{A}) \in \operatorname{spec}(\mathbf{A})$. So $\rho(\mathbf{A}+t\mathbf{I}) = \rho(\mathbf{A})+t$. Finally $(\mathbf{A}+t\mathbf{I})\mathbf{v} = (\rho(\mathbf{A})+t)\mathbf{v}$ and $\mathbf{w}^\top(\mathbf{A}+t\mathbf{I}) = (\rho(\mathbf{A})+t)\mathbf{w}^\top$, with $\mathbf{v}, \mathbf{w} > \mathbf{0}$.

(b) By (a) and Theorem 18.5.2 applied to $\mathbf{A}+t\mathbf{I}$. For the swap $\mathbf{S}$, $\rho = 1$, and $\mathbf{1}$ is a positive right and left eigenvector, so the limit is $\mathbf{1}\mathbf{1}^\top/(\mathbf{1}^\top\mathbf{1}) = \mathbf{1}\mathbf{1}^\top/2$. Directly, $(\mathbf{S}+\mathbf{I})/2 = \frac{1}{2}\begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix}$, whose powers are all equal to itself, in agreement.

Exercise C2: Traces detect the period.

Let $\mathbf{A} \geq 0$ be irreducible, not the 1×1 zero matrix, with period h.

(a) Prove that $\operatorname{tr}(\mathbf{A}^m) = 0$ for every $m \geq 1$ that is not a multiple of h, in two ways: from Theorem 18.5.4 (b), and from Lemma 18.2.1 (a).

(b) Deduce that if $\operatorname{tr}(\mathbf{A}^2) > 0$ and $\operatorname{tr}(\mathbf{A}^3) > 0$, then $\mathbf{A}$ is primitive.

(c) Check (b) on the matrix $\mathbf{W}$ of the examples.

Solution.

(a) *Spectrum.* Let $\omega = e^{2\pi i/h}$ and $p_{\mathbf{A}} = \prod_i (x - \lambda_i)$. By Theorem 18.5.4 (c), the period h is also the number of peripheral eigenvalues, so part (b) of that theorem applies with this ω. By Corollary 8.10.2, applied over $\mathbb{C}$, $\operatorname{tr}(\mathbf{A}^m) = \sum_i \lambda_i^m$. By Theorem 18.5.4 (b), the list $\omega\lambda_1, \dots, \omega\lambda_n$ is a rearrangement of $\lambda_1, \dots, \lambda_n$, so $\sum_i \lambda_i^m = \sum_i (\omega\lambda_i)^m = \omega^m \sum_i \lambda_i^m$. If $h \nmid m$, then $\omega^m \neq 1$ (Example (Roots of Unity)), so $\operatorname{tr}(\mathbf{A}^m) = 0$.
Walks. $\operatorname{tr}(\mathbf{A}^m) = \sum_i (\mathbf{A}^m)_{ii}$ is a sum of non-negative terms, positive exactly when some $(\mathbf{A}^m)_{ii} > 0$, that is, by Lemma 18.2.1 (a), when there is a closed walk of length m. Every closed walk has length a multiple of the period, so for $h \nmid m$ the trace is 0.

(b) By (a), $h \mid 2$ and $h \mid 3$, so $h = 1$, and $\mathbf{A}$ is primitive by Corollary 18.5.5.

(c) $\mathbf{W}^2 = \begin{pmatrix} 0 & 0 & 1 \\ 1 & 1 & 0 \\ 0 & 1 & 1 \end{pmatrix}$ has trace 2, and $\mathbf{W}^3 = \begin{pmatrix} 1 & 1 & 0 \\ 0 & 1 & 1 \\ 1 & 1 & 1 \end{pmatrix}$ has trace 3; so $\mathbf{W}$ is primitive, as found directly.

Exercise C3: A finite test for primitivity.

Let $\mathbf{A} \in M_n(\mathbb{R})$, $\mathbf{A} \geq 0$, and let $\mathbf{Z}_m$ be the zero pattern of $\mathbf{A}^m$: the 0/1 matrix with a 1 exactly where $\mathbf{A}^m$ is positive.

(a) Prove that $\mathbf{Z}_{m+1}$ is determined by $\mathbf{Z}_m$ and $\mathbf{Z}_1$.

(b) Deduce that if $\mathbf{Z}_a = \mathbf{Z}_b$ with $a < b$, then $\mathbf{Z}_{a+j} = \mathbf{Z}_{b+j}$ for every $j \geq 0$.

(c) Prove that if $\mathbf{A}$ is primitive, then $\mathbf{A}^k > 0$ for some $k \leq 2^{n^2}$. Compare with Theorem 18.5.6.

Hint: there are only 2^{n^2} zero patterns; use Proposition 18.5.1 (a).

Solution.

(a) $(\mathbf{A}^{m+1})_{ij} = \sum_l (\mathbf{A}^m)_{il} a_{lj}$ is a sum of non-negative terms, positive exactly when some l has $(\mathbf{A}^m)_{il} > 0$ and $a_{lj} > 0$. So $(\mathbf{Z}_{m+1})_{ij} = 1$ if and only if $(\mathbf{Z}_m)_{il} = (\mathbf{Z}_1)_{lj} = 1$ for some l, which depends only on $\mathbf{Z}_m$ and $\mathbf{Z}_1$.

(b) By induction on j: the case $j = 0$ is the hypothesis, and if $\mathbf{Z}_{a+j} = \mathbf{Z}_{b+j}$, then (a) applied to both gives $\mathbf{Z}_{a+j+1} = \mathbf{Z}_{b+j+1}$.

(c) Among $\mathbf{Z}_1, \dots, \mathbf{Z}_{N+1}$, $N = 2^{n^2}$, two agree, say $\mathbf{Z}_a = \mathbf{Z}_b$ with $a < b \leq N + 1$, so $a \leq N$. By (b), $\mathbf{Z}_{a+q(b-a)} = \mathbf{Z}_a$ for every $q \geq 0$, by induction on q. If $\mathbf{A}^k > 0$, then by Proposition 18.5.1 (a) $\mathbf{A}^m > 0$ for all $m \geq k$; choosing q with $a + q(b - a) \geq k$ shows that $\mathbf{Z}_a$ is the all-ones pattern, so $\mathbf{A}^a > 0$ with $a \leq 2^{n^2}$. Wielandt's bound $(n-1)^2 + 1$ is enormously smaller: for $n = 3$ it is 5 against 512.

18.6 Markov Chains

Chapter 8 §11 proved that a Markov chain settles down to a unique steady state, but only under three hypotheses on the eigenvalues of its transition matrix, one of them diagonalizability. It closed with a promise: the Perron–Frobenius theorem would give the same conclusions "for every stochastic matrix with some power having all entries positive, without assuming diagonalizability and without computing eigenvalues". This section keeps that promise, using the limit theorem of §05. It then asks what happens when no power is positive. Irreducible chains still have a unique steady state, and they approach it on average even when they oscillate. Reducible chains can have many steady states, and among them the absorbing chains, which end in a trap, have an exact theory built on the Neumann series.

Conventions. Stochastic means **column**-stochastic, as in Definition 8.11.1: $\mathbf{A} \geq 0$ and every column sums to 1, that is, $\mathbf{1}^{\top}\mathbf{A} = \mathbf{1}^{\top}$. The entry a_{ij} is the probability of moving **to** state i **from** state j, and a Markov chain is $\mathbf{x}_{k+1} = \mathbf{A}\mathbf{x}_k$ (Definition 8.11.2). Many books use rows and the transposed matrix; we never do. The order $\geq$ is entrywise.

18.6.1 Steady states and the Perron root

We first place stochastic matrices inside the theory of this chapter. Since $\mathbf{x}_m = \mathbf{A}^m\mathbf{x}_0$, the entry $(\mathbf{A}^m)_{ij}$ is the probability of being in state i after m steps when starting from state j. By Lemma 18.2.1 (a) it is positive exactly when the graph $G(\mathbf{A})$ has a walk of length m from j to i: the edges of the graph are the moves the chain can make in one step, and the walks are the routes it can take.

Proposition 18.6.1 — The Perron Root of a Stochastic Matrix

Let $\mathbf{A} \in M_n(\mathbb{R})$ be stochastic. Then:

(a) $\rho(\mathbf{A}) = 1$, and $\mathbf{1}$ is a positive left eigenvector for it;

(b) the steady states of $\mathbf{A}$ are exactly the non-negative eigenvectors for $\rho(\mathbf{A})$ whose entries sum to 1;

(c) if $\mathbf{A}$ is irreducible, then $\mathbf{A}$ has **exactly one** steady state $\mathbf{v}$, and $\mathbf{v} > \mathbf{0}$.

Idea. Example (An irreducible stochastic matrix) already found these facts for one matrix, and the argument there is general. The column sums make $\mathbf{1}^{\top}$ a left eigenvector for 1, and no eigenvalue is larger in modulus; so a steady state is a non-negative eigenvector for the Perron root; when $\mathbf{A}$ is irreducible, Perron–Frobenius with the normalization $\mathbf{1}^{\top}\mathbf{v} = 1$ leaves room for only one.

Proof.

(a) By Proposition 8.11.3 (c), $1 \in \operatorname{spec}(\mathbf{A})$ and $\mathbf{1}^{\top}\mathbf{A} = \mathbf{1}^{\top}$. By Corollary 9.10.5 (a), every eigenvalue has modulus at most 1. So $\rho(\mathbf{A}) = 1$.

(b) This is Definition 8.11.2 read with (a): a steady state is a probability vector $\mathbf{v}$ with $\mathbf{A}\mathbf{v} = \mathbf{v} = \rho(\mathbf{A})\mathbf{v}$.

(c) By Theorem 18.3.2 (a), there is $\mathbf{u} > \mathbf{0}$ with $\mathbf{A}\mathbf{u} = \mathbf{u}$; then $\mathbf{v} = \mathbf{u}/(\mathbf{1}^{\top}\mathbf{u})$ is a steady state with $\mathbf{v} > \mathbf{0}$. If $\mathbf{v}'$ is any steady state, it is a non-negative eigenvector, so

$\mathbf{v}' = c\mathbf{v}$ with $c > 0$ by Theorem 18.3.2 (c), and $1 = \mathbf{1}^\top \mathbf{v}' = c\,\mathbf{1}^\top \mathbf{v} = c$. Hence $\mathbf{v}' = \mathbf{v}$.

■

In the notation of §03, the Perron root of a stochastic matrix is 1, the all-ones vector is a positive left eigenvector, and for an irreducible stochastic matrix the steady state is the right Perron vector.

Warning. **A unique positive steady state does not make the chain converge.** The swap $\mathbf{S} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$ is stochastic and irreducible, so by (c) it has exactly one steady state, $(\frac{1}{2}, \frac{1}{2})$, and it is positive. Yet the chain started at $\mathbf{e}_1$ alternates $\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_1, \dots$ and never approaches it. Existence and uniqueness of the steady state come from irreducibility; convergence needs more.

18.6.2 The long-run theorem

The "more" is primitivity. Here are the three conclusions of Theorem 8.11.4, in the same words, under the hypothesis that Chapter 8 §11 promised.

Theorem 18.6.2 — Long-Run Behavior of a Markov Chain

Let $\mathbf{A} \in M_n(\mathbb{R})$ be stochastic, and suppose that $\mathbf{A}^k > 0$ for some $k \geq 1$. Then:

(a) $\mathbf{A}$ has exactly one steady state $\mathbf{v}$, and $\mathbf{v} > \mathbf{0}$;

(b) $\mathbf{A}^m \to \mathbf{v}\mathbf{1}^\top$ entrywise as $m \to \infty$;

(c) for every probability vector $\mathbf{x}_0$, the Markov chain $\mathbf{x}_m = \mathbf{A}^m \mathbf{x}_0$ converges entrywise to $\mathbf{v}$.

Idea. For a stochastic matrix, Theorem 18.5.2 has $\rho = 1$, and the left eigenvector can be taken to be $\mathbf{1}$, so the limit $\mathbf{v}\mathbf{w}^\top/(\mathbf{w}^\top\mathbf{v})$ becomes $\mathbf{v}\mathbf{1}^\top$ once the steady state is normalized by $\mathbf{1}^\top\mathbf{v} = 1$. The chain inherits the limit column by column.

Proof. By hypothesis $\mathbf{A}$ is primitive (Definition 18.5.1), hence irreducible (Proposition 18.5.1 (b)). So (a) is Proposition 18.6.1 (c).

(b) By Proposition 18.6.1 (a), $\rho(\mathbf{A}) = 1$ and $\mathbf{w} = \mathbf{1}$ is positive with $\mathbf{w}^\top\mathbf{A} = \mathbf{w}^\top$; and $\mathbf{v} > \mathbf{0}$ satisfies $\mathbf{A}\mathbf{v} = \mathbf{v}$. By Theorem 18.5.2,

$$\mathbf{A}^m = \Big(\frac{1}{\rho(\mathbf{A})}\mathbf{A}\Big)^m \longrightarrow \frac{\mathbf{v}\mathbf{1}^\top}{\mathbf{1}^\top\mathbf{v}} = \mathbf{v}\mathbf{1}^\top,$$

since $\mathbf{1}^\top\mathbf{v} = 1$.

(c) Entry r of $\mathbf{A}^m\mathbf{x}_0$ is $\sum_s (\mathbf{A}^m)_{rs}(\mathbf{x}_0)_s$, which by (b) converges to $\sum_s v_r(\mathbf{x}_0)_s = v_r\,(\mathbf{1}^\top\mathbf{x}_0) = v_r$.

■

Compare the hypotheses with those of Theorem 8.11.4. That theorem asked for three facts about the eigenvalues: $\mathbf{A}$ diagonalizable over $\mathbb{C}$, $a_{\mathbf{A}}(1) = 1$, and $|\lambda| < 1$ for every other eigenvalue. Chapter 9 §10 (Corollary 9.10.5) removed the first, but still asked to locate every eigenvalue on the unit circle. The new hypothesis is a statement about the **zero pattern** of one power of $\mathbf{A}$, checked by multiplying matrices; no eigenvalue is computed, and none needs to be. The last two eigenvalue conditions become conclusions, by Proposition 18.5.1 (c) and Theorem 18.3.2 (b), and diagonalizability is simply irrelevant. By Corollary 18.5.5 the hypothesis can often be checked without multiplying at all: an irreducible stochastic matrix with one positive diagonal entry, a state that can stay put, qualifies. In the vocabulary of probability, a stochastic matrix with a positive power is called **regular**.

Example. (A Chain that Cannot Be Diagonalized)

A token moves among three positions. From position 1 it always moves to 3; from 2 it moves to 1 or 3 with probability $\frac{1}{2}$ each; from 3 it moves to 1 or 2 with probability $\frac{1}{2}$ each. So

$$\mathbf{A} = \begin{pmatrix} 0 & 1/2 & 1/2 \\ 0 & 0 & 1/2 \\ 1 & 1/2 & 0 \end{pmatrix}.$$

Show that Theorem 8.11.4 does not apply but Theorem 18.6.2 does, and find the long-run distribution.

Solution. Diagonalization fails. Expanding $\det(x\mathbf{I} - \mathbf{A})$ along the first column,

$$\begin{aligned} p_{\mathbf{A}} &= x\Big(x^2 - \frac{1}{4}\Big) - \Big(\frac{1}{4} + \frac{x}{2}\Big) \\ &= x^3 - \frac{3}{4}x - \frac{1}{4} = (x-1)\Big(x + \frac{1}{2}\Big)^2. \end{aligned}$$

For the double eigenvalue, $\mathbf{A} + \frac{1}{2}\mathbf{I} = \begin{pmatrix} 1/2 & 1/2 & 1/2 \\ 0 & 1/2 & 1/2 \\ 1 & 1/2 & 1/2 \end{pmatrix}$ has rank 2: its first two rows are independent, and the third is twice the first minus the second. So $g_{\mathbf{A}}(-\frac{1}{2}) = 1 < 2 = a_{\mathbf{A}}(-\frac{1}{2})$, and $\mathbf{A}$ is not diagonalizable (Theorem 8.4.1). Theorem 8.11.4 does not apply.

A positive power. Squaring,

$$\mathbf{A}^2 = \begin{pmatrix} 1/2 & 1/4 & 1/4 \\ 1/2 & 1/4 & 0 \\ 0 & 1/2 & 3/4 \end{pmatrix}, \qquad \mathbf{A}^4 = (\mathbf{A}^2)^2 = \begin{pmatrix} 3/8 & 5/16 & 5/16 \\ 3/8 & 3/16 & 1/8 \\ 1/4 & 1/2 & 9/16 \end{pmatrix} > 0.$$

So Theorem 18.6.2 applies with $k = 4$. ($\mathbf{A}^3$ still has a zero at position $(2,1)$: three steps cannot take the token from 1 to 2.)

The steady state. $(\mathbf{A} - \mathbf{I})\mathbf{v} = \mathbf{0}$ reads $-v_1 + \frac{1}{2}v_2 + \frac{1}{2}v_3 = 0$ and $-v_2 + \frac{1}{2}v_3 = 0$. So $v_3 = 2v_2$, then $v_1 = \frac{1}{2}v_2 + v_2 = \frac{3}{2}v_2$, and $\mathbf{v}$ is a multiple of $(3,2,4)$. Scaling to sum 1,

$$\mathbf{v} = \Big(\frac{1}{3}, \frac{2}{9}, \frac{4}{9}\Big), \qquad \mathbf{A}^m \longrightarrow \mathbf{v}\mathbf{1}^{\top}.$$

Check: $\mathbf{A}\mathbf{v} = (\frac{1}{9} + \frac{2}{9},\ \frac{2}{9},\ \frac{1}{3} + \frac{1}{9}) = (\frac{1}{3}, \frac{2}{9}, \frac{4}{9})$. In the long run the token is at position 3 four times out of nine, wherever it starts.

What the Jordan block does. Solving the recurrence exactly (for instance from the Jordan

form, as in Chapter 9 §10) gives

$$(\mathbf{A}^m)_{11} = \frac{1}{3}\Big(1 + 2\Big(-\frac{1}{2}\Big)^m\Big),$$
$$(\mathbf{A}^m)_{21} = \frac{2}{9}\Big(1 + (3m-1)\Big(-\frac{1}{2}\Big)^m\Big),$$

which one can confirm for $m = 0, 1, 2$ against $\mathbf{I}, \mathbf{A}, \mathbf{A}^2$. The factor m in the second formula comes from the 2×2 Jordan block for $-\frac{1}{2}$, whose powers carry the entry $m\lambda^{m-1}$ (Chapter 9 §10): the error decays like $m\,2^{-m}$ rather than 2^{-m}. It still decays, and the theorem never needed to know.

Quick check. Does Theorem 18.6.2 apply to $\mathbf{A} = \begin{pmatrix} 1/2 & 1 \\ 1/2 & 0 \end{pmatrix}$? If so, what is $\lim_m \mathbf{A}^m$?

Solution. Yes: $\mathbf{A}$ is stochastic and $\mathbf{A}^2 = \begin{pmatrix} 3/4 & 1/2 \\ 1/4 & 1/2 \end{pmatrix} > 0$. The steady state solves $-\frac{1}{2}v_1 + v_2 = 0$, so $\mathbf{v} = (\frac{2}{3}, \frac{1}{3})$, and $\mathbf{A}^m \to \mathbf{v}\mathbf{1}^\top = \begin{pmatrix} 2/3 & 2/3 \\ 1/3 & 1/3 \end{pmatrix}$.

The hypothesis of Theorem 18.6.2 is also necessary for the theorem as stated: if $\mathbf{A}^m \to \mathbf{v}\mathbf{1}^\top$ with $\mathbf{v} > \mathbf{0}$, then $\mathbf{A}$ is primitive (exercise C2). Without the positivity of $\mathbf{v}$ it is not needed for convergence: $\begin{pmatrix} 1 & 1/2 \\ 0 & 1/2 \end{pmatrix}$ has no positive power, yet its powers converge to $\mathbf{e}_1\mathbf{1}^\top$, whose steady state has a zero entry.

18.6.3 Irreducible chains: convergence on average

Now drop primitivity but keep irreducibility. By Proposition 18.6.1 (c) the steady state $\mathbf{v}$ is still unique and positive, but by Theorem 18.5.3 and Theorem 18.5.4 the chain has $h \geq 2$ eigenvalues on the unit circle, and its powers do not converge (Corollary 9.10.5 (b)). What survives is convergence of **averages**. The average $\frac{1}{m}(\mathbf{x}_0 + \mathbf{x}_1 + \cdots + \mathbf{x}_{m-1})$ is, entry by entry, the average over the first m steps of the probability of being in each state; read through linearity of expectation (see the end of this section), it is the expected fraction of those steps spent there. It is this that settles down.

Theorem 18.6.3 — Averages of an Irreducible Chain

Let $\mathbf{A} \in M_n(\mathbb{R})$ be stochastic and irreducible, with steady state $\mathbf{v}$. Then:

(a) $\frac{1}{m}(\mathbf{I} + \mathbf{A} + \mathbf{A}^2 + \cdots + \mathbf{A}^{m-1}) \to \mathbf{v}\mathbf{1}^\top$ as $m \to \infty$;
(b) for every probability vector $\mathbf{x}_0$, the averages $\frac{1}{m}(\mathbf{x}_0 + \mathbf{x}_1 + \cdots + \mathbf{x}_{m-1})$ of the chain converge to $\mathbf{v}$;
(c) $\mathbf{A}^m$ converges if and only if $\mathbf{A}$ is primitive.

Idea. Split every vector into its component along $\mathbf{v}$ and a remainder whose entries sum to 0. The remainder lies in the image of $\mathbf{I} - \mathbf{A}$, by a dimension count, and on that image

the sum $\sum_{k<m} \mathbf{A}^k$ telescopes: $\sum_{k<m} \mathbf{A}^k(\mathbf{I}-\mathbf{A})\mathbf{y} = \mathbf{y} - \mathbf{A}^m\mathbf{y}$, which stays bounded, so dividing by m kills it. The component along $\mathbf{v}$ is fixed by every power.

Proof.

(a) Let $U = \{\mathbf{x} \in \mathbb{R}^n : \mathbf{1}^\top\mathbf{x} = 0\}$, the kernel of the non-zero linear functional $\mathbf{x} \mapsto \mathbf{1}^\top\mathbf{x}$, so $\dim U = n-1$ by Rank–Nullity (Theorem 3.3.1). Since $\mathbf{1}^\top(\mathbf{I}-\mathbf{A}) = \mathbf{1}^\top - \mathbf{1}^\top = \mathbf{0}^\top$, the image of $\mathbf{I}-\mathbf{A}$ lies in U. The kernel of $\mathbf{I}-\mathbf{A}$ on $\mathbb{R}^n$ is the real eigenspace of $\mathbf{A}$ for 1; it contains $\mathbf{v} \neq \mathbf{0}$, and it has dimension at most $g_{\mathbf{A}}(1) \leq a_{\mathbf{A}}(1) = 1$ by Theorem 8.3.1 and Theorem 18.3.2 (b). (The real and the complex kernel of the real matrix $\mathbf{I}-\mathbf{A}$ have the same dimension, n minus its rank, since row reduction uses only real arithmetic.) So $\operatorname{rank}(\mathbf{I}-\mathbf{A}) = n-1$ by Rank–Nullity, and an inclusion of subspaces of equal dimension is an equality: $\operatorname{im}(\mathbf{I}-\mathbf{A}) = U$.
Now fix $\mathbf{x} \in \mathbb{R}^n$. Since $\mathbf{1}^\top\mathbf{v} = 1$, the vector $\mathbf{x} - (\mathbf{1}^\top\mathbf{x})\mathbf{v}$ lies in U, so $\mathbf{x} = (\mathbf{1}^\top\mathbf{x})\mathbf{v} + (\mathbf{I}-\mathbf{A})\mathbf{y}$ for some $\mathbf{y} \in \mathbb{R}^n$. As $\mathbf{A}^k\mathbf{v} = \mathbf{v}$ for every k,

$$\begin{aligned}\sum_{k=0}^{m-1} \mathbf{A}^k\mathbf{x} &= m\,(\mathbf{1}^\top\mathbf{x})\mathbf{v} + \sum_{k=0}^{m-1} \left(\mathbf{A}^k\mathbf{y} - \mathbf{A}^{k+1}\mathbf{y}\right) \\ &= m\,(\mathbf{1}^\top\mathbf{x})\mathbf{v} + \mathbf{y} - \mathbf{A}^m\mathbf{y}.\end{aligned}$$

Every $\mathbf{A}^m$ is stochastic (Proposition 8.11.3 (b)), so its entries lie in $[0,1]$ and $|(\mathbf{A}^m\mathbf{y})_i| \leq \sum_j |y_j|$. Hence each entry of $\frac{1}{m}(\mathbf{y} - \mathbf{A}^m\mathbf{y})$ has modulus at most $\frac{2}{m}\sum_j |y_j|$, which tends to 0 because $\frac{1}{m} \to 0$, by the Archimedean property, a consequence of completeness (fact (A1) in the introduction to Chapter 15). Dividing the display by m, $\frac{1}{m}\sum_{k<m} \mathbf{A}^k\mathbf{x} \to (\mathbf{1}^\top\mathbf{x})\mathbf{v} = \mathbf{v}\mathbf{1}^\top\mathbf{x}$. Taking $\mathbf{x} = \mathbf{e}_j$ gives the convergence of column j, for each j.

(b) $\frac{1}{m}\sum_{k<m} \mathbf{x}_k = \left(\frac{1}{m}\sum_{k<m} \mathbf{A}^k\right)\mathbf{x}_0 \to \mathbf{v}\mathbf{1}^\top\mathbf{x}_0 = \mathbf{v}$ by (a), entry by entry as in the proof of Theorem 18.6.2 (c).

(c) ($\Leftarrow$) is Theorem 18.6.2 (b). ($\Rightarrow$) Suppose $\mathbf{A}^m \to \text{Ł}$. Then $\mathbf{A}^{m+1} = \mathbf{A}\mathbf{A}^m$ tends both to Ł and to $\mathbf{A}$Ł, so $\mathbf{A}$Ł $=$ Ł, and every column of Ł lies in the real eigenspace for 1, which is $\operatorname{span}(\mathbf{v})$ by the proof of (a). Each column of $\mathbf{A}^m$ has entries ≥ 0 summing to 1, and both properties survive the limit, by the elementary algebra of limits recalled in the introduction to Chapter 15 (limits respect sums, and a non-strict inequality survives a limit), so each column of Ł is a probability vector on the line $\operatorname{span}(\mathbf{v})$, namely $\mathbf{v}$ itself. Thus Ł $= \mathbf{v}\mathbf{1}^\top > 0$. As in the proof of Theorem 18.5.3, the n^2 entries of $\mathbf{A}^m$ are then positive for all large m, so $\mathbf{A}$ is primitive.

■

The proof of (a) used irreducibility only to know that the eigenspace for 1 is a line through a probability vector $\mathbf{v}$; nothing about the period or the other eigenvalues entered.

Example. (A Walk that Oscillates)

A walker on three sites $1, 2, 3$ in a row steps to a neighboring site at every step, choosing

each neighbor with probability $\frac{1}{2}$ when there are two. So

$$\mathbf{A} = \begin{pmatrix} 0 & 1/2 & 0 \\ 1 & 0 & 1 \\ 0 & 1/2 & 0 \end{pmatrix}.$$

Show that $\mathbf{A}^m$ does not converge, and compute the averages of Theorem 18.6.3 exactly.

Solution. The edges of $G(\mathbf{A})$ are $1 \to 2$, $2 \to 1$, $2 \to 3$ and $3 \to 2$. Every site reaches every other through site 2, so $\mathbf{A}$ is irreducible (Theorem 18.2.5); and every edge joins site 2 to $\{1,3\}$, so closed walks have even length and the period is 2. The steady state solves $v_1 = \frac{1}{2}v_2$, $v_3 = \frac{1}{2}v_2$, so $\mathbf{v} = (\frac{1}{4}, \frac{1}{2}, \frac{1}{4})$. Multiplying out,

$$\mathbf{A}^2 = \begin{pmatrix} 1/2 & 0 & 1/2 \\ 0 & 1 & 0 \\ 1/2 & 0 & 1/2 \end{pmatrix}, \qquad \mathbf{A}^3 = \mathbf{A}\mathbf{A}^2 = \mathbf{A}.$$

So $\mathbf{A}^m = \mathbf{A}$ for odd m and $\mathbf{A}^m = \mathbf{A}^2$ for even $m \geq 2$, and since $\mathbf{A} \neq \mathbf{A}^2$ the powers do not converge. A walker who starts at site 2 is at site 2 at every even step and never at an odd one.

For the averages, note that $\frac{1}{2}(\mathbf{A} + \mathbf{A}^2) = \begin{pmatrix} 1/4 & 1/4 & 1/4 \\ 1/2 & 1/2 & 1/2 \\ 1/4 & 1/4 & 1/4 \end{pmatrix} = \mathbf{v}\mathbf{1}^\top$. For $m = 2p$, the sum $\sum_{k<2p} \mathbf{A}^k$ contains $\mathbf{I}$ once, $\mathbf{A}$ p times and $\mathbf{A}^2$ $p-1$ times, so

$$\begin{aligned} \frac{1}{2p}\sum_{k=0}^{2p-1} \mathbf{A}^k &= \frac{\mathbf{I} - \mathbf{A}^2 + p(\mathbf{A} + \mathbf{A}^2)}{2p} \\ &= \mathbf{v}\mathbf{1}^\top + \frac{1}{2p}(\mathbf{I} - \mathbf{A}^2) \longrightarrow \mathbf{v}\mathbf{1}^\top. \end{aligned}$$

For $m = 2p+1$ there is one more term, $\mathbf{A}^{2p} = \mathbf{A}^2$, which changes the average by at most $\frac{1}{m}$ in each entry. So the walker spends, in the long run, half its time at the middle site and a quarter at each end, although at no single time is its distribution close to $\mathbf{v}$ if it starts at a site.

The oscillation can also be removed rather than averaged. The **lazy** chain $\frac{1}{2}(\mathbf{I} + \mathbf{A})$, which at each step stays put with probability $\frac{1}{2}$ and otherwise moves by $\mathbf{A}$, is stochastic, irreducible and has positive diagonal, so it is primitive by Corollary 18.5.5, and it has the same steady state; exercise C1 works this out.

18.6.4 Reducible chains: many steady states

Without irreducibility, uniqueness fails too. The chain can split into parts that never communicate, and each can carry its own equilibrium.

Example. (Two Traps)

States 1 and 2 exchange with each other and are never left; state 3 is never left either; state 4 stays with probability $\frac{1}{4}$ and otherwise moves to 1, 2 or 3 with probability $\frac{1}{4}$

each:

$$\mathbf{A} = \begin{pmatrix} 1/2 & 1/4 & 0 & 1/4 \\ 1/2 & 3/4 & 0 & 1/4 \\ 0 & 0 & 1 & 1/4 \\ 0 & 0 & 0 & 1/4 \end{pmatrix}.$$

Find all steady states, and the limit of the chain from each starting state.

Solution. Steady states. Let $\mathbf{Au} = \mathbf{u}$ with $\mathbf{u}$ a probability vector. The last row gives $\frac{1}{4}u_4 = u_4$, so $u_4 = 0$. The first row then gives $\frac{1}{2}u_1 + \frac{1}{4}u_2 = u_1$, so $u_2 = 2u_1$; the second and third rows then hold automatically. So $\mathbf{u} = (s, 2s, t, 0)$ with $s, t \geq 0$ and $3s + t = 1$. Writing $\mathbf{v}_1 = (\frac{1}{3}, \frac{2}{3}, 0, 0)$ and $\mathbf{v}_2 = \mathbf{e}_3$, the steady states are exactly

$$\mathbf{u} = c\,\mathbf{v}_1 + (1 - c)\,\mathbf{v}_2, \qquad 0 \leq c \leq 1,$$

the whole segment $[\mathbf{v}_2, \mathbf{v}_1]$ of Chapter 17. There are infinitely many, and $E_1(\mathbf{A}) = \operatorname{span}(\mathbf{v}_1, \mathbf{v}_2)$ is a plane: $a_{\mathbf{A}}(1) = 2$, since $p_{\mathbf{A}} = (x-1)^2(x - \frac{1}{4})^2$, the first factor from the block of states $1, 2$ and from state 3, the second from the block's other eigenvalue $\frac{1}{4}$ and from state 4. In particular $\mathbf{A}$ is not irreducible, by Proposition 18.6.1 (c).

Limits. The only eigenvalue of modulus 1 is 1, so $\mathbf{A}^m$ converges by Corollary 9.10.5 (b). Its limit $\mathbf{\Pi}$ satisfies $\mathbf{A\Pi} = \mathbf{\Pi}$, as in the proof of Theorem 18.6.3 (c), and its columns are limits of probability vectors, hence probability vectors; so each column of $\mathbf{\Pi}$ is a steady state. Columns 1 and 2 of every $\mathbf{A}^m$ have zeros in rows 3 and 4, by induction on m: $\mathbf{A}$ maps a vector with zeros in those rows to a combination of its own first two columns, which again has zeros there. So columns 1 and 2 of $\mathbf{\Pi}$ are steady states with $u_3 = 0$, that is, $\mathbf{v}_1$. Column 3 of $\mathbf{A}$ is $\mathbf{e}_3$, so column 3 of every power, and of $\mathbf{\Pi}$, is $\mathbf{e}_3 = \mathbf{v}_2$. For column 4, write it as $c\mathbf{v}_1 + (1-c)\mathbf{v}_2$ and find c from a conserved quantity: the row vector $\mathbf{y}^\top = (1, 1, 0, \frac{2}{3})$ satisfies $\mathbf{y}^\top\mathbf{A} = \mathbf{y}^\top$, as a column-by-column check shows (column 4: $\frac{1}{4} + \frac{1}{4} + \frac{2}{3} \cdot \frac{1}{4} = \frac{2}{3}$). Then $\mathbf{y}^\top\mathbf{A}^m = \mathbf{y}^\top$ for all m, hence $\mathbf{y}^\top\mathbf{\Pi} = \mathbf{y}^\top$, and entry 4 gives $\mathbf{y}^\top(c\mathbf{v}_1 + (1-c)\mathbf{v}_2) = c = \frac{2}{3}$. Thus

$$\mathbf{\Pi} = \begin{pmatrix} 1/3 & 1/3 & 0 & 2/9 \\ 2/3 & 2/3 & 0 & 4/9 \\ 0 & 0 & 1 & 1/3 \\ 0 & 0 & 0 & 0 \end{pmatrix},$$

with last column $\frac{2}{3}\mathbf{v}_1 + \frac{1}{3}\mathbf{v}_2$. The long run depends on where the chain starts: from state 4, the chain ends up in the pair $\{1, 2\}$ with probability $\frac{2}{3}$ and in state 3 with probability $\frac{1}{3}$, the ratio $\frac{1}{2} : \frac{1}{4}$ of the one-step probabilities of leaving 4 for each.

In general the steady states of a stochastic matrix form a convex set, since a convex combination of probability vectors fixed by $\mathbf{A}$ is again one; the example shows it can be a segment rather than a point. One steady state for each part of the chain that, once entered, is never left, and all convex combinations of these: that is the general picture, which we do not prove here.

18.6.5 Absorbing chains

The simplest traps are single states. A state j is **absorbing** if $a_{jj} = 1$, so that column j of $\mathbf{A}$ is $\mathbf{e}_j$: once there, the chain stays. Absorbing states model the end of a process: a game won or lost, a customer who has left, a molecule that has reacted.

Definition 18.6.1 — Absorbing Chain

A stochastic matrix $\mathbf{A} \in M_n(\mathbb{R})$ is **absorbing** if it has at least one absorbing state, and **from every state some absorbing state can be reached**: for every j there are an absorbing state i and an $m \geq 0$ with $(\mathbf{A}^m)_{ij} > 0$. The states that are not absorbing are called **transient**.

Number the states so that the $t \geq 1$ transient states come first and the $r \geq 1$ absorbing states last. Column j for a transient j splits into the probabilities of moving to transient states and to absorbing states, and the column of an absorbing state is a standard basis vector. So $\mathbf{A}$ has the block form

$$\mathbf{A} = \begin{pmatrix} \mathbf{Q} & 0 \\ \mathbf{R} & \mathbf{I}_r \end{pmatrix}, \qquad \mathbf{Q} \in M_t(\mathbb{R}), \quad \mathbf{R} \in M_{r\times t}(\mathbb{R}),$$

with $\mathbf{Q}, \mathbf{R} \geq 0$ and $\mathbf{1}^\top \mathbf{Q} + \mathbf{1}^\top \mathbf{R} = \mathbf{1}^\top$. Multiplying blocks and inducting on m,

$$\mathbf{A}^m = \begin{pmatrix} \mathbf{Q}^m & 0 \\ \mathbf{R}_m & \mathbf{I}_r \end{pmatrix}, \qquad \mathbf{R}_m = \mathbf{R}\big(\mathbf{I} + \mathbf{Q} + \cdots + \mathbf{Q}^{m-1}\big),$$

since $\mathbf{A}^{m+1} = \mathbf{A}\mathbf{A}^m$ has lower-left block $\mathbf{R}\mathbf{Q}^m + \mathbf{R}_m = \mathbf{R}_{m+1}$. The entry $(\mathbf{Q}^m)_{ij}$ is the probability of being at transient state i after m steps from transient state j; the column sums of $\mathbf{Q}^m$ are the probabilities of not yet having been absorbed.

Lemma 18.6.4 — Transient Mass Dies Out

If $\mathbf{A}$ is absorbing, with $\mathbf{Q}$ as above, then every eigenvalue of $\mathbf{Q}$ has modulus less than 1, and $\mathbf{Q}^m \to 0$.

Idea. Every column of $\mathbf{Q}$ sums to at most 1, which only gives $\rho(\mathbf{Q}) \leq 1$. But after enough steps every transient state has leaked some mass into an absorbing state, so every column of a suitable power $\mathbf{Q}^M$ sums to **strictly** less than 1, and the column-sum bound of Chapter 15 gives $\rho(\mathbf{Q}^M) < 1$.

Proof. For absorbing i and any j, $(\mathbf{A}^{m+1})_{ij} = \sum_l a_{il}(\mathbf{A}^m)_{lj} \geq a_{ii}(\mathbf{A}^m)_{ij} = (\mathbf{A}^m)_{ij}$, since all terms are non-negative; so the probability of being at i never decreases. Fix a transient j. By Definition 18.6.1 there are an absorbing i and m_j with $(\mathbf{A}^{m_j})_{ij} > 0$, and then $(\mathbf{A}^m)_{ij} > 0$ for every $m \geq m_j$. Let M be the largest of the m_j over the transient j. Column j of $\mathbf{A}^M$ sums to 1 (Proposition 8.11.3 (b)) and has a positive entry $(\mathbf{A}^M)_{ij}$ in the absorbing rows, so column j of $\mathbf{Q}^M$ sums to less than 1. Since $\mathbf{Q}^M \geq 0$, its largest absolute column sum is some $c < 1$, and by Corollary 15.4.2, $\rho(\mathbf{Q}^M) \leq c < 1$. By Theorem 8.10.1 with $q = x^M$, the eigenvalues of $\mathbf{Q}^M$ are the M-th powers of those of $\mathbf{Q}$, so $\rho(\mathbf{Q})^M = \rho(\mathbf{Q}^M) < 1$ and $\rho(\mathbf{Q}) < 1$. Finally $\mathbf{Q}^m \to 0$ by Theorem 9.10.2. ∎

The Neumann series now does all the work.

Theorem 18.6.5 — Absorbing Chains

Let $\mathbf{A} = \begin{pmatrix} \mathbf{Q} & 0 \\ \mathbf{R} & \mathbf{I}_r \end{pmatrix}$ be absorbing, in the block form above. Then:

(a) $\mathbf{I} - \mathbf{Q}$ is invertible, and the **fundamental matrix** $\mathbf{N} := (\mathbf{I} - \mathbf{Q})^{-1} = \sum_{k \geq 0} \mathbf{Q}^k$ satisfies $\mathbf{N} \geq 0$;

(b) $\mathbf{A}^m \to \begin{pmatrix} 0 & 0 \\ \mathbf{RN} & \mathbf{I}_r \end{pmatrix}$ entrywise;

(c) every column of the $r \times t$ matrix $\mathbf{B} := \mathbf{RN}$ is a probability vector.

Idea. The lemma gives $\rho(\mathbf{Q}) < 1$, which is exactly what the Neumann series needs. In the block formula for $\mathbf{A}^m$, the lower-left block is $\mathbf{R}$ times a partial sum of that series, so it converges to $\mathbf{RN}$; and column sums equal to 1 pass to the limit.

Proof.

(a) By Lemma 18.6.4 and Theorem 9.10.6, $\sum_k \mathbf{Q}^k$ converges and equals $(\mathbf{I} - \mathbf{Q})^{-1}$. Each partial sum is ≥ 0, and a limit of non-negative numbers is non-negative, since a non-strict inequality survives a limit (the elementary algebra of limits, recalled in the introduction to Chapter 15); so $\mathbf{N} \geq 0$.

(b) By the block formula, the upper-left block of $\mathbf{A}^m$ is $\mathbf{Q}^m \to 0$ (Lemma 18.6.4), and the lower-left block is $\mathbf{R}_m = \mathbf{R} \sum_{k<m} \mathbf{Q}^k$. Each entry of $\mathbf{R}_m$ is a fixed linear combination of entries of the partial sum, so $\mathbf{R}_m \to \mathbf{RN}$ by the algebra of limits, (B3) of Chapter 9 §10. The other two blocks do not depend on m.

(c) Every column of $\mathbf{A}^m$ sums to 1, and so does every column of the limit in (b). For a transient j, column j of the limit is $(\mathbf{0}, \mathbf{Be}_j)$, so the entries of $\mathbf{Be}_j$ sum to 1; they are non-negative because $\mathbf{R}, \mathbf{N} \geq 0$.

■

Reading the answer. The theorem is pure algebra; its meaning comes from reading entries as probabilities. The (i, j)-entry of the limit in (b), for absorbing i and transient j, is the limit of the non-decreasing probabilities of being at i after m steps from j: the **probability of being absorbed at** i. So $\mathbf{B} = \mathbf{RN}$ is the matrix of absorption probabilities. Two further readings use a fact from probability that this book does not develop, **linearity of expectation**: the expected number of steps at which an event occurs is the sum over the steps of the probabilities of that event. With it, since $(\mathbf{Q}^k)_{ij}$ is the probability of being at transient i at step k from j,

$$\begin{aligned} N_{ij} &= \sum_{k \geq 0} (\mathbf{Q}^k)_{ij} \\ &= \text{expected number of visits to } i \text{ starting from } j, \end{aligned}$$

counting the visit at step 0 when $i = j$; and summing over i, the column sums $\tau_j = (\mathbf{1}^\top \mathbf{N})_j$ are the **expected numbers of steps before absorption**. Nothing in the proofs depends on these readings.

Example. (Gambler's Ruin)

A gambler holds 1, 2 or 3 coins and bets one coin at a time on a fair toss, winning or losing a coin with probability $\frac{1}{2}$ each. Play stops when the gambler holds 0 coins (ruin) or 4 coins (target). Find the fundamental matrix, the expected length of play, and the

probability of reaching the target, from each starting fortune.

Solution. The transient states are the fortunes $1, 2, 3$, in that order, and the absorbing ones are 0 and 4, in that order. From fortune j the gambler moves to $j-1$ or $j+1$ with probability $\frac{1}{2}$ each, so

$$\mathbf{Q} = \begin{pmatrix} 0 & 1/2 & 0 \\ 1/2 & 0 & 1/2 \\ 0 & 1/2 & 0 \end{pmatrix}, \qquad \mathbf{R} = \begin{pmatrix} 1/2 & 0 & 0 \\ 0 & 0 & 1/2 \end{pmatrix},$$

the first row of $\mathbf{R}$ recording ruin from fortune 1 and the second reaching the target from fortune 3. Each column of $\begin{pmatrix} \mathbf{Q} \\ \mathbf{R} \end{pmatrix}$ sums to 1, and every fortune reaches 0 by losing, so the chain is absorbing.

The fundamental matrix. Solve $(\mathbf{I}-\mathbf{Q})\mathbf{N} = \mathbf{I}$ with $\mathbf{I}-\mathbf{Q} = \begin{pmatrix} 1 & -1/2 & 0 \\ -1/2 & 1 & -1/2 \\ 0 & -1/2 & 1 \end{pmatrix}$. The result is

$$\mathbf{N} = \begin{pmatrix} 3/2 & 1 & 1/2 \\ 1 & 2 & 1 \\ 1/2 & 1 & 3/2 \end{pmatrix};$$

check the first column: $(\mathbf{I}-\mathbf{Q})(\frac{3}{2}, 1, \frac{1}{2}) = (\frac{3}{2}-\frac{1}{2},\ -\frac{3}{4}+1-\frac{1}{4},\ -\frac{1}{2}+\frac{1}{2}) = (1, 0, 0)$, and the other columns likewise. A gambler starting with 2 coins holds exactly 2 coins at 2 steps on average, counting the start, and holds 1 or 3 coins at one step each on average.

Length of play. $\mathbf{1}^{\top}\mathbf{N} = (3, 4, 3)$: from fortunes $1, 2, 3$ the game lasts 3, 4, 3 tosses on average.

Absorption.

$$\mathbf{B} = \mathbf{R}\mathbf{N} = \begin{pmatrix} 3/4 & 1/2 & 1/4 \\ 1/4 & 1/2 & 3/4 \end{pmatrix}.$$

From fortune j the gambler reaches the target with probability $j/4$ and is ruined with probability $1-j/4$. Each column sums to 1, as Theorem 18.6.5 (c) requires: the game ends with probability 1. Both answers match the classical formulas for a fair game with target $T = 4$: success probability j/T and expected length $j(T-j)$, which gives $3, 4, 3$.

The matrix $\mathbf{Q}$ of this example has eigenvalues 0 and $\pm\frac{1}{\sqrt{2}}$, of modulus less than 1 as Lemma 18.6.4 requires; but the lemma was proved without finding them, which is the pattern of this whole section.

18.6.6 Exercises

18.6.6.1 A. Check your understanding

Exercise A1.

(a) State the long-run theorem Theorem 18.6.2, and name the three hypotheses of Theorem 8.11.4 that it no longer needs.

(b) True or false: every irreducible stochastic matrix has exactly one steady state.

Justify your answer.

(c) True or false: for every irreducible stochastic matrix, $\mathbf{A}^m$ converges. Justify your answer.

(d) True or false: if a stochastic matrix has two different steady states, it has infinitely many. Justify your answer.

(e) In an absorbing chain, what do the column sums of the fundamental matrix measure, and why do the columns of $\mathbf{RN}$ sum to 1?

Solution.

(a) If $\mathbf{A}$ is stochastic and $\mathbf{A}^k > 0$ for some k, then $\mathbf{A}$ has exactly one steady state $\mathbf{v}$, it is positive, $\mathbf{A}^m \to \mathbf{v}\mathbf{1}^\top$, and every chain $\mathbf{A}^m\mathbf{x}_0$ converges to $\mathbf{v}$. It no longer assumes that $\mathbf{A}$ is diagonalizable, that $a_{\mathbf{A}}(1) = 1$, or that every other eigenvalue has modulus less than 1.

(b) True, by Proposition 18.6.1 (c); moreover the steady state is positive.

(c) False. The swap $\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$ is irreducible and stochastic, and its powers alternate between $\mathbf{I}$ and itself. By Theorem 18.6.3 (c), the powers converge exactly when the matrix is primitive.

(d) True. If $\mathbf{u} \neq \mathbf{u}'$ are steady states, then $c\mathbf{u} + (1-c)\mathbf{u}'$ for $0 \leq c \leq 1$ is non-negative, has entries summing to 1, and is fixed by $\mathbf{A}$; different c give different vectors, since $\mathbf{u} - \mathbf{u}' \neq \mathbf{0}$.

(e) The column sum $(\mathbf{1}^\top\mathbf{N})_j$ is the expected number of steps before absorption from transient state j. The columns of $\mathbf{RN}$ sum to 1 because the columns of $\mathbf{A}^m$ do and $\mathbf{Q}^m \to 0$ (Theorem 18.6.5 (c)): absorption is certain.

18.6.6.2 B. Practice

Exercise B1: When does the long-run theorem apply?.

For each stochastic matrix, determine whether Theorem 18.6.2 applies. Justify your answer, and when it applies, find the limit of $\mathbf{A}^m$.

(a) $\begin{pmatrix} 0 & 0 & 1/2 \\ 1 & 0 & 0 \\ 0 & 1 & 1/2 \end{pmatrix}$.

(b) $\begin{pmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix}$.

(c) $\begin{pmatrix} 1/2 & 0 \\ 1/2 & 1 \end{pmatrix}$.

Solution.

(a) It applies. The edges of $G(\mathbf{A})$ are $1 \to 2$, $2 \to 3$, $3 \to 1$ and the loop $3 \to 3$. The cycle $1 \to 2 \to 3 \to 1$ reaches every state from every state, so $\mathbf{A}$ is irreducible (Theorem 18.2.5). It has the positive diagonal entry a_{33}, so it is primitive by Corollary 18.5.5. The steady state solves $v_1 = \frac{1}{2}v_3$, $v_2 = v_1$, so $\mathbf{v} = (1, 1, 2)/4$, and

$\mathbf{A}^m \to \mathbf{v}\mathbf{1}^\top$, every column equal to $(\frac{1}{4}, \frac{1}{4}, \frac{1}{2})$. Check: $\mathbf{A}\mathbf{v} = (\frac{1}{4}, \frac{1}{4}, \frac{1}{4} + \frac{1}{4}) = \mathbf{v}$.

(b) It does not apply. This is a permutation matrix, so every power is a permutation matrix (Lemma 2.6.6) and has zero entries. Its powers cycle with period 3 (Example (The Cyclic Permutation)) and do not converge.

(c) It does not apply. Every power is lower triangular with $(1,2)$-entry 0, as one checks by induction: $\mathbf{A}^m = \begin{pmatrix} 2^{-m} & 0 \\ 1 - 2^{-m} & 1 \end{pmatrix}$. The powers converge nonetheless, to $\begin{pmatrix} 0 & 0 \\ 1 & 1 \end{pmatrix} = \mathbf{e}_2\mathbf{1}^\top$: state 2 is absorbing, and $\mathbf{e}_2$ is the unique steady state, with a zero entry.

Exercise B2: A three-state chain.

Let $\mathbf{A} = \begin{pmatrix} 1/2 & 1/4 & 0 \\ 1/2 & 1/2 & 1/2 \\ 0 & 1/4 & 1/2 \end{pmatrix}$.

(a) Show that $\mathbf{A}$ is stochastic and that $\mathbf{A}^2 > 0$.

(b) Find the steady state, and hence $\lim_m \mathbf{A}^m$ and the long-run distribution of every chain with this transition matrix.

Solution.

(a) The entries are non-negative and the columns sum to 1. Multiplying out,

$$\mathbf{A}^2 = \begin{pmatrix} 3/8 & 1/4 & 1/8 \\ 1/2 & 1/2 & 1/2 \\ 1/8 & 1/4 & 3/8 \end{pmatrix} > 0.$$

(b) $(\mathbf{A} - \mathbf{I})\mathbf{v} = \mathbf{0}$: the first row gives $-\frac{1}{2}v_1 + \frac{1}{4}v_2 = 0$, so $v_2 = 2v_1$, and the third gives $\frac{1}{4}v_2 - \frac{1}{2}v_3 = 0$, so $v_3 = \frac{1}{2}v_2 = v_1$. So $\mathbf{v}$ is a multiple of $(1, 2, 1)$, and scaling to sum 1 gives $\mathbf{v} = (\frac{1}{4}, \frac{1}{2}, \frac{1}{4})$. By Theorem 18.6.2, $\mathbf{A}^m \to \mathbf{v}\mathbf{1}^\top$, every column equal to $\mathbf{v}$, and every chain converges to $\mathbf{v}$ whatever its initial distribution.

Exercise B3: An unfair game.

A gambler holds 1 or 2 coins and wins each toss with probability $\frac{1}{3}$, losing with probability $\frac{2}{3}$. Play stops at 0 or 3 coins. Find the fundamental matrix, the expected length of play and the probability of reaching 3 coins from each starting fortune.

Solution. Order the states as $1, 2$ (transient) and $0, 3$ (absorbing). From 1: to 2 with probability $\frac{1}{3}$, to 0 with $\frac{2}{3}$. From 2: to 3 with $\frac{1}{3}$, to 1 with $\frac{2}{3}$. So

$$\mathbf{Q} = \begin{pmatrix} 0 & 2/3 \\ 1/3 & 0 \end{pmatrix}, \qquad \mathbf{R} = \begin{pmatrix} 2/3 & 0 \\ 0 & 1/3 \end{pmatrix}.$$

The chain is absorbing, since from either fortune repeated losses reach 0. Then $\mathbf{I} - \mathbf{Q} =$

$\begin{pmatrix} 1 & -2/3 \\ -1/3 & 1 \end{pmatrix}$ has determinant $1 - \frac{2}{9} = \frac{7}{9}$, so by Theorem 0.9.8

$$\mathbf{N} = \frac{9}{7}\begin{pmatrix} 1 & 2/3 \\ 1/3 & 1 \end{pmatrix} = \begin{pmatrix} 9/7 & 6/7 \\ 3/7 & 9/7 \end{pmatrix}.$$

The expected lengths of play are $\mathbf{1}^\top\mathbf{N} = (\frac{12}{7}, \frac{15}{7})$, and

$$\mathbf{RN} = \begin{pmatrix} 6/7 & 4/7 \\ 1/7 & 3/7 \end{pmatrix}.$$

So the probability of reaching 3 coins is $\frac{1}{7}$ from 1 coin and $\frac{3}{7}$ from 2 coins, far below the fair values $\frac{1}{3}$ and $\frac{2}{3}$. The columns of $\mathbf{RN}$ sum to 1, as they must.

18.6.6.3 C. Going deeper

Exercise C1: The lazy chain.

Let $\mathbf{A} \in M_n(\mathbb{R})$ be stochastic and irreducible, with steady state $\mathbf{v}$, and let $\mathbf{M} = \frac{1}{2}(\mathbf{I}+\mathbf{A})$.

(a) Prove that $\mathbf{M}$ is stochastic and primitive, and that $\mathbf{v}$ is its unique steady state. Deduce that $\mathbf{M}^m \to \mathbf{v}\mathbf{1}^\top$.

(b) Let $\mathbf{A}$ be the walk of Example (A Walk that Oscillates). Show that $\mathbf{M}$ is the matrix of exercise B2, and that $\mathbf{M}^m = \mathbf{v}\mathbf{1}^\top + 2^{-m}\mathbf{F}$ for every $m \geq 1$, where $\mathbf{F} = \frac{1}{2}\begin{pmatrix} 1 & 0 & -1 \\ 0 & 0 & 0 \\ -1 & 0 & 1 \end{pmatrix}$.

Hint: write $\mathbf{M}$ *in terms of* $\mathbf{v}\mathbf{1}^\top$ *and* $\mathbf{F}$.

Solution.

(a) $\mathbf{M} \geq 0$, and $\mathbf{1}^\top\mathbf{M} = \frac{1}{2}(\mathbf{1}^\top + \mathbf{1}^\top\mathbf{A}) = \mathbf{1}^\top$, so $\mathbf{M}$ is stochastic. By Exercise (C1: Shifting by the identity) (a) with $t = 1$, $\mathbf{A} + \mathbf{I}$ is primitive, say $(\mathbf{A} + \mathbf{I})^k > 0$; then $\mathbf{M}^k = 2^{-k}(\mathbf{A} + \mathbf{I})^k > 0$, so $\mathbf{M}$ is primitive. Also $\mathbf{M}\mathbf{v} = \frac{1}{2}(\mathbf{v} + \mathbf{v}) = \mathbf{v}$. By Theorem 18.6.2 (a), $\mathbf{M}$ has exactly one steady state, so it is $\mathbf{v}$, and by part (b) of that theorem $\mathbf{M}^m \to \mathbf{v}\mathbf{1}^\top$.

(b) With $\mathbf{A}$ as in Example (A Walk that Oscillates),

$$\mathbf{M} = \frac{1}{2}\begin{pmatrix} 1 & 1/2 & 0 \\ 1 & 1 & 1 \\ 0 & 1/2 & 1 \end{pmatrix} = \begin{pmatrix} 1/2 & 1/4 & 0 \\ 1/2 & 1/2 & 1/2 \\ 0 & 1/4 & 1/2 \end{pmatrix},$$

the matrix of Exercise (B2: A three-state chain), and $\mathbf{v} = (\frac{1}{4}, \frac{1}{2}, \frac{1}{4})$. Put $Ł = \mathbf{v}\mathbf{1}^\top$, every column equal to $\mathbf{v}$. Then $Ł^2 = \mathbf{v}(\mathbf{1}^\top\mathbf{v})\mathbf{1}^\top = Ł$; $\mathbf{1}^\top\mathbf{F} = \mathbf{0}^\top$, since each column of $\mathbf{F}$ sums to 0, so $Ł\mathbf{F} = \mathbf{v}(\mathbf{1}^\top\mathbf{F}) = 0$; and $\mathbf{F}\mathbf{v} = \frac{1}{2}(\frac{1}{4} - \frac{1}{4},\ 0,\ -\frac{1}{4} + \frac{1}{4}) = \mathbf{0}$, so $\mathbf{F}Ł = (\mathbf{F}\mathbf{v})\mathbf{1}^\top = 0$. Also $\mathbf{F}^2 = \frac{1}{4}\begin{pmatrix} 2 & 0 & -2 \\ 0 & 0 & 0 \\ -2 & 0 & 2 \end{pmatrix} = \mathbf{F}$. Subtracting, $\mathbf{M} - Ł =$

$\frac{1}{4}\begin{pmatrix}1&0&-1\\0&0&0\\-1&0&1\end{pmatrix} = \frac{1}{2}\mathbf{F}$, so $\mathbf{M} = Ł + \frac{1}{2}\mathbf{F}$. If $\mathbf{M}^m = Ł + 2^{-m}\mathbf{F}$, then

$$\begin{aligned}\mathbf{M}^{m+1} &= \left(Ł + \frac{1}{2}\mathbf{F}\right)\left(Ł + 2^{-m}\mathbf{F}\right)\\ &= Ł^2 + 2^{-m}Ł\mathbf{F} + \frac{1}{2}\mathbf{F}Ł + 2^{-m-1}\mathbf{F}^2 = Ł + 2^{-(m+1)}\mathbf{F},\end{aligned}$$

so the formula holds for every $m \geq 1$ by induction, starting from $\mathbf{M} = Ł + \frac{1}{2}\mathbf{F}$. The lazy walk converges although the walk itself oscillates, and its distance to the limit halves at every step.

Exercise C2: The converse of the long-run theorem.

Let $\mathbf{A} \in M_n(\mathbb{R})$ be stochastic.

(a) Prove that if $\mathbf{A}^m \to \mathbf{v}\mathbf{1}^\top$ for some $\mathbf{v} > \mathbf{0}$, then $\mathbf{A}$ is primitive.

(b) Give a stochastic $\mathbf{A}$ with $\mathbf{A}^m \to \mathbf{v}\mathbf{1}^\top$ for a probability vector $\mathbf{v}$, but no power of $\mathbf{A}$ positive. Which entry of $\mathbf{v}$ is responsible?

Solution.

(a) The limit $\mathbf{v}\mathbf{1}^\top$ has (i,j)-entry $v_i > 0$. Each of the n^2 entries of $\mathbf{A}^m$ converges to a positive number, so it is positive for all m beyond some m_{ij}; for m larger than all the m_{ij}, $\mathbf{A}^m > 0$. So $\mathbf{A}$ is primitive.

(b) $\mathbf{A} = \begin{pmatrix}1&1/2\\0&1/2\end{pmatrix}$. By induction $\mathbf{A}^m = \begin{pmatrix}1&1-2^{-m}\\0&2^{-m}\end{pmatrix}$: indeed $\mathbf{A}\mathbf{A}^m$ has first row $(1,\ 1-2^{-m}+2^{-m-1}) = (1,\ 1-2^{-(m+1)})$ and second row $(0,\ 2^{-(m+1)})$. So $\mathbf{A}^m \to \begin{pmatrix}1&1\\0&0\end{pmatrix} = \mathbf{e}_1\mathbf{1}^\top$, while every power has $(2,1)$-entry 0. The responsible entry is $v_2 = 0$: (a) fails exactly because $\mathbf{v}$ is not positive.

Exercise C3: First-step analysis.

Let $\mathbf{A}$ be absorbing, with fundamental matrix $\mathbf{N}$ and $\boldsymbol{\tau}^\top = \mathbf{1}^\top\mathbf{N}$.

(a) Prove that $\mathbf{N} = \mathbf{I} + \mathbf{N}\mathbf{Q}$, and deduce that $\tau_j = 1 + \sum_i q_{ij}\tau_i$ for every transient j. Interpret this equation.

(b) Prove, by multiplying by $\mathbf{R}$, that $\mathbf{B} = \mathbf{R}\mathbf{N}$ satisfies $\mathbf{B} = \mathbf{R} + \mathbf{B}\mathbf{Q}$, and interpret it.

(c) Use (a) to recompute the expected lengths of play $(3,4,3)$ of Example (Gambler's Ruin) without inverting a matrix.

Solution.

(a) $\mathbf{N}(\mathbf{I}-\mathbf{Q}) = \mathbf{I}$ because $\mathbf{N}$ is the inverse of $\mathbf{I}-\mathbf{Q}$, so $\mathbf{N} = \mathbf{I}+\mathbf{N}\mathbf{Q}$. Multiplying on the left by $\mathbf{1}^\top$, $\boldsymbol{\tau}^\top = \mathbf{1}^\top + \boldsymbol{\tau}^\top\mathbf{Q}$, whose j-th entry is $\tau_j = 1 + \sum_i \tau_i q_{ij}$. In words: from j, one step is taken, the chain lands at transient i with probability q_{ij}, and from there the expected remaining time is τ_i; landing at an absorbing state contributes

nothing more.

(b) Multiply $\mathbf{N} = \mathbf{I} + \mathbf{NQ}$ on the left by $\mathbf{R}$: $\mathbf{B} = \mathbf{R} + \mathbf{BQ}$, that is, $b_{ij} = r_{ij} + \sum_l b_{il} q_{lj}$. The probability of absorption at i from j is the probability of stepping into i at once, plus the probability of stepping to a transient l and being absorbed at i from there.

(c) With $\mathbf{Q}$ as in Example (Gambler's Ruin), (a) reads $\tau_1 = 1 + \frac{1}{2}\tau_2$, $\tau_2 = 1 + \frac{1}{2}\tau_1 + \frac{1}{2}\tau_3$, $\tau_3 = 1 + \frac{1}{2}\tau_2$. The first and third equations give $\tau_1 = \tau_3 = 1 + \frac{1}{2}\tau_2$, so $\tau_2 = 1 + \tau_1 = 1 + 1 + \frac{1}{2}\tau_2$, giving $\tau_2 = 4$ and $\tau_1 = \tau_3 = 3$. (The system has only one solution, since its matrix is $(\mathbf{I} - \mathbf{Q})^\top$, which is invertible by Theorem 18.6.5 (a).)

18.7 Birkhoff's Theorem

Chapter 17 §08 met the doubly stochastic matrices, the non-negative matrices whose rows and columns all add up to 1. It showed that every permutation matrix is an extreme point of the set Ω_n they form, stated Birkhoff's theorem that there are no other extreme points, proved that this is equivalent to "every doubly stochastic matrix is an average of permutation matrices", and left the proof to this chapter. This section supplies it. The proof is a count: a corner of Ω_n has so many zero entries that some row holds a single 1, and deleting that row and its column leaves a corner of Ω_{n-1}. We then bound how many permutation matrices an average needs, turn the theorem into a procedure for finding them, and use it to give the second proof of Schur's majorization theorem that Chapter 17 §08 sketched.

Throughout, the field is $\mathbb{R}$, and inequalities between matrices or vectors are entrywise, as in §01. Recall Definition 17.8.4: $\mathbf{M} \in M_n(\mathbb{R})$ is **doubly stochastic** if $m_{ij} \geq 0$ for all i, j, and every row and every column adds up to 1; in terms of the all-ones vector, $\mathbf{M1} = \mathbf{1}$ and $\mathbf{1}^\top \mathbf{M} = \mathbf{1}^\top$. So $\mathbf{M}$ is stochastic in the book's column sense (Definition 8.11.1), and so is $\mathbf{M}^\top$.

18.7.1 What is left to prove

Here is where Chapter 17 §08 stopped. The set Ω_n is convex and compact. The $n!$ permutation matrices $\mathbf{P}_\sigma$, $\sigma \in S_n$ (Definition 2.6.2), lie in it, and each is an extreme point (Proposition 17.8.9). The two forms of Birkhoff's theorem, "the extreme points are the permutation matrices" and "Ω_n is the convex hull of the permutation matrices", were shown to be equivalent there, using Minkowski's theorem (Theorem 17.8.5) in one direction and Proposition 17.8.2 in the other. For $n = 2$, the Quick check after the statement found Ω_2 by hand: it is the segment from $\mathbf{I}$ to the swap matrix.

So one implication is missing: **every extreme point of Ω_n is a permutation matrix.** For $n \geq 3$ nothing as simple as the 2×2 computation is available, since Ω_3 already has four free parameters. What does the work instead is a result of Chapter 17 §09 that recognizes a corner of a polyhedron from its tight constraints.

18.7.2 The doubly stochastic matrices form a polyhedron

Recall Definition 17.9.2 and Theorem 17.9.2. A polyhedron is a set $\{\mathbf{x} \in \mathbb{R}^N : \mathbf{A}\mathbf{x} \le \mathbf{b}\}$; its extreme points are called vertices; and a point $\mathbf{x}$ of it is a vertex exactly when the rows $\mathbf{a}_i^\top$ of the constraints that hold with equality at $\mathbf{x}$, the **active** rows, include N linearly independent ones. An equation is allowed, as a pair of inequalities $\mathbf{a}^\top\mathbf{x} \le \beta$ and $-\mathbf{a}^\top\mathbf{x} \le -\beta$; both are active at every point of the polyhedron.

To put Ω_n in this form, list the n^2 entries of a matrix $\mathbf{X}$ as one column, the vectorization $\operatorname{vec}\mathbf{X} \in \mathbb{R}^{n^2}$ of Chapter 7. A linear expression $\sum_{i,j} b_{ij}x_{ij}$ in the entries is then the dot product of $\operatorname{vec}\mathbf{X}$ with $\operatorname{vec}\mathbf{B}$, and we may treat the coefficient matrix $\mathbf{B} \in M_n(\mathbb{R})$ itself as the row of the constraint. Three families of coefficient matrices appear. With $\mathbf{E}_{ij}$ the matrix unit (a 1 in position (i,j), zeros elsewhere), let

$$\mathbf{R}_i = \mathbf{e}_i\mathbf{1}^\top, \qquad \mathbf{C}_j = \mathbf{1}\mathbf{e}_j^\top \qquad (1 \le i, j \le n),$$

the matrices whose i-th row, respectively j-th column, consists of ones and whose other entries are zero. The letter $\mathbf{C}_j$ is local to this section; elsewhere $\mathbf{C}(p)$ is a companion matrix and $\mathbf{C}_k(\lambda)$ a real Jordan block. Then $\sum_{k,l}(\mathbf{R}_i)_{kl}x_{kl}$ is the i-th row sum of $\mathbf{X}$, and $\mathbf{C}_j$ gives the j-th column sum. So $\Omega_n \subseteq M_n(\mathbb{R}) \cong \mathbb{R}^{n^2}$ is the polyhedron cut out by

(i) the n^2 inequalities $-x_{ij} \le 0$, with rows $-\mathbf{E}_{ij}$;
(ii) the n row equations "row sum i equals 1", with rows $\pm\mathbf{R}_i$;
(iii) the n column equations "column sum j equals 1", with rows $\pm\mathbf{C}_j$.

At a point $\mathbf{M} \in \Omega_n$, every row $\pm\mathbf{R}_i$ and $\pm\mathbf{C}_j$ is active, and $-\mathbf{E}_{ij}$ is active exactly when $m_{ij} = 0$. The whole argument turns on how much the $2n$ equations are worth. They are not independent: adding all row sums and adding all column sums both give the sum of all entries, that is,

$$\mathbf{R}_1 + \cdots + \mathbf{R}_n = \mathbf{J} = \mathbf{C}_1 + \cdots + \mathbf{C}_n,$$

with $\mathbf{J}$ the all-ones matrix. The next lemma says that this is the only relation.

Lemma 18.7.1 — The Row and Column Sum Conditions

Let $n \ge 1$, and let

$$W_n = \{\mathbf{X} \in M_n(\mathbb{R}) : \mathbf{X}\mathbf{1} = \mathbf{0},\ \mathbf{1}^\top\mathbf{X} = \mathbf{0}^\top\}$$

be the space of real matrices whose rows and columns all add up to 0. Then:

(a) $\dim W_n = (n-1)^2$;
(b) the $2n$ matrices $\mathbf{R}_1, \dots, \mathbf{R}_n, \mathbf{C}_1, \dots, \mathbf{C}_n$ span a subspace of $M_n(\mathbb{R})$ of dimension $2n-1$.

Idea. A matrix in W_n is determined by its top-left $(n-1)\times(n-1)$ block, which can be anything: the last column and the last row are then forced by the zero sums, and the corner comes out consistent. That gives (a). For (b), W_n is exactly the set of matrices killed by the $2n$ sum conditions, so rank–nullity converts one count into the other.

Proof.

(a) If $n = 1$, $W_1 = \{\mathbf{0}\}$ and $(n-1)^2 = 0$. Let $n \geq 2$, and let $\varphi\colon W_n \to M_{n-1}(\mathbb{R})$ delete the last row and the last column; it is linear. It is injective: if $\mathbf{X} \in W_n$ has top-left block zero, then for $i < n$ the i-th row sum is $x_{in} = 0$, for $j < n$ the j-th column sum is $x_{nj} = 0$, and then the last row sum is $x_{nn} = 0$. So $\mathbf{X} = \mathbf{0}$. It is surjective: given $\mathbf{B} \in M_{n-1}(\mathbb{R})$, with row sums r_i, column sums c_j and total $s = \sum_i r_i = \sum_j c_j$, let $\mathbf{X}$ have top-left block $\mathbf{B}$, last column $(-r_1, \dots, -r_{n-1}, s)$ and last row $(-c_1, \dots, -c_{n-1}, s)$. The i-th row sum for $i < n$ is $r_i - r_i = 0$, the j-th column sum for $j < n$ is $c_j - c_j = 0$, and the last row and last column both sum to $-s + s = 0$. So $\mathbf{X} \in W_n$ and $\varphi(\mathbf{X}) = \mathbf{B}$. Hence φ is an isomorphism and $\dim W_n = \dim M_{n-1}(\mathbb{R}) = (n-1)^2$.

(b) Let $\mathbf{K}$ be the $2n \times n^2$ matrix whose rows are the transposed vectorizations $(\operatorname{vec} \mathbf{R}_i)^\top$ and $(\operatorname{vec} \mathbf{C}_j)^\top$, for $1 \leq i, j \leq n$. Then $\mathbf{K} \operatorname{vec} \mathbf{X}$ lists the row sums and the column sums of $\mathbf{X}$, so the null space of $\mathbf{K}$ is $\operatorname{vec}(W_n)$, of dimension $(n-1)^2$ by (a), as vec is an isomorphism. By Theorem 2.5.7, $\operatorname{rank} \mathbf{K} = n^2 - (n-1)^2 = 2n - 1$, and by Theorem 2.5.5 this is the dimension of the span of the rows of $\mathbf{K}$. Since vec is an isomorphism, the $2n$ matrices $\mathbf{R}_i, \mathbf{C}_j$ span a subspace of dimension $2n - 1$, as claimed.

■

So of the $n^2 + 4n$ constraints defining Ω_n, the $4n$ that come from equations contribute only $2n - 1$ dimensions to the active rows, wherever we stand. The rest must come from zero entries.

Quick check. A vertex of Ω_3 needs 9 linearly independent active rows. How many zero entries must it therefore have, at least? Does the identity matrix $\mathbf{I}_3$ meet this requirement?

Solution. The row and column equations supply at most $2 \cdot 3 - 1 = 5$ independent rows, by Lemma 18.7.1 (b). Each zero entry adds one row $-\mathbf{E}_{ij}$, so at least $9 - 5 = 4$ zero entries are needed; that is, at most 5 non-zero entries. The identity has 6 zero entries and 3 non-zero ones, so it meets the requirement with room to spare.

18.7.3 Birkhoff's theorem

Now the main theorem. We state both forms, since both are used, but prove only the missing implication.

Theorem 18.7.2 — Birkhoff's Theorem

Let $n \geq 1$. The extreme points of Ω_n are exactly the $n!$ permutation matrices of size n. Equivalently, every doubly stochastic matrix is a convex combination of permutation matrices:

$$\Omega_n = \operatorname{conv}\{\mathbf{P}_\sigma : \sigma \in S_n\}.$$

Idea. **Step roadmap.** Let $\mathbf{M}$ be an extreme point of Ω_n and induct on n.

① **Count.** $\mathbf{M}$ is a vertex of the polyhedron above, so it has n^2 independent active rows.

At most $2n-1$ of them come from the equations, so at least $n^2-(2n-1)$ entries of $\mathbf{M}$ are zero, and at most $2n-1$ are non-zero.

② **Pigeonhole.** Every row has a non-zero entry, since it adds up to 1. With n rows and fewer than $2n$ non-zero entries, some row has exactly one, and that entry is 1. Its column then has no room for anything else.

③ **Strip.** Delete that row and column. What is left is doubly stochastic of size $n-1$, and, the key point, it is again **extreme**: any way of splitting it would split $\mathbf{M}$.

④ **Induct.** The smaller matrix is a permutation matrix, and putting the 1 back gives one of size n.

Proof. By Proposition 17.8.9, every permutation matrix is an extreme point of Ω_n. Distinct permutations give distinct matrices, since column j of $\mathbf{P}_\sigma$ is $\mathbf{e}_{\sigma(j)}$, so there are $n!$ of them. The equivalence of the two forms was proved in Chapter 17 §08, from Theorem 17.8.5 and Proposition 17.8.2. It remains to show that every extreme point of Ω_n is a permutation matrix. We prove this by induction on $n \geq 1$.

For $n=1$, $\Omega_1 = \{(1)\}$, and $(1) = \mathbf{P}_{\mathrm{id}}$.

Let $n \geq 2$, assume the statement for $n-1$, and let $\mathbf{M}$ be an extreme point of Ω_n.

Step 1: at most $2n-1$ non-zero entries. As shown above, Ω_n is a polyhedron in $M_n(\mathbb{R}) \cong \mathbb{R}^{n^2}$, and $\mathbf{M}$ is one of its vertices (Definition 17.9.2). By Theorem 17.9.2, the active rows at $\mathbf{M}$ include n^2 linearly independent ones. Let z be the number of zero entries of $\mathbf{M}$. The active rows are $\pm\mathbf{R}_i$, $\pm\mathbf{C}_j$, and $-\mathbf{E}_{ij}$ for the z positions with $m_{ij}=0$. All of them lie in the subspace

$$\operatorname{span}\{\mathbf{R}_1,\dots,\mathbf{R}_n,\mathbf{C}_1,\dots,\mathbf{C}_n\} + \operatorname{span}\{\mathbf{E}_{ij} : m_{ij}=0\},$$

whose dimension is at most $(2n-1)+z$, by Lemma 18.7.1 (b) and the dimension formula for sums (Theorem 1.7.3). A subspace containing n^2 linearly independent vectors has dimension at least n^2, by Theorem 1.6.3 (a) applied in that subspace. Hence $n^2 \leq 2n-1+z$, and the number of non-zero entries of $\mathbf{M}$ is $n^2-z \leq 2n-1$.

Step 2: a row with a single 1. Each row of $\mathbf{M}$ adds up to 1, so it has at least one non-zero entry. If every row had at least two, $\mathbf{M}$ would have at least $2n$ non-zero entries, contradicting Step 1. So some row i has exactly one non-zero entry, say m_{ij}, and the row sum gives $m_{ij}=1$. Column j consists of non-negative entries adding up to 1, one of which is $m_{ij}=1$; so $m_{kj}=0$ for every $k \neq i$.

Step 3: the reduced matrix is extreme. Let $\mathbf{M}' \in M_{n-1}(\mathbb{R})$ be $\mathbf{M}$ with row i and column j deleted. Its entries are non-negative. Each of its rows is a row $k \neq i$ of $\mathbf{M}$ with the entry $m_{kj}=0$ removed, so it still adds up to 1; likewise each of its columns is a column $l \neq j$ of $\mathbf{M}$ with $m_{il}=0$ removed. So $\mathbf{M}' \in \Omega_{n-1}$. For $\mathbf{Y} \in M_{n-1}(\mathbb{R})$, let $E(\mathbf{Y}) \in M_n(\mathbb{R})$ be the matrix obtained by inserting a new row at position i and a new column at position j, with a 1 where they cross and zeros elsewhere along them. Then $E(\mathbf{M}')=\mathbf{M}$; $E(\mathbf{Y}) \in \Omega_n$ whenever $\mathbf{Y} \in \Omega_{n-1}$, since the inserted row and column add up to 1 and add 0 to every old row and column; $E(\mathbf{Y})=E(\mathbf{Z})$ only if $\mathbf{Y}=\mathbf{Z}$; and $E\big(\tfrac{1}{2}(\mathbf{Y}+\mathbf{Z})\big) = \tfrac{1}{2}\big(E(\mathbf{Y})+E(\mathbf{Z})\big)$, because the inserted entries are the same for $\mathbf{Y}$, $\mathbf{Z}$ and their midpoint. Now suppose $\mathbf{M}' = \tfrac{1}{2}(\mathbf{Y}+\mathbf{Z})$ with $\mathbf{Y},\mathbf{Z} \in \Omega_{n-1}$. Then $\mathbf{M} = \tfrac{1}{2}\big(E(\mathbf{Y})+E(\mathbf{Z})\big)$ with $E(\mathbf{Y}), E(\mathbf{Z}) \in \Omega_n$, and since $\mathbf{M}$ is extreme, $E(\mathbf{Y})=E(\mathbf{Z})$, so $\mathbf{Y}=\mathbf{Z}$. By the midpoint test (Lemma 17.8.1), $\mathbf{M}'$ is an extreme point of Ω_{n-1}.

Step 4: induction. By the induction hypothesis, $\mathbf{M}'$ is a permutation matrix: it has exactly one 1 in each row and each column and zeros elsewhere. Then so does $\mathbf{M} = E(\mathbf{M}')$: row i and column j contain only the inserted 1, and every other row and column is one of $\mathbf{M}'$ with a 0 inserted. By the remark after Definition 2.6.2, $\mathbf{M}$ is a permutation matrix. This completes the induction and proves the theorem.

■

This pays Chapter 17 §08's promise. With Minkowski's theorem it describes Ω_n completely: a compact convex set with exactly $n!$ corners, each a permutation matrix.

Step 3 is not decoration. It is tempting to finish from Step 1 alone, by an induction on the number of non-zero entries, and that induction does not close.

Warning. **Few non-zero entries do not by themselves make a permutation matrix.** The matrix

$$\mathbf{N} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \frac{1}{2} & \frac{1}{2} \\ 0 & \frac{1}{2} & \frac{1}{2} \end{pmatrix} \in \Omega_3$$

has $5 = 2 \cdot 3 - 1$ non-zero entries, the most Step 1 allows, and it is not a permutation matrix; it is the midpoint of $\mathbf{I}_3$ and the permutation matrix that swaps the last two coordinates. Deleting its first row and column leaves $\frac{1}{2}\mathbf{J}_2$, with 4 non-zero entries, more than the $2 \cdot 2 - 1 = 3$ that a vertex of Ω_2 may have. The count must be applied afresh at each size, and that needs the smaller matrix to be extreme, which is what Step 3 proves.

18.7.4 How many permutation matrices

Birkhoff's theorem writes every doubly stochastic matrix as an average of permutation matrices, but a priori with up to $n!$ terms. Carathéodory's theorem (Theorem 17.2.2) cuts this down to one more than the dimension, and the dimension is the one computed in Lemma 18.7.1.

Corollary 18.7.3 — Birkhoff's Theorem with a Count

Let $n \geq 1$. Every $\mathbf{M} \in \Omega_n$ is a convex combination of at most $(n-1)^2 + 1$ permutation matrices.

Idea. All of Ω_n lies in the coset of matrices with row and column sums 1, which is $\frac{1}{n}\mathbf{J} + W_n$, of dimension $(n-1)^2$. Translate to W_n and apply Carathéodory's theorem there.

Proof. Let $\mathbf{M} \in \Omega_n$. By Theorem 18.7.2 and Theorem 17.1.3, $\mathbf{M} = \sum_{k=1}^{m} t_k \mathbf{P}_k$ for some permutation matrices $\mathbf{P}_k$ and weights $(t_1, \ldots, t_m) \in \Delta_m$. Put $\mathbf{X}_0 = \frac{1}{n}\mathbf{J} \in \Omega_n$. Every doubly stochastic matrix $\mathbf{X}$ satisfies $(\mathbf{X} - \mathbf{X}_0)\mathbf{1} = \mathbf{1} - \mathbf{1} = \mathbf{0}$ and $\mathbf{1}^\top(\mathbf{X} - \mathbf{X}_0) = \mathbf{0}^\top$, so $\mathbf{X} - \mathbf{X}_0 \in W_n$. As the weights add up to 1,

$$\mathbf{M} - \mathbf{X}_0 = \sum_{k=1}^{m} t_k(\mathbf{P}_k - \mathbf{X}_0),$$

so $\mathbf{M} - \mathbf{X}_0$ lies in the convex hull of $S = \{\mathbf{P}_\sigma - \mathbf{X}_0 : \sigma \in S_n\}$, a subset of the real vector

space W_n, which has dimension $(n-1)^2$ by Lemma 18.7.1 (a). By Theorem 17.2.2, $\mathbf{M} - \mathbf{X}_0 = \sum_{k=1}^{r} s_k(\mathbf{P}'_k - \mathbf{X}_0)$ for some $r \le (n-1)^2 + 1$, permutation matrices $\mathbf{P}'_k$ and weights $(s_1, \dots, s_r) \in \Delta_r$. Adding $\mathbf{X}_0 = \sum_k s_k \mathbf{X}_0$ back gives $\mathbf{M} = \sum_{k=1}^{r} s_k \mathbf{P}'_k$, as claimed.

■

For $n = 2$ the bound is 2, and every point strictly inside the segment Ω_2 needs both ends. For $n = 3$, Exercise C1 shows that 5 can be needed. That $(n-1)^2 + 1$ is best possible for every $n \ge 2$ is a known result which we state without proof. Compare the density matrices of Chapter 17 §08, where the spectral theorem did much better than Carathéodory's count. Here there is no such structure to exploit.

18.7.5 Finding the permutations

The proof of Birkhoff's theorem says that the permutation matrices suffice. It does not say how to find them. One consequence of the theorem does, because it only concerns which entries are zero.

Corollary 18.7.4 — A Positive Diagonal

Let $\mathbf{M} \in \Omega_n$. Then there is a permutation $\sigma \in S_n$ with $m_{\sigma(j)j} > 0$ for **every** $j = 1, \dots, n$.

Proof. By Theorem 18.7.2, $\mathbf{M} = \sum_{\tau \in S_n} t_\tau \mathbf{P}_\tau$ with every $t_\tau \ge 0$ and $\sum_\tau t_\tau = 1$, so some $t_\sigma > 0$. The $(\sigma(j), j)$ entry of $\mathbf{P}_\sigma$ is 1, and every term of the sum has non-negative entries. Hence $m_{\sigma(j)j} \ge t_\sigma > 0$ for every j.

■

In words, one can pick one positive entry in each column, all in different rows. This gives a procedure, often called **peeling**. Given $\mathbf{M} \in \Omega_n$, choose σ as in the corollary and let $t = \min_j m_{\sigma(j)j}$, so $0 < t \le 1$.

- If $t = 1$, then each column j has its whole sum 1 at position $\sigma(j)$, and $\mathbf{M} = \mathbf{P}_\sigma$.
- If $t < 1$, then $\mathbf{M} - t\mathbf{P}_\sigma$ has non-negative entries and all row and column sums $1 - t$, so $\mathbf{M}_1 = (\mathbf{M} - t\mathbf{P}_\sigma)/(1-t) \in \Omega_n$ and $\mathbf{M} = t\mathbf{P}_\sigma + (1-t)\mathbf{M}_1$. Every zero of $\mathbf{M}$ is a zero of $\mathbf{M}_1$, since $\mathbf{P}_\sigma$ has its 1's at positive entries of $\mathbf{M}$, and the entry where the minimum t was attained becomes a new zero.

Repeat with $\mathbf{M}_1$, producing $\mathbf{M}_2, \mathbf{M}_3, \dots$, and write $\mathbf{M}_0 = \mathbf{M}$. A doubly stochastic matrix has at least n non-zero entries, one per column, and each round removes at least one, so the procedure stops after at most $n^2 - n + 1$ rounds, with a permutation matrix. Unwinding the rounds writes $\mathbf{M}$ as a convex combination of the permutation matrices found. In fact peeling never needs more than the $(n-1)^2 + 1$ of Corollary 18.7.3. Let U_k be the subspace of those $\mathbf{X} \in W_n$ with $x_{ij} = 0$ wherever $\mathbf{M}_k$ has a zero; since zeros of $\mathbf{M}_k$ stay zeros, $U_{k+1} \subseteq U_k$, and $\mathbf{M}_k - \mathbf{M}_{k+1}$ lies in U_k but not in U_{k+1}, being positive at the new zero. So each round with $t < 1$ lowers $\dim U_k$, which starts at most $\dim W_n = (n-1)^2$ by Lemma 18.7.1 (a) and never drops below 0; there are at most $(n-1)^2$ such rounds, and one final round. Still, peeling finds **a** decomposition, not necessarily the shortest one.

Example. (Peeling a 4 × 4 matrix)

Write

$$\mathbf{M} = \frac{1}{8}\begin{pmatrix} 4 & 2 & 2 & 0 \\ 1 & 3 & 0 & 4 \\ 3 & 0 & 4 & 1 \\ 0 & 3 & 2 & 3 \end{pmatrix}$$

as a convex combination of permutation matrices.

Solution. The entries are non-negative, each row of $8\mathbf{M}$ adds up to 8, and so does each column: $4+1+3+0$, $2+3+0+3$, $2+0+4+2$, $0+4+1+3$. So $\mathbf{M} \in \Omega_4$. We peel $\mathbf{N} = 8\mathbf{M}$, whose row and column sums start at 8; subtracting w times a permutation matrix lowers them all by w. A permutation is recorded by the positions $(\sigma(1), 1), \ldots, (\sigma(4), 4)$ of its 1's, one per column.

Round 1. The diagonal of $\mathbf{N}$ is $4, 3, 4, 3$, all positive, so take $\sigma_1 = \mathrm{id}$ with weight $w_1 = 3$. Subtracting $3\mathbf{I}$ leaves

$$\begin{pmatrix} 1 & 2 & 2 & 0 \\ 1 & 0 & 0 & 4 \\ 3 & 0 & 1 & 1 \\ 0 & 3 & 2 & 0 \end{pmatrix} \quad \text{(sums 5)}.$$

Round 2. Column 2 is now non-zero only in rows 1 and 4. Try row 4 there: the positions $(1, 1)$, $(4, 2)$, $(3, 3)$, $(2, 4)$ carry $1, 3, 1, 4$, so take this σ_2 with weight $w_2 = 1$:

$$\begin{pmatrix} 0 & 2 & 2 & 0 \\ 1 & 0 & 0 & 3 \\ 3 & 0 & 0 & 1 \\ 0 & 2 & 2 & 0 \end{pmatrix} \quad \text{(sums 4)}.$$

Round 3. The positions $(3, 1), (1, 2), (4, 3), (2, 4)$ carry $3, 2, 2, 3$; weight $w_3 = 2$:

$$\begin{pmatrix} 0 & 0 & 2 & 0 \\ 1 & 0 & 0 & 1 \\ 1 & 0 & 0 & 1 \\ 0 & 2 & 0 & 0 \end{pmatrix} \quad \text{(sums 2)}.$$

Round 4. The positions $(2, 1), (4, 2), (1, 3), (3, 4)$ carry $1, 2, 2, 1$; weight $w_4 = 1$. What remains has a single 1 in positions $(3, 1), (4, 2), (1, 3), (2, 4)$, a permutation matrix $\mathbf{P}_{\sigma_5}$, with weight $w_5 = 1$.

The weights $3 + 1 + 2 + 1 + 1 = 8$ account for the whole sum, and dividing by 8,

$$\mathbf{M} = \tfrac{3}{8}\,\mathbf{P}_{\sigma_1} + \tfrac{1}{8}\,\mathbf{P}_{\sigma_2} + \tfrac{2}{8}\,\mathbf{P}_{\sigma_3} + \tfrac{1}{8}\,\mathbf{P}_{\sigma_4} + \tfrac{1}{8}\,\mathbf{P}_{\sigma_5},$$

where $\sigma_1 = \mathrm{id}$, and $\sigma_2, \sigma_3, \sigma_4, \sigma_5$ send $1, 2, 3, 4$ to $1, 4, 3, 2$, to $3, 1, 4, 2$, to $2, 4, 1, 3$ and to $3, 4, 1, 2$ respectively. Five terms, within the bound $(4-1)^2 + 1 = 10$. To check, add up any entry: position $(1, 3)$ is covered by σ_4 and σ_5, giving $\frac{1}{8} + \frac{1}{8} = \frac{2}{8}$, which is m_{13}.

Remark. The route can be run the other way. Corollary 18.7.4 is a statement about the zero pattern of $\mathbf{M}$ alone, and it can be proved directly by combinatorics: by Hall's

marriage theorem, or by the Frobenius–König theorem, which says that every $n \times n$ matrix in which each choice of one entry per column, in distinct rows, meets a zero has an $r \times s$ block of zeros with $r + s = n + 1$. With the corollary in hand first, peeling proves Birkhoff's theorem constructively. Both routes are standard; the one taken here uses only what Chapter 17 had already built.

18.7.6 Schur's theorem again

Chapter 16 §08 proved Schur's majorization theorem, Theorem 16.8.2: for a Hermitian $\mathbf{A}$, the diagonal vector $\mathbf{d}(\mathbf{A})$ is majorized by the eigenvalue vector $\boldsymbol{\lambda}(\mathbf{A})$. The proof there went through Ky Fan's maximum principle. Chapter 17 §08 noted that Birkhoff's theorem would give a second proof, and sketched it. Here it is in full. The first ingredient says that the diagonal is a doubly stochastic image of the spectrum.

Lemma 18.7.5 — The Diagonal Is a Doubly Stochastic Image of the Spectrum

Let $F = \mathbb{R}$ or $\mathbb{C}$, let $\mathbf{A} \in M_n(F)$ be Hermitian, and let $\mathbf{A} = \mathbf{U}\mathbf{D}\mathbf{U}^*$ with $\mathbf{U}$ unitary and $\mathbf{D} = \operatorname{diag}(\lambda_1(\mathbf{A}), \dots, \lambda_n(\mathbf{A}))$. Then the matrix $\mathbf{S} = (|u_{ij}|^2)$ is doubly stochastic, and

$$\mathbf{d}(\mathbf{A}) = \mathbf{S}\,\boldsymbol{\lambda}(\mathbf{A}).$$

Such a $\mathbf{U}$ exists by Corollary 11.4.3, after reordering the columns of $\mathbf{U}$, since a Hermitian matrix is normal: the diagonal entries of the $\mathbf{D}$ it gives are the eigenvalues of $\mathbf{A}$ with multiplicity, because similar matrices have the same characteristic polynomial $p_{\mathbf{A}}$ (Theorem 6.10.3), and they are real (Theorem 11.2.1), so they can be put in decreasing order.

Proof. Write $\lambda_j = \lambda_j(\mathbf{A})$. By the definition of the matrix product, $a_{ii} = \sum_j u_{ij}\lambda_j\overline{u_{ij}} = \sum_j |u_{ij}|^2\lambda_j$, which is the i-th entry of $\mathbf{S}\boldsymbol{\lambda}(\mathbf{A})$. The entries of $\mathbf{S}$ are non-negative. Row i of $\mathbf{S}$ adds up to $\sum_j |u_{ij}|^2 = (\mathbf{U}\mathbf{U}^*)_{ii} = 1$, and column j adds up to $\sum_i |u_{ij}|^2 = (\mathbf{U}^*\mathbf{U})_{jj} = 1$, since $\mathbf{U}$ is unitary. So $\mathbf{S} \in \Omega_n$. ∎

A doubly stochastic matrix of the form $(|u_{ij}|^2)$ is called **unistochastic**. Not every doubly stochastic matrix is one (Exercise C3 asks for a witness), but the lemma needs only that $\mathbf{S} \in \Omega_n$. The second ingredient is Birkhoff's theorem, which makes $\mathbf{S}\boldsymbol{\lambda}$ an average of rearrangements of $\boldsymbol{\lambda}$.

Proposition 18.7.6 — Doubly Stochastic Maps Even Out

Let $\mathbf{S} \in \Omega_n$ and $\mathbf{y} \in \mathbb{R}^n$. Then $\mathbf{S}\mathbf{y} \prec \mathbf{y}$.

Idea. A permutation matrix only rearranges $\mathbf{y}$, and rearrangements are invisible to majorization. Birkhoff's theorem writes $\mathbf{S}\mathbf{y}$ as an average of rearrangements, and the vectors majorized by $\mathbf{y}$ form a convex set.

Proof. By Theorem 18.7.2, $\mathbf{S} = \sum_{k=1}^{m} t_k \mathbf{P}_{\sigma_k}$ with $(t_1, \dots, t_m) \in \Delta_m$, so $\mathbf{S}\mathbf{y} = \sum_k t_k \mathbf{P}_{\sigma_k}\mathbf{y}$. Each $\mathbf{P}_\sigma \mathbf{y} = \sum_j y_j \mathbf{e}_{\sigma(j)}$ has entry y_j in position $\sigma(j)$, so it is a rearrangement of $\mathbf{y}$. As observed after Definition 16.8.1, majorization sees only which numbers occur and how often, so $\mathbf{y} \prec \mathbf{y}$ (Proposition 16.8.1 (a)) gives $\mathbf{P}_\sigma \mathbf{y} \prec \mathbf{y}$. By Example (The vectors majorized by a fixed vector) the set $\{\mathbf{x} : \mathbf{x} \prec \mathbf{y}\}$ is convex, and a convex set contains every convex combination of its points (Lemma 17.1.2). Hence $\mathbf{S}\mathbf{y} \prec \mathbf{y}$.

■

Second proof of Theorem 16.8.2. Let $\mathbf{A}$ be Hermitian. By Lemma 18.7.5, $\mathbf{d}(\mathbf{A}) = \mathbf{S}\boldsymbol{\lambda}(\mathbf{A})$ with $\mathbf{S} \in \Omega_n$, and by Proposition 18.7.6, $\mathbf{S}\boldsymbol{\lambda}(\mathbf{A}) \prec \boldsymbol{\lambda}(\mathbf{A})$. So $\mathbf{d}(\mathbf{A}) \prec \boldsymbol{\lambda}(\mathbf{A})$. □

The first proof compared running totals using a variational principle; this one never compares running totals directly. It sees Schur's theorem as a statement about averaging: the diagonal entries are weighted averages of the eigenvalues, with weights that form a doubly stochastic matrix, and averaging can only even out a vector.

Example. (The averaging made visible)

For

$$\mathbf{A} = \begin{pmatrix} 3 & 2 & 0 \\ 2 & 4 & 2 \\ 0 & 2 & 5 \end{pmatrix}$$

of Chapter 16 §08, whose eigenvalues are $\boldsymbol{\lambda}(\mathbf{A}) = (7, 4, 1)$ with unit eigenvectors $\mathbf{u}_1 = \frac{1}{3}(1, 2, 2)$, $\mathbf{u}_2 = \frac{1}{3}(-2, -1, 2)$, $\mathbf{u}_3 = \frac{1}{3}(2, -2, 1)$ (Example (Coordinate vectors against eigenvectors)), compute $\mathbf{S}$, check $\mathbf{d}(\mathbf{A}) = \mathbf{S}\boldsymbol{\lambda}(\mathbf{A})$, and write $\mathbf{d}(\mathbf{A})$ as an average of rearrangements of $\boldsymbol{\lambda}(\mathbf{A})$.

Solution. Take $\mathbf{U}$ with columns $\mathbf{u}_1, \mathbf{u}_2, \mathbf{u}_3$; it is orthogonal and $\mathbf{A} = \mathbf{U}\mathbf{D}\mathbf{U}^{\top}$. Squaring its entries,

$$\mathbf{U} = \frac{1}{3}\begin{pmatrix} 1 & -2 & 2 \\ 2 & -1 & -2 \\ 2 & 2 & 1 \end{pmatrix}, \qquad \mathbf{S} = \frac{1}{9}\begin{pmatrix} 1 & 4 & 4 \\ 4 & 1 & 4 \\ 4 & 4 & 1 \end{pmatrix}.$$

Every row and column of $9\mathbf{S}$ adds up to 9. Then

$$\mathbf{S}\boldsymbol{\lambda}(\mathbf{A}) = \frac{1}{9}\begin{pmatrix} 7 + 16 + 4 \\ 28 + 4 + 4 \\ 28 + 16 + 1 \end{pmatrix} = \begin{pmatrix} 3 \\ 4 \\ 5 \end{pmatrix} = \mathbf{d}(\mathbf{A}).$$

To decompose $\mathbf{S}$, let $\mathbf{P}$ be the permutation matrix of $\sigma = (1\ 2\ 3)$, $\sigma(1) = 2$, $\sigma(2) = 3$, $\sigma(3) = 1$. Then $\mathbf{P} + \mathbf{P}^2 = \mathbf{J} - \mathbf{I}$, since $\mathbf{P}$ and $\mathbf{P}^2$ have their 1's in the off-diagonal positions and never in the same place, so

$$\mathbf{S} = \tfrac{1}{9}\mathbf{I} + \tfrac{4}{9}\mathbf{P} + \tfrac{4}{9}\mathbf{P}^2.$$

With $\mathbf{P}\boldsymbol{\lambda} = (1, 7, 4)$ and $\mathbf{P}^2\boldsymbol{\lambda} = (4, 1, 7)$, the cyclic shifts of $(7, 4, 1)$,

$$\mathbf{d}(\mathbf{A}) = \tfrac{1}{9}(7, 4, 1) + \tfrac{4}{9}(1, 7, 4) + \tfrac{4}{9}(4, 1, 7) = (3, 4, 5).$$

Each diagonal entry is an average of all three eigenvalues, with weight $\frac{1}{9}$ on one of them and $\frac{4}{9}$ on the other two. That is why the diagonal $(3, 4, 5)$ is so much flatter than $(7, 4, 1)$.

Together with Theorem 16.8.5, the lemma and the proposition already show that the diagonals of the Hermitian matrices with spectrum $\boldsymbol{\lambda}$ are exactly the vectors $\mathbf{S}\boldsymbol{\lambda}$ with $\mathbf{S} \in \Omega_n$. The lemma puts every such diagonal among the $\mathbf{S}\boldsymbol{\lambda}$; the proposition puts every $\mathbf{S}\boldsymbol{\lambda}$ among the $\mathbf{x} \prec \boldsymbol{\lambda}$; and Schur–Horn realizes every $\mathbf{x} \prec \boldsymbol{\lambda}$ as a diagonal. So all three sets coincide, and in particular every $\mathbf{x} \prec \boldsymbol{\lambda}$ is $\mathbf{S}\boldsymbol{\lambda}$ for some $\mathbf{S} \in \Omega_n$. This converse of the proposition is part of the theorem of Hardy, Littlewood and Pólya, which Chapter 20 takes up.

18.7.7 Exercises

18.7.7.1 A. Check your understanding

Exercise A1.

(a) State Birkhoff's theorem in both forms.

(b) Name the results of Chapter 17 that the proof of Theorem 18.7.2 uses, and say what each contributes.

(c) What upper bound does Step 1 of the proof give for the number of non-zero entries of a vertex of Ω_4? How many does a vertex actually have?

(d) True or false: every matrix in Ω_n with at most $2n-1$ non-zero entries is a permutation matrix. Justify your answer.

(e) True or false: the product of two doubly stochastic matrices is doubly stochastic. Justify your answer.

(f) True or false: every $\mathbf{M} \in \Omega_3$ is a convex combination of at most five permutation matrices. Justify your answer.

Solution.

(a) The extreme points of Ω_n are exactly the $n!$ permutation matrices; equivalently, Ω_n is the convex hull of the permutation matrices, that is, every doubly stochastic matrix is a convex combination of them.

(b) Theorem 17.9.2, which says that a vertex has n^2 independent active constraints and so forces many zero entries; Lemma 17.8.1, the midpoint test, used to show that the stripped matrix is again extreme; and Proposition 17.8.9 with the equivalence of the two forms, which rests on Theorem 17.8.5 and Proposition 17.8.2.

(c) At most $2 \cdot 4 - 1 = 7$. By Theorem 18.7.2 a vertex is a permutation matrix, with exactly 4 non-zero entries. The bound of Step 1 is far from sharp; it is only the first step of an induction.

(d) False. The matrix $\mathbf{N}$ in the warning after Theorem 18.7.2 lies in Ω_3 and has $5 = 2 \cdot 3 - 1$ non-zero entries, but it is not a permutation matrix.

(e) True. If $\mathbf{A}, \mathbf{B} \in \Omega_n$, the entries of $\mathbf{AB}$ are sums of products of non-negative numbers, and $\mathbf{AB1} = \mathbf{A1} = \mathbf{1}$, $\mathbf{1}^{\top}\mathbf{AB} = \mathbf{1}^{\top}\mathbf{B} = \mathbf{1}^{\top}$.

(f) True, by Corollary 18.7.3 with $n = 3$: $(3-1)^2 + 1 = 5$.

18.7.7.2 B. Practice

Exercise B1: Which are corners?.

For each matrix, determine whether it lies in Ω_3 and, if so, whether it is an extreme point of Ω_3. Justify your answers.

$$\mathbf{M}_1 = \begin{pmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix}, \qquad \mathbf{M}_2 = \frac{1}{2}\begin{pmatrix} 1 & 1 & 0 \\ 0 & 1 & 1 \\ 1 & 0 & 1 \end{pmatrix},$$

$$\mathbf{M}_3 = \frac{1}{2}\begin{pmatrix} 2 & 0 & 0 \\ 0 & 1 & 1 \\ 0 & 0 & 1 \end{pmatrix}, \qquad \mathbf{M}_4 = \begin{pmatrix} 1 & 1 & -1 \\ 0 & 0 & 1 \\ 0 & 0 & 1 \end{pmatrix}.$$

Solution. $\mathbf{M}_1$ has exactly one 1 in each row and each column and zeros elsewhere, so it is a permutation matrix, in Ω_3 and extreme by Proposition 17.8.9.

$\mathbf{M}_2$ has non-negative entries and every row and column of $2\mathbf{M}_2$ adds up to 2, so $\mathbf{M}_2 \in \Omega_3$. It is not a permutation matrix, so by Theorem 18.7.2 it is not extreme. Explicitly, $\mathbf{M}_2 = \frac{1}{2}\mathbf{I} + \frac{1}{2}\mathbf{P}$ with $\mathbf{P}$ the permutation matrix with 1's at $(1,2), (2,3), (3,1)$, and $\mathbf{I} \neq \mathbf{P}$.

$\mathbf{M}_3$ is not in Ω_3: its rows add up to $1, 1, \frac{1}{2}$.

$\mathbf{M}_4$ is not in Ω_3: its rows and columns add up to 1 (rows $1, 1, 1$; columns $1, 1, 1$), but the entry -1 is negative. It is in the coset $\frac{1}{3}\mathbf{J} + W_3$ of the proof of Corollary 18.7.3, which shows that the non-negativity conditions matter.

Exercise B2: Peeling a 3×3 matrix.

Let

$$\mathbf{M} = \frac{1}{6}\begin{pmatrix} 3 & 3 & 0 \\ 1 & 2 & 3 \\ 2 & 1 & 3 \end{pmatrix}.$$

Check that $\mathbf{M} \in \Omega_3$, and write $\mathbf{M}$ as a convex combination of permutation matrices by peeling. Hence confirm the bound of Corollary 18.7.3 for this $\mathbf{M}$.

Solution. The entries are non-negative; the rows of $6\mathbf{M}$ add up to $3+3+0$, $1+2+3$, $2+1+3$, and the columns to $3+1+2$, $3+2+1$, $0+3+3$, all 6. So $\mathbf{M} \in \Omega_3$. Peel $\mathbf{N} = 6\mathbf{M}$.

Round 1. The diagonal $3, 2, 3$ is positive; subtract $2\mathbf{I}$:

$$\begin{pmatrix} 1 & 3 & 0 \\ 1 & 0 & 3 \\ 2 & 1 & 1 \end{pmatrix} \quad \text{(sums 4)}.$$

Round 2. The positions $(3,1), (1,2), (2,3)$ carry $2, 3, 3$; subtract $2\mathbf{P}_1$, where $\mathbf{P}_1$ has its 1's there:

$$\begin{pmatrix} 1 & 1 & 0 \\ 1 & 0 & 1 \\ 0 & 1 & 1 \end{pmatrix} \quad \text{(sums 2)}.$$

Round 3. The positions $(1,1), (3,2), (2,3)$ carry $1, 1, 1$; subtract $\mathbf{P}_2$, with 1's there. What

remains has 1's at $(2,1),(1,2),(3,3)$: a permutation matrix $\mathbf{P}_3$, with weight 1.

So $6\mathbf{M} = 2\mathbf{I} + 2\mathbf{P}_1 + \mathbf{P}_2 + \mathbf{P}_3$ and

$$\mathbf{M} = \tfrac{1}{3}\,\mathbf{I} + \tfrac{1}{3}\,\mathbf{P}_1 + \tfrac{1}{6}\,\mathbf{P}_2 + \tfrac{1}{6}\,\mathbf{P}_3,$$

with weights non-negative and adding up to 1. Hence $\mathbf{M}$ uses four permutation matrices, within the bound $(3-1)^2 + 1 = 5$.

Exercise B3: Schur's theorem by averaging.

Let $\mathbf{A} = \begin{pmatrix} 4 & 2 \\ 2 & 1 \end{pmatrix}$.

(a) Find $\boldsymbol{\lambda}(\mathbf{A})$ and an orthogonal $\mathbf{U}$ with $\mathbf{A} = \mathbf{U}\,\mathrm{diag}(\boldsymbol{\lambda}(\mathbf{A}))\mathbf{U}^\top$.

(b) Compute $\mathbf{S} = (u_{ij}^2)$ and check that $\mathbf{d}(\mathbf{A}) = \mathbf{S}\boldsymbol{\lambda}(\mathbf{A})$.

(c) Write $\mathbf{S}$ as a convex combination of permutation matrices, and hence $\mathbf{d}(\mathbf{A})$ as an average of rearrangements of $\boldsymbol{\lambda}(\mathbf{A})$. Confirm $\mathbf{d}(\mathbf{A}) \prec \boldsymbol{\lambda}(\mathbf{A})$ from Definition 16.8.1.

Solution.

(a) $\mathbf{A}(2,1) = (10,5) = 5(2,1)$ and $\mathbf{A}(1,-2) = (0,0)$, so $\boldsymbol{\lambda}(\mathbf{A}) = (5,0)$. With the unit eigenvectors $\frac{1}{\sqrt{5}}(2,1)$ and $\frac{1}{\sqrt{5}}(1,-2)$ as columns,

$$\mathbf{U} = \frac{1}{\sqrt{5}}\begin{pmatrix} 2 & 1 \\ 1 & -2 \end{pmatrix},$$

which is orthogonal, and $\mathbf{A} = \mathbf{U}\,\mathrm{diag}(5,0)\mathbf{U}^\top$ by Corollary 11.5.2.

(b) $\mathbf{S} = \frac{1}{5}\begin{pmatrix} 4 & 1 \\ 1 & 4 \end{pmatrix}$, and $\mathbf{S}(5,0) = (4,1) = \mathbf{d}(\mathbf{A})$.

(c) $\mathbf{S} = \frac{4}{5}\mathbf{I} + \frac{1}{5}\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$, so $\mathbf{d}(\mathbf{A}) = \frac{4}{5}(5,0) + \frac{1}{5}(0,5) = (4,1)$. Directly: both vectors are decreasing, the totals are $5 = 5$, and at $k = 1$, $4 \le 5$. So $\mathbf{d}(\mathbf{A}) \prec \boldsymbol{\lambda}(\mathbf{A})$.

18.7.7.3 C. Going deeper

Exercise C1: Five permutation matrices can be needed.

Let $\mathbf{P}$ be the permutation matrix of the 3-cycle $1 \mapsto 2 \mapsto 3 \mapsto 1$, and let $\mathbf{T}_{12}, \mathbf{T}_{13}, \mathbf{T}_{23}$ be those of the transpositions $(1\ 2), (1\ 3), (2\ 3)$. The six permutation matrices of size 3 are $\mathbf{I}, \mathbf{P}, \mathbf{P}^2$ (the **even** ones) and $\mathbf{T}_{12}, \mathbf{T}_{13}, \mathbf{T}_{23}$ (the **odd** ones).

(a) Show that each of the nine positions (i,j) holds a 1 in exactly one even and exactly one odd permutation matrix, and that each even and each odd permutation matrix share exactly one position of a 1.

(b) Deduce that if $\sum_\sigma c_\sigma \mathbf{P}_\sigma = \mathbf{0}$ for real numbers c_σ, then $c_\sigma = c$ for the even σ and $c_\sigma = -c$ for the odd σ, for some $c \in \mathbb{R}$.

(c) Let $\mathbf{M} = \frac{1}{15}\big(\mathbf{I} + 2\mathbf{P} + 3\mathbf{P}^2 + 4\mathbf{T}_{12} + 5\mathbf{T}_{13}\big)$. Show that every way of writing $\mathbf{M}$ as a convex combination of permutation matrices uses at least five of them with

positive weight.

Hint: in (a), a permutation of $\{1,2,3\}$ *is determined by where it sends any two points.*

Solution.

(a) A permutation matrix $\mathbf{P}_\sigma$ has a 1 in position (i,j) exactly when $\sigma(j) = i$. The permutations of $\{1,2,3\}$ with $\sigma(j) = i$ are determined by where they send the other two points, which must go to the other two values in one of two ways, so there are exactly two. If σ is one of them, the other is $\tau\sigma$, with τ the transposition exchanging the two remaining values, so their signs are opposite (Definition 6.3.2, Theorem 6.3.1): one is even and one is odd. For the second claim, let σ be even and τ odd. They cannot agree at all three points, since they differ; they cannot agree at exactly two, since two agreements force the third; and if they agreed nowhere, $\tau^{-1}\sigma$ would fix no point and so be a 3-cycle, which is even, while $\tau^{-1}\sigma$ is odd. So they agree at exactly one point j, that is, they share exactly one position $(\sigma(j), j)$.

(b) Look at position (i,j): by (a) exactly one even σ and one odd τ have a 1 there, so the equation gives $c_\sigma + c_\tau = 0$. By (a) again, every pair of an even σ and an odd τ arises in this way at their shared position, so $c_\sigma = -c_\tau$ for every such pair. Fixing one odd τ, all even c_σ equal $c = -c_\tau$, and then every odd $c_{\tau'} = -c$.

(c) The given weights are $\frac{1}{15}(1,2,3)$ on $\mathbf{I}, \mathbf{P}, \mathbf{P}^2$ and $\frac{1}{15}(4,5,0)$ on $\mathbf{T}_{12}, \mathbf{T}_{13}, \mathbf{T}_{23}$; they are non-negative with sum 1. If $\mathbf{M} = \sum_\sigma t_\sigma \mathbf{P}_\sigma$ is any other convex combination, the difference of the two weight lists satisfies (b), so the even weights are $\frac{1}{15}(1,2,3) + s$ and the odd ones $\frac{1}{15}(4,5,0) - s$ for some real s. Non-negativity needs $s \geq -\frac{1}{15}$ (from $\mathbf{I}$) and $s \leq 0$ (from $\mathbf{T}_{23}$). For $-\frac{1}{15} < s < 0$, all six weights are positive. At $s = 0$ exactly one vanishes, that of $\mathbf{T}_{23}$; at $s = -\frac{1}{15}$ exactly one vanishes, that of $\mathbf{I}$, the others being $\frac{1}{15}(1,2)$ and $\frac{1}{15}(5,6,1)$. So every representation has at least five positive weights, and the bound $(3-1)^2 + 1 = 5$ of Corollary 18.7.3 is attained.

Exercise C2: Integer matrices with equal line sums.

Let $k \geq 1$, and let $\mathbf{N} \in M_n(\mathbb{R})$ have non-negative **integer** entries, with every row and every column adding up to k.

(a) Prove that $\mathbf{N}$ is a sum of k permutation matrices, not necessarily distinct.

(b) Carry this out for $\mathbf{N} = \begin{pmatrix} 2 & 1 & 0 \\ 0 & 1 & 2 \\ 1 & 1 & 1 \end{pmatrix}$.

Hint: apply Corollary 18.7.4 to $\frac{1}{k}\mathbf{N}$.

Solution.

(a) By induction on k. The matrix $\frac{1}{k}\mathbf{N}$ is doubly stochastic, so by Corollary 18.7.4 there is σ with $n_{\sigma(j)j} > 0$ for every j. These are positive integers, so each is at least 1, and $\mathbf{N} - \mathbf{P}_\sigma$ has non-negative integer entries with every row and column adding up to $k-1$. If $k = 1$, then $\mathbf{N} - \mathbf{P}_\sigma$ has line sums 0 and non-negative entries, so it is $\mathbf{0}$ and $\mathbf{N} = \mathbf{P}_\sigma$. If $k \geq 2$, the induction hypothesis writes $\mathbf{N} - \mathbf{P}_\sigma$ as a sum of $k-1$ permutation matrices, and adding $\mathbf{P}_\sigma$ gives k.

(b) Every row and column adds up to 3. The diagonal $2, 1, 1$ is positive; subtracting $\mathbf{I}$

leaves

$$\begin{pmatrix} 1 & 1 & 0 \\ 0 & 0 & 2 \\ 1 & 1 & 0 \end{pmatrix}.$$

The positions $(1,1),(3,2),(2,3)$ are positive; subtracting that permutation matrix leaves the permutation matrix with 1's at $(3,1),(1,2),(2,3)$. So $\mathbf{N}$ is $\mathbf{I}$ plus these two permutation matrices.

Exercise C3: The dimension, and a matrix that is not unistochastic.

Let $n \geq 2$.

(a) Prove that if $\mathbf{X} \in W_n$ has every $|x_{ij}| \leq \frac{1}{n}$, then $\frac{1}{n}\mathbf{J} + \mathbf{X} \in \Omega_n$. Deduce that $\operatorname{aff}\Omega_n = \frac{1}{n}\mathbf{J} + W_n$ and $\dim \Omega_n = (n-1)^2$.

(b) Show that $\mathbf{M} = \frac{1}{2}\begin{pmatrix} 1 & 1 & 0 \\ 0 & 1 & 1 \\ 1 & 0 & 1 \end{pmatrix}$ is doubly stochastic but is not of the form $(|u_{ij}|^2)$ for any unitary $\mathbf{U} \in M_3(\mathbb{C})$.

Hint for (b): two columns of $\mathbf{U}$ *must be orthogonal; look at which rows both can be non-zero in.*

Solution.

(a) The entries of $\frac{1}{n}\mathbf{J} + \mathbf{X}$ are $\frac{1}{n} + x_{ij} \geq \frac{1}{n} - \frac{1}{n} = 0$, and its rows and columns add up to $1 + 0 = 1$, since $\mathbf{X} \in W_n$. So it lies in Ω_n. The proof of Corollary 18.7.3 showed $\Omega_n \subseteq \frac{1}{n}\mathbf{J} + W_n$, a coset, which is an affine set containing Ω_n, so $\operatorname{aff}\Omega_n \subseteq \frac{1}{n}\mathbf{J} + W_n$. Conversely, let $\mathbf{X} \in W_n$, $\mathbf{X} \neq \mathbf{0}$, and put $c = n \max_{i,j}|x_{ij}| > 0$. Then $\frac{1}{n}\mathbf{J}$ and $\frac{1}{n}\mathbf{J} + \frac{1}{c}\mathbf{X}$ lie in Ω_n, and the affine combination

$$\tfrac{1}{n}\mathbf{J} + \mathbf{X} = (1-c)\,\tfrac{1}{n}\mathbf{J} + c\left(\tfrac{1}{n}\mathbf{J} + \tfrac{1}{c}\mathbf{X}\right)$$

lies in $\operatorname{aff}\Omega_n$. So $\operatorname{aff}\Omega_n = \frac{1}{n}\mathbf{J} + W_n$, and $\dim \Omega_n = \dim W_n = (n-1)^2$ by Lemma 18.7.1 (a).

(b) The entries are non-negative and every row and column adds up to 1. Suppose $\mathbf{M} = (|u_{ij}|^2)$ with $\mathbf{U}$ unitary. The zero entries $m_{13} = m_{21} = m_{32} = 0$ force $u_{13} = u_{21} = u_{32} = 0$. Columns 1 and 2 of $\mathbf{U}$ are $(u_{11}, 0, u_{31})$ and $(u_{12}, u_{22}, 0)$, and they are orthogonal because $\mathbf{U}$ is unitary:

$$0 = u_{11}\overline{u_{12}} + 0 \cdot \overline{u_{22}} + u_{31} \cdot 0 = u_{11}\overline{u_{12}}.$$

But $|u_{11}|^2 = |u_{12}|^2 = \frac{1}{2}$, so $u_{11}\overline{u_{12}} \neq 0$, a contradiction. Hence $\mathbf{M}$ is not unistochastic.

18.8 PageRank

A search engine that finds thousands of pages containing a word must decide which to list first. One answer, which made a search engine famous, is to let the pages vote. Each page spreads

its vote over the pages it links to, a vote counts for more when it comes from a page that is itself important, and "important" is whatever this circular description settles on. Written out, the circle is an eigenvector equation for a stochastic matrix. This section sets up that matrix, shows why the raw web does not give a well-defined ranking, repairs it with a single parameter, and uses Perron's theorem (Theorem 18.1.5) to prove that the repaired matrix has exactly one ranking, with every entry positive. We then prove how fast the ranking can be computed, and work a small web exactly.

Throughout, the field is $\mathbb{R}$, inequalities between vectors and matrices are entrywise as in §01, and **stochastic** means column-stochastic (Definition 8.11.1): non-negative entries, every column adding up to 1. Many accounts of PageRank use rows instead; their matrices are the transposes of ours. We write $\mathbf{1}$ for the all-ones vector and $\mathbf{J} = \mathbf{1}\mathbf{1}^\top$ for the all-ones matrix.

18.8.1 The web as a Markov chain

Number the pages $1, \dots, n$. Page j **links to** page i if it contains a link to it; we ignore links from a page to itself, and several links from j to i count as one. Let d_j be the number of pages that page j links to, its **out-degree**. A page with $d_j = 0$ is called **dangling**: a document with no links out, such as an image or a file.

Imagine a surfer who, on page j, clicks one of its d_j links, each with probability $1/d_j$. If $\mathbf{x}_k$ is the probability vector of the surfer's position after k clicks, then, exactly as in Chapter 8 §11, $\mathbf{x}_{k+1} = \mathbf{H}\mathbf{x}_k$, where $h_{ij} = 1/d_j$ if j links to i and $h_{ij} = 0$ otherwise. This hyperlink matrix $\mathbf{H}$ is local to this section; elsewhere in the book $\mathbf{H}$ is a Hessian. The long-run share of time the surfer spends on page i is the candidate for page i's importance. It captures the circular description: page i receives, from each page j linking to it, the share $1/d_j$ of j's own weight.

At a dangling page the surfer has nowhere to go, and column j of $\mathbf{H}$ is zero. The standard patch sends the surfer to a page chosen uniformly at random.

Definition 18.8.1 — Link Matrix

Let a web have pages $1, \dots, n$, with $n \geq 1$, and out-degrees $d_1, \dots, d_n$. Its **link matrix** is the $n \times n$ matrix $\mathbf{P}$ whose column j is:

(a) if $d_j \geq 1$: the vector with entry $1/d_j$ in each position i such that page j links to page i, and 0 elsewhere;

(b) if $d_j = 0$ (page j is **dangling**): the vector $\frac{1}{n}\mathbf{1}$.

Each column is a probability vector: in case (a) it has d_j entries equal to $1/d_j$, and in case (b) n entries equal to $1/n$. So $\mathbf{P}$ is stochastic. For instance, the web on three pages in which page 1 links to pages 2 and 3, page 2 links to page 3, and page 3 links nowhere, has

$$\mathbf{P} = \begin{pmatrix} 0 & 0 & \frac{1}{3} \\ \frac{1}{2} & 0 & \frac{1}{3} \\ \frac{1}{2} & 1 & \frac{1}{3} \end{pmatrix}.$$

A ranking should then be a steady state of $\mathbf{P}$ (Definition 8.11.2): a probability vector $\mathbf{x}$ with $\mathbf{P}\mathbf{x} = \mathbf{x}$. When $\mathbf{P}$ is irreducible (Definition 18.2.3), there is exactly one, with every entry positive, by Proposition 18.6.1 (c); part (a) of the same proposition gives $\rho(\mathbf{P}) = 1$ for every

stochastic $\mathbf{P}$. The real web is very far from irreducible, and the three failures below are the typical ones.

Example. (Three ways a web can fail to rank)

For each web, describe what goes wrong with the surfer's chain.

(a) Two pages; page 1 links to page 2, and page 2 is dangling, but we use $\mathbf{H}$, without the patch.

(b) Four pages; pages 1 and 2 link to each other, and so do pages 3 and 4.

(c) Two pages that link to each other.

Solution.

(a) $\mathbf{H} = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix}$ has a zero column, so it is not stochastic, and $\mathbf{H}^2 = \mathbf{0}$. From any start the surfer is gone after two clicks: $\mathbf{H}^2\mathbf{x}_0 = \mathbf{0}$ is not a probability vector, and $\mathbf{H}$ has no steady state at all, since $\mathbf{Hx} = \mathbf{x}$ forces $x_1 = 0$ and then $x_2 = x_1 = 0$. The patched $\mathbf{P}$ has second column $(\frac{1}{2}, \frac{1}{2})$ and the steady state $(\frac{1}{3}, \frac{2}{3})$, since $\mathbf{P}(1,2) = (0 \cdot 1 + \frac{1}{2} \cdot 2,\ 1 \cdot 1 + \frac{1}{2} \cdot 2) = (1,2)$.

(b) $\mathbf{P}$ is block diagonal with two copies of the swap $\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$. Both $(\frac{1}{2}, \frac{1}{2}, 0, 0)$ and $(0, 0, \frac{1}{2}, \frac{1}{2})$ are steady states, and so is every average of the two. The chain cannot say whether page 1 matters more than page 3: the ranking is not unique.

(c) $\mathbf{P}$ is the swap. Its steady state $(\frac{1}{2}, \frac{1}{2})$ is unique, but from $\mathbf{x}_0 = \mathbf{e}_1$ the chain alternates $\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_1, \ldots$ and never settles. The eigenvalue -1 of the swap has the same modulus as 1.

In (b) the matrix is reducible, and in (c) it is irreducible but not primitive (Definition 18.5.1): the powers of the swap are $\mathbf{I}$ and the swap, and neither is positive. Real webs have all three features, on a vast scale.

18.8.2 The Google matrix

The dangling patch of Definition 18.8.1 already repairs failure (a). One modification repairs the remaining two at once. Let the surfer, at every step, toss a biased coin: with probability α follow a link as before, and with probability $1 - \alpha$ get bored and jump to a page chosen uniformly at random from all n. The jump is called **teleportation**, and α the **damping factor**; a value around 0.85 is customary.

The Google matrix mixes following links with jumping to a random page; its fixed probability vector is the ranking.

Definition 18.8.2 — Google Matrix, PageRank Vector

Let $\mathbf{P} \in M_n(\mathbb{R})$ be the link matrix of a web with $n \geq 1$ pages, and let $0 < \alpha < 1$. The matrix

$$\mathbf{G} = \alpha\mathbf{P} + \frac{1 - \alpha}{n}\mathbf{J}$$

is called the **Google matrix** in the literature, with damping factor α. A **PageRank vector** of the web is a probability vector $\boldsymbol{\pi} \in \mathbb{R}^n$ with $\mathbf{G}\boldsymbol{\pi} = \boldsymbol{\pi}$. Page i is ranked above page k when $\pi_i > \pi_k$.

In words: column j of $\mathbf{G}$ is α times column j of $\mathbf{P}$, the link step, plus $1-\alpha$ times the uniform vector $\frac{1}{n}\mathbf{1}$, the jump. A PageRank vector is a steady state of the surfer's new chain. The letter $\mathbf{G}$ is local to this section; elsewhere in the book $\mathbf{G}$ is a Gram matrix. The theorem below shows that there is exactly one, which justifies calling it **the** PageRank vector.

Two properties of $\mathbf{G}$ do all the work.

- **$\mathbf{G}$ is stochastic.** Its entries are non-negative, and column j adds up to $\alpha \cdot 1 + (1-\alpha)\cdot\frac{1}{n}\cdot n = 1$.
- **$\mathbf{G}$ is positive.** Every entry is at least $\frac{1-\alpha}{n} > 0$, because $\alpha\mathbf{P} \geq \mathbf{0}$ and $\alpha < 1$ **strictly**.

Two degenerate values of α are excluded, and each shows why. With $\alpha = 1$, $\mathbf{G} = \mathbf{P}$, and the failures (b) and (c) of Example (Three ways a web can fail to rank) come back. With $\alpha = 0$, $\mathbf{G} = \frac{1}{n}\mathbf{J}$ for every web, the PageRank vector is $\frac{1}{n}\mathbf{1}$, and the links are ignored: every page ties. The damping factor trades faithfulness to the links against the good behavior of the chain, and we will see that the speed of the computation is governed by α alone.

For the three-page web above, with $\alpha = \frac{1}{2}$,

$$\mathbf{G} = \frac{1}{2}\mathbf{P} + \frac{1}{6}\mathbf{J} = \begin{pmatrix} \frac{1}{6} & \frac{1}{6} & \frac{1}{3} \\ \frac{5}{12} & \frac{1}{6} & \frac{1}{3} \\ \frac{5}{12} & \frac{2}{3} & \frac{1}{3} \end{pmatrix},$$

with columns adding up to 1 and every entry positive.

A non-example by minimal change. Replace the uniform jump by a jump to page 1 only: $\mathbf{G}' = \alpha\mathbf{P} + (1-\alpha)\mathbf{e}_1\mathbf{1}^\top$. It is still stochastic, since each column of $\mathbf{e}_1\mathbf{1}^\top$ is $\mathbf{e}_1$. What fails is positivity: in the web of Example (Three ways a web can fail to rank) (b), $\mathbf{G}'$ has zeros in rows 3 and 4 of columns 1 and 2, so Perron's theorem no longer applies. (Here the ranking is still unique, but it gives pages 3 and 4 weight zero, since no surfer ever returns to them from pages 1 and 2.) Exercise B3 shows that any jump distribution with all entries positive works as well as the uniform one.

Warning. **PageRank is not a count of incoming links.** A link is worth the rank of the page it comes from, divided by that page's out-degree. In the four-page example at the end of this section, page 3 has more incoming links than any other page, yet page 1, with a single incoming link, ranks above it, because that link comes from page 3 and is page 3's only link.

18.8.3 A unique positive ranking

Perron's theorem, applied to the positive matrix $\mathbf{G}$, settles existence, uniqueness and positivity at once. It also turns the eigenvector problem into a linear system.

Theorem 18.8.1 — The PageRank Vector

Let $\mathbf{P} \in M_n(\mathbb{R})$ be stochastic, $0 < \alpha < 1$, and $\mathbf{G} = \alpha\mathbf{P} + \frac{1-\alpha}{n}\mathbf{J}$. Then:

(a) $\rho(\mathbf{G}) = 1$, and 1 is an eigenvalue of $\mathbf{G}$ of algebraic multiplicity one;

(b) there is **exactly one** probability vector $\boldsymbol{\pi}$ with $\mathbf{G}\boldsymbol{\pi} = \boldsymbol{\pi}$, and every entry of $\boldsymbol{\pi}$ is **positive**;

(c) $\mathbf{I} - \alpha\mathbf{P}$ is invertible, and $\boldsymbol{\pi}$ is the unique solution of

$$(\mathbf{I} - \alpha\mathbf{P})\,\boldsymbol{\pi} = \frac{1-\alpha}{n}\,\mathbf{1}.$$

Idea. Perron's theorem hands us a simple eigenvalue $\rho(\mathbf{G})$ with a positive eigenvector, so the only question is the value of $\rho(\mathbf{G})$; the column sums pin it at 1. For (c), on probability vectors the rank-one part $\frac{1-\alpha}{n}\mathbf{J}\mathbf{x}$ is the constant vector $\frac{1-\alpha}{n}\mathbf{1}$, so the eigenvector equation becomes linear with a right-hand side.

Proof.

(a) By Theorem 15.3.3 (a), $\|\mathbf{G}\|_1$ is the largest column sum of $|\mathbf{G}|$, which is 1 since $\mathbf{G}$ is stochastic; so $\rho(\mathbf{G}) \le 1$ by Theorem 15.4.1 (a). By Proposition 8.11.3 (c), 1 is an eigenvalue of $\mathbf{G}$. Hence $\rho(\mathbf{G}) = 1$. Since every entry of $\mathbf{G}$ is at least $\frac{1-\alpha}{n} > 0$, Perron's theorem (Theorem 18.1.5) applies: by its parts (a) and (b), $\rho(\mathbf{G}) = 1$ is an eigenvalue of algebraic multiplicity one, with an eigenvector $\mathbf{v} > \mathbf{0}$ spanning $E_1(\mathbf{G})$.

(b) Put $\boldsymbol{\pi} = \mathbf{v}/(\mathbf{1}^\top\mathbf{v})$, which is defined because $\mathbf{1}^\top\mathbf{v} > 0$. It is a probability vector with positive entries and $\mathbf{G}\boldsymbol{\pi} = \boldsymbol{\pi}$. If $\boldsymbol{\pi}'$ is another probability vector with $\mathbf{G}\boldsymbol{\pi}' = \boldsymbol{\pi}'$, then $\boldsymbol{\pi}'$ lies in $E_1(\mathbf{G}) = \operatorname{span}(\mathbf{v})$, so $\boldsymbol{\pi}' = c\boldsymbol{\pi}$ for some c, and comparing entry sums gives $1 = c$. Hence $\boldsymbol{\pi}' = \boldsymbol{\pi}$. In the language of §01, $\boldsymbol{\pi}$ is the Perron vector of $\mathbf{G}$ (Definition 18.1.2).

(c) If $(\mathbf{I} - \alpha\mathbf{P})\mathbf{z} = \mathbf{0}$ with $\mathbf{z} \neq \mathbf{0}$, then $\mathbf{P}\mathbf{z} = \alpha^{-1}\mathbf{z}$, so $\alpha^{-1} > 1$ is an eigenvalue of $\mathbf{P}$; but $\rho(\mathbf{P}) \le \|\mathbf{P}\|_1 = 1$ as in (a). So 0 is not an eigenvalue of $\mathbf{I} - \alpha\mathbf{P}$, and $\mathbf{I} - \alpha\mathbf{P}$ is invertible by Theorem 8.2.6. For a probability vector $\mathbf{x}$, $\mathbf{J}\mathbf{x} = \mathbf{1}(\mathbf{1}^\top\mathbf{x}) = \mathbf{1}$, so

$$\mathbf{G}\mathbf{x} = \alpha\mathbf{P}\mathbf{x} + \frac{1-\alpha}{n}\,\mathbf{1},$$

and $\mathbf{G}\boldsymbol{\pi} = \boldsymbol{\pi}$ is the equation $(\mathbf{I} - \alpha\mathbf{P})\boldsymbol{\pi} = \frac{1-\alpha}{n}\mathbf{1}$. So $\boldsymbol{\pi}$ solves the system, and by invertibility it is the only solution.

■

So the ranking exists, is unique, and gives every page a positive score: no page is ignored, however obscure. Part (c) is how one computes it for a small web: solve an $n \times n$ linear system, with no eigenvalue in sight. A useful bonus is that the solution of (c) is automatically a probability vector. Multiplying the system on the left by $\mathbf{1}^\top$, and using $\mathbf{1}^\top\mathbf{P} = \mathbf{1}^\top$,

$$(1-\alpha)\,\mathbf{1}^\top\boldsymbol{\pi} = \frac{1-\alpha}{n}\,\mathbf{1}^\top\mathbf{1} = 1 - \alpha,$$

so $\mathbf{1}^\top\boldsymbol{\pi} = 1$ without being imposed.

Quick check. Two pages link to each other, and $\alpha = \frac{1}{2}$. Write down $\mathbf{G}$, find $\boldsymbol{\pi}$, and find the eigenvalues of $\mathbf{G}$.

Solution. $\mathbf{P}$ is the swap, so

$$\mathbf{G} = \frac{1}{2}\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} + \frac{1}{4}\begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix} = \begin{pmatrix} \frac{1}{4} & \frac{3}{4} \\ \frac{3}{4} & \frac{1}{4} \end{pmatrix}.$$

Then $\mathbf{G}(1,1) = (1,1)$ and $\mathbf{G}(1,-1) = (-\frac{1}{2}, \frac{1}{2}) = -\frac{1}{2}(1,-1)$. So $\boldsymbol{\pi} = (\frac{1}{2}, \frac{1}{2})$, and the eigenvalues are 1 and $-\frac{1}{2}$. The swap has eigenvalues 1 and -1: the second one has been multiplied by α. The next theorem says that this always happens.

18.8.4 The second eigenvalue

The PageRank vector of a real web is computed by iterating $\mathbf{x}_{k+1} = \mathbf{G}\mathbf{x}_k$, since the web has billions of pages and no one solves a system of that size exactly. How fast the iterates settle depends on the eigenvalues of $\mathbf{G}$ other than 1. For a general positive matrix, Perron's theorem says only that they are strictly smaller than ρ in modulus, with no bound on how much smaller. For the Google matrix there is an exact description.

Theorem 18.8.2 — The Eigenvalues of the Google Matrix

Let $n \geq 2$, let $\mathbf{P} \in M_n(\mathbb{R})$ be stochastic, let $0 \leq \alpha \leq 1$, and let $\mathbf{G} = \alpha\mathbf{P} + \frac{1-\alpha}{n}\mathbf{J}$. Since 1 is an eigenvalue of $\mathbf{P}$ (Proposition 8.11.3) and $p_{\mathbf{P}}$ splits over $\mathbb{C}$ (Theorem 5.5.1), it factors as $p_{\mathbf{P}}(x) = (x-1)(x-\mu_2)\cdots(x-\mu_n)$ with $\mu_2, \dots, \mu_n \in \mathbb{C}$. Then

$$p_{\mathbf{G}}(x) = (x-1)(x-\alpha\mu_2)\cdots(x-\alpha\mu_n).$$

In particular, if $\alpha < 1$, every eigenvalue $\lambda \neq 1$ of $\mathbf{G}$ satisfies $|\lambda| \leq \alpha$.

Idea. Both $\mathbf{P}$ and $\mathbf{G}$ have $\mathbf{1}^{\top}$ as a left eigenvector for 1. Change basis so that $\mathbf{1}^{\top}$ becomes the first coordinate functional $\mathbf{e}_1^{\top}$; then both matrices become block lower triangular with a 1 in the corner. The teleportation term $\frac{1}{n}\mathbf{J} = \frac{1}{n}\mathbf{1}\mathbf{1}^{\top}$ only touches the first column in the new basis, so the lower-right blocks are $\mathbf{P}_1$ and $\alpha\mathbf{P}_1$ for the **same** $\mathbf{P}_1$. The eigenvalues of $\mathbf{P}$ other than the 1 in the corner are those of $\mathbf{P}_1$; those of $\mathbf{G}$ are α times them.

Proof. Let $\mathbf{N} = \mathbf{e}_1(\mathbf{1} - \mathbf{e}_1)^{\top}$, the matrix whose first row is $(0, 1, \dots, 1)$ and whose other rows are zero, and let $\mathbf{S} = \mathbf{I} + \mathbf{N}$. Its first row is $\mathbf{1}^{\top}$ and its other rows are those of $\mathbf{I}$, so $\mathbf{e}_1^{\top}\mathbf{S} = \mathbf{1}^{\top}$. Since $(\mathbf{1} - \mathbf{e}_1)^{\top}\mathbf{e}_1 = 0$, $\mathbf{N}^2 = \mathbf{e}_1\big((\mathbf{1} - \mathbf{e}_1)^{\top}\mathbf{e}_1\big)(\mathbf{1} - \mathbf{e}_1)^{\top} = \mathbf{0}$, and therefore $(\mathbf{I} + \mathbf{N})(\mathbf{I} - \mathbf{N}) = \mathbf{I} - \mathbf{N}^2 = \mathbf{I}$. So $\mathbf{S}$ is invertible with $\mathbf{S}^{-1} = \mathbf{I} - \mathbf{N}$ (Theorem 2.4.5).

> *Claim.* **Claim.** If $\mathbf{M} \in M_n(\mathbb{R})$ satisfies $\mathbf{1}^{\top}\mathbf{M} = \mathbf{1}^{\top}$, then the first row of $\mathbf{S}\mathbf{M}\mathbf{S}^{-1}$ is $\mathbf{e}_1^{\top}$.
>
> *Proof.* The first row is $\mathbf{e}_1^{\top}\mathbf{S}\mathbf{M}\mathbf{S}^{-1} = \mathbf{1}^{\top}\mathbf{M}\mathbf{S}^{-1} = \mathbf{1}^{\top}\mathbf{S}^{-1} = \mathbf{e}_1^{\top}\mathbf{S}\mathbf{S}^{-1} = \mathbf{e}_1^{\top}$. ∎

Since $\mathbf{P}$ is stochastic, $\mathbf{1}^{\top}\mathbf{P} = \mathbf{1}^{\top}$, and the claim gives

$$\mathbf{S}\mathbf{P}\mathbf{S}^{-1} = \begin{pmatrix} 1 & \mathbf{0}^{\top} \\ \mathbf{b} & \mathbf{P}_1 \end{pmatrix}$$

for some $\mathbf{b} \in \mathbb{R}^{n-1}$ and $\mathbf{P}_1 \in M_{n-1}(\mathbb{R})$. For the teleportation term,

$$\mathbf{S}\big(\tfrac{1}{n}\mathbf{1}\mathbf{1}^{\top}\big)\mathbf{S}^{-1} = \tfrac{1}{n}(\mathbf{S}\mathbf{1})(\mathbf{1}^{\top}\mathbf{S}^{-1}) = \tfrac{1}{n}(\mathbf{S}\mathbf{1})\,\mathbf{e}_1^{\top},$$

using $\mathbf{1}^{\top}\mathbf{S}^{-1} = \mathbf{e}_1^{\top}$ from the proof of the claim. Its only non-zero column is the first, $\frac{1}{n}\mathbf{S}\mathbf{1}$, whose first entry is $\frac{1}{n}\mathbf{1}^{\top}\mathbf{1} = 1$. So it equals $\begin{pmatrix} 1 & \mathbf{0}^{\top} \\ \mathbf{c} & \mathbf{0} \end{pmatrix}$ for some $\mathbf{c} \in \mathbb{R}^{n-1}$, and

$$\begin{aligned} \mathbf{S}\mathbf{G}\mathbf{S}^{-1} &= \alpha\,\mathbf{S}\mathbf{P}\mathbf{S}^{-1} + (1-\alpha)\,\mathbf{S}\big(\tfrac{1}{n}\mathbf{J}\big)\mathbf{S}^{-1} \\ &= \begin{pmatrix} 1 & \mathbf{0}^{\top} \\ \alpha\mathbf{b} + (1-\alpha)\mathbf{c} & \alpha\mathbf{P}_1 \end{pmatrix}. \end{aligned}$$

Similar matrices have the same characteristic polynomial (Theorem 6.10.3), and $x\mathbf{I}$ minus a block lower triangular matrix is block lower triangular, so by Theorem 6.8.4

$$p_{\mathbf{P}}(x) = (x-1)\,p_{\mathbf{P}_1}(x), \qquad p_{\mathbf{G}}(x) = (x-1)\,p_{\alpha\mathbf{P}_1}(x).$$

Comparing the first with $p_{\mathbf{P}}(x) = (x-1)(x-\mu_2)\cdots(x-\mu_n)$ and canceling the non-zero factor $x-1$ (in $\mathbb{C}[x]$, a product of non-zero polynomials is non-zero) gives $p_{\mathbf{P}_1}(x) = (x-\mu_2)\cdots(x-\mu_n)$. If $\alpha > 0$, then

$$\begin{aligned} p_{\alpha\mathbf{P}_1}(x) &= \det(x\mathbf{I} - \alpha\mathbf{P}_1) = \alpha^{n-1}\det\big(\tfrac{x}{\alpha}\mathbf{I} - \mathbf{P}_1\big) \\ &= \alpha^{n-1}\prod_{j=2}^{n}\Big(\frac{x}{\alpha} - \mu_j\Big) = \prod_{j=2}^{n}(x - \alpha\mu_j), \end{aligned}$$

where the second step takes the factor α out of each of the $n-1$ rows. If $\alpha = 0$, then $p_{\alpha\mathbf{P}_1}(x) = \det(x\mathbf{I}) = x^{n-1} = \prod_j (x - 0\cdot\mu_j)$. Either way the formula for $p_{\mathbf{G}}$ follows.

For the last sentence, each μ_j is an eigenvalue of $\mathbf{P}$, so $|\mu_j| \le \rho(\mathbf{P}) \le \|\mathbf{P}\|_1 = 1$ by Theorem 15.4.1 (a) and Theorem 15.3.3 (a). The eigenvalues of $\mathbf{G}$ are the roots of $p_{\mathbf{G}}$: the number 1 and the $\alpha\mu_j$, each of modulus at most α. If $\alpha < 1$, none of the $\alpha\mu_j$ equals 1, so every eigenvalue $\lambda \ne 1$ is some $\alpha\mu_j$, and $|\lambda| \le \alpha$. This proves the theorem.

■

The theorem gives more than a bound. It shows again that 1 is a simple eigenvalue of $\mathbf{G}$ when $\alpha < 1$, without Perron's theorem, and it says that the rest of the spectrum of $\mathbf{G}$ is the rest of the spectrum of $\mathbf{P}$, shrunk by the factor α. The bound is attained whenever $\mathbf{P}$ itself has 1 as a repeated eigenvalue, as for the two separate webs of Example (Three ways a web can fail to rank) (b) (Exercise C2), and whenever $\mathbf{P}$ has -1 as an eigenvalue, as in the Quick check. So for a web with two or more pieces that no link leaves, as large webs typically have, the second eigenvalue of $\mathbf{G}$ has modulus exactly α, and no better bound is possible.

18.8.5 How fast the iteration converges

The eigenvalue bound predicts that iterates approach $\boldsymbol{\pi}$ at a rate like α^k. For this particular matrix the prediction can be proved directly, with an explicit constant, by measuring errors in the 1-norm of Chapter 15.

Proposition 18.8.3 — Convergence at the Damping Rate

Let $\mathbf{P}$, α, $\mathbf{G}$ and $\boldsymbol{\pi}$ be as in Theorem 18.8.1, let $\mathbf{x}_0$ be any probability vector, and let $\mathbf{x}_k = \mathbf{G}^k\mathbf{x}_0$. Then for every $k \geq 0$,

$$\|\mathbf{x}_k - \boldsymbol{\pi}\|_1 \leq \alpha^k \|\mathbf{x}_0 - \boldsymbol{\pi}\|_1 \leq 2\alpha^k.$$

In particular, $\mathbf{x}_k \to \boldsymbol{\pi}$ entrywise.

Idea. The error $\boldsymbol{\epsilon}_k = \mathbf{x}_k - \boldsymbol{\pi}$ is a difference of probability vectors, so its entries add up to 0, and the teleportation term kills it. What remains is $\alpha\mathbf{P}$, and a stochastic matrix never increases the 1-norm.

Proof. Each $\mathbf{x}_k$ is a probability vector by Proposition 8.11.3 (a), since $\mathbf{G}$ is stochastic. Put $\boldsymbol{\epsilon}_k = \mathbf{x}_k - \boldsymbol{\pi}$, so $\mathbf{1}^\top \boldsymbol{\epsilon}_k = 1 - 1 = 0$. Since $\mathbf{G}\boldsymbol{\pi} = \boldsymbol{\pi}$,

$$\boldsymbol{\epsilon}_{k+1} = \mathbf{G}\mathbf{x}_k - \mathbf{G}\boldsymbol{\pi} = \mathbf{G}\boldsymbol{\epsilon}_k = \alpha\mathbf{P}\boldsymbol{\epsilon}_k + \frac{1-\alpha}{n}\,\mathbf{1}(\mathbf{1}^\top\boldsymbol{\epsilon}_k) = \alpha\mathbf{P}\boldsymbol{\epsilon}_k.$$

By Theorem 15.3.3 (a), $\|\mathbf{P}\|_1 = 1$, the largest column sum of the non-negative matrix $\mathbf{P}$, so $\|\mathbf{P}\boldsymbol{\epsilon}_k\|_1 \leq \|\boldsymbol{\epsilon}_k\|_1$ (Definition 15.3.2). Hence $\|\boldsymbol{\epsilon}_{k+1}\|_1 \leq \alpha\|\boldsymbol{\epsilon}_k\|_1$, and by induction on k, $\|\boldsymbol{\epsilon}_k\|_1 \leq \alpha^k\|\boldsymbol{\epsilon}_0\|_1$. Finally $\|\boldsymbol{\epsilon}_0\|_1 \leq \|\mathbf{x}_0\|_1 + \|\boldsymbol{\pi}\|_1 = 2$, as both are probability vectors. Each entry of $\boldsymbol{\epsilon}_k$ has modulus at most $\|\boldsymbol{\epsilon}_k\|_1 \leq 2\alpha^k$, and $\alpha^k \to 0$ because $0 < \alpha < 1$, one of the calculus facts recorded in Chapter 8 §11. A sequence whose terms are at most $2\alpha^k$ in absolute value, with $2\alpha^k \to 0$, tends to 0 straight from the definition of a limit: once $2\alpha^k < \varepsilon$, so is every such term. So $\mathbf{x}_k \to \boldsymbol{\pi}$ entrywise.

■

The bound does not depend on the web at all: not on the number of pages, not on how they link. With $\alpha = 0.85$, fifty steps guarantee $\|\mathbf{x}_{50} - \boldsymbol{\pi}\|_1 \leq 2(0.85)^{50} < 6 \cdot 10^{-4}$, and ninety guarantee an error below 10^{-6}, for a web of any size. Each step is cheap, because $\mathbf{G}$ is never formed: by the proof of Theorem 18.8.1 (c), $\mathbf{G}\mathbf{x} = \alpha\mathbf{P}\mathbf{x} + \frac{1-\alpha}{n}\mathbf{1}$ for a probability vector $\mathbf{x}$, and $\mathbf{P}\mathbf{x}$ needs one operation per link, plus one shared correction for the dangling pages.

In the language of §05, $\mathbf{G}$ is primitive (Definition 18.5.1), since $\mathbf{G}^1$ is already positive, and Theorem 18.5.2 gives $\mathbf{G}^k \to \boldsymbol{\pi}\mathbf{1}^\top$, with right Perron vector $\boldsymbol{\pi}$ and left Perron vector $\mathbf{1}$, normalized by $\mathbf{1}^\top\boldsymbol{\pi} = 1$. The proposition adds the rate, and the rate is what makes the method practical. The iteration $\mathbf{x}_{k+1} = \mathbf{G}\mathbf{x}_k$ is the **power method**; Chapter 23 studies it for general matrices, where the rate is governed by the ratio of the two largest eigenvalue moduli, here at most α.

18.8.6 A small web, exactly

Example. (Four pages, one dangling)

A web has four pages. Page 1 links to pages 2 and 3; page 2 links to pages 3 and 4; page 3 links to page 1; page 4 is dangling. With $\alpha = \frac{4}{5}$, find the Google matrix, the PageRank vector and the ranking, and compare $|\lambda_2|$ with α.

Solution. The link matrix. Pages 1 and 2 have out-degree 2, page 3 has out-degree 1, and page 4 is dangling, so by Definition 18.8.1

$$\mathbf{P} = \begin{pmatrix} 0 & 0 & 1 & \frac{1}{4} \\ \frac{1}{2} & 0 & 0 & \frac{1}{4} \\ \frac{1}{2} & \frac{1}{2} & 0 & \frac{1}{4} \\ 0 & \frac{1}{2} & 0 & \frac{1}{4} \end{pmatrix}, \qquad 20\,\mathbf{G} = 16\,\mathbf{P} + \mathbf{J} = \begin{pmatrix} 1 & 1 & 17 & 5 \\ 9 & 1 & 1 & 5 \\ 9 & 9 & 1 & 5 \\ 1 & 9 & 1 & 5 \end{pmatrix},$$

since $20\alpha = 16$ and $20 \cdot \frac{1-\alpha}{4} = 1$. Every column of $20\mathbf{G}$ adds up to 20, and every entry is positive.

The linear system. By Theorem 18.8.1 (c), $(\mathbf{I} - \frac{4}{5}\mathbf{P})\boldsymbol{\pi} = \frac{1}{20}\mathbf{1}$. Multiplying by 5 gives $(5\mathbf{I} - 4\mathbf{P})\boldsymbol{\pi} = \frac{1}{4}\mathbf{1}$, that is,

$$\begin{aligned} 5\pi_1 - 4\pi_3 - \pi_4 &= \tfrac{1}{4}, & -2\pi_1 + 5\pi_2 - \pi_4 &= \tfrac{1}{4}, \\ -2\pi_1 - 2\pi_2 + 5\pi_3 - \pi_4 &= \tfrac{1}{4}, & -2\pi_2 + 4\pi_4 &= \tfrac{1}{4}. \end{aligned}$$

Express everything through π_4. The fourth equation gives $\pi_2 = 2\pi_4 - \frac{1}{8}$. The second then gives $2\pi_1 = 5\pi_2 - \pi_4 - \frac{1}{4} = 9\pi_4 - \frac{7}{8}$, so $\pi_1 = \frac{9}{2}\pi_4 - \frac{7}{16}$. The first gives $4\pi_3 = 5\pi_1 - \pi_4 - \frac{1}{4} = \frac{43}{2}\pi_4 - \frac{39}{16}$, so $\pi_3 = \frac{43}{8}\pi_4 - \frac{39}{64}$. Substituting into the third,

$$\Big(-9 - 4 + \tfrac{215}{8} - 1\Big)\pi_4 + \Big(\tfrac{7}{8} + \tfrac{1}{4} - \tfrac{195}{64}\Big) = \tfrac{103}{8}\pi_4 - \tfrac{123}{64} = \tfrac{1}{4},$$

so $\frac{103}{8}\pi_4 = \frac{139}{64}$ and $\pi_4 = \frac{139}{824}$. Back-substituting,

$$\boldsymbol{\pi} = \frac{1}{824}\,(265,\ 175,\ 245,\ 139).$$

Check. The entries add up to $824/824 = 1$, as they must. With $\mathbf{y} = (265, 175, 245, 139)$, the first row of $20\mathbf{G}$ gives $265 + 175 + 17 \cdot 245 + 5 \cdot 139 = 5300 = 20 \cdot 265$, and the other rows give $3500 = 20 \cdot 175$, $4900 = 20 \cdot 245$ and $2780 = 20 \cdot 139$. So $\mathbf{G}\boldsymbol{\pi} = \boldsymbol{\pi}$.

The ranking. Page 1 first (≈ 0.322), then page 3 (≈ 0.297), page 2 (≈ 0.212) and page 4 (≈ 0.169). Page 3 is linked from pages 1 and 2, while the dangling page 4 feeds every page equally; page 1 is linked only from page 3. Yet page 1 wins, because page 3 passes its whole weight to it, while pages 1, 2 and 4 split theirs.

The second eigenvalue. Expanding the determinant gives

$$\begin{aligned} p_{\mathbf{P}}(x) &= (x-1)\Big(x^3 + \tfrac{3}{4}x^2 + \tfrac{1}{8}x - \tfrac{1}{16}\Big), \\ p_{\mathbf{G}}(x) &= (x-1)\Big(x^3 + \tfrac{3}{5}x^2 + \tfrac{2}{25}x - \tfrac{4}{125}\Big), \end{aligned}$$

and the second cubic is α^3 times the first evaluated at x/α, as Theorem 18.8.2 predicts: $\frac{3}{4} \cdot \frac{4}{5} = \frac{3}{5}$, $\frac{1}{8} \cdot \frac{16}{25} = \frac{2}{25}$, $\frac{1}{16} \cdot \frac{64}{125} = \frac{4}{125}$. The cubic for $\mathbf{P}$ has one real root near 0.199 and two complex ones of modulus about 0.560. So $|\lambda_2(\mathbf{G})| \approx 0.8 \times 0.560 \approx 0.448$, comfortably below $\alpha = 0.8$: for this web the iteration converges faster than Proposition 18.8.3 guarantees.

18.8.7 Exercises

18.8.7.1 A. Check your understanding

Exercise A1.

(a) Define the Google matrix of a web and its PageRank vector.

(b) Why is every entry of $\mathbf{G}$ positive, and which three conclusions does Theorem 18.1.5 then give?

(c) True or false: with $\alpha = 1$, every web has exactly one PageRank vector. Justify your answer.

(d) True or false: the page with the most incoming links always has the highest PageRank. Justify your answer.

(e) For $\alpha = 0.85$, what does Theorem 18.8.2 say about the eigenvalues of $\mathbf{G}$ other than 1? Can the bound be improved for every web?

(f) True or false: after 10 steps of $\mathbf{x}_{k+1} = \mathbf{G}\mathbf{x}_k$ from any probability vector, $\|\mathbf{x}_{10} - \boldsymbol{\pi}\|_1 \le 2\alpha^{10}$. Justify your answer.

Solution.

(a) For a web with link matrix $\mathbf{P}$ (Definition 18.8.1) and $0 < \alpha < 1$, $\mathbf{G} = \alpha\mathbf{P} + \frac{1-\alpha}{n}\mathbf{J}$. A PageRank vector is a probability vector $\boldsymbol{\pi}$ with $\mathbf{G}\boldsymbol{\pi} = \boldsymbol{\pi}$.

(b) $\alpha\mathbf{P}$ has non-negative entries and $\frac{1-\alpha}{n}\mathbf{J}$ has every entry equal to $\frac{1-\alpha}{n} > 0$, since $\alpha < 1$. Perron's theorem then gives: $\rho(\mathbf{G})$ is an eigenvalue of algebraic multiplicity one; it has an eigenvector with all entries positive; every other eigenvalue has modulus strictly less than $\rho(\mathbf{G})$. Here $\rho(\mathbf{G}) = 1$.

(c) False. With $\alpha = 1$, $\mathbf{G} = \mathbf{P}$, and for two pairs of pages linking only to each other, Example (Three ways a web can fail to rank) (b) gives two different steady states.

(d) False. In Example (Four pages, one dangling), page 3 has the most incoming links, but page 1 ranks first.

(e) Every eigenvalue $\lambda \neq 1$ has $|\lambda| \le 0.85$. The bound cannot be improved for every web: when the link matrix has -1 or a repeated 1 among its eigenvalues, $\mathbf{G}$ has an eigenvalue of modulus exactly 0.85 (the Quick check, and Exercise C2).

(f) True, by Proposition 18.8.3 with $k = 10$.

18.8.7.2 B. Practice

Exercise B1: A three-page web.

For the three-page web after Definition 18.8.1 (page 1 links to pages 2 and 3, page 2 to page 3, page 3 is dangling), with $\alpha = \frac{1}{2}$, find the PageRank vector by solving the system of Theorem 18.8.1 (c). Hence rank the pages.

Solution. With $\mathbf{P}$ as in the text, $(\mathbf{I} - \frac{1}{2}\mathbf{P})\boldsymbol{\pi} = \frac{1}{6}\mathbf{1}$. Multiplying by 12 gives $(12\mathbf{I} - 6\mathbf{P})\boldsymbol{\pi} =$

$2\,\mathbf{1}$:

$$\begin{aligned} 12\pi_1 - 2\pi_3 &= 2,\\ -3\pi_1 + 12\pi_2 - 2\pi_3 &= 2,\\ -3\pi_1 - 6\pi_2 + 10\pi_3 &= 2. \end{aligned}$$

The first gives $\pi_3 = 6\pi_1 - 1$. The second becomes $-3\pi_1 + 12\pi_2 - 12\pi_1 + 2 = 2$, so $\pi_2 = \frac{5}{4}\pi_1$. The third becomes $-3\pi_1 - \frac{15}{2}\pi_1 + 60\pi_1 - 10 = 2$, so $\frac{99}{2}\pi_1 = 12$ and $\pi_1 = \frac{8}{33}$. Then $\pi_2 = \frac{10}{33}$ and $\pi_3 = \frac{48}{33} - 1 = \frac{15}{33}$. So

$$\boldsymbol{\pi} = \frac{1}{33}(8,\ 10,\ 15),$$

whose entries add up to 1. Check against the original system: $12\cdot 8 - 2\cdot 15 = 66 = 2\cdot 33$, $-24 + 120 - 30 = 66$, $-24 - 60 + 150 = 66$. Hence page 3 ranks first, then page 2, then page 1.

Exercise B2: A cycle of three pages.

Three pages link in a cycle: 1 to 2, 2 to 3, 3 to 1. Let $0 < \alpha < 1$.

(a) Write down $\mathbf{P}$ and show that $p_{\mathbf{P}}(x) = x^3 - 1$.

(b) Use Theorem 18.8.2 to find the eigenvalues of $\mathbf{G}$, and check your answer against $\operatorname{tr}\mathbf{G}$.

(c) Find $\boldsymbol{\pi}$, and explain why the bound of Theorem 18.8.2 is attained.

Solution.

(a) Column j of $\mathbf{P}$ is $\mathbf{e}_{j+1}$, with $\mathbf{e}_4$ read as $\mathbf{e}_1$:

$$\mathbf{P} = \begin{pmatrix} 0 & 0 & 1\\ 1 & 0 & 0\\ 0 & 1 & 0 \end{pmatrix}, \qquad \det(x\mathbf{I} - \mathbf{P}) = \det\begin{pmatrix} x & 0 & -1\\ -1 & x & 0\\ 0 & -1 & x \end{pmatrix}$$
$$= x\cdot x^2 + (-1)\cdot\big((-1)(-1) - x\cdot 0\big) = x^3 - 1,$$

expanding along the first row.

(b) $x^3 - 1 = (x-1)(x-\omega)(x-\overline{\omega})$ with $\omega = -\frac{1}{2} + \frac{\sqrt{3}}{2}i$, so $\mu_2 = \omega$, $\mu_3 = \overline{\omega}$, and the eigenvalues of $\mathbf{G}$ are $1, \alpha\omega, \alpha\overline{\omega}$. Their sum is $1 + \alpha(\omega + \overline{\omega}) = 1 - \alpha$. Directly, $\operatorname{tr}\mathbf{G} = \alpha\operatorname{tr}\mathbf{P} + \frac{1-\alpha}{3}\operatorname{tr}\mathbf{J} = 0 + (1-\alpha)$, which agrees (Theorem 8.3.3).

(c) $\mathbf{P}\mathbf{1} = \mathbf{1}$ and $\mathbf{J}\mathbf{1} = 3\,\mathbf{1}$, so $\mathbf{G}\mathbf{1} = \alpha\mathbf{1} + (1-\alpha)\mathbf{1} = \mathbf{1}$, and $\boldsymbol{\pi} = \frac{1}{3}\mathbf{1}$ by the uniqueness in Theorem 18.8.1. The eigenvalues $\alpha\omega$ and $\alpha\overline{\omega}$ have modulus $\alpha|\omega| = \alpha$, so the bound $|\lambda| \le \alpha$ holds with equality.

Exercise B3: Personalized jumps.

Let $\mathbf{P} \in M_n(\mathbb{R})$ be stochastic, $0 < \alpha < 1$, and let $\mathbf{v}$ be a probability vector with **every** $v_i > 0$. Put $\mathbf{G}_{\mathbf{v}} = \alpha\mathbf{P} + (1-\alpha)\mathbf{v}\mathbf{1}^{\top}$: the surfer now jumps to page i with probability v_i.

(a) Prove that $\mathbf{G}_{\mathbf{v}}$ is stochastic and positive, and deduce that it has exactly one probability vector $\boldsymbol{\pi}$ with $\mathbf{G}_{\mathbf{v}}\boldsymbol{\pi} = \boldsymbol{\pi}$, and that $\boldsymbol{\pi} > \mathbf{0}$.

(b) Prove that $\boldsymbol{\pi}$ is the unique solution of $(\mathbf{I} - \alpha\mathbf{P})\boldsymbol{\pi} = (1-\alpha)\mathbf{v}$.

(c) For two pages linking to each other, $\alpha = \frac{1}{2}$ and $\mathbf{v} = (\frac{3}{4}, \frac{1}{4})$, find $\boldsymbol{\pi}$.

Solution.

(a) The entries of $\mathbf{G_v}$ are $\alpha p_{ij} + (1-\alpha)v_i \geq (1-\alpha)v_i > 0$. Column j adds up to $\alpha + (1-\alpha)\mathbf{1}^\top \mathbf{v} = \alpha + 1 - \alpha = 1$. So $\mathbf{G_v}$ is stochastic and positive. The proof of Theorem 18.8.1 (a) and (b) used only these two facts, so it applies word for word: $\rho(\mathbf{G_v}) = 1$ is an eigenvalue of algebraic multiplicity one with a positive eigenvector, and its normalization $\boldsymbol{\pi}$ is the only probability vector fixed by $\mathbf{G_v}$.

(b) For a probability vector $\mathbf{x}$, $\mathbf{G_v x} = \alpha \mathbf{P x} + (1-\alpha)\mathbf{v}(\mathbf{1}^\top \mathbf{x}) = \alpha \mathbf{P x} + (1-\alpha)\mathbf{v}$, so $\mathbf{G_v}\boldsymbol{\pi} = \boldsymbol{\pi}$ says $(\mathbf{I} - \alpha \mathbf{P})\boldsymbol{\pi} = (1-\alpha)\mathbf{v}$. The matrix $\mathbf{I} - \alpha \mathbf{P}$ is invertible, as in the proof of Theorem 18.8.1 (c), so the solution is unique.

(c) $\mathbf{P}$ is the swap, and the system is $\pi_1 - \frac{1}{2}\pi_2 = \frac{3}{8}$, $-\frac{1}{2}\pi_1 + \pi_2 = \frac{1}{8}$. The first gives $\pi_1 = \frac{3}{8} + \frac{1}{2}\pi_2$, and the second becomes $-\frac{3}{16} + \frac{3}{4}\pi_2 = \frac{1}{8}$, so $\pi_2 = \frac{5}{12}$ and $\pi_1 = \frac{3}{8} + \frac{5}{24} = \frac{7}{12}$. So $\boldsymbol{\pi} = (\frac{7}{12}, \frac{5}{12})$: the preferred page 1 gains, but less than its jump weight $\frac{3}{4}$, because half the time the surfer follows the link to page 2.

18.8.7.3 C. Going deeper

Exercise C1: PageRank as a sum over paths.

Let $\mathbf{P}$, α, $\mathbf{G}$ and $\boldsymbol{\pi}$ be as in Theorem 18.8.1.

(a) Prove that $\boldsymbol{\pi} = \dfrac{1-\alpha}{n} \displaystyle\sum_{k=0}^{\infty} \alpha^k \mathbf{P}^k \mathbf{1}$.

(b) Deduce that $\pi_i \geq \frac{1-\alpha}{n}$ for every i.

(c) Suppose no page is dangling and no page links to page i. Prove that $\pi_i = \frac{1-\alpha}{n}$ exactly.

Hint for (a): Theorem 15.5.1 with the 1-norm.

Solution.

(a) By Theorem 15.3.3 (a), $\|\alpha \mathbf{P}\|_1 = \alpha \|\mathbf{P}\|_1 = \alpha < 1$, the largest column sum of $\alpha \mathbf{P}$. By Theorem 15.5.1 (a), $\mathbf{I} - \alpha \mathbf{P}$ is invertible and $(\mathbf{I} - \alpha \mathbf{P})^{-1} = \sum_{k \geq 0} \alpha^k \mathbf{P}^k$. By Theorem 18.8.1 (c), $\boldsymbol{\pi} = \frac{1-\alpha}{n}(\mathbf{I} - \alpha \mathbf{P})^{-1}\mathbf{1}$, which is the stated series.

(b) Every term $\alpha^k \mathbf{P}^k \mathbf{1}$ has non-negative entries, and the term $k = 0$ is $\mathbf{1}$. So each entry of the sum is at least 1, since a limit of partial sums that are all at least 1 is at least 1, and $\pi_i \geq \frac{1-\alpha}{n}$.

(c) From $\mathbf{G}\boldsymbol{\pi} = \boldsymbol{\pi}$ and the proof of Theorem 18.8.1 (c), $\boldsymbol{\pi} = \alpha \mathbf{P}\boldsymbol{\pi} + \frac{1-\alpha}{n}\mathbf{1}$. Row i of $\mathbf{P}$ is zero: $p_{ij} \neq 0$ only if page j links to page i or page j is dangling, and neither happens. So $(\mathbf{P}\boldsymbol{\pi})_i = 0$ and $\pi_i = \frac{1-\alpha}{n}$, the smallest possible value by (b).

Exercise C2: When the bound is attained.

Let $\mathbf{P} \in M_n(\mathbb{R})$ be stochastic, $0 < \alpha < 1$, and $\mathbf{G} = \alpha \mathbf{P} + \frac{1-\alpha}{n}\mathbf{J}$.

(a) Suppose $\mathbf{P}$ has two **different** steady states $\mathbf{u} \neq \mathbf{w}$. Prove that $\mathbf{G}(\mathbf{u} - \mathbf{w}) =$

$\alpha(\mathbf{u}-\mathbf{w})$, so that α is an eigenvalue of $\mathbf{G}$.

(b) For the web of Example (Three ways a web can fail to rank) (b), find all eigenvalues of $\mathbf{G}$, with multiplicity, and check your answer against (a).

Solution.

(a) Put $\mathbf{z}=\mathbf{u}-\mathbf{w}\neq\mathbf{0}$. Both are probability vectors, so $\mathbf{1}^{\top}\mathbf{z}=0$ and $\mathbf{J}\mathbf{z}=\mathbf{1}(\mathbf{1}^{\top}\mathbf{z})=\mathbf{0}$. Hence $\mathbf{G}\mathbf{z}=\alpha\mathbf{P}\mathbf{u}-\alpha\mathbf{P}\mathbf{w}+\mathbf{0}=\alpha(\mathbf{u}-\mathbf{w})=\alpha\mathbf{z}$, and α is an eigenvalue of $\mathbf{G}$ with eigenvector $\mathbf{z}$.

(b) $\mathbf{P}$ is block diagonal with two blocks $\begin{pmatrix}0&1\\1&0\end{pmatrix}$, each with characteristic polynomial x^2-1, so $p_{\mathbf{P}}(x)=(x^2-1)^2=(x-1)(x-1)(x+1)(x+1)$ by Theorem 6.8.4. By Theorem 18.8.2, with $\mu_2=1$ and $\mu_3=\mu_4=-1$, the eigenvalues of $\mathbf{G}$ are $1,\alpha,-\alpha,-\alpha$. The eigenvalue α is the one found in (a), with $\mathbf{u}=(\frac{1}{2},\frac{1}{2},0,0)$, $\mathbf{w}=(0,0,\frac{1}{2},\frac{1}{2})$ and eigenvector $\mathbf{z}=\frac{1}{2}(1,1,-1,-1)$; indeed $\mathbf{P}\mathbf{z}=\mathbf{z}$ and $\mathbf{J}\mathbf{z}=\mathbf{0}$, so $\mathbf{G}\mathbf{z}=\alpha\mathbf{z}$.

18.9 M-Matrices

Every section of this chapter so far has studied a non-negative matrix $\mathbf{B}$ through its spectral radius. This last section looks at the matrices $s\mathbf{I}-\mathbf{B}$ built from one, which turn up wherever a quantity is balanced against what flows into it from its neighbors: a discretized differential equation, an economy that consumes part of its own output, the fundamental matrix of an absorbing Markov chain. The question is always the same. When is $s\mathbf{I}-\mathbf{B}$ invertible with a **non-negative** inverse, so that a non-negative right-hand side is guaranteed a non-negative solution? The answer is a single inequality, $s>\rho(\mathbf{B})$, and the section's main theorem shows that six other conditions, several of which can be checked by hand, say the same thing. The chapter's summary closes the section.

Throughout, matrices have real entries, the spectrum $\operatorname{spec}(\mathbf{A})$ of $\mathbf{A}\in M_n(\mathbb{R})$ is taken in $\mathbb{C}$, as in the definition of the spectral radius (Definition 15.4.1), and $\geq$, $>$ between matrices or vectors are entrywise.

18.9.1 Z-matrices and M-matrices

A matrix of the form $s\mathbf{I}-\mathbf{B}$ with $\mathbf{B}\geq 0$ has an unmistakable sign pattern: the diagonal entries $s-b_{ii}$ can be anything, and every entry off the diagonal is $-b_{ij}\leq 0$. The pattern comes first, because it is what one sees on the page.

Definition 18.9.1 — Z-Matrix

A matrix $\mathbf{A}=(a_{ij})\in M_n(\mathbb{R})$, $n\geq 1$, is a **Z-matrix** if $a_{ij}\leq 0$ for **every** pair $i\neq j$.

The diagonal is unrestricted. The identity is a Z-matrix, and so is $-\mathbf{I}$; every 1×1 matrix is one, since there is no off-diagonal entry to check. The matrix $\left(\begin{smallmatrix}2&-1\\-1&2\end{smallmatrix}\right)$ is one; $\left(\begin{smallmatrix}2&1\\-1&2\end{smallmatrix}\right)$ is not, because of the single entry $a_{12}=1>0$.

Lemma 18.9.1 — Z-Matrices Are Shifts of Non-negative Matrices

A matrix $\mathbf{A} \in M_n(\mathbb{R})$ is a Z-matrix if and only if $\mathbf{A} = s\mathbf{I} - \mathbf{B}$ for some real s and some $\mathbf{B} \in M_n(\mathbb{R})$ with $\mathbf{B} \geq 0$. For a Z-matrix, **every** $s \geq \max_i a_{ii}$ gives such a representation, with $\mathbf{B} = s\mathbf{I} - \mathbf{A}$.

Proof. If $\mathbf{A} = s\mathbf{I} - \mathbf{B}$ with $\mathbf{B} \geq 0$, then $a_{ij} = -b_{ij} \leq 0$ for $i \neq j$. Conversely, let $\mathbf{A}$ be a Z-matrix, let $s \geq \max_i a_{ii}$ and put $\mathbf{B} = s\mathbf{I} - \mathbf{A}$. Its diagonal entries are $s - a_{ii} \geq 0$ by the choice of s, and its off-diagonal entries are $-a_{ij} \geq 0$ because $\mathbf{A}$ is a Z-matrix. So $\mathbf{B} \geq 0$ and $\mathbf{A} = s\mathbf{I} - \mathbf{B}$. ∎

The representation is far from unique: raising s by t raises every diagonal entry of $\mathbf{B}$ by t. A definition built on it must therefore not depend on which representation is used, and that is the first thing to check below.

Now the goal. For a Z-matrix $\mathbf{A} = s\mathbf{I} - \mathbf{B}$ with $s > 0$, write $\mathbf{A} = s(\mathbf{I} - s^{-1}\mathbf{B})$. If $\rho(\mathbf{B}) < s$, the Neumann series of Chapter 9 (Theorem 9.10.6) inverts the second factor as $\sum_k (s^{-1}\mathbf{B})^k$, a sum of non-negative matrices. So a comparison between s and $\rho(\mathbf{B})$ is exactly what decides whether the inverse is non-negative, and it deserves a name.

An M-matrix is a non-negative matrix subtracted from a multiple of the identity large enough to dominate its spectral radius.

Definition 18.9.2 — M-Matrix

A matrix $\mathbf{A} \in M_n(\mathbb{R})$, $n \geq 1$, is an **M-matrix** if it can be written as

$$\mathbf{A} = s\mathbf{I} - \mathbf{B} \qquad \text{with } s \in \mathbb{R},\ \mathbf{B} \in M_n(\mathbb{R}),\ \mathbf{B} \geq 0 \text{ and } s \geq \rho(\mathbf{B}).$$

An M-matrix that is **invertible** is a **non-singular M-matrix**.

In words: the first clause asks that $\mathbf{A}$ be a Z-matrix (by Lemma 18.9.1, that is what "$s\mathbf{I} - \mathbf{B}$ with $\mathbf{B} \geq 0$" means), and the second asks that the shift s be **at least** the spectral radius of what is subtracted. The definition says "can be written", so a single good representation suffices. The next lemma shows that one representation is as good as any other, and also identifies the singular case.

Lemma 18.9.2 — The Smallest Real Eigenvalue of a Z-Matrix

Let $\mathbf{A} \in M_n(\mathbb{R})$ be a Z-matrix, and let $\mathbf{A} = s\mathbf{I} - \mathbf{B}$ with $\mathbf{B} \geq 0$ be **any** representation as in Lemma 18.9.1.

(a) $s - \rho(\mathbf{B})$ is an eigenvalue of $\mathbf{A}$, and every $\lambda \in \operatorname{spec}(\mathbf{A})$ satisfies $\operatorname{Re}\lambda \geq s - \rho(\mathbf{B})$. In particular $s - \rho(\mathbf{B})$ is the **smallest real eigenvalue** of $\mathbf{A}$, and so it is the same number for every representation.

(b) $\mathbf{A}$ is an M-matrix if and only if $s \geq \rho(\mathbf{B})$, and a non-singular M-matrix if and only if $s > \rho(\mathbf{B})$.

Idea. Shifting by $s\mathbf{I}$ moves the spectrum rigidly: the eigenvalues of $\mathbf{A}$ are $s-\mu$ for the eigenvalues μ of $\mathbf{B}$. All of those μ lie in the disc of radius $\rho(\mathbf{B})$, and the point of that disc farthest to the right, $\rho(\mathbf{B})$ itself, is an eigenvalue because $\mathbf{B} \geq 0$. Reflected through s, that point becomes the leftmost point of the spectrum of $\mathbf{A}$, and it is real.

Proof.

(a) For $\mathbf{v} \in \mathbb{C}^n$ and $\lambda \in \mathbb{C}$, $\mathbf{A}\mathbf{v} = \lambda\mathbf{v}$ if and only if $\mathbf{B}\mathbf{v} = (s-\lambda)\mathbf{v}$. Hence $\operatorname{spec}(\mathbf{A}) = \{s-\mu : \mu \in \operatorname{spec}(\mathbf{B})\}$. By Theorem 18.3.1, $\rho(\mathbf{B}) \in \operatorname{spec}(\mathbf{B})$, so $s-\rho(\mathbf{B}) \in \operatorname{spec}(\mathbf{A})$. Now let $\lambda \in \operatorname{spec}(\mathbf{A})$ and put $\mu = s-\lambda \in \operatorname{spec}(\mathbf{B})$. By Definition 15.4.1, $|\mu| \leq \rho(\mathbf{B})$, so

$$\operatorname{Re}\lambda = s - \operatorname{Re}\mu \geq s - |\mu| \geq s - \rho(\mathbf{B}).$$

For real λ this reads $\lambda \geq s-\rho(\mathbf{B})$. So $s-\rho(\mathbf{B})$ is the smallest real eigenvalue of $\mathbf{A}$, a number determined by $\mathbf{A}$ alone.

(b) If $s \geq \rho(\mathbf{B})$, then $\mathbf{A}$ is an M-matrix by Definition 18.9.2. Conversely, if $\mathbf{A}$ is an M-matrix, there is a representation $\mathbf{A} = s'\mathbf{I} - \mathbf{B}'$ with $\mathbf{B}' \geq 0$ and $s' \geq \rho(\mathbf{B}')$, and by (a) $s-\rho(\mathbf{B}) = s'-\rho(\mathbf{B}') \geq 0$. For the second statement, $\mathbf{A}$ is invertible if and only if $0 \notin \operatorname{spec}(\mathbf{A})$ (Theorem 8.2.6). If $s > \rho(\mathbf{B})$, every eigenvalue has real part at least $s-\rho(\mathbf{B}) > 0$ by (a), so $0 \notin \operatorname{spec}(\mathbf{A})$. If $s = \rho(\mathbf{B})$, then $0 = s-\rho(\mathbf{B}) \in \operatorname{spec}(\mathbf{A})$ by (a), and $\mathbf{A}$ is singular. This proves the lemma.

■

So the M-matrix test can be run with the most convenient representation, usually the smallest admissible shift $s = \max_i a_{ii}$, and the verdict does not change.

Examples.

- *Size one.* The 1×1 matrix (a) is $s-(s-a)$ for any $s \geq a$, and $\rho(s-a) = s-a$. So (a) is an M-matrix exactly when $s \geq s-a$, that is, $a \geq 0$, and non-singular exactly when $a > 0$. This degenerate case is worth keeping in mind: an M-matrix is the matrix version of a **non-negative number**, and a non-singular one the version of a **positive number**, whose reciprocal is again positive.
- *A standard example.* $\mathbf{A} = \left(\begin{smallmatrix} 2 & -1 \\ -1 & 2 \end{smallmatrix}\right) = 2\mathbf{I} - \mathbf{B}$ with $\mathbf{B} = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$. Here $p_{\mathbf{B}}(x) = x^2 - 1$, so $\operatorname{spec}(\mathbf{B}) = \{1, -1\}$ and $\rho(\mathbf{B}) = 1 < 2$. By Lemma 18.9.2, $\mathbf{A}$ is a non-singular M-matrix, and indeed $\mathbf{A}^{-1} = \frac{1}{3}\left(\begin{smallmatrix} 2 & 1 \\ 1 & 2 \end{smallmatrix}\right) \geq 0$.

Non-example by minimal change. Double the off-diagonal entries of the standard example: $\mathbf{A}' = \left(\begin{smallmatrix} 2 & -2 \\ -2 & 2 \end{smallmatrix}\right) = 2\mathbf{I} - 2\mathbf{B}$, with $\rho(2\mathbf{B}) = 2$. It is still a Z-matrix and still has the smallest shift $s = 2$, but now $s = \rho(2\mathbf{B})$: an M-matrix, and a singular one ($\mathbf{A}'\mathbf{1} = \mathbf{0}$). Go one step further, to $\mathbf{A}'' = \left(\begin{smallmatrix} 1 & -2 \\ -2 & 1 \end{smallmatrix}\right) = \mathbf{I} - 2\mathbf{B}$. The clause that fails is the comparison of the shift with the spectral radius: here $s = 1 < 2 = \rho(2\mathbf{B})$. By Lemma 18.9.2 its smallest real eigenvalue is $1-2 = -1$, and its inverse, $-\frac{1}{3}\left(\begin{smallmatrix} 1 & 2 \\ 2 & 1 \end{smallmatrix}\right)$, is entrywise negative.

Why this definition. Drop the clause $s \geq \rho(\mathbf{B})$ and the definition describes every Z-matrix, including $\mathbf{A}''$, whose inverse has the wrong sign everywhere; the whole point is lost. Drop the sign pattern instead, and ask only that some shift of $\mathbf{A}$ have small spectral radius, and the non-negativity of the terms $(s^{-1}\mathbf{B})^k$ in the Neumann series disappears with it. The strict inequality $s > \rho(\mathbf{B})$ is what the series needs to converge, and the lemma shows that the boundary case $s = \rho(\mathbf{B})$ is exactly the singular one, which is why the definition admits it but names the non-singular case separately.

Warning. **Positive diagonal and non-positive off-diagonal entries do not make an M-matrix.** The matrix $\mathbf{A}'' = \left(\begin{smallmatrix} 1 & -2 \\ -2 & 1 \end{smallmatrix}\right)$ has both, yet $\det \mathbf{A}'' = -3 < 0$ and its inverse has no non-negative entry at all. The sign pattern is only half the definition; the size of the off-diagonal entries relative to the diagonal is the other half, and it is measured by $\rho(\mathbf{B})$, not entry by entry.

Quick check. Is $\left(\begin{smallmatrix} 1 & -1 \\ -1 & 1 \end{smallmatrix}\right)$ an M-matrix? Is it a non-singular one?

Solution. Take $s = 1$ and $\mathbf{B} = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right) \geq 0$, whose spectrum is $\{1, -1\}$, so $\rho(\mathbf{B}) = 1 = s$. By Lemma 18.9.2 (b) the matrix is an M-matrix but not a non-singular one. Directly: it sends $\mathbf{1}$ to $\mathbf{0}$.

The payoff of the lemma is already visible: for a Z-matrix, the leftmost point of the spectrum is a real eigenvalue, and being a (non-singular) M-matrix means precisely that this eigenvalue is non-negative (positive). The theorem below turns that into conditions that can be checked without finding any eigenvalue.

18.9.2 The characterization theorem

Deciding $s > \rho(\mathbf{B})$ directly means locating the eigenvalues of $\mathbf{B}$, which is the one computation we would like to avoid. The theorem gives three kinds of substitute: a certificate (one positive vector), a sign condition on the inverse, and a finite list of determinants. Its proof needs one small observation about certificates.

Lemma 18.9.3 — Test Vectors Survive Deletion

Let $\mathbf{A} \in M_n(\mathbb{R})$ be a Z-matrix, and let $\mathbf{x} \in \mathbb{R}^n$ satisfy $\mathbf{x} > \mathbf{0}$ and $\mathbf{Ax} > \mathbf{0}$. Let $S \subseteq [n]$ be non-empty, let $\mathbf{A}_{S,S}$ be the principal submatrix on rows and columns S (Definition 6.7.1), and let $\mathbf{x}_S$ be the vector of the entries x_j, $j \in S$, in increasing order of j. Then $\mathbf{A}_{S,S}$ is a Z-matrix, $\mathbf{x}_S > \mathbf{0}$ and $\mathbf{A}_{S,S}\mathbf{x}_S > \mathbf{0}$.

Idea. Deleting columns throws away only non-positive contributions to each row, so the surviving rows can only get more positive. That is the whole reason principal minors enter the story.

Proof. The off-diagonal entries of $\mathbf{A}_{S,S}$ are off-diagonal entries of $\mathbf{A}$, so they are ≤ 0, and $\mathbf{x}_S > \mathbf{0}$ because $\mathbf{x} > \mathbf{0}$. Let $i \in S$. The entry of $\mathbf{A}_{S,S}\mathbf{x}_S$ belonging to i is

$$\sum_{j \in S} a_{ij} x_j = (\mathbf{Ax})_i - \sum_{j \notin S} a_{ij} x_j \geq (\mathbf{Ax})_i > 0,$$

because each $j \notin S$ differs from $i \in S$, so $a_{ij} \leq 0$, while $x_j > 0$; every subtracted term is therefore ≤ 0. This proves the lemma.

■

Write $\mathbf{A}_k$ for the leading principal submatrix $\mathbf{A}_{[k],[k]}$, the top-left $k \times k$ corner, as in Sylvester's criterion (Theorem 12.1.5).

Theorem 18.9.4 — Characterizations of Non-singular M-Matrices

Let $\mathbf{A} \in M_n(\mathbb{R})$, $n \geq 1$, be a Z-matrix. The following are equivalent.

(a) $\mathbf{A}$ is a non-singular M-matrix.
(b) $\mathbf{A}$ is invertible and $\mathbf{A}^{-1} \geq 0$.
(c) There is $\mathbf{x} \in \mathbb{R}^n$ with $\mathbf{x} > \mathbf{0}$ and $\mathbf{A}\mathbf{x} > \mathbf{0}$.
(d) Every eigenvalue of $\mathbf{A}$ in $\mathbb{C}$ has positive real part.
(e) Every real eigenvalue of $\mathbf{A}$ is positive.
(f) Every principal minor of $\mathbf{A}$ is positive: $\det \mathbf{A}_{S,S} > 0$ for every non-empty $S \subseteq [n]$.
(g) Every leading principal minor of $\mathbf{A}$ is positive: $\det \mathbf{A}_k > 0$ for $k = 1, \ldots, n$.

Idea. Three loops, all passing through (a), (b) or (c).

① (a) ⇒ (b) ⇒ (c) ⇒ (a). The Neumann series writes $\mathbf{A}^{-1}$ as a sum of non-negative matrices. The vector $\mathbf{A}^{-1}\mathbf{1}$ is then a certificate for (c). And a certificate $\mathbf{x}$ bounds $\rho(\mathbf{B})$: rescaling the coordinates by $\mathbf{x}$ turns $\mathbf{B}\mathbf{x} < s\mathbf{x}$ into "every row sum is less than s", and Chapter 15 bounds a spectral radius by row sums.

② (a) ⇒ (d) ⇒ (e) ⇒ (a). This is Lemma 18.9.2 read three ways.

③ (c) ⇒ (f) ⇒ (g) ⇒ (b). A certificate survives deletion (Lemma 18.9.3), so every principal submatrix has a non-negative inverse by ①, and one cofactor of that inverse compares two nested minors. The way back from (g) is the induction of Sylvester's criterion: peel off the last row and column, and read the sign of every block of the inverse from Chapter 7's block inverse formula.

Proof. **(a) ⇒ (b).** By Lemma 18.9.2 (b), $\mathbf{A} = s\mathbf{I} - \mathbf{B}$ with $\mathbf{B} \geq 0$ and $s > \rho(\mathbf{B}) \geq 0$; in particular $s > 0$. Put $\mathbf{C} = s^{-1}\mathbf{B} \geq 0$. Its eigenvalues are the numbers μ/s, $\mu \in \operatorname{spec}(\mathbf{B})$, so $\rho(\mathbf{C}) = \rho(\mathbf{B})/s < 1$. By Theorem 9.10.6, $\mathbf{I} - \mathbf{C}$ is invertible and $(\mathbf{I} - \mathbf{C})^{-1} = \sum_{k \geq 0} \mathbf{C}^k$. Every partial sum $\sum_{k=0}^{K} \mathbf{C}^k$ is ≥ 0, since sums and products of non-negative matrices are non-negative; a non-strict inequality survives a limit (the algebra of limits quoted in Chapter 15's introduction), so $(\mathbf{I} - \mathbf{C})^{-1} \geq 0$. Hence $\mathbf{A} = s(\mathbf{I} - \mathbf{C})$ is invertible with $\mathbf{A}^{-1} = s^{-1}(\mathbf{I} - \mathbf{C})^{-1} \geq 0$.

(b) ⇒ (c). Put $\mathbf{x} = \mathbf{A}^{-1}\mathbf{1}$, so that $\mathbf{A}\mathbf{x} = \mathbf{1} > \mathbf{0}$. Each $x_i = \sum_j (\mathbf{A}^{-1})_{ij}$ is a sum of non-negative numbers, and it is 0 only if row i of $\mathbf{A}^{-1}$ is zero. That cannot happen: row i of $\mathbf{A}^{-1}\mathbf{A} = \mathbf{I}$ is $\mathbf{e}_i^{\top} \neq \mathbf{0}$. Hence $\mathbf{x} > \mathbf{0}$.

(c) ⇒ (a). Let $\mathbf{x} > \mathbf{0}$ with $\mathbf{A}\mathbf{x} > \mathbf{0}$. Choose $s \geq \max_i a_{ii}$, so that $\mathbf{B} = s\mathbf{I} - \mathbf{A} \geq 0$ by Lemma 18.9.1. Then $\mathbf{B}\mathbf{x} = s\mathbf{x} - \mathbf{A}\mathbf{x}$, so $(\mathbf{B}\mathbf{x})_i < s x_i$ for every i. Let $\mathbf{D} = \operatorname{diag}(x_1, \ldots, x_n)$, invertible because every $x_i > 0$. The matrix $\mathbf{D}^{-1}\mathbf{B}\mathbf{D}$ has entries $b_{ij}x_j/x_i \geq 0$, and its i-th row sum is $(\mathbf{B}\mathbf{x})_i/x_i < s$. By Corollary 15.4.2, $\rho(\mathbf{D}^{-1}\mathbf{B}\mathbf{D})$ is at most the largest of these row sums, so $\rho(\mathbf{D}^{-1}\mathbf{B}\mathbf{D}) < s$. Similar matrices have the same characteristic polynomial (Theorem 6.10.3), hence the same eigenvalues, so $\rho(\mathbf{B}) < s$. By Lemma 18.9.2 (b), $\mathbf{A}$ is a non-singular M-matrix.

(a) ⇒ (d). Write $\mathbf{A} = s\mathbf{I} - \mathbf{B}$ with $\mathbf{B} \geq 0$ and $s > \rho(\mathbf{B})$, by Lemma 18.9.2 (b). By part (a) of the same lemma, every $\lambda \in \operatorname{spec}(\mathbf{A})$ has $\operatorname{Re}\lambda \geq s - \rho(\mathbf{B}) > 0$.

(d) ⇒ (e). A real eigenvalue is its own real part.

(e) ⇒ (a). Write $\mathbf{A} = s\mathbf{I} - \mathbf{B}$ with $\mathbf{B} \geq 0$ (Lemma 18.9.1). By Lemma 18.9.2 (a), $s - \rho(\mathbf{B})$ is a real eigenvalue of $\mathbf{A}$, so it is positive by (e). Hence $s > \rho(\mathbf{B})$, and $\mathbf{A}$ is a non-singular M-matrix by part (b) of the lemma.

(c) ⇒ (f). Let $\mathbf{x} > \mathbf{0}$ with $\mathbf{Ax} > \mathbf{0}$. We show $\det \mathbf{A}_{S,S} > 0$ by induction on $k = |S|$. If $k = 1$, say $S = \{i\}$, then $a_{ii}x_i > 0$ by Lemma 18.9.3, so $\det \mathbf{A}_{S,S} = a_{ii} > 0$. Let $k \geq 2$, and suppose every principal minor of size $k-1$ is positive. Put $\mathbf{N} = \mathbf{A}_{S,S} \in M_k(\mathbb{R})$. By Lemma 18.9.3, $\mathbf{N}$ is a Z-matrix satisfying (c), so the implications (c) ⇒ (a) ⇒ (b), already proved for Z-matrices of every size, show that $\mathbf{N}$ is invertible with $\mathbf{N}^{-1} \geq 0$. In particular $\det \mathbf{N} \neq 0$ (Theorem 6.5.2). Deleting the last row and column of $\mathbf{N}$ leaves $\mathbf{A}_{S',S'}$, where S' is S without its largest element; so the (k,k) cofactor of $\mathbf{N}$ is $\det \mathbf{A}_{S',S'}$, which is positive by the induction hypothesis. By Corollary 6.6.3, $\mathbf{N}^{-1} = (\det \mathbf{N})^{-1} \operatorname{adj} \mathbf{N}$, whose (k,k)-entry is therefore

$$(\mathbf{N}^{-1})_{kk} = \frac{\det \mathbf{A}_{S',S'}}{\det \mathbf{N}}.$$

This number is ≥ 0 because $\mathbf{N}^{-1} \geq 0$, and non-zero because its numerator is. So it is positive, and $\det \mathbf{N} = \det \mathbf{A}_{S',S'} / (\mathbf{N}^{-1})_{kk} > 0$.

(f) ⇒ (g). A leading principal minor is the principal minor with $S = [k]$.

(g) ⇒ (b). By induction on n. If $n = 1$, then $\mathbf{A} = (a_{11})$ with $a_{11} = \det \mathbf{A}_1 > 0$, and $\mathbf{A}^{-1} = (1/a_{11}) \geq 0$. Let $n \geq 2$, and assume the implication for Z-matrices of size $n-1$. Partition

$$\mathbf{A} = \begin{pmatrix} \mathbf{A}_{n-1} & \mathbf{b} \\ \mathbf{c}^{\top} & a_{nn} \end{pmatrix}, \qquad \mathbf{b}, \mathbf{c} \in \mathbb{R}^{n-1}.$$

The corner $\mathbf{A}_{n-1}$ is a Z-matrix whose leading principal minors $\det \mathbf{A}_1, \dots, \det \mathbf{A}_{n-1}$ are positive, so by the induction hypothesis it is invertible with $\mathbf{A}_{n-1}^{-1} \geq 0$. The entries of $\mathbf{b}$ and $\mathbf{c}$ are off-diagonal entries of $\mathbf{A}$, so $\mathbf{b} \leq \mathbf{0}$ and $\mathbf{c} \leq \mathbf{0}$. By Theorem 7.3.2 (a), $\det \mathbf{A} = \det \mathbf{A}_{n-1} \cdot \sigma$, where $\sigma = a_{nn} - \mathbf{c}^{\top} \mathbf{A}_{n-1}^{-1} \mathbf{b}$ is the Schur complement of $\mathbf{A}_{n-1}$; since $\det \mathbf{A} > 0$ and $\det \mathbf{A}_{n-1} > 0$, $\sigma > 0$. By Theorem 7.3.4 (a), $\mathbf{A}$ is invertible and

$$\mathbf{A}^{-1} = \begin{pmatrix} \mathbf{A}_{n-1}^{-1} + \sigma^{-1} \mathbf{u}\mathbf{w}^{\top} & -\sigma^{-1}\mathbf{u} \\ -\sigma^{-1}\mathbf{w}^{\top} & \sigma^{-1} \end{pmatrix}, \qquad \mathbf{u} = \mathbf{A}_{n-1}^{-1}\mathbf{b}, \quad \mathbf{w}^{\top} = \mathbf{c}^{\top}\mathbf{A}_{n-1}^{-1}.$$

Now $\mathbf{u} \leq \mathbf{0}$, being a non-negative matrix times a non-positive vector, and likewise $\mathbf{w} \leq \mathbf{0}$. Hence $\mathbf{u}\mathbf{w}^{\top} \geq 0$, each of its entries being a product of two non-positive numbers, and $-\sigma^{-1}\mathbf{u} \geq \mathbf{0}$, $-\sigma^{-1}\mathbf{w} \geq \mathbf{0}$, $\sigma^{-1} > 0$. Every block of $\mathbf{A}^{-1}$ is therefore non-negative, so $\mathbf{A}^{-1} \geq 0$.

The three loops connect all seven conditions, which proves the theorem.

■

Each condition has its use. Condition (c) is a **certificate**: to prove that a given Z-matrix is a non-singular M-matrix, exhibit one positive vector and multiply. Condition (g) is a **finite test** of n determinants, the counterpart for Z-matrices of Sylvester's criterion for Hermitian matrices, and condition (b) is the **payoff**: $\mathbf{Ax} = \mathbf{b}$ with $\mathbf{b} \geq \mathbf{0}$ has exactly one solution, and it is $\geq \mathbf{0}$. Condition (d) links the theorem to differential equations: $-\mathbf{A}$ is stable, so the solutions of $\mathbf{x}' = -\mathbf{Ax}$ decay (exercise C3).

Remark. The two determinant conditions need the Z-hypothesis, and they need **strict** positivity. The matrix $\left(\begin{smallmatrix} 1 & 2 \\ 0 & 1 \end{smallmatrix}\right)$ has all three principal minors equal to 1, but it is not a Z-matrix and its inverse $\left(\begin{smallmatrix} 1 & -2 \\ 0 & 1 \end{smallmatrix}\right)$ has a negative entry. And the Z-matrix $\left(\begin{smallmatrix} 0 & -1 \\ 0 & -1 \end{smallmatrix}\right)$ has

leading principal minors 0 and 0, both non-negative, but its eigenvalue -1 shows it is not an M-matrix of any kind (exercise C2).

Remark. **Stated, not proved.** There is a companion statement for M-matrices that may be singular: *a Z-matrix is an M-matrix if and only if every principal minor is non-negative.* Exercise C2 proves the forward direction by a limiting argument; the converse is not proved in this book and is used nowhere. Longer lists of equivalent conditions exist in the literature; the seven above are the ones proved here.

Warning. **A non-negative inverse does not make a matrix a Z-matrix, and so does not make it an M-matrix.** Condition (b) characterizes non-singular M-matrices only **among Z-matrices**. Take

$$\mathbf{W} = \begin{pmatrix} 1 & -1 & 1 \\ 1 & 1 & -1 \\ -1 & 1 & 1 \end{pmatrix}, \qquad \mathbf{W}^{-1} = \frac{1}{2}\begin{pmatrix} 1 & 1 & 0 \\ 0 & 1 & 1 \\ 1 & 0 & 1 \end{pmatrix} \geq 0.$$

Multiplying out confirms $\mathbf{W}\mathbf{W}^{-1} = \mathbf{I}$: for instance row 1 of $\mathbf{W}$ against the columns of $2\mathbf{W}^{-1}$ gives $1-0+1=2$, $1-1+0=0$ and $0-1+1=0$. The diagonal of $\mathbf{W}$ is positive, its principal minors are $1, 1, 1, 2, 2, 2, 4$, $\mathbf{W}\mathbf{1} = \mathbf{1} > \mathbf{0}$, and its eigenvalues 1 and $1 \pm i\sqrt{3}$ have positive real parts. So $\mathbf{W}$ satisfies every one of (b)–(g), yet $w_{13} = 1 > 0$: it is not a Z-matrix, and not an M-matrix.

Quick check. Let $\mathbf{A} = \left(\begin{smallmatrix} a & -b \\ -c & d \end{smallmatrix}\right)$ with $b, c \geq 0$. Use the theorem to write down exactly when $\mathbf{A}$ is a non-singular M-matrix, and explain why the condition $d > 0$ need not be listed.

Solution. $\mathbf{A}$ is a Z-matrix, so by (g) it is a non-singular M-matrix if and only if $a > 0$ and $ad - bc > 0$. Then $ad > bc \geq 0$ and $a > 0$ force $d > 0$; so condition (f), which also asks for $d > 0$, adds nothing, as the theorem says it cannot.

A symmetric Z-matrix has one more characterization, because condition (g) is Sylvester's criterion word for word.

Corollary 18.9.5 — Symmetric M-Matrices Are Positive Definite

A symmetric Z-matrix $\mathbf{A} \in M_n(\mathbb{R})$ is a non-singular M-matrix if and only if $\mathbf{A} \succ 0$.

Proof. By Theorem 18.9.4, $\mathbf{A}$ is a non-singular M-matrix if and only if $\det \mathbf{A}_k > 0$ for every k. By Sylvester's criterion, Theorem 12.1.5 (d), a real symmetric matrix satisfies this if and only if $\mathbf{A} \succ 0$. ∎

The Z-hypothesis cannot be dropped here either: $\left(\begin{smallmatrix} 2 & 1 \\ 1 & 2 \end{smallmatrix}\right) \succ 0$, but its inverse $\frac{1}{3}\left(\begin{smallmatrix} 2 & -1 \\ -1 & 2 \end{smallmatrix}\right)$ has negative entries. Entrywise order and the Loewner order answer different questions, and the corollary is a place where they meet.

18.9.3 The second-difference matrix

The first application is the one that gave M-matrices their importance. To solve $-u''(t) = f(t)$ on $[0,1]$ with $u(0) = u(1) = 0$, choose n, put $h = 1/(n+1)$ and $t_i = ih$, and replace $u(t_i)$ by an unknown u_i and $-u''(t_i)$ by the second difference $(2u_i - u_{i-1} - u_{i+1})/h^2$, with $u_0 = u_{n+1} = 0$. The equations become

$$\frac{1}{h^2}\mathbf{K}_n\mathbf{u} = \mathbf{f}, \qquad \mathbf{K}_n = \begin{pmatrix} 2 & -1 & & \\ -1 & 2 & \ddots & \\ & \ddots & \ddots & -1 \\ & & -1 & 2 \end{pmatrix} \in M_n(\mathbb{R}),$$

where $\mathbf{f} = (f(t_1), \dots, f(t_n))$. Physically u is the sag of a string under the load f, and a load pushing everywhere in one direction should never make any part of the string move the other way. In matrix language: $\mathbf{K}_n^{-1}$ should be non-negative.

$\mathbf{K}_n$ is a Z-matrix, but the obvious certificate fails. Its rows sum to $1, 0, \dots, 0, 1$, so $\mathbf{K}_n\mathbf{1}$ has zero entries once $n \geq 3$: the matrix is diagonally dominant, but only weakly. The continuous problem suggests a better test vector. The function $u(t) = t(1-t)$ solves $-u'' = 2$ with zero boundary values, so try its samples, scaled to be integers.

Proposition 18.9.6 — The Second-Difference Matrix

Let $n \geq 1$. Then $\mathbf{K}_n$ is a non-singular M-matrix, and its inverse is the matrix with entries

$$(\mathbf{K}_n^{-1})_{ij} = \frac{\min(i,j)\,\big(n+1-\max(i,j)\big)}{n+1}, \qquad 1 \leq i, j \leq n.$$

In particular every entry of $\mathbf{K}_n^{-1}$ is positive.

Idea. For the M-matrix property, feed $\mathbf{K}_n$ the vector $x_i = i(n+1-i)$, a sampled parabola: second differences of a quadratic are constant, so $\mathbf{K}_n\mathbf{x} = 2\mathbf{1}$. For the inverse, guess column j from the continuous picture: the response to a point load at t_j is a tent, linear on each side of j and zero at both ends. The second difference of a function that is linear on each side of j vanishes except at the kink, and there it equals the change in slope.

Proof. The certificate. Put $x_i = i(n+1-i)$ for $0 \leq i \leq n+1$, so that $x_0 = x_{n+1} = 0$ and $x_i > 0$ for $1 \leq i \leq n$. For $1 \leq i \leq n$, the i-th entry of $\mathbf{K}_n\mathbf{x}$ is $2x_i - x_{i-1} - x_{i+1}$, where the terms x_0 and x_{n+1}, which do not occur in rows 1 and n, are zero anyway. Writing $x_i = (n+1)i - i^2$, the linear part contributes $(n+1)(2i - (i-1) - (i+1)) = 0$, and the quadratic part contributes

$$-2i^2 + (i-1)^2 + (i+1)^2 = 2.$$

So $\mathbf{K}_n\mathbf{x} = 2\mathbf{1} > \mathbf{0}$ with $\mathbf{x} > \mathbf{0}$, and Theorem 18.9.4, (c) $\Rightarrow$ (a), shows that $\mathbf{K}_n$ is a non-singular M-matrix.

The inverse. Let $\mathbf{G}$ be the matrix given by the formula, fix a column j, and put

$g_i = \min(i,j)(n+1-\max(i,j))/(n+1)$ for $0 \le i \le n+1$. Then

$$g_i = \begin{cases} i\,\dfrac{n+1-j}{n+1} & (0 \le i \le j), \\ j\,\dfrac{n+1-i}{n+1} & (j \le i \le n+1), \end{cases}$$

the two lines agreeing at $i = j$. So $g_0 = g_{n+1} = 0$, and (g_i) is an affine function of i on $0 \le i \le j$, with slope $(n+1-j)/(n+1)$, and on $j \le i \le n+1$, with slope $-j/(n+1)$. For $1 \le i \le n$, entry i of $\mathbf{K}_n$ times column j of $\mathbf{G}$ is $2g_i - g_{i-1} - g_{i+1} = (g_i - g_{i-1}) - (g_{i+1} - g_i)$. If $i < j$ or $i > j$, the three points $i-1, i, i+1$ lie on one side of j, both differences are the same slope, and the entry is 0. If $i = j$, it is

$$\frac{n+1-j}{n+1} - \left(-\frac{j}{n+1}\right) = 1.$$

Hence $\mathbf{K}_n\mathbf{G} = \mathbf{I}$, so $\mathbf{G} = \mathbf{K}_n^{-1}$. Finally $\min(i,j) \ge 1$ and $n+1-\max(i,j) \ge 1$, so every entry is at least $1/(n+1) > 0$.

■

The matrix $\mathbf{K}_n^{-1}$ is a **discrete Green's function**: column j is the sag produced by a unit load at the single point t_j, and positivity of every entry says that a load at one point moves every point of the string, in the same direction. The non-negativity of $\mathbf{K}_n^{-1}$ is the discrete **maximum principle**: if $\mathbf{K}_n\mathbf{u} \ge \mathbf{0}$ then $\mathbf{u} \ge \mathbf{0}$. Since $\mathbf{K}_n$ is symmetric, Corollary 18.9.5 also shows $\mathbf{K}_n \succ 0$, which Chapter 6 foreshadowed by computing $\det \mathbf{K}_n = n+1$ in Exercise (B2: The second-difference matrix).

Example. (The Case n = 4)

Write down $\mathbf{K}_4^{-1}$, check one column against $\mathbf{K}_4$, and recover the certificate $\mathbf{x}$ from it.

Solution. With $n+1 = 5$, Proposition 18.9.6 gives

$$\mathbf{K}_4^{-1} = \frac{1}{5}\begin{pmatrix} 4 & 3 & 2 & 1 \\ 3 & 6 & 4 & 2 \\ 2 & 4 & 6 & 3 \\ 1 & 2 & 3 & 4 \end{pmatrix}.$$

Check of column 2. $\mathbf{K}_4$ applied to $(3,6,4,2)$ gives $(6-6,\ -3+12-4,\ -6+8-2,\ -4+4) = (0,5,0,0)$, and dividing by 5 gives $\mathbf{e}_2$, as it must. Each column is a tent: column 2 rises by 3 per step up to row 2 and then falls by 2 per step towards the zero at the fictitious row 5.

The certificate. The row sums of $5\mathbf{K}_4^{-1}$ are $10, 15, 15, 10$, so $\mathbf{K}_4^{-1}\mathbf{1} = (2,3,3,2)$, which is $\frac{1}{2}(1\cdot 4, 2\cdot 3, 3\cdot 2, 4\cdot 1) = \frac{1}{2}\mathbf{x}$. This is the proof of (b) $\Rightarrow$ (c) run backwards: the vector $\mathbf{A}^{-1}\mathbf{1}$ is always a certificate, and here it is the sampled parabola.

18.9.4 The Leontief input–output model

The second application comes from economics. An economy has n sectors, each producing one good. To produce one unit of good j, sector j consumes $c_{ij} \geq 0$ units of good i, so column j of the **consumption matrix** $\mathbf{C} = (c_{ij}) \geq 0$ is sector j's recipe. A production plan $\mathbf{x} \geq \mathbf{0}$ uses up $\mathbf{Cx}$ as inputs and leaves the net output $\mathbf{x} - \mathbf{Cx}$ for outside use. Given a final demand $\mathbf{d} \geq \mathbf{0}$, the planner needs

$$(\mathbf{I} - \mathbf{C})\mathbf{x} = \mathbf{d}, \qquad \mathbf{x} \geq \mathbf{0}.$$

The economy is **productive** if this has a solution for **every** $\mathbf{d} \geq \mathbf{0}$. The matrix $\mathbf{I} - \mathbf{C}$ is a Z-matrix, and the theorem answers the question completely.

Corollary 18.9.7 — Productive Economies

Let $\mathbf{C} \in M_n(\mathbb{R})$ with $\mathbf{C} \geq 0$. The following are equivalent.

(i) For every $\mathbf{d} \geq \mathbf{0}$ there is $\mathbf{x} \geq \mathbf{0}$ with $(\mathbf{I} - \mathbf{C})\mathbf{x} = \mathbf{d}$.

(ii) There is $\mathbf{x} \geq \mathbf{0}$ with $\mathbf{x} - \mathbf{Cx} > \mathbf{0}$: some plan leaves a surplus of every good.

(iii) $\rho(\mathbf{C}) < 1$.

(iv) $\mathbf{I} - \mathbf{C}$ is invertible and $(\mathbf{I} - \mathbf{C})^{-1} \geq 0$.

(v) Every leading principal minor of $\mathbf{I} - \mathbf{C}$ is positive.

When they hold, the solution in (i) is unique, and $(\mathbf{I} - \mathbf{C})^{-1} = \mathbf{I} + \mathbf{C} + \mathbf{C}^2 + \cdots$. They hold in particular when every column sum of $\mathbf{C}$ is less than 1.

Idea. The matrix $\mathbf{I} - \mathbf{C}$ is a Z-matrix, so this is the main theorem read in economic terms: (iii) is (a) with $s = 1$; (ii), (iv) and (v) are (c), (b) and (g), where in (ii) a plan $\mathbf{x} \geq \mathbf{0}$ with a surplus is automatically positive, since $\mathbf{x} > \mathbf{Cx} \geq \mathbf{0}$; and (i) sits between (iv) and (ii).

Proof. $\mathbf{I} - \mathbf{C}$ is a Z-matrix with the representation $s = 1$, $\mathbf{B} = \mathbf{C}$, so (iii) says, by Lemma 18.9.2 (b), that $\mathbf{I} - \mathbf{C}$ is a non-singular M-matrix. By Theorem 18.9.4, (iii) is therefore equivalent to (iv) (condition (b) there) and to (v) (condition (g)). It is also equivalent to (ii): if $\mathbf{x} \geq \mathbf{0}$ and $\mathbf{x} - \mathbf{Cx} > \mathbf{0}$, then $\mathbf{x} > \mathbf{Cx} \geq \mathbf{0}$, so $\mathbf{x} > \mathbf{0}$ and condition (c) of the theorem holds; conversely (c) supplies such an $\mathbf{x}$.

(iv) $\Rightarrow$ (i): given $\mathbf{d} \geq \mathbf{0}$, the vector $\mathbf{x} = (\mathbf{I} - \mathbf{C})^{-1}\mathbf{d}$ is a product of non-negative factors, hence $\geq \mathbf{0}$, and it solves the system. (i) $\Rightarrow$ (ii): take $\mathbf{d} = \mathbf{1}$.

When they hold, $\mathbf{I} - \mathbf{C}$ is invertible, so the solution is unique, and $\rho(\mathbf{C}) < 1$ gives the series by Theorem 9.10.6. Finally, if every column sum of $\mathbf{C}$ is less than 1, then $\rho(\mathbf{C}) \leq \|\mathbf{C}\|_1 < 1$ by Corollary 15.4.2, which is (iii). ∎

Condition (v) is known to economists as the Hawkins–Simon condition, and the series has a direct reading. To deliver $\mathbf{d}$, the economy must first produce $\mathbf{d}$; that production consumes $\mathbf{Cd}$, which must also be produced; that consumes $\mathbf{C}^2\mathbf{d}$; and so on. The Leontief inverse $(\mathbf{I} - \mathbf{C})^{-1}$ adds up all the rounds, and its (i, j)-entry is the total amount of good i that the economy must produce, directly and indirectly, to deliver one unit of good j.

Example. (Three Sectors)

An economy has three sectors, agriculture, manufacturing and services, with consumption matrix

$$\mathbf{C} = \frac{1}{5}\begin{pmatrix} 1 & 1 & 1 \\ 2 & 0 & 1 \\ 0 & 2 & 1 \end{pmatrix}.$$

Show that it is productive, find $\rho(\mathbf{C})$ exactly, compute the Leontief inverse, and find the production plan meeting the demand $\mathbf{d} = (12, 6, 6)$.

Solution. Productive. Every column of $5\mathbf{C}$ sums to 3, so every column sum of $\mathbf{C}$ is $\frac{3}{5} < 1$, and Corollary 18.9.7 applies.

The spectral radius. Expanding $\det(x\mathbf{I} - \mathbf{C})$ along the first row gives

$$p_{\mathbf{C}}(x) = x^3 - \tfrac{2}{5}x^2 - \tfrac{3}{25}x = x\big(x - \tfrac{3}{5}\big)\big(x + \tfrac{1}{5}\big),$$

so $\operatorname{spec}(\mathbf{C}) = \{0, \frac{3}{5}, -\frac{1}{5}\}$ and $\rho(\mathbf{C}) = \frac{3}{5}$, equal to the column-sum bound $\|\mathbf{C}\|_1$ of Corollary 15.4.2. The bound is attained because all column sums are equal: $\mathbf{C}^{\top}\mathbf{1} = \frac{3}{5}\mathbf{1}$.

The Leontief inverse. Here $\mathbf{I} - \mathbf{C} = \frac{1}{5}\left(\begin{smallmatrix} 4 & -1 & -1 \\ -2 & 5 & -1 \\ 0 & -2 & 4 \end{smallmatrix}\right)$, and

$$(\mathbf{I} - \mathbf{C})^{-1} = \frac{1}{6}\begin{pmatrix} 9 & 3 & 3 \\ 4 & 8 & 3 \\ 2 & 4 & 9 \end{pmatrix}.$$

To check, multiply $\left(\begin{smallmatrix} 4 & -1 & -1 \\ -2 & 5 & -1 \\ 0 & -2 & 4 \end{smallmatrix}\right)$ by $\left(\begin{smallmatrix} 9 & 3 & 3 \\ 4 & 8 & 3 \\ 2 & 4 & 9 \end{smallmatrix}\right)$: the first row gives $36-4-2 = 30$, $12-8-4 = 0$, $12-3-9 = 0$; the second $-18+20-2 = 0$, $-6+40-4 = 30$, $-6+15-9 = 0$; the third $-8+8 = 0$, $-16+16 = 0$, $-6+36 = 30$. The product is $30\mathbf{I}$, and $\frac{1}{5}\cdot\frac{1}{6}\cdot 30 = 1$. Every entry of the inverse is positive: extra demand for any one good raises the output of every sector. For instance, one extra unit of services requires $\frac{1}{2}$ unit of agricultural output in total, although services consume only $\frac{1}{5}$ unit of it directly.

The plan.

$$\mathbf{x} = (\mathbf{I} - \mathbf{C})^{-1}\mathbf{d} = \frac{1}{6}\begin{pmatrix} 108 + 18 + 18 \\ 48 + 48 + 18 \\ 24 + 24 + 54 \end{pmatrix} = \begin{pmatrix} 24 \\ 19 \\ 17 \end{pmatrix}.$$

Check: $\mathbf{C}\mathbf{x} = \frac{1}{5}(24{+}19{+}17,\ 48{+}17,\ 38{+}17) = (12, 13, 11)$, and $\mathbf{x} - \mathbf{C}\mathbf{x} = (12, 6, 6) = \mathbf{d}$. Delivering this demand takes 24 units of agricultural output, twice the 12 that leave the economy.

Quick check. A two-sector economy has $\mathbf{C} = \left(\begin{smallmatrix} 1/2 & 1 \\ 1/2 & 0 \end{smallmatrix}\right)$. Is it productive?

Solution. No. The leading principal minors of $\mathbf{I} - \mathbf{C} = \left(\begin{smallmatrix} 1/2 & -1 \\ -1/2 & 1 \end{smallmatrix}\right)$ are $\frac{1}{2}$ and $\frac{1}{2} - \frac{1}{2} = 0$, so (v) of Corollary 18.9.7 fails. Indeed $\mathbf{C}\left(\begin{smallmatrix} 2 \\ 1 \end{smallmatrix}\right) = \left(\begin{smallmatrix} 2 \\ 1 \end{smallmatrix}\right)$: running the sectors in the ratio $2:1$ exactly reproduces its own inputs and leaves nothing over, and $\rho(\mathbf{C}) = 1$.

18.9.5 Summary and transfer

The chapter set out to explain what the sign of the entries alone forces on the spectrum. For a positive matrix the answer is Perron's theorem (§01, Positive matrices and Perron's theorem): the spectral radius is a simple eigenvalue with a positive eigenvector, and it strictly dominates every other eigenvalue in modulus. Irreducibility, a property of the zero pattern read off a directed graph (§02, Irreducibility and graphs), is what keeps most of that conclusion alive when zeros are allowed (§03, The Perron–Frobenius theorem), and without it one still has $\rho(\mathbf{B})$ as an eigenvalue with a non-negative eigenvector. From there the chapter drew the long-run behavior of powers (§05, Primitive matrices), Markov chains (§06, Markov chains), the extreme points of the doubly stochastic matrices (§07, Birkhoff's theorem), a ranking of web pages (§08, PageRank), and in this section the matrices $s\mathbf{I} - \mathbf{B}$. Six moves did the work.

- **Compare entrywise, then take the spectral radius.** Non-negativity makes the spectral radius monotone and lets $|\mathbf{Ax}| \leq |\mathbf{A}||\mathbf{x}|$ replace cancellation by an inequality (§01, Positive matrices and Perron's theorem). *Transfer:* to bound the spectral radius of a matrix you do not understand, dominate it entrywise by one you do.
- **A positive test vector bounds ρ from both sides.** The ratios $(\mathbf{Ax})_i/x_i$ for a single $\mathbf{x} > \mathbf{0}$ trap $\rho(\mathbf{A})$ between their minimum and maximum (§04, The Collatz–Wielandt formula), and in this section one $\mathbf{x} > \mathbf{0}$ with $\mathbf{Ax} > \mathbf{0}$ certified a non-singular M-matrix. The mechanism used here is the rescaling $\mathbf{D}^{-1}\mathbf{BD}$ with $\mathbf{D} = \operatorname{diag}(\mathbf{x})$, which turns $\mathbf{Bx}$ into row sums. *Transfer:* guess a positive vector from the structure of the problem, the parabola for $\mathbf{K}_n$, and verify it by one multiplication.
- **Read the zero pattern as a graph.** Which entries of $\mathbf{A}^k$ are positive depends only on which entries of $\mathbf{A}$ are, and that is a question about paths (§02, Irreducibility and graphs; §05, Primitive matrices). *Transfer:* when only signs matter, draw the graph and count paths.
- **Prove it for positive matrices, then reach the boundary.** Perron's theorem is proved where every entry is positive, and the non-negative and irreducible cases are reached from it through positive matrices built from $\mathbf{A}$ (§03, The Perron–Frobenius theorem). *Transfer:* when a hypothesis is an inequality that may hold with equality, prove the strict case and ask what survives the passage to the boundary; $s > \rho(\mathbf{B})$ versus $s \geq \rho(\mathbf{B})$ in this section is the same division.
- **Divide by the Perron root, then use Chapter 9.** Once $\rho(\mathbf{A})$ is known to be a simple eigenvalue dominating the others, $\mathbf{A}/\rho(\mathbf{A})$ meets the hypotheses of the convergence theorems of Chapter 9 §10, and no diagonalizability is ever needed (§05, Primitive matrices; §06, Markov chains). *Transfer:* normalize the dominant eigenvalue to 1 before asking about limits.
- **Invert with a series of non-negative terms.** If $\mathbf{B} \geq 0$ and $\rho(\mathbf{B}) < 1$, then $(\mathbf{I}-\mathbf{B})^{-1} = \sum_k \mathbf{B}^k \geq 0$. This is the fundamental matrix of an absorbing chain (§06, Markov chains), the Leontief inverse, and the non-negativity of the inverse of every non-singular M-matrix. *Transfer:* to prove that an inverse is non-negative, or to interpret its entries, expand it as the sum of the rounds of a process.

The chapter also paid promises made in earlier chapters.

The promise	Made in	Paid by
"Chapter 18 proves the Perron–Frobenius theorem, which gives the conclusions of Theorem 8.11.4 for every stochastic matrix with some power having all entries positive, without assuming diagonalizability and without computing eigenvalues"	Chapter 8 §11	§06 (Stochastic matrices and Markov chains), resting on §03 (The Perron–Frobenius theorem) and §05 (Primitive matrices and the limit theorem)
"We do not prove Birkhoff's theorem here; Chapter 18 does"	Chapter 17 §08, and again in its summary, §11	§07 (Doubly stochastic matrices and Birkhoff's theorem)

Some things the chapter did not do. The characterization of possibly singular M-matrices by non-negative principal minors was stated here and proved in one direction only. The theorem of Hardy, Littlewood and Pólya, that $\mathbf{x} \prec \mathbf{y}$ exactly when $\mathbf{x} = \mathbf{D}\mathbf{y}$ for a doubly stochastic $\mathbf{D}$, belongs to Chapter 20. And the power method, the algorithm that computes a Perron vector at the size of the web, belongs to Chapter 23.

18.9.6 Exercises

18.9.6.1 A. Check your understanding

Exercise A1.

(a) Define a Z-matrix and a non-singular M-matrix.

(b) True or false: every Z-matrix with positive diagonal entries is a non-singular M-matrix. Justify your answer.

(c) True or false: every principal submatrix of a non-singular M-matrix is a non-singular M-matrix. Justify your answer.

(d) True or false: if $\mathbf{A}$ is invertible and $\mathbf{A}^{-1} \geq 0$, then $\mathbf{A}$ is an M-matrix. Justify your answer.

(e) True or false: the inverse of a non-singular M-matrix has every entry positive. Justify your answer.

(f) Name a vector $\mathbf{x} > \mathbf{0}$ with $\mathbf{K}_n\mathbf{x} > \mathbf{0}$, and explain why $\mathbf{x} = \mathbf{1}$ does not work when $n \geq 3$.

Solution.

(a) $\mathbf{A} \in M_n(\mathbb{R})$ is a Z-matrix if $a_{ij} \leq 0$ for all $i \neq j$ (Definition 18.9.1). It is a non-singular M-matrix if $\mathbf{A} = s\mathbf{I} - \mathbf{B}$ with $\mathbf{B} \geq 0$ and $s \geq \rho(\mathbf{B})$, and $\mathbf{A}$ is invertible; equivalently, $s > \rho(\mathbf{B})$ (Definition 18.9.2, Lemma 18.9.2 (b)).

(b) False. $\left(\begin{smallmatrix} 1 & -2 \\ -2 & 1 \end{smallmatrix}\right)$ is a Z-matrix with positive diagonal, but its determinant is $1 - 4 = -3$, so condition (g) of Theorem 18.9.4 fails.

(c) True. Let $\mathbf{A}$ be a non-singular M-matrix. By Theorem 18.9.4 there is $\mathbf{x} > \mathbf{0}$ with $\mathbf{A}\mathbf{x} > \mathbf{0}$. By Lemma 18.9.3, $\mathbf{A}_{S,S}$ is a Z-matrix with $\mathbf{A}_{S,S}\mathbf{x}_S > \mathbf{0}$ and $\mathbf{x}_S > \mathbf{0}$, so

it is a non-singular M-matrix by (c) $\Rightarrow$ (a) of the theorem.

(d) False. The swap $\mathbf{P} = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$ satisfies $\mathbf{P}^{-1} = \mathbf{P} \geq 0$, but $p_{12} = 1 > 0$, so $\mathbf{P}$ is not a Z-matrix, and every M-matrix is one.

(e) False. $\mathbf{I}_2$ is a non-singular M-matrix, and $\mathbf{I}_2^{-1} = \mathbf{I}_2$ has zero off-diagonal entries.

(f) $x_i = i(n+1-i)$, for which $\mathbf{K}_n\mathbf{x} = 2\mathbf{1}$ (Proposition 18.9.6). For $\mathbf{x} = \mathbf{1}$, row i of $\mathbf{K}_n\mathbf{1}$ is $2 - 1 - 1 = 0$ for every $2 \leq i \leq n-1$, and such rows exist when $n \geq 3$.

18.9.6.2 B. Practice

Exercise B1: Which are non-singular M-matrices?.

Determine which of the following are non-singular M-matrices. Justify your answer.

(a) $\begin{pmatrix} 3 & -1 & -1 \\ -1 & 3 & -1 \\ -1 & -1 & 3 \end{pmatrix}$

(b) $\begin{pmatrix} 1 & -1 & 0 \\ -1 & 2 & -1 \\ 0 & -1 & 1 \end{pmatrix}$

(c) $\begin{pmatrix} 2 & -3 \\ -1 & 2 \end{pmatrix}$

(d) $\begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix}$

(e) $\begin{pmatrix} 1 & -2 & 0 \\ 0 & 1 & -2 \\ -2 & 0 & 1 \end{pmatrix}$

Solution.

(a) Yes. It is a Z-matrix, and every row sums to 1, so $\mathbf{x} = \mathbf{1} > \mathbf{0}$ gives $\mathbf{A}\mathbf{x} = \mathbf{1} > \mathbf{0}$. By Theorem 18.9.4, (c) $\Rightarrow$ (a), it is a non-singular M-matrix. (Its inverse is $\frac{1}{4}\left(\begin{smallmatrix} 2 & 1 & 1 \\ 1 & 2 & 1 \\ 1 & 1 & 2 \end{smallmatrix}\right) \geq 0$, as (b) predicts.)

(b) No. Every row sums to 0, so $\mathbf{A}\mathbf{1} = \mathbf{0}$ and $\mathbf{A}$ is singular. (It is a singular M-matrix: with $s = 2$, $\mathbf{B} = 2\mathbf{I} - \mathbf{A}$ has every row sum equal to 2, so $\rho(\mathbf{B}) \leq 2$ by Corollary 15.4.2, while $\mathbf{B}\mathbf{1} = 2\mathbf{1}$ gives $\rho(\mathbf{B}) \geq 2$.)

(c) Yes. It is a Z-matrix with leading principal minors $2 > 0$ and $4 - 3 = 1 > 0$, so (g) $\Rightarrow$ (a) applies. Check: $\mathbf{A}^{-1} = \left(\begin{smallmatrix} 2 & 3 \\ 1 & 2 \end{smallmatrix}\right) \geq 0$.

(d) No. The off-diagonal entries are $1 > 0$, so it is not a Z-matrix. (It is positive definite, and its inverse $\frac{1}{3}\left(\begin{smallmatrix} 2 & -1 \\ -1 & 2 \end{smallmatrix}\right)$ has negative entries.)

(e) No. It is a Z-matrix, but expanding along the first row,

$$\det \mathbf{A} = 1 \cdot (1 - 0) - (-2) \cdot (0 - 4) + 0 = 1 - 8 = -7 < 0,$$

so condition (f) of Theorem 18.9.4 fails.

Exercise B2: A string with a free end.

Let

$$\mathbf{A} = \begin{pmatrix} 2 & -1 & 0 \\ -1 & 2 & -1 \\ 0 & -1 & 1 \end{pmatrix}.$$

(a) Show that $\mathbf{A1}$ is not positive, and find $\mathbf{x} > \mathbf{0}$ with $\mathbf{Ax} > \mathbf{0}$.

(b) Compute the leading principal minors of $\mathbf{A}$, and check that they agree with (a).

(c) Compute $\mathbf{A}^{-1}$ and check that $\mathbf{A}^{-1} \geq 0$. Hence solve $\mathbf{Au} = \mathbf{e}_3$, and say why the answer had to be non-negative.

Hint: try an increasing $\mathbf{x}$ *whose increments decrease.*

Solution.

(a) $\mathbf{A1} = (1, 0, 0)$, which is not positive. Take $\mathbf{x} = (3, 5, 6)$: then $\mathbf{Ax} = (6 - 5,\ -3 + 10 - 6,\ -5 + 6) = (1, 1, 1) > \mathbf{0}$. Since $\mathbf{A}$ is a Z-matrix, it is a non-singular M-matrix by Theorem 18.9.4, (c) $\Rightarrow$ (a).

(b) $\det \mathbf{A}_1 = 2$, $\det \mathbf{A}_2 = 4 - 1 = 3$, and, expanding along the first row, $\det \mathbf{A} = 2(2 - 1) - (-1)(-1 - 0) = 2 - 1 = 1$. All three are positive, which is condition (g), as (a) and the theorem require.

(c)

$$\mathbf{A}^{-1} = \begin{pmatrix} 1 & 1 & 1 \\ 1 & 2 & 2 \\ 1 & 2 & 3 \end{pmatrix},$$

the matrix with entries $\min(i, j)$. Check: row 1 of $\mathbf{A}$ against the columns gives $2 - 1 = 1$, $2 - 2 = 0$, $2 - 2 = 0$; row 2 gives $-1 + 2 - 1 = 0$, $-1 + 4 - 2 = 1$, $-1 + 4 - 3 = 0$; row 3 gives $-1 + 1 = 0$, $-2 + 2 = 0$, $-2 + 3 = 1$. So $\mathbf{AA}^{-1} = \mathbf{I}$, and $\mathbf{A}^{-1} \geq 0$. Hence $\mathbf{u} = \mathbf{A}^{-1}\mathbf{e}_3 = (1, 2, 3)$. It had to be $\geq \mathbf{0}$ because $\mathbf{e}_3 \geq \mathbf{0}$ and $\mathbf{A}^{-1} \geq 0$. Note that $\mathbf{A}^{-1}\mathbf{1} = (3, 5, 6)$ is the certificate of (a).

Exercise B3: A two-sector economy.

Let

$$\mathbf{C} = \begin{pmatrix} 1/5 & 2/5 \\ 3/10 & 1/10 \end{pmatrix}.$$

(a) Show that the economy with consumption matrix $\mathbf{C}$ is productive.

(b) Compute the Leontief inverse $(\mathbf{I} - \mathbf{C})^{-1}$.

(c) Find the production plan meeting the demand $\mathbf{d} = (30, 60)$, and check it.

(d) Find $\rho(\mathbf{C})$ exactly.

Solution.

(a) The column sums are $\frac{1}{5} + \frac{3}{10} = \frac{1}{2}$ and $\frac{2}{5} + \frac{1}{10} = \frac{1}{2}$, both less than 1, so the economy is productive by Corollary 18.9.7.

(b) $\mathbf{I}-\mathbf{C}=\left(\begin{smallmatrix}4/5 & -2/5\\ -3/10 & 9/10\end{smallmatrix}\right)$, with determinant $\frac{36}{50}-\frac{6}{50}=\frac{3}{5}$. By Theorem 0.9.8,

$$(\mathbf{I}-\mathbf{C})^{-1}=\frac{5}{3}\begin{pmatrix}9/10 & 2/5\\ 3/10 & 4/5\end{pmatrix}=\begin{pmatrix}3/2 & 2/3\\ 1/2 & 4/3\end{pmatrix}\geq 0.$$

(c) $\mathbf{x}=(\frac{3}{2}\cdot 30+\frac{2}{3}\cdot 60,\ \frac{1}{2}\cdot 30+\frac{4}{3}\cdot 60)=(85,95)$. Check: $\mathbf{C}\mathbf{x}=(17+38,\ \frac{51}{2}+\frac{19}{2})=(55,35)$, and $\mathbf{x}-\mathbf{C}\mathbf{x}=(30,60)$.

(d) $p_{\mathbf{C}}(x)=x^2-\frac{3}{10}x+\left(\frac{1}{50}-\frac{12}{100}\right)=x^2-\frac{3}{10}x-\frac{1}{10}=(x-\frac{1}{2})(x+\frac{1}{5})$. So $\operatorname{spec}(\mathbf{C})=\{\frac{1}{2},-\frac{1}{5}\}$ and $\rho(\mathbf{C})=\frac{1}{2}$. Here the column-sum bound $\|\mathbf{C}\|_1=\frac{1}{2}$ is attained, as it must be when all column sums are equal.

18.9.6.3 C. Going deeper

Exercise C1: Raising the diagonal.

(a) Let $\mathbf{A}$ be a non-singular M-matrix and $\mathbf{M}$ a Z-matrix of the same size with $\mathbf{M}\geq\mathbf{A}$ entrywise. Prove that $\mathbf{M}$ is a non-singular M-matrix and that $0\leq\mathbf{M}^{-1}\leq\mathbf{A}^{-1}$.

(b) Deduce that for every diagonal $\mathbf{D}\geq 0$, $\mathbf{K}_n+\mathbf{D}$ is a non-singular M-matrix with $(\mathbf{K}_n+\mathbf{D})^{-1}\leq\mathbf{K}_n^{-1}$. Check this for $n=2$ and $\mathbf{D}=\operatorname{diag}(1,0)$.

Hint: for the inequality, factor $\mathbf{A}^{-1}-\mathbf{M}^{-1}$.

Solution.

(a) By Theorem 18.9.4 there is $\mathbf{x}>\mathbf{0}$ with $\mathbf{A}\mathbf{x}>\mathbf{0}$. Since $\mathbf{M}-\mathbf{A}\geq 0$ and $\mathbf{x}>\mathbf{0}$, $(\mathbf{M}-\mathbf{A})\mathbf{x}\geq\mathbf{0}$, so $\mathbf{M}\mathbf{x}=\mathbf{A}\mathbf{x}+(\mathbf{M}-\mathbf{A})\mathbf{x}>\mathbf{0}$. As $\mathbf{M}$ is a Z-matrix, (c) $\Rightarrow$ (a) of the theorem makes it a non-singular M-matrix, and (a) $\Rightarrow$ (b) gives $\mathbf{M}^{-1}\geq 0$. Next,

$$\mathbf{A}^{-1}-\mathbf{M}^{-1}=\mathbf{A}^{-1}\mathbf{M}\mathbf{M}^{-1}-\mathbf{A}^{-1}\mathbf{A}\mathbf{M}^{-1}=\mathbf{A}^{-1}(\mathbf{M}-\mathbf{A})\mathbf{M}^{-1},$$

a product of three non-negative matrices, hence ≥ 0. This proves $0\leq\mathbf{M}^{-1}\leq\mathbf{A}^{-1}$.

(b) $\mathbf{K}_n$ is a non-singular M-matrix by Proposition 18.9.6, and $\mathbf{K}_n+\mathbf{D}$ is a Z-matrix with $\mathbf{K}_n+\mathbf{D}\geq\mathbf{K}_n$, since $\mathbf{D}$ only changes the diagonal and does so upwards. Part (a) gives the claim. For $n=2$: $\mathbf{K}_2^{-1}=\frac{1}{3}\left(\begin{smallmatrix}2 & 1\\ 1 & 2\end{smallmatrix}\right)$, and $\mathbf{K}_2+\mathbf{D}=\left(\begin{smallmatrix}3 & -1\\ -1 & 2\end{smallmatrix}\right)$ has determinant 5 and inverse $\frac{1}{5}\left(\begin{smallmatrix}2 & 1\\ 1 & 3\end{smallmatrix}\right)$. The difference is

$$\frac{1}{3}\begin{pmatrix}2 & 1\\ 1 & 2\end{pmatrix}-\frac{1}{5}\begin{pmatrix}2 & 1\\ 1 & 3\end{pmatrix}=\frac{1}{15}\begin{pmatrix}4 & 2\\ 2 & 1\end{pmatrix}\geq 0.$$

Exercise C2: The singular case.

(a) Show that the Z-matrix $\mathbf{Z}=\left(\begin{smallmatrix}0 & -1\\ 0 & -1\end{smallmatrix}\right)$ has non-negative leading principal minors but is not an M-matrix.

(b) Let $\mathbf{A}$ be an M-matrix. Prove that $\mathbf{A}+\varepsilon\mathbf{I}$ is a non-singular M-matrix for every real $\varepsilon>0$.

(c) Deduce that every principal minor of an M-matrix is non-negative.

(d) Check (c) for $\left(\begin{smallmatrix} 1 & -1 \\ -1 & 1 \end{smallmatrix}\right)$, and explain why (a) does not contradict the stated converse in the remark after Theorem 18.9.4.

Solution.

(a) $\det \mathbf{Z}_1 = 0$ and $\det \mathbf{Z} = 0 \cdot (-1) - (-1) \cdot 0 = 0$, both non-negative. $\mathbf{Z}$ is upper triangular, so its eigenvalues are its diagonal entries 0 and -1 (Theorem 8.7.4). Its smallest real eigenvalue is $-1 < 0$, so by Lemma 18.9.2 it is not an M-matrix: for any representation $\mathbf{Z} = s\mathbf{I} - \mathbf{B}$, $s - \rho(\mathbf{B}) = -1$.

(b) Write $\mathbf{A} = s\mathbf{I} - \mathbf{B}$ with $\mathbf{B} \geq 0$ and $s \geq \rho(\mathbf{B})$. Then $\mathbf{A} + \varepsilon\mathbf{I} = (s + \varepsilon)\mathbf{I} - \mathbf{B}$ with $s + \varepsilon > \rho(\mathbf{B})$, so it is a non-singular M-matrix by Lemma 18.9.2 (b).

(c) Fix a non-empty $S \subseteq [n]$ with k elements. Then $(\mathbf{A} + \varepsilon\mathbf{I})_{S,S} = \mathbf{A}_{S,S} + \varepsilon\mathbf{I}_k$. By (b) and condition (f) of Theorem 18.9.4, $q(\varepsilon) = \det(\mathbf{A}_{S,S} + \varepsilon\mathbf{I}_k) > 0$ for every $\varepsilon > 0$. By the Leibniz formula, q is a polynomial in ε, hence continuous by the algebra of limits quoted in Chapter 15's introduction, so $q(1/m) \to q(0)$ as $m \to \infty$. A non-strict inequality survives a limit, so $\det \mathbf{A}_{S,S} = q(0) \geq 0$.

(d) It is an M-matrix (see the Quick check after Lemma 18.9.2). Its principal minors are 1, 1 and $1 - 1 = 0$, all non-negative. The converse in the remark asks for **all** principal minors to be non-negative, and $\mathbf{Z}$ of (a) has the principal minor $\det \mathbf{Z}_{\{2\},\{2\}} = -1 < 0$. Only its **leading** ones are non-negative, and for the non-strict inequality leading minors are not enough.

Exercise C3: Non-negative dynamics.

Let $\mathbf{A} \in M_n(\mathbb{R})$ be a Z-matrix, written as $\mathbf{A} = s\mathbf{I} - \mathbf{B}$ with $\mathbf{B} \geq 0$.

(a) Prove that $e^{-t\mathbf{A}} \geq 0$ for every real $t \geq 0$.

(b) Suppose $\mathbf{A}$ is a non-singular M-matrix, and let $\mathbf{x}$ be the solution of $\mathbf{x}' = -\mathbf{A}\mathbf{x}$ with $\mathbf{x}(0) = \mathbf{x}_0 \geq \mathbf{0}$. Prove that $\mathbf{x}(t) \geq \mathbf{0}$ for every $t \geq 0$ and that $\mathbf{x}(t) \to \mathbf{0}$ as $t \to \infty$.

Hint: split $-t\mathbf{A}$ into two commuting matrices.

Solution.

(a) $-t\mathbf{A} = t\mathbf{B} + (-ts)\mathbf{I}$, and the two terms commute because every matrix commutes with a multiple of $\mathbf{I}$. By Theorem 9.9.4 (d), $e^{-t\mathbf{A}} = e^{t\mathbf{B}}e^{-ts\mathbf{I}}$. Every partial sum of the series for $e^{-ts\mathbf{I}}$ is $\left(\sum_{m=0}^{M}(-ts)^m/m!\right)\mathbf{I}$, so $e^{-ts\mathbf{I}} = e^{-ts}\mathbf{I}$. The series for $e^{t\mathbf{B}}$ converges by Theorem 9.9.3, and its partial sums $\sum_{m=0}^{M} t^m\mathbf{B}^m/m!$ are ≥ 0 because $t \geq 0$ and $\mathbf{B} \geq 0$; a non-strict inequality survives a limit, so $e^{t\mathbf{B}} \geq 0$. Hence $e^{-t\mathbf{A}} = e^{-ts}e^{t\mathbf{B}} \geq 0$.

(b) By Theorem 9.9.6, $\mathbf{x}(t) = e^{-t\mathbf{A}}\mathbf{x}_0$, which is $\geq \mathbf{0}$ for $t \geq 0$ by (a). By Theorem 18.9.4 (d), every eigenvalue of $\mathbf{A}$ has positive real part, so every eigenvalue of $-\mathbf{A}$ has negative real part: $-\mathbf{A}$ is stable. By Theorem 15.6.3, $\mathbf{x}(t) \to \mathbf{0}$. Both conclusions matter in models of concentrations or populations, which must stay non-negative and, when $-\mathbf{A}$ is stable, die out.

Chapter 19

Perturbation Theory

Every matrix that comes from a measurement or a computation is slightly wrong, so the eigenvalues one actually knows are those of a nearby matrix $\mathbf{A}+\mathbf{E}$. Two earlier chapters began to say what that costs. Chapter 15 showed that the eigenvalues move continuously with the matrix (Corollary 15.7.4), and that "continuously" can be very bad: a perturbation of size ε moves the eigenvalue of a $k\times k$ Jordan block by $\varepsilon^{1/k}$ (Example (A Jordan block's eigenvalues move like $\varepsilon^{1/k}$)). Chapter 16 showed that Hermitian matrices are as good as one could hope: each eigenvalue moves by at most $\|\mathbf{E}\|_2$ (Corollary 16.3.6). Most matrices are neither Jordan blocks nor Hermitian, and this chapter handles them. It asks four questions.

- **Where are the eigenvalues,** before any of them is computed? Discs and ovals read off the entries, and the numerical range, locate them.
- **How far do they move** when $\mathbf{A}$ is not Hermitian? For every matrix there is a bound with an n-th root, and the Jordan block shows that the root cannot be removed. For a diagonalizable matrix, the Bauer–Fike theorem gives a bound proportional to $\|\mathbf{E}\|$, with a factor that measures how far the eigenvectors are from orthonormal.
- **Which eigenvalue goes where?** A bound saying that each new eigenvalue is near **some** old one does not say that they can be paired off. For normal matrices they can, and the pairing comes from Birkhoff's theorem of Chapter 18.
- **What happens to the rest?** Eigenvectors and invariant subspaces, singular values, and the factors of the polar decomposition all move, and the chapter bounds each of them. It ends with the first-order sensitivity of a single simple eigenvalue.

One result settles an old account. Chapter 15 quoted the theorem that the roots of a polynomial depend continuously on its coefficients (Theorem 15.7.3) and left the proof to this chapter. §03 gives it from compactness and unique factorization alone, so Corollary 15.7.4, and everything Chapter 15 built on it, now rests on a proved theorem.

The field is $\mathbb{C}$ throughout, unless a statement says $\mathbb{R}$. A real matrix is read in $M_n(\mathbb{C})$ when its eigenvalues are wanted. Three conventions hold in every section.

- **The perturbation is E,** and the perturbed matrix is $\mathbf{A}+\mathbf{E}$, as in Chapters 15 and 16. A different letter, $\widetilde{\mathbf{A}}$, is used only where the perturbed matrix is not naturally written as a sum.
- **Every bound names its norm.** $\|\cdot\|_2$ is the spectral norm and $\|\cdot\|_F$ the Frobenius norm. A norm without a subscript means an arbitrary operator norm, and it is written that way only where the statement holds for all of them. There is one other use, announced where it starts: in §§09–10 a norm without a subscript stands for either the spectral or

the Frobenius norm, the same one throughout the statement, and there it ranges over just those two.

- **Near some eigenvalue is not the same as matched.** "Every eigenvalue of $\mathbf{A}+\mathbf{E}$ lies within r of some eigenvalue of $\mathbf{A}$" is a one-sided statement. "The eigenvalues can be **numbered** so that each pair is within r" is a matching, and it is stronger. §§03–05 are largely about the difference, and the chapter never blurs it.

19.0.1 The analysis this chapter imports

The list is Chapter 15's, facts (A1)–(A6) of that chapter's introduction, together with the algebra of limits, and each fact is named again where it is used. Two carry most of the weight. **(A3)**, compactness of closed bounded sets, is the engine of §03's proof of the continuity of roots, and it is also what makes the numerical range of §02 compact. **(A5)**, the intermediate value theorem, gives the convexity of the numerical range in §02. **(A4)**, the extreme value theorem, is used once, also in §02, to know that the numerical radius — the largest modulus on the numerical range — is attained. §03's counting theorem needs one more fact, that an integer-valued function on an interval that is locally constant is constant, and it derives this from (A5) as well. Nothing else analytic is used. In particular, the first-order formula of §11 for the derivative of a simple eigenvalue is proved without the implicit function theorem.

19.0.2 What you need

- **Chapter 5** — polynomials over $\mathbb{C}$: Corollary 5.5.5, Theorem 5.3.5, Theorem 5.4.5.
- **Chapter 6** — determinants, the adjugate and minors: Definition 6.6.2, Theorem 6.6.2, Theorem 6.7.1, Theorem 6.10.2, Theorem 6.10.4, Theorem 6.8.4.
- **Chapter 7** — block matrices and the Kronecker and vec identities: Theorem 7.1.1, Theorem 7.4.4.
- **Chapter 8** — eigenvalues, multiplicities, diagonalization and left eigenvectors: Theorem 8.2.1, Definition 8.3.1, Theorem 8.3.1, Definition 8.4.1, Theorem 8.4.1, Definition 8.10.1, Proposition 8.10.5, Proposition 8.10.7.
- **Chapter 9** — the Jordan form, and its warning that the form is unstable: Theorem 9.3.1, Definition 9.3.1.
- **Chapter 10** — inner products, orthogonal projections and unitary maps: Theorem 10.1.5, Definition 10.3.2, Theorem 10.3.2, Corollary 10.2.3, Theorem 10.7.3.
- **Chapter 11** — Schur's theorem, the spectral theorem, the Sylvester equation and the departure from normality: Theorem 11.1.2, Corollary 11.4.3, Theorem 11.3.3, Definition 11.10.1, Theorem 11.10.2, Corollary 11.10.3, Lemma 11.11.1, Definition 11.11.1, Example (A perturbation that moves the eigenvalues a thousand times as far).
- **Chapter 12** — the singular value and polar decompositions, and Hadamard's inequality: Theorem 12.8.1, Definition 12.8.1, Theorem 12.9.1, Theorem 12.6.4.
- **Chapter 13** — Sylvester's law of inertia: Theorem 13.5.1.
- **Chapter 15** — operator norms, the Neumann series, continuity of eigenvalues and condition numbers: Definition 15.3.2, Theorem 15.3.2, Theorem 15.3.3, Theorem 15.5.1, Lemma 15.7.1, Theorem 15.7.3, Corollary 15.7.4, Example (A Jordan block's eigenvalues move like $\varepsilon^{1/k}$), Definition 15.8.1.
- **Chapter 16** — the Rayleigh quotient, Weyl's inequalities, Lidskii's inequality, majorization and the Hermitian dilation: Definition 16.1.1, Theorem 16.2.3, Theorem 16.3.3, Corollary 16.3.6, Theorem 16.7.2, Definition 16.8.1, Proposition 16.9.3, Corollary 16.9.5.
- **Chapter 17** — extreme points, and linear functions on compact convex sets: Defini-

tion 17.8.1, Corollary 17.8.6.
- **Chapter 18** — irreducible matrices, and Birkhoff's theorem: Definition 18.2.3, Theorem 18.2.5, Theorem 18.7.2.

19.0.3 Roadmap

- **Gershgorin discs.** Every eigenvalue lies in a union of discs read off the rows, a diagonal rescaling moves the discs, and an irreducible matrix can have an eigenvalue on the boundary only if it lies on every circle.
- **Other inclusion regions.** Brauer's ovals, which are never worse than the discs, and the numerical range: it contains the spectrum, it is convex by the Toeplitz–Hausdorff theorem, and it equals the convex hull of the eigenvalues for a normal matrix.
- **Continuity of roots.** Chapter 15's quoted theorem, proved by compactness. Elsner's bound, with its exponent $1/n$ shown to be sharp by a Jordan block, and its matching version. The counting theorem: a group of Gershgorin discs separated from the others contains exactly as many eigenvalues as discs.
- **The Bauer–Fike theorem.** For a diagonalizable matrix, each perturbed eigenvalue lies within $\kappa_2(\mathbf{X})\|\mathbf{E}\|_2$ of an old one, with factor 1 for a normal matrix. It comes with a residual bound for computed eigenpairs and a version with an m-th root for defective matrices.
- **The Hoffman–Wielandt theorem.** The eigenvalues of two normal matrices can be matched within their Frobenius distance, by Birkhoff's theorem. The inequality fails for non-normal matrices.
- **Hermitian perturbations.** Residual bounds, the Kato–Temple bound, which is quadratic in the residual, and Ostrowski's theorem, which says that a congruence changes each eigenvalue by a bounded relative factor.
- **The Sylvester equation, quantitatively.** The separation of two matrices, which measures how badly conditioned $\mathbf{AX} - \mathbf{XB} = \mathbf{Y}$ is. For normal matrices it is the distance between the spectra, and in general it can be much smaller. Bounds for separated Hermitian spectra follow.
- **Principal angles.** The angles between two subspaces, their sines, and the distance $\|P_U - P_W\|_2$ between the orthogonal projections.
- **The Davis–Kahan theorem.** An invariant subspace of a Hermitian matrix moves by at most the perturbation divided by the spectral gap. Single eigenvectors inside a cluster may not be stable, but the subspace of the whole cluster is.
- **Singular values and polar factors.** Mirsky's Frobenius bound for singular values, and bounds for the positive and the unitary factors of the polar decomposition of an invertible matrix.
- **Condition numbers of eigenvalues.** The derivative of a simple eigenvalue, from a right and a left eigenvector, and its worst size, which is the condition number. The chapter's summary closes this section.

19.0.4 Named moves

- **Dominant coordinate plus the triangle inequality.** Read the eigen-equation at the coordinate where the eigenvector is largest.
- **A determinant bounded two ways.** A product of distances to the eigenvalues is a determinant, and Hadamard's inequality bounds it by column lengths.
- **Compactness plus uniqueness.** Bound the roots, extract a convergent subsequence, and let unique factorization identify the limit.

- **An integer-valued continuous function is constant.** Count eigenvalues along a path on which none of them can escape the region.
- **Factor out the resolvent.** Write $\mathbf{A}+\mathbf{E}-\mu\mathbf{I} = (\mathbf{A}-\mu\mathbf{I})\big(\mathbf{I}+(\mathbf{A}-\mu\mathbf{I})^{-1}\mathbf{E}\big)$ and invert the second factor by the Neumann series.
- **Birkhoff turns a doubly stochastic weight into a permutation.** Minimize a linear function over the doubly stochastic matrices, and the minimum sits at a permutation.
- **The perturbation of a subspace is a Sylvester equation.** The block coupling an invariant subspace to the new complement solves one, so the spectral gap is the conditioning.
- **The singular-pair trick.** Test a matrix equation against the top singular pair of the unknown.
- **The adjugate as a polynomial eigenvector.** A column of $\operatorname{adj}(\mu\mathbf{I}-\mathbf{B})$ is an eigenvector whose entries are polynomials, so it moves continuously with the data.

19.1 Gershgorin Discs

Chapter 15 bounded the whole spectrum with one number: every eigenvalue lies in the disc $|z| \le \|\mathbf{A}\|_\infty$ (Corollary 15.4.2). That disc is centered at 0, and it knows nothing about where in it the eigenvalues sit. For a matrix that is nearly diagonal the answer ought to be visible at a glance: the eigenvalues should sit near the diagonal entries, and the off-diagonal entries should say how near. This section makes that precise. It puts one disc around each diagonal entry, with radius measured from the rest of its row, and proves that the discs together hold every eigenvalue. It then sharpens the picture twice: by rescaling the coordinates, and, for irreducible matrices, by looking at the boundary.

Throughout, matrices are complex. A real matrix is read inside $M_n(\mathbb{C})$, as in Chapter 15 §04, because its eigenvalues may be non-real, and they are what we want to locate.

19.1.1 Discs around the diagonal

Here is the situation to keep in mind. Take

$$\mathbf{A} = \begin{pmatrix} 6 & 2 & 5 \\ 1 & -1 & 1 \\ 1 & 1 & -1 \end{pmatrix}.$$

The row-sum bound gives $|\lambda| \le \|\mathbf{A}\|_\infty = 13$ for every eigenvalue λ, a disc of radius 13 about 0. But if the off-diagonal entries were 0, the eigenvalues would be exactly $6, -1, -1$. The off-diagonal entries are a perturbation of the diagonal matrix, and the natural guess is that each eigenvalue stays within reach of some diagonal entry, where the reach of row i is measured by the size of the entries of row i off the diagonal. We give that reach a name.

Around each diagonal entry, draw the disc whose radius is the total size of the other entries in its row.

Definition 19.1.1 — Gershgorin Discs

Let $n \ge 1$ and $\mathbf{A} = (a_{ij}) \in M_n(\mathbb{C})$. For $i = 1, \dots, n$, the **i-th Gershgorin radius** of

A is the real number

$$r_i(\mathbf{A}) := \sum_{j \neq i} |a_{ij}| \ \geq 0,$$

the sum over **all** $j \in \{1, \ldots, n\}$ **other than** i, and the i**-th Gershgorin disc** is the **closed** disc

$$D_i(\mathbf{A}) := \{\, z \in \mathbb{C} : |z - a_{ii}| \leq r_i(\mathbf{A}) \,\}.$$

The discs $D_i(\mathbf{A}^\top)$, whose radii $r_i(\mathbf{A}^\top) = \sum_{j \neq i} |a_{ji}|$ are taken from the **columns** of **A**, are the **column discs**.

In words: the center of $D_i(\mathbf{A})$ is the diagonal entry a_{ii}, and the radius adds up the moduli of the entries of row i that are **not** on the diagonal. The disc includes its boundary circle. A radius may be 0, and then the disc is the single point a_{ii}. Since $\mathbf{A}^\top$ has the same diagonal as **A**, the column discs have the same centers as the row discs and, in general, different radii. The letter r is lowercase on purpose, since $R_{\mathbf{A}}$ is the Rayleigh quotient, and the plain D_i is a set of complex numbers, not the bold diagonal matrix **D**.

Some examples, simplest first.

- **Diagonal matrices and $n = 1$.** For $\mathbf{A} = \operatorname{diag}(d_1, \ldots, d_n)$ every radius is 0, because every off-diagonal entry is 0, and $D_i(\mathbf{A}) = \{d_i\}$. The discs are the eigenvalues. A 1×1 matrix (a) is the case $n = 1$: the sum defining r_1 is empty, so $D_1 = \{a\}$. These degenerate cases are the ones any theorem about the discs must get exactly right.
- **A 2×2 matrix.** For $\mathbf{B} = \left(\begin{smallmatrix} 0 & 1 \\ 4 & 0 \end{smallmatrix}\right)$, $r_1(\mathbf{B}) = 1$ and $r_2(\mathbf{B}) = 4$, so the row discs are $|z| \leq 1$ and $|z| \leq 4$. The column discs swap the radii: $|z| \leq 4$ and $|z| \leq 1$.
- **The matrix above.** $r_1(\mathbf{A}) = 2 + 5 = 7$, $r_2(\mathbf{A}) = 1 + 1 = 2$ and $r_3(\mathbf{A}) = 1 + 1 = 2$, so $D_1(\mathbf{A}) = \{|z - 6| \leq 7\}$ and $D_2(\mathbf{A}) = D_3(\mathbf{A}) = \{|z + 1| \leq 2\}$. The column radii are $1 + 1 = 2$, $2 + 1 = 3$ and $5 + 1 = 6$.

Non-example by minimal change. Keep the radius and move the center to 0: replace $D_i(\mathbf{A})$ by $\{|z| \leq r_i(\mathbf{A})\}$. For $\operatorname{diag}(1, 2)$ both radii are 0 and the modified "discs" are both $\{0\}$, which misses both eigenvalues. The clause that changed is the center, and the diagonal example shows it is the part that carries the information: the radius only measures how far the off-diagonal part can pull an eigenvalue away from it.

19.1.2 The theorem

It turns out that the guess is right, with no loss at all in the constant:

Theorem 19.1.1 — Gershgorin's Theorem

Let $n \geq 1$, $\mathbf{A} \in M_n(\mathbb{C})$, and let λ be an eigenvalue of **A** with eigenvector $\mathbf{x} = (x_1, \ldots, x_n)$. If k is an index with $|x_k| = \max_j |x_j|$, then $\lambda \in D_k(\mathbf{A})$. Consequently:

(a) every eigenvalue of **A** lies in the union $D_1(\mathbf{A}) \cup \cdots \cup D_n(\mathbf{A})$ of the row discs;

(b) every eigenvalue of **A** lies in the union $D_1(\mathbf{A}^\top) \cup \cdots \cup D_n(\mathbf{A}^\top)$ of the column discs;

(c) hence every eigenvalue lies in the intersection of the two unions.

Idea. We want $|\lambda - a_{kk}|$ to be small for one well-chosen k, so look at row k of $\mathbf{Ax} = \lambda\mathbf{x}$ and move the diagonal term across: $(\lambda - a_{kk})x_k = \sum_{j\neq k} a_{kj}x_j$. The triangle inequality bounds the right side by $\sum_{j\neq k}|a_{kj}||x_j|$, and this becomes $r_k(\mathbf{A})|x_k|$ exactly when every $|x_j| \leq |x_k|$. So choose k where the eigenvector is largest in modulus. Then divide by $|x_k|$, which is positive because $\mathbf{x} \neq \mathbf{0}$.

Proof. Let $\mathbf{Ax} = \lambda\mathbf{x}$ with $\mathbf{x} \neq \mathbf{0}$, and let k be as in the statement; such a k exists because a finite set of real numbers has a largest element. Since $\mathbf{x} \neq \mathbf{0}$, some $x_j \neq 0$, so $|x_k| > 0$. Row k of $\mathbf{Ax} = \lambda\mathbf{x}$ reads $\sum_j a_{kj}x_j = \lambda x_k$, that is,

$$(\lambda - a_{kk})\, x_k = \sum_{j\neq k} a_{kj}x_j.$$

Taking moduli and using the triangle inequality (Theorem 0.6.4), then $|x_j| \leq |x_k|$ for every j,

$$|\lambda - a_{kk}|\,|x_k| \leq \sum_{j\neq k}|a_{kj}|\,|x_j| \leq \Big(\sum_{j\neq k}|a_{kj}|\Big)|x_k| = r_k(\mathbf{A})\,|x_k|.$$

Dividing by $|x_k| > 0$ gives $|\lambda - a_{kk}| \leq r_k(\mathbf{A})$, that is, $\lambda \in D_k(\mathbf{A})$.

(a) Every eigenvalue has an eigenvector, and the disc just found is one of the $D_i(\mathbf{A})$.

(b) By Proposition 8.10.5 (b), $\mathbf{A}^\top$ has the same eigenvalues as $\mathbf{A}$. Applying (a) to $\mathbf{A}^\top$ puts each of them in $D_1(\mathbf{A}^\top) \cup \cdots \cup D_n(\mathbf{A}^\top)$.

(c) A point lying in each of two sets lies in their intersection. This proves the theorem.

■

The move in this proof is worth naming, since the chapter uses it again: **choose the dominant coordinate of an eigenvector, then apply the triangle inequality to its row.** The choice of the largest coordinate is exactly what lets every $|x_j|$ be replaced by $|x_k|$ without looking at the others.

The theorem recovers Chapter 15's bound and improves on it. If $\lambda \in D_k(\mathbf{A})$, then

$$\begin{aligned}|\lambda| &\leq |a_{kk}| + |\lambda - a_{kk}| \leq |a_{kk}| + r_k(\mathbf{A}) \\ &= \sum_j |a_{kj}| \leq \|\mathbf{A}\|_\infty,\end{aligned}$$

so (a) implies $\rho(\mathbf{A}) \leq \|\mathbf{A}\|_\infty$, and (b) likewise implies $\rho(\mathbf{A}) \leq \|\mathbf{A}\|_1$. The union of the discs is never larger than the row-sum disc, and it is usually much smaller, because it keeps the centers.

Example. (Discs, eigenvectors, and where each eigenvalue sits)

Let $\mathbf{A} = \begin{pmatrix} 6 & 2 & 5 \\ 1 & -1 & 1 \\ 1 & 1 & -1 \end{pmatrix}$. Describe the regions given by Theorem 19.1.1 (a) and (b). Then check that $(7, 1, 1)$, $(-1, 1, 1)$ and $(1, 1, -2)$ are eigenvectors, and locate each eigenvalue in the disc the theorem assigns to it.

Solution. From the radii computed after Definition 19.1.1, the row discs give

$$\{|z - 6| \leq 7\} \cup \{|z + 1| \leq 2\},$$

the second disc counted twice, and the column discs give $\{|z-6| \le 2\} \cup \{|z+1| \le 3\} \cup \{|z+1| \le 6\}$, where the middle disc lies inside the last. So every eigenvalue lies in $\{|z-6| \le 2\} \cup \{|z+1| \le 6\}$, and also in $\{|z-6| \le 7\} \cup \{|z+1| \le 2\}$. The column discs have separated the two groups of centers; the row discs have not.

Multiplying out,

$$\mathbf{A}\begin{pmatrix}7\\1\\1\end{pmatrix} = \begin{pmatrix}49\\7\\7\end{pmatrix}, \quad \mathbf{A}\begin{pmatrix}-1\\1\\1\end{pmatrix} = \begin{pmatrix}1\\-1\\-1\end{pmatrix}, \quad \mathbf{A}\begin{pmatrix}1\\1\\-2\end{pmatrix} = \begin{pmatrix}-2\\-2\\4\end{pmatrix},$$

so the eigenvalues include 7, -1 and -2. These are three distinct eigenvalues of a 3×3 matrix, hence three distinct roots of the degree-3 polynomial $p_{\mathbf{A}}$ (Theorem 8.2.1), so by Corollary 5.1.4 there are no others.

- The eigenvector $(7,1,1)$ peaks at $k=1$, and indeed $|7-6| = 1 \le 7$: $7 \in D_1(\mathbf{A})$.
- The eigenvector $(1,1,-2)$ peaks at $k=3$, and $|-2+1| = 1 \le 2$: $-2 \in D_3(\mathbf{A})$.
- The eigenvector $(-1,1,1)$ has all three coordinates of modulus 1, so every k is a peak and -1 must lie in every row disc. It does: $|-1-6| = 7 = r_1(\mathbf{A})$, so it sits on the boundary circle of $D_1(\mathbf{A})$, and it is the center of the other two.

Both unions pass the test, and the eigenvector tells us which disc to look in. The row-sum disc $|z| \le 13$ says only that $|\lambda| \le 13$.

Warning. **The union is the claim, not each disc.** A single Gershgorin disc need not contain any eigenvalue. For $\mathbf{B} = \left(\begin{smallmatrix}0&1\\4&0\end{smallmatrix}\right)$, $p_{\mathbf{B}}(x) = x^2 - 4$, so the eigenvalues are ± 2, while the first row disc is $|z| \le 1$: it contains neither. Both eigenvalues lie in the second disc $|z| \le 4$. Nor may the row disc and the column disc of the same index be intersected: $D_1(\mathbf{B}) \cap D_1(\mathbf{B}^\top)$ and $D_2(\mathbf{B}) \cap D_2(\mathbf{B}^\top)$ are both $|z| \le 1$, and ± 2 lies in neither. Part (c) of the theorem intersects the two **unions**.

Quick check. Without computing any eigenvalue, show that every eigenvalue of $\mathbf{M} = \begin{pmatrix}5&2&-1\\1&6&2\\-1&0&3\end{pmatrix}$ has real part at least 2.

Solution. The row discs are $|z-5| \le 3$, $|z-6| \le 3$ and $|z-3| \le 1$. A point z of the first has $\operatorname{Re} z \ge 5 - |z-5| \ge 2$, of the second $\operatorname{Re} z \ge 3$, of the third $\operatorname{Re} z \ge 2$. By Theorem 19.1.1 (a) every eigenvalue lies in one of them, so its real part is at least 2. In particular 0 is not an eigenvalue, and $\mathbf{M}$ is invertible.

19.1.3 Diagonal dominance

The last sentence of the Quick check is a pattern. If 0 lies outside every disc, then 0 is not an eigenvalue, and the matrix is invertible. The point 0 lies outside $D_i(\mathbf{A})$ exactly when $|0 - a_{ii}| > r_i(\mathbf{A})$, which is a condition on row i alone.

Corollary 19.1.2 — Strict Diagonal Dominance Implies Invertibility

Let $n \geq 1$ and $\mathbf{A} \in M_n(\mathbb{C})$. Call **A strictly diagonally dominant** (by rows) if

$$|a_{ii}| > r_i(\mathbf{A}) = \sum_{j \neq i} |a_{ij}| \qquad \text{for **every** } i = 1, \ldots, n.$$

A strictly diagonally dominant matrix is invertible. The same holds if $\mathbf{A}$ is strictly diagonally dominant **by columns**, that is, if $\mathbf{A}^\top$ is strictly diagonally dominant.

Proof. Suppose $\mathbf{A}$ is strictly diagonally dominant. For every i, $|0 - a_{ii}| > r_i(\mathbf{A})$, so $0 \notin D_i(\mathbf{A})$. Hence 0 lies in no row disc, and by Theorem 19.1.1 (a) it is not an eigenvalue. By Theorem 8.2.1, $0\mathbf{I} - \mathbf{A} = -\mathbf{A}$ is invertible, and so is $\mathbf{A}$. If instead $\mathbf{A}^\top$ is strictly diagonally dominant, then 0 lies in no column disc, and Theorem 19.1.1 (b) finishes in the same way.

■

This is the **Lévy–Desplanques theorem**. The word **strictly** carries the weight, and the definition asks it of **every** row. Examples: $\left(\begin{smallmatrix} 3 & 1 & 1 \\ 0 & 2 & 1 \\ 1 & -1 & 4 \end{smallmatrix}\right)$ is strictly dominant, since $3 > 2$, $2 > 1$, $4 > 2$; every diagonal matrix with non-zero diagonal is, since every radius is 0; and a 1×1 matrix (a) is strictly dominant exactly when $a \neq 0$. A minimal change breaks it. $\left(\begin{smallmatrix} 1 & 1 \\ 1 & 1 \end{smallmatrix}\right)$ has $|a_{ii}| = 1 = r_i$ in both rows: it is dominant only weakly, and it is singular. The converse of the corollary is false: $\left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$ is invertible and has zero diagonal. Diagonal dominance is a certificate of invertibility, cheap to check and often available, not a characterization.

19.1.4 Hermitian matrices, and intervals

For a Hermitian $\mathbf{A}$ the eigenvalues are real (Theorem 11.2.1), and so are the diagonal entries, since $a_{ii} = \overline{a_{ii}}$. So only the part of each disc on the real line matters, which is the interval $[a_{ii} - r_i(\mathbf{A}),\, a_{ii} + r_i(\mathbf{A})]$. Theorem 19.1.1 (a) then says

$$\min_i \big(a_{ii} - r_i(\mathbf{A})\big) \leq \lambda_n(\mathbf{A}) \leq \lambda_1(\mathbf{A}) \leq \max_i \big(a_{ii} + r_i(\mathbf{A})\big).$$

For $\mathbf{A} = \left(\begin{smallmatrix} 4 & 1 & 0 \\ 1 & 6 & 2 \\ 0 & 2 & 9 \end{smallmatrix}\right)$ the intervals are $[3, 5]$, $[3, 9]$ and $[7, 11]$, so every eigenvalue lies in $[3, 11]$, and $\mathbf{A}$ is positive definite by Theorem 12.1.5, since its eigenvalues are positive; Exercise C1 turns this into a general criterion. For a Hermitian matrix the row and column discs coincide, since $|a_{ji}| = |\overline{a_{ij}}|$, so (b) adds nothing.

19.1.5 Scaling the discs

The discs depend on the matrix, and the eigenvalues depend only on its similarity class. So any similarity that is easy to compute gives new discs for the same eigenvalues. The cheapest one rescales the coordinates.

Proposition 19.1.3 — Rescaling the Gershgorin Discs

Let $\mathbf{A} \in M_n(\mathbb{C})$, let $d_1, \ldots, d_n$ be **positive** real numbers, and $\mathbf{D} = \operatorname{diag}(d_1, \ldots, d_n)$. Then:

(a) $\mathbf{D}^{-1}\mathbf{A}\mathbf{D}$ has entries $a_{ij}d_j/d_i$. It has the same diagonal as $\mathbf{A}$, and the same eigenvalues with the same algebraic multiplicities.

(b) $r_i(\mathbf{D}^{-1}\mathbf{A}\mathbf{D}) = \dfrac{1}{d_i}\sum_{j\neq i}|a_{ij}|\,d_j$ for each i.

(c) Every eigenvalue of $\mathbf{A}$ lies in

$$\bigcup_{i=1}^{n}\Big\{\, z : |z-a_{ii}| \le \frac{1}{d_i}\sum_{j\neq i}|a_{ij}|\,d_j \,\Big\}.$$

Proof.

(a) $\mathbf{D}$ is invertible with $\mathbf{D}^{-1} = \operatorname{diag}(1/d_1,\dots,1/d_n)$, because every $d_i \neq 0$. Multiplying by a diagonal matrix on the left scales rows and on the right scales columns, so $(\mathbf{D}^{-1}\mathbf{A}\mathbf{D})_{ij} = d_i^{-1}a_{ij}d_j$, and for $i=j$ this is a_{ii}. The matrices $\mathbf{A}$ and $\mathbf{D}^{-1}\mathbf{A}\mathbf{D}$ are similar, so they have the same characteristic polynomial (Theorem 6.10.3), hence the same eigenvalues with the same multiplicities.

(b) By (a) and $d_i, d_j > 0$, $|a_{ij}d_j/d_i| = |a_{ij}|d_j/d_i$; sum over $j \neq i$.

(c) Apply Theorem 19.1.1 (a) to $\mathbf{D}^{-1}\mathbf{A}\mathbf{D}$ and use (a) and (b).

■

Taking $d_1 > 1$ and the other $d_j = 1$ divides the first radius by d_1 and multiplies the entry $|a_{i1}|$ inside every other radius by d_1. So scaling shrinks some discs at the expense of others, and the art is to shrink the disc we care about while the others can afford to grow. The same move appeared in Chapter 18 §09, where $\mathbf{D} = \operatorname{diag}(\mathbf{x})$ turned the entries of $\mathbf{B}\mathbf{x}$ into row sums.

Example. (Separating a disc by scaling)

For $\mathbf{A} = \begin{pmatrix} 6 & 2 & 5 \\ 1 & -1 & 1 \\ 1 & 1 & -1 \end{pmatrix}$ of Example (Discs, eigenvectors, and where each eigenvalue sits), the row disc $D_1(\mathbf{A}) = \{|z-6| \le 7\}$ overlaps $\{|z+1| \le 2\}$. Find a scaling $\mathbf{D} = \operatorname{diag}(d,1,1)$ whose row discs split into two disjoint groups, and find the range of d that does it.

Solution. By Proposition 19.1.3 (b) with $d_1 = d$ and $d_2 = d_3 = 1$, the scaled radii are

$$r_1 = \frac{2+5}{d} = \frac{7}{d}, \qquad r_2 = 1\cdot d + 1 = d+1, \qquad r_3 = d+1,$$

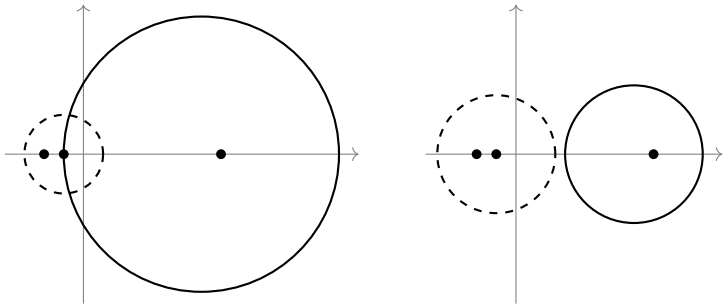
with centers $6, -1, -1$. The first disc is disjoint from the other two exactly when the distance 7 between the centers exceeds the sum of the radii:

$$\frac{7}{d} + d + 1 < 7 \iff d^2 - 6d + 7 < 0 \iff 3-\sqrt{2} < d < 3+\sqrt{2},$$

where we multiplied by $d > 0$. For instance $d = 2$ gives $\mathbf{D}^{-1}\mathbf{A}\mathbf{D} = \begin{pmatrix} 6 & 1 & 5/2 \\ 2 & -1 & 1 \\ 2 & 1 & -1 \end{pmatrix}$ and the discs

$$\{|z-6| \le \tfrac{7}{2}\} \quad \text{and} \quad \{|z+1| \le 3\},$$

the second counted twice, which are disjoint since $\frac{7}{2}+3<7$. The eigenvalues 7, -1, -2 are distributed one in the first disc and two in the second, as the figure shows.



unscaled scaled by $\mathrm{diag}(2,1,1)$

Row discs of the matrix of the example before and after scaling: the solid disc is centered at 6, the dashed disc at -1 (rows 2 and 3), and the dots are the eigenvalues 7, -1, -2

Scaling has bought a picture in which the eigenvalues fall into two groups, one near 6 and two near -1. What it has **not** yet bought is the statement that the first disc contains exactly one eigenvalue. Theorem 19.1.1 says only that the union holds all three, and nothing so far forbids all three from lying in the second disc. The counting statement is true, but it needs the eigenvalues to move continuously as the off-diagonal part is switched on, and §03 proves it. For a real matrix like this one, §03 will also show that an isolated disc centered on the real axis holds a **real** eigenvalue.

19.1.6 Eigenvalues on the boundary

Diagonal dominance fails for a matrix that matters. The second-difference matrix $\mathbf{K}_n$ of Chapter 18 §09 has 2 on the diagonal and -1 beside it, so for $n \geq 3$ its interior rows have $|a_{ii}| = 2 = r_i(\mathbf{K}_n)$. The discs $|z-2| \leq 2$ pass through 0, and Corollary 19.1.2 says nothing, although $\mathbf{K}_n$ is invertible. Only the first and last rows are strict. What rescues it is that the rows are **linked**: the dominant coordinate of an eigenvector cannot stay in the equality rows without spreading to the strict ones. The link is irreducibility, in the sense of Definition 18.2.3, and by Theorem 18.2.5 it means that the graph $G(\mathbf{A})$, with an edge $j \to i$ whenever $a_{ij} \neq 0$, is strongly connected.

Theorem 19.1.4 — Taussky's Theorem

Let $n \geq 1$, let $\mathbf{A} \in M_n(\mathbb{C})$ be **irreducible**, and let λ be an eigenvalue of $\mathbf{A}$ with

$$|\lambda - a_{ii}| \geq r_i(\mathbf{A}) \qquad \text{for **every** } i,$$

that is, λ lies in no open disc $\{|z-a_{ii}| < r_i(\mathbf{A})\}$. Then $|\lambda - a_{ii}| = r_i(\mathbf{A})$ for every i: the eigenvalue lies on the boundary circle of **every** Gershgorin disc. Moreover, every eigenvector for λ has all its coordinates of the same modulus. The hypothesis holds in particular when λ is a boundary point (Definition 17.3.2) of $D_1(\mathbf{A}) \cup \cdots \cup D_n(\mathbf{A})$.

Idea. Run the proof of Theorem 19.1.1 at a peak index k. The hypothesis $|\lambda - a_{kk}| \geq r_k$ makes the two ends of its chain of inequalities equal, so every inequality in the chain is an equality. The second one, $\sum_{j \neq k} |a_{kj}||x_j| \leq r_k |x_k|$, is an equality only if $|x_j| = |x_k|$

whenever $a_{kj} \neq 0$. So the set of peak indices is closed under following edges of $G(\mathbf{A})$ backwards. Strong connectivity then drags every index into it.

Proof. Let $\mathbf{Ax} = \lambda\mathbf{x}$ with $\mathbf{x} \neq \mathbf{0}$, put $m = \max_j |x_j| > 0$ and $S = \{k : |x_k| = m\}$, which is non-empty.

Claim. If $k \in S$, then $|\lambda - a_{kk}| = r_k(\mathbf{A})$, and every $j \neq k$ with $a_{kj} \neq 0$ lies in S.

Proof. By the hypothesis and the chain of inequalities in the proof of Theorem 19.1.1, with $|x_k| = m$,

$$r_k(\mathbf{A})\, m \leq |\lambda - a_{kk}|\, m \leq \sum_{j \neq k} |a_{kj}|\, |x_j| \leq r_k(\mathbf{A})\, m.$$

The two ends agree, so every inequality is an equality. The first gives $|\lambda - a_{kk}| = r_k(\mathbf{A})$, after dividing by $m > 0$. The last says $\sum_{j \neq k} |a_{kj}|\,(m - |x_j|) = 0$. Each term is non-negative, so each is 0, and $a_{kj} \neq 0$ forces $|x_j| = m$, that is, $j \in S$.

■

Now let i be any index and fix $k \in S$. By Theorem 18.2.5, $G(\mathbf{A})$ has a walk $i = i_0, i_1, \ldots, i_t = k$. We show $i_s \in S$ for $s = t, t-1, \ldots, 0$. For $s = t$ this is $k \in S$. If $i_s \in S$ with $s \geq 1$, then $i_{s-1} \to i_s$ is an edge, so $a_{i_s i_{s-1}} \neq 0$; either $i_{s-1} = i_s \in S$, or the Claim applied to i_s puts i_{s-1} in S. Hence $i \in S$. So $S = \{1, \ldots, n\}$: every coordinate of $\mathbf{x}$ has modulus m, and the Claim gives $|\lambda - a_{ii}| = r_i(\mathbf{A})$ for every i.

For the last sentence, suppose $|\lambda - a_{ii}| < r_i(\mathbf{A})$ for some i, and put $\delta = r_i(\mathbf{A}) - |\lambda - a_{ii}| > 0$. Every z with $|z - \lambda| < \delta$ satisfies $|z - a_{ii}| \leq |z - \lambda| + |\lambda - a_{ii}| < r_i(\mathbf{A})$, so it lies in $D_i(\mathbf{A})$ and in the union. Then λ is an interior point of the union, not a boundary point. This proves the theorem.

■

For $n = 1$ the theorem is empty but true: $r_1 = 0$ and the only eigenvalue is a_{11}. For the all-ones matrix $\mathbf{J} \in M_n(\mathbb{C})$, $n \geq 2$, which is irreducible because every entry is non-zero, every disc is $|z - 1| \leq n - 1$, and the eigenvalue n, with eigenvector $\mathbf{1}$, satisfies $|n - 1| = n - 1$: it lies on all of the boundary circles at once, and its eigenvector has equal coordinates, exactly as the theorem predicts.

The corollary is the one $\mathbf{K}_n$ needed: equality in most rows is allowed, provided one row is strict and the rows are linked.

Corollary 19.1.5 — Irreducible Diagonal Dominance Implies Invertibility

Let $n \geq 1$ and let $\mathbf{A} \in M_n(\mathbb{C})$ be **irreducible**, with

$$|a_{ii}| \geq r_i(\mathbf{A}) \quad \text{for every } i, \qquad |a_{ii}| > r_i(\mathbf{A}) \quad \text{for **at least one** } i.$$

Then $\mathbf{A}$ is invertible.

Proof. Suppose $\mathbf{A}$ is not invertible. By Theorem 8.2.1, 0 is an eigenvalue. The first hypothesis says $|0 - a_{ii}| \geq r_i(\mathbf{A})$ for every i, so Theorem 19.1.4 applies to $\lambda = 0$ and gives $|a_{ii}| = r_i(\mathbf{A})$ for every i. This contradicts the second hypothesis. Hence $\mathbf{A}$ is invertible. ■

Both hypotheses are needed. $\left(\begin{smallmatrix} 1 & 1 \\ 1 & 1 \end{smallmatrix}\right)$ is irreducible and weakly dominant, with no strict row, and it is singular: its eigenvalue 0 lies on both circles $|z - 1| = 1$. Exercise C2 shows that irreducibility cannot be dropped either.

Example. (The second-difference matrix)

Show that $\mathbf{K}_n$ is invertible for every $n \geq 1$, and that its eigenvalues lie in the open interval $(0, 4)$.

Solution. For $n = 1$, $\mathbf{K}_1 = (2)$, with eigenvalue 2. Let $n \geq 2$. (Chapter 18 §09 proved invertibility by exhibiting the inverse, Proposition 18.9.6; here the entries alone suffice.) The only non-zero entries off the diagonal are $a_{i,i+1} = a_{i+1,i} = -1$, so $G(\mathbf{K}_n)$ has the edges $i \to i+1$ and $i+1 \to i$, and walking along them reaches every vertex from every vertex. So $\mathbf{K}_n$ is irreducible by Theorem 18.2.5. Its rows have $r_1 = r_n = 1 < 2$ and, when $n \geq 3$, $r_i = 2$ for $1 < i < n$. So $|a_{ii}| \geq r_i$ everywhere, strictly in row 1, and $\mathbf{K}_n$ is invertible by Corollary 19.1.5.

$\mathbf{K}_n$ is real symmetric, so its eigenvalues are real, and by Theorem 19.1.1 (a) they lie in $\bigcup_i [2 - r_i, 2 + r_i] \subseteq [0, 4]$. The value 0 is excluded by invertibility. The value 4 satisfies $|4 - 2| = 2 \geq r_i$ for every i, so if it were an eigenvalue, Theorem 19.1.4 would give $2 = r_1 = 1$, which is false. Hence every eigenvalue lies in $(0, 4)$. In particular $\mathbf{K}_n \succ 0$, which Chapter 18 §09 obtained from its M-matrix structure.

Quick check. The all-ones matrix $\mathbf{J} \in M_3(\mathbb{C})$ is irreducible, and 0 is an eigenvalue of it, since $\mathbf{J}$ has rank 1. But 0 does not lie on the circle $|z - 1| = 2$. Does this contradict Theorem 19.1.4?

Solution. No. The theorem applies only to an eigenvalue with $|\lambda - a_{ii}| \geq r_i(\mathbf{J})$ for every i, and $|0 - 1| = 1 < 2 = r_i(\mathbf{J})$: the eigenvalue 0 lies inside every open disc, so the hypothesis fails and the theorem says nothing about it. The other eigenvalue, 3, satisfies $|3 - 1| = 2$, and it does lie on every circle.

The picture to take away is this. The union of the discs holds the spectrum. An eigenvalue sits in the disc of the row where its eigenvector peaks. Scaling moves radius from one disc to another. And for an irreducible matrix, an eigenvalue can reach the outer edge of the union only by reaching the edge of every disc at once. §02 replaces the discs by other regions built from the same entries, and §03 counts the eigenvalues inside a group of discs.

19.1.7 Exercises

19.1.7.1 A. Check your understanding

Exercise A1.

(a) Define the Gershgorin radius $r_i(\mathbf{A})$ and the disc $D_i(\mathbf{A})$, and state Theorem 19.1.1, including the statement about the peak coordinate of an eigenvector.

(b) True or false: every Gershgorin disc of $\mathbf{A}$ contains an eigenvalue of $\mathbf{A}$. Justify your answer.

(c) True or false: every eigenvalue of $\mathbf{A}$ lies in $\bigcup_i \big(D_i(\mathbf{A}) \cap D_i(\mathbf{A}^\top)\big)$. Justify your answer.

(d) True or false: an invertible matrix is strictly diagonally dominant by rows or by columns. Justify your answer.

(e) True or false: an irreducible matrix with $|a_{ii}| \geq r_i(\mathbf{A})$ for every i is invertible. Justify your answer.

(f) Name the method of proof of Theorem 19.1.1 in one line.

Solution.

(a) $r_i(\mathbf{A}) = \sum_{j \neq i} |a_{ij}|$ and $D_i(\mathbf{A}) = \{z \in \mathbb{C} : |z - a_{ii}| \leq r_i(\mathbf{A})\}$. If $\mathbf{A}\mathbf{x} = \lambda \mathbf{x}$ with $\mathbf{x} \neq \mathbf{0}$ and $|x_k| = \max_j |x_j|$, then $\lambda \in D_k(\mathbf{A})$; hence every eigenvalue lies in $\bigcup_i D_i(\mathbf{A})$, in $\bigcup_i D_i(\mathbf{A}^\top)$, and in the intersection of these two unions.

(b) False. For $\left(\begin{smallmatrix} 0 & 1 \\ 4 & 0 \end{smallmatrix}\right)$ the eigenvalues are ± 2 and the first disc is $|z| \leq 1$.

(c) False. For the same matrix both intersections are $|z| \leq 1$, which misses ± 2.

(d) False. $\left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$ is invertible, and $|a_{11}| = 0 < 1$ both for rows and for columns.

(e) False. $\left(\begin{smallmatrix} 1 & 1 \\ 1 & 1 \end{smallmatrix}\right)$ is irreducible, with $|a_{ii}| = 1 = r_i$, and singular. Corollary 19.1.5 needs one strict row.

(f) Choose the coordinate of the eigenvector of largest modulus, and apply the triangle inequality (Theorem 0.6.4) to that row of $\mathbf{A}\mathbf{x} = \lambda \mathbf{x}$.

19.1.7.2 B. Practice

Exercise B1: Deciding invertibility.

Determine which of the following matrices are invertible. Justify your answers, using the results of this section where they apply and a direct computation where they do not.

(a) $\begin{pmatrix} 5 & 2 & -2 \\ 1 & -4 & 2 \\ 0 & 3 & 4i \end{pmatrix}$

(b) $\begin{pmatrix} 3 & 1 & 2 \\ 1 & 3 & 1 \\ 1 & 1 & 3 \end{pmatrix}$

(c) $\begin{pmatrix} 2 & 1 & 1 \\ 1 & 2 & 1 \\ 1 & 1 & 2 \end{pmatrix}$

(d) $\begin{pmatrix} 1 & 1 & 0 \\ 1 & 1 & 0 \\ 0 & 1 & 2 \end{pmatrix}$

Solution.

(a) The radii are $4, 3, 3$ and the diagonal moduli $5, 4, |4i| = 4$, so every row is strictly dominant. The matrix is invertible by Corollary 19.1.2.

(b) Row 1 has $3 = 1 + 2$, and rows 2 and 3 have $3 > 2$. Every off-diagonal entry is non-zero, so every edge $j \to i$ with $i \neq j$ is present in the graph, which is strongly connected, and the matrix is irreducible (Theorem 18.2.5). It is invertible by Corollary 19.1.5. (Indeed its determinant is 18.)

(c) Every row has $2 = 1+1$: no row is strict, so neither corollary applies. Directly, the matrix is $\mathbf{I} + \mathbf{J}$, and $\mathbf{J1} = 3 \cdot \mathbf{1}$, while $\mathbf{Jv} = \mathbf{0}$ for $\mathbf{v} = (1, -1, 0)$ and $\mathbf{v} = (1, 0, -1)$. So the eigenvalues of $\mathbf{I} + \mathbf{J}$ are $4, 1, 1$, none zero, and the matrix is invertible, with determinant 4. The corollaries give sufficient conditions only.

(d) Rows 1 and 2 have equality and row 3 is strict, but the matrix is singular: its first two rows are equal. The corollary does not apply because the matrix is reducible: column 3 is zero outside row 3, so no edge leaves vertex 3, and there is no walk from 3 to 1.

Exercise B2: An interval for a symmetric matrix.

Let $\mathbf{A} = \begin{pmatrix} 5 & 1 & -1 \\ 1 & 3 & 1 \\ -1 & 1 & 6 \end{pmatrix}$.

(a) Use Theorem 19.1.1 to find an interval containing every eigenvalue of $\mathbf{A}$, and compare it with the interval $[-\|\mathbf{A}\|_\infty, \|\mathbf{A}\|_\infty]$ given by Corollary 15.4.2.

(b) Hence show that $\mathbf{A}$ is positive definite, and that $\det \mathbf{A}$ lies between 1 and 8^3.

Solution.

(a) $\mathbf{A}$ is real symmetric, so its eigenvalues are real. The radii are $2, 2, 2$, so the discs meet $\mathbb{R}$ in $[3, 7]$, $[1, 5]$, $[4, 8]$, whose union is $[1, 8]$. By Theorem 19.1.1 (a), every eigenvalue lies in $[1, 8]$. The largest absolute row sum is $\|\mathbf{A}\|_\infty = 8$, so Chapter 15's bound gives only $[-8, 8]$; the upper ends agree, but only the discs see that the eigenvalues are positive.

(b) Every eigenvalue is at least $1 > 0$, so $\mathbf{A} \succ 0$ by Theorem 12.1.5. The determinant is the product of the three eigenvalues, each in $[1, 8]$, so $1 \leq \det \mathbf{A} \leq 8^3 = 512$. (In fact $\det \mathbf{A} = 74$.)

Exercise B3: Choosing the scaling.

Let $\mathbf{A} = \begin{pmatrix} 7 & 4 & 4 \\ 1 & 0 & -1 \\ -1 & -2 & -1 \end{pmatrix}$.

(a) Show that the row disc $D_1(\mathbf{A})$ meets the other two row discs.

(b) For $\mathbf{D} = \operatorname{diag}(d, 1, 1)$ with $d > 0$, find the scaled radii, and find all d for which the first scaled disc is disjoint from the other two.

(c) Check that $(-6, -1, 1)$ is an eigenvector of $\mathbf{A}$, and that its eigenvalue lies in the first scaled disc for $d = 3$.

Solution.

(a) The discs are $|z - 7| \le 8$, $|z| \le 2$ and $|z + 1| \le 3$. The point 0 lies in the first two, and -1 in the first and third.

(b) By Proposition 19.1.3 (b), the radii of $\mathbf{D}^{-1}\mathbf{A}\mathbf{D}$ are $r_1 = 8/d$, $r_2 = 1 \cdot d + 1 = d + 1$ and $r_3 = 1 \cdot d + 2 = d + 2$, with centers $7, 0, -1$. The first disc misses the second when $8/d + d + 1 < 7$, and misses the third when $8/d + d + 2 < 8$: both say $d + 8/d < 6$. Multiplying by $d > 0$, this is $d^2 - 6d + 8 < 0$, that is, $(d - 2)(d - 4) < 0$, so $2 < d < 4$. At $d = 2$ the discs touch.

(c) $\mathbf{A}(-6, -1, 1) = (-42 - 4 + 4,\ -6 + 0 - 1,\ 6 + 2 - 1) = (-42, -7, 7) = 7\,(-6, -1, 1)$, so 7 is an eigenvalue. For $d = 3$ the first scaled disc is $|z - 7| \le \frac{8}{3}$, which contains 7. The eigenvector peaks at the first coordinate, so Theorem 19.1.1 already placed 7 in D_1; the scaled theorem places it in the smaller disc.

19.1.7.3 C. Going deeper

Exercise C1: Dominance and definiteness.

(a) Prove that a Hermitian matrix $\mathbf{A}$ with $a_{ii} > r_i(\mathbf{A})$ for every i is positive definite.

(b) Prove that a Hermitian **irreducible** matrix with $a_{ii} \ge r_i(\mathbf{A})$ for every i, strictly for at least one i, is positive definite.

(c) Deduce that for every $n \ge 1$ and every real $t \ge 0$, the matrix $\mathbf{K}_n + t\,\mathbf{e}_1\mathbf{e}_1^{\top}$ is positive definite.

Hint for (b): apply (a)'s argument to find where the eigenvalues can be, and then use Theorem 19.1.4.

Solution.

(a) The diagonal entries of a Hermitian matrix are real, and so are its eigenvalues (Theorem 11.2.1). By Theorem 19.1.1 (a), each eigenvalue λ lies in some $D_k(\mathbf{A})$, so $\lambda \ge a_{kk} - |\lambda - a_{kk}| \ge a_{kk} - r_k(\mathbf{A}) > 0$. A Hermitian matrix with only positive eigenvalues is positive definite (Theorem 12.1.5).

(b) As in (a), every eigenvalue satisfies $\lambda \ge a_{kk} - r_k(\mathbf{A}) \ge 0$ for some k, so it is enough to show that 0 is not an eigenvalue. The hypothesis gives $|0 - a_{ii}| = a_{ii} \ge r_i(\mathbf{A})$ for every i, since $a_{ii} \ge r_i(\mathbf{A}) \ge 0$. If 0 were an eigenvalue, Theorem 19.1.4 would give $a_{ii} = r_i(\mathbf{A})$ for every i, contradicting the strict row. Hence all eigenvalues are positive and $\mathbf{A} \succ 0$. (This is also Corollary 19.1.5, together with the sign information from (a).)

(c) The matrix is real symmetric, and it differs from $\mathbf{K}_n$ only in the $(1, 1)$ entry, which is $2 + t$. The graph is unchanged, so for $n \ge 2$ it is irreducible, as shown in Example (The second-difference matrix). Its rows satisfy $a_{ii} \ge r_i$, with $2 + t > 1$ in row 1. By (b), it is positive definite. For $n = 1$ the matrix is $(2 + t)$ with $2 + t > 0$.

Exercise C2: Irreducibility cannot be dropped.

(a) Give a 3×3 reducible matrix with $|a_{ii}| \geq r_i(\mathbf{A})$ for every i, strictly in at least one row, that is singular. Which step of the proof of Theorem 19.1.4 fails for it?

(b) Let $\mathbf{A}$ be irreducible and let λ be an eigenvalue with $|\lambda - a_{ii}| \geq r_i(\mathbf{A})$ for every i. Prove that the eigenspace $E_\lambda(\mathbf{A})$ has dimension 1.

Hint for (b): given two independent eigenvectors, form a combination with a zero coordinate.

Solution.

(a) Take $\mathbf{A} = \left(\begin{smallmatrix} 1 & 1 & 0 \\ 1 & 1 & 0 \\ 0 & 1 & 2 \end{smallmatrix}\right)$ from Exercise (B1: Deciding invertibility) (d): rows 1 and 2 have equality, row 3 is strict, and the first two rows are equal, so $\mathbf{A}$ is singular. The eigenvector $\mathbf{x} = (1, -1, \frac{1}{2})$ for 0 has $\mathbf{Ax} = (0, 0, -1 + 1) = \mathbf{0}$. Its peak set is $S = \{1, 2\}$, and the Claim of the proof holds: the rows in S have equality and their off-diagonal non-zero entries point into S. What fails is the spreading step. There is no walk from 3 to 1 in $G(\mathbf{A})$, so nothing forces $3 \in S$, and the strict row 3 is never reached.

(b) Suppose $\mathbf{x}$ and $\mathbf{y}$ are linearly independent eigenvectors for λ. Since $\mathbf{y} \neq \mathbf{0}$, choose i with $y_i \neq 0$, and put $\mathbf{z} = \mathbf{x} - (x_i/y_i)\mathbf{y}$. Then $\mathbf{z} \neq \mathbf{0}$, by independence, and $\mathbf{Az} = \lambda\mathbf{z}$, so $\mathbf{z}$ is an eigenvector for λ with $z_i = 0$. But by Theorem 19.1.4 every eigenvector for λ has all coordinates of the same modulus, which is positive because the vector is non-zero. This contradiction shows $\dim E_\lambda(\mathbf{A}) \leq 1$, and $\dim E_\lambda(\mathbf{A}) \geq 1$ because λ is an eigenvalue.

19.2 Other Inclusion Regions

The Gershgorin discs of §01 come from one row of $\mathbf{Ax} = \lambda\mathbf{x}$, read at the largest coordinate of $\mathbf{x}$. That leaves two kinds of information unused. The first is the second largest coordinate, which the triangle inequality simply replaced by the largest; using it gives a region of ovals that is never worse than the discs. The second is the geometry of the inner product, which the discs ignore entirely: the number $\mathbf{x}^*\mathbf{Ax}$ over unit vectors $\mathbf{x}$ fills a region of the plane, the numerical range, that contains every eigenvalue. This section builds both regions. Its main theorem is that the numerical range is always convex. It ends with a rectangle for the spectrum whose sides are eigenvalues of Hermitian matrices, and with a warning about what these regions cannot do.

Throughout, matrices are complex and $n \geq 1$**,** and $\|\cdot\|$ on $\mathbb{C}^n$ is the Euclidean norm. As in §01, $r_i(\mathbf{A}) = \sum_{j \neq i} |a_{ij}|$ is the i-th Gershgorin radius and $D_i(\mathbf{A})$ the i-th disc (Definition 19.1.1). The plane $\mathbb{C}$ is treated as a real vector space when convexity is discussed, as Chapter 17 §01 does.

19.2.1 Using two coordinates: Brauer's ovals

In the proof of Theorem 19.1.1 every $|x_j|$ with $j \neq k$ was bounded by the largest one, $|x_k|$. That is wasteful when the second largest coordinate is much smaller. So keep two indices: p, where $|x_p|$ is largest, and $q \neq p$, where it is largest among the rest. Row p bounds $|\lambda - a_{pp}||x_p|$

by $r_p|x_q|$, since every other coordinate is at most $|x_q|$. Row q bounds $|\lambda - a_{qq}||x_q|$ by $r_q|x_p|$. Multiplying the two bounds cancels the unknown coordinates. The result is a region defined by a product of distances.

Theorem 19.2.1 — Brauer's Ovals of Cassini

Let $n \geq 2$ and $\mathbf{A} \in M_n(\mathbb{C})$. For $i \neq j$ put

$$O_{ij}(\mathbf{A}) := \{\, z \in \mathbb{C} : |z - a_{ii}|\,|z - a_{jj}| \leq r_i(\mathbf{A})\, r_j(\mathbf{A}) \,\}.$$

(a) Every eigenvalue of $\mathbf{A}$ lies in $\bigcup_{i \neq j} O_{ij}(\mathbf{A})$.
(b) $O_{ij}(\mathbf{A}) \subseteq D_i(\mathbf{A}) \cup D_j(\mathbf{A})$ for every $i \neq j$. Hence $\bigcup_{i \neq j} O_{ij}(\mathbf{A}) \subseteq \bigcup_i D_i(\mathbf{A})$.

Idea. For (a), take the two largest coordinates of an eigenvector as above and multiply the two row estimates. One case needs separate care: if the second largest coordinate is 0, there is nothing to divide by, but then $\mathbf{x}$ is a multiple of $\mathbf{e}_p$ and $\lambda = a_{pp}$, which lies in every oval through a_{pp}. For (b), a point outside both discs is farther than r_i from a_{ii} and farther than r_j from a_{jj}, so the product of its distances exceeds $r_i r_j$.

Proof.

(a) Let $\mathbf{A}\mathbf{x} = \lambda \mathbf{x}$ with $\mathbf{x} \neq \mathbf{0}$. Choose p with $|x_p| = \max_j |x_j|$, which is positive, and then $q \neq p$ with $|x_q| = \max_{j \neq p} |x_j|$; this is possible because $n \geq 2$.
Case 1: $x_q = 0$. Then $x_j = 0$ for every $j \neq p$, and row p of $\mathbf{A}\mathbf{x} = \lambda \mathbf{x}$ reads $a_{pp} x_p = \lambda x_p$. As $x_p \neq 0$, $\lambda = a_{pp}$. The left side of the inequality defining $O_{pq}(\mathbf{A})$ is then 0, and the right side is ≥ 0, so $\lambda \in O_{pq}(\mathbf{A})$.
Case 2: $x_q \neq 0$. Row p gives $(\lambda - a_{pp}) x_p = \sum_{j \neq p} a_{pj} x_j$. Every $j \neq p$ has $|x_j| \leq |x_q|$, so by the triangle inequality (Theorem 0.6.4)

$$|\lambda - a_{pp}|\,|x_p| \leq r_p(\mathbf{A})\,|x_q|.$$

Row q gives $(\lambda - a_{qq}) x_q = \sum_{j \neq q} a_{qj} x_j$. Every j has $|x_j| \leq |x_p|$, so

$$|\lambda - a_{qq}|\,|x_q| \leq r_q(\mathbf{A})\,|x_p|.$$

Both sides of both inequalities are non-negative, so they may be multiplied:

$$|\lambda - a_{pp}|\,|\lambda - a_{qq}|\,|x_p|\,|x_q| \leq r_p(\mathbf{A})\, r_q(\mathbf{A})\,|x_p|\,|x_q|.$$

Dividing by $|x_p||x_q| > 0$ gives $\lambda \in O_{pq}(\mathbf{A})$.

(b) Let $z \notin D_i(\mathbf{A}) \cup D_j(\mathbf{A})$, so $a := |z - a_{ii}| > r_i(\mathbf{A}) \geq 0$ and $c := |z - a_{jj}| > r_j(\mathbf{A}) \geq 0$. Since $c > 0$ and $r_i(\mathbf{A}) \geq 0$,

$$ac > r_i(\mathbf{A})\, c \geq r_i(\mathbf{A})\, r_j(\mathbf{A}),$$

so $z \notin O_{ij}(\mathbf{A})$. Taking complements, $O_{ij}(\mathbf{A}) \subseteq D_i(\mathbf{A}) \cup D_j(\mathbf{A})$, and taking the union over all pairs gives the last claim. This proves the theorem.

■

The sets $O_{ij}(\mathbf{A})$ are the **ovals of Cassini**: the points whose distances to two fixed foci have

product at most a constant. Since $O_{ij}(\mathbf{A}) = O_{ji}(\mathbf{A})$, there are $n(n-1)/2$ of them to draw, against n discs. The hypothesis $n \geq 2$ is there because an oval needs two distinct indices; for $n = 1$ there are none, and the eigenvalue a_{11} must be found some other way. For $n = 2$ the single oval is as good as a region can be. The eigenvalues satisfy $(\lambda - a_{11})(\lambda - a_{22}) = a_{12}a_{21}$, so taking moduli, $|\lambda - a_{11}||\lambda - a_{22}| = r_1 r_2$: both eigenvalues lie on the boundary curve of O_{12}.

Example. (Ovals where discs fail)

Let $\mathbf{A} = \begin{pmatrix} 4 & 1 & 0 \\ 0 & 4 & 1 \\ 1 & 1 & 1 \end{pmatrix}$. Show that the Gershgorin discs cannot prove $\mathbf{A}$ invertible, and that the ovals can.

Solution. The radii are $r_1 = 1$, $r_2 = 1$, $r_3 = 2$, and $D_3(\mathbf{A}) = \{|z - 1| \leq 2\}$ contains 0. So Theorem 19.1.1 (a) allows the eigenvalue 0. The column radii are $1, 2, 1$, and the second column disc $|z - 4| \leq 2$ misses 0, but the third, $|z - 1| \leq 1$, contains it. So the discs cannot decide.

Now test $z = 0$ against the three ovals:

$$\begin{aligned} O_{12}: &\ |0-4|\,|0-4| = 16 > 1 = r_1 r_2, \\ O_{13}: &\ |0-4|\,|0-1| = 4 > 2 = r_1 r_3, \\ O_{23}: &\ |0-4|\,|0-1| = 4 > 2 = r_2 r_3. \end{aligned}$$

So 0 lies in no oval, it is not an eigenvalue by Theorem 19.2.1 (a), and $\mathbf{A}$ is invertible by Theorem 8.2.1. Indeed, expanding along the first row, $\det \mathbf{A} = 4(4-1) - 1(0-1) = 13$. The ovals also exclude the point -1, which lies on the boundary of $D_3(\mathbf{A})$: there $|-1-4|\,|-1-4| = 25 > 1$ rules out O_{12}, and $|-1-4|\,|-1-1| = 10 > 2$ rules out O_{13} and O_{23}.

The same test gives a criterion in the spirit of Corollary 19.1.2: if $n \geq 2$, as in Theorem 19.2.1, and $|a_{ii}|\,|a_{jj}| > r_i(\mathbf{A})\, r_j(\mathbf{A})$ for **every** pair $i \neq j$, then 0 lies in no oval and $\mathbf{A}$ is invertible. One row may fail to dominate, as row 3 did above, provided every other row dominates enough to compensate.

Quick check. Why does the proof of Theorem 19.2.1 (a) choose q to maximize $|x_q|$ among the indices other than p, rather than taking any $q \neq p$?

Solution. The estimate from row p bounds every $|x_j|$, $j \neq p$, by $|x_q|$. That is true only if $|x_q|$ is the largest of them. With an arbitrary q the row-p estimate could fail, and the product of the two estimates would no longer cancel down to $r_p r_q$.

19.2.2 The numerical range

Now a different source of information. For a Hermitian $\mathbf{A}$, Chapter 16 §01 studied the Rayleigh quotient, and Proposition 16.1.1 showed that its values $\mathbf{x}^*\mathbf{A}\mathbf{x}$ on unit vectors fill exactly the interval $[\lambda_n(\mathbf{A}), \lambda_1(\mathbf{A})]$, which contains every eigenvalue. The number $\mathbf{x}^*\mathbf{A}\mathbf{x} = \langle \mathbf{A}\mathbf{x}, \mathbf{x} \rangle$ makes sense for every square matrix. Without the Hermitian hypothesis it is complex, and its values fill a region of the plane rather than an interval.

The numerical range is the set of all values $\mathbf{x}^*\mathbf{A}\mathbf{x}$ as $\mathbf{x}$ runs over the unit vectors.

Definition 19.2.1 — Numerical Range

Let $\mathbf{A} \in M_n(\mathbb{C})$. The **numerical range** of $\mathbf{A}$ is the subset of $\mathbb{C}$

$$W(\mathbf{A}) \coloneqq \{\, \mathbf{x}^*\mathbf{A}\mathbf{x} : \mathbf{x} \in \mathbb{C}^n,\ \|\mathbf{x}\| = 1 \,\}.$$

In words: feed $\mathbf{A}$ a vector of length **exactly** 1, take the inner product of the output with the input, and collect all the complex numbers that arise. The vectors range over **complex** unit vectors, even when $\mathbf{A}$ is real, and the conjugate in $\mathbf{x}^*$ is part of the definition. $W(\mathbf{A})$ is always non-empty, since $\mathbf{e}_1$ is a unit vector, and $\mathbf{e}_i^*\mathbf{A}\mathbf{e}_i = a_{ii}$, so every diagonal entry lies in $W(\mathbf{A})$. The notation always carries its argument: $W(\mathbf{A})$, never W alone, since W also names subspaces.

Examples, simplest first.

- $n = 1$**, and scalar matrices.** For $\mathbf{A} = (a)$ the unit vectors are the scalars x with $|x| = 1$, and $\overline{x}ax = a|x|^2 = a$. So $W((a)) = \{a\}$. Likewise $W(c\mathbf{I}) = \{c\}$, since $\mathbf{x}^*(c\mathbf{I})\mathbf{x} = c\|\mathbf{x}\|^2 = c$.
- **Diagonal matrices.** For $\mathbf{A} = \operatorname{diag}(d_1, \dots, d_n)$, $\mathbf{x}^*\mathbf{A}\mathbf{x} = \sum_i d_i|x_i|^2$. The weights $t_i = |x_i|^2$ are non-negative with sum $\|\mathbf{x}\|^2 = 1$, and every such list of weights arises, from $x_i = \sqrt{t_i}$. So $W(\mathbf{A})$ is the set of all weighted averages of $d_1, \dots, d_n$, which is $\operatorname{conv}\{d_1, \dots, d_n\}$ by Theorem 17.1.3. For $\operatorname{diag}(1, i, -1)$ it is the filled triangle with these three vertices.
- **Hermitian matrices.** By Proposition 16.1.1, $W(\mathbf{A}) = [\lambda_n(\mathbf{A}), \lambda_1(\mathbf{A})]$, a segment of the real axis.
- **A Jordan block.** The next example computes $W(\mathbf{J}_2(0))$, and it is a whole disc, although the only eigenvalue is 0.

Example. (The numerical range of a Jordan block)

Show that $W(\mathbf{J}_2(0)) = \{z \in \mathbb{C} : |z| \le \frac{1}{2}\}$.

Solution. Write $\mathbf{x} = (x_1, x_2)$ with $|x_1|^2 + |x_2|^2 = 1$. Then $\mathbf{J}_2(0)\mathbf{x} = (x_2, 0)$, so $\mathbf{x}^*\mathbf{J}_2(0)\mathbf{x} = \overline{x_1}\, x_2$.

($\subseteq$) Since $0 \le (|x_1| - |x_2|)^2 = 1 - 2|x_1||x_2|$, we get $|\overline{x_1}x_2| = |x_1||x_2| \le \frac{1}{2}$.

($\supseteq$) Let $z = \rho\,\omega$ with $0 \le \rho \le \frac{1}{2}$ and $|\omega| = 1$. Since $1 - 4\rho^2 \ge 0$, we may put

$$a = \sqrt{\tfrac{1+\sqrt{1-4\rho^2}}{2}}, \qquad b = \sqrt{\tfrac{1-\sqrt{1-4\rho^2}}{2}},$$

both real and non-negative. Then $a^2 + b^2 = 1$ and $a^2b^2 = \frac{1}{4}\big(1 - (1 - 4\rho^2)\big) = \rho^2$, so $ab = \rho$. The unit vector $\mathbf{x} = (a, b\,\omega)$ gives $\mathbf{x}^*\mathbf{J}_2(0)\mathbf{x} = a\,b\,\omega = z$. Hence $W(\mathbf{J}_2(0))$ is the closed disc of radius $\frac{1}{2}$ about 0.

Non-example by minimal change. Drop the conjugate, and collect the numbers $\mathbf{x}^\top\mathbf{A}\mathbf{x}$ for unit $\mathbf{x}$ instead. For $\mathbf{A} = \mathbf{I}_2$ and the unit vector $\mathbf{x} = \frac{1}{\sqrt{2}}(1, i)$, $\mathbf{x}^\top\mathbf{I}_2\mathbf{x} = \frac{1}{2}(1 + i^2) = 0$, while $\mathbf{x}^*\mathbf{I}_2\mathbf{x} = 1$. The modified set for $\mathbf{I}_2$ contains 0, which is not an eigenvalue, while $W(\mathbf{I}_2) = \{1\}$ is exactly the spectrum. What breaks is that $\mathbf{x}^\top\mathbf{x}$ is not $\|\mathbf{x}\|^2$ over $\mathbb{C}$. The conjugate is what makes $\mathbf{x}^*(c\mathbf{I})\mathbf{x} = c$ on the unit sphere, and every property below leans on that.

Why this definition. The unit length plays the role that division by $\|\mathbf{x}\|^2$ played for the Rayleigh quotient. Without it the values $\mathbf{x}^*\mathbf{A}\mathbf{x}$ over all $\mathbf{x}$ form a set closed under multiplication by positive reals, which is all of $\mathbb{C}$ or a cone, and records nothing about the size of $\mathbf{A}$. With it, the set is bounded, and the eigenvalues are in it.

Proposition 19.2.2 — Basic Properties of the Numerical Range

Let $\mathbf{A} \in M_n(\mathbb{C})$.

(a) $\operatorname{spec}(\mathbf{A}) \subseteq W(\mathbf{A})$.

(b) $W(\alpha\mathbf{A} + \beta\mathbf{I}) = \alpha W(\mathbf{A}) + \beta \coloneqq \{\alpha w + \beta : w \in W(\mathbf{A})\}$ for all $\alpha, \beta \in \mathbb{C}$.

(c) $W(\mathbf{U}^*\mathbf{A}\mathbf{U}) = W(\mathbf{A})$ for every unitary $\mathbf{U} \in M_n(\mathbb{C})$.

(d) $W(\mathbf{A})$ is compact: every sequence in $W(\mathbf{A})$ has a subsequence converging to a point of $W(\mathbf{A})$. In particular $W(\mathbf{A})$ is closed.

(e) $W(\mathbf{A}) \subseteq \{z : |z| \le \|\mathbf{A}\|_2\}$.

Idea. Four of the five parts are one line of algebra with a unit vector: evaluate at a unit eigenvector for (a), push the scalars or the unitary through $\mathbf{x}^*(\cdot)\mathbf{x}$ for (b) and (c), and apply Cauchy–Schwarz for (e). Only (d) needs analysis, and there the point is that $W(\mathbf{A})$ is the image of the unit sphere under a continuous map, so the compactness of the sphere passes to it.

Proof.

(a) Let $\lambda \in \operatorname{spec}(\mathbf{A})$, with eigenvector $\mathbf{v}$. Then $\mathbf{x} = \mathbf{v}/\|\mathbf{v}\|$ is a unit eigenvector, and $\mathbf{x}^*\mathbf{A}\mathbf{x} = \lambda\,\mathbf{x}^*\mathbf{x} = \lambda$.

(b) For a unit $\mathbf{x}$, $\mathbf{x}^*(\alpha\mathbf{A} + \beta\mathbf{I})\mathbf{x} = \alpha\,\mathbf{x}^*\mathbf{A}\mathbf{x} + \beta\,\mathbf{x}^*\mathbf{x} = \alpha\,\mathbf{x}^*\mathbf{A}\mathbf{x} + \beta$. As $\mathbf{x}$ runs over the unit vectors, the left side runs over $W(\alpha\mathbf{A}+\beta\mathbf{I})$ and the right side over $\alpha W(\mathbf{A})+\beta$.

(c) For a unit $\mathbf{x}$, $\mathbf{x}^*\mathbf{U}^*\mathbf{A}\mathbf{U}\mathbf{x} = (\mathbf{U}\mathbf{x})^*\mathbf{A}(\mathbf{U}\mathbf{x})$, and $\mathbf{U}\mathbf{x}$ is a unit vector because $\mathbf{U}$ is an isometry (Theorem 10.7.3). So $W(\mathbf{U}^*\mathbf{A}\mathbf{U}) \subseteq W(\mathbf{A})$. Conversely, every unit $\mathbf{y}$ equals $\mathbf{U}\mathbf{x}$ for the unit vector $\mathbf{x} = \mathbf{U}^*\mathbf{y}$, so every value $\mathbf{y}^*\mathbf{A}\mathbf{y}$ arises, and the two sets are equal.

(d) First, $f(\mathbf{x}) = \mathbf{x}^*\mathbf{A}\mathbf{x}$ is continuous on the unit sphere. For unit vectors $\mathbf{x}, \mathbf{y}$,

$$\begin{aligned} |f(\mathbf{x}) - f(\mathbf{y})| &= |\mathbf{x}^*\mathbf{A}(\mathbf{x}-\mathbf{y}) + (\mathbf{x}-\mathbf{y})^*\mathbf{A}\mathbf{y}| \\ &\le 2\,\|\mathbf{A}\|_2\,\|\mathbf{x}-\mathbf{y}\|, \end{aligned}$$

by the triangle inequality (Theorem 0.6.4), the Cauchy–Schwarz inequality (Theorem 10.1.5) and Theorem 15.3.2 (a). This is a bound of the kind fixed as the book's continuity test in Chapter 15's introduction. Now let (w_k) be a sequence in $W(\mathbf{A})$, with $w_k = f(\mathbf{x}_k)$ and $\|\mathbf{x}_k\| = 1$. By **the compactness of the unit sphere, fact (A3) of Chapter 15's introduction**, a subsequence $(\mathbf{x}_{k_l})$ converges to a unit vector $\mathbf{x}$. By continuity, $w_{k_l} = f(\mathbf{x}_{k_l}) \to f(\mathbf{x}) \in W(\mathbf{A})$. If (w_k) itself converges to w, its subsequence converges to w too, and limits are unique, so $w = f(\mathbf{x}) \in W(\mathbf{A})$: the set is closed.

(e) For a unit $\mathbf{x}$, by the Cauchy–Schwarz inequality and Theorem 15.3.2 (a), $|\mathbf{x}^*\mathbf{A}\mathbf{x}| = |\langle \mathbf{A}\mathbf{x}, \mathbf{x}\rangle| \le \|\mathbf{A}\mathbf{x}\|\,\|\mathbf{x}\| \le \|\mathbf{A}\|_2$.

■

Part (a) makes $W(\mathbf{A})$ an inclusion region for the spectrum, and (e) puts it inside the disc of radius $\|\mathbf{A}\|_2$, which upgrades $\rho(\mathbf{A}) \le \|\mathbf{A}\|_2$ from the spectrum to the whole numerical range. Part (b) is the tool that lets us move any two points of $W(\mathbf{A})$ to 0 and 1, and the next proof depends on it. Part (c) says $W(\mathbf{A})$ depends only on the operator $T_{\mathbf{A}}$ and the inner product, not on the orthonormal basis used to write it down.

19.2.3 Convexity: the Toeplitz–Hausdorff theorem

The examples so far were all convex: a point, a segment, a triangle, a disc. That is not a coincidence. To prove it, split $\mathbf{A}$ into two Hermitian pieces, the way a complex number splits into its real and imaginary parts.

Lemma 19.2.3 — Real and Imaginary Parts of a Matrix

Let $\mathbf{A} \in M_n(\mathbb{C})$, and put

$$\mathbf{H} = \frac{\mathbf{A} + \mathbf{A}^*}{2}, \qquad \mathbf{K} = \frac{\mathbf{A} - \mathbf{A}^*}{2i}.$$

Then $\mathbf{H}$ and $\mathbf{K}$ are Hermitian, $\mathbf{A} = \mathbf{H} + i\mathbf{K}$, and for every $\mathbf{x} \in \mathbb{C}^n$ the numbers $\mathbf{x}^*\mathbf{H}\mathbf{x}$ and $\mathbf{x}^*\mathbf{K}\mathbf{x}$ are real, with

$$\operatorname{Re}(\mathbf{x}^*\mathbf{A}\mathbf{x}) = \mathbf{x}^*\mathbf{H}\mathbf{x}, \qquad \operatorname{Im}(\mathbf{x}^*\mathbf{A}\mathbf{x}) = \mathbf{x}^*\mathbf{K}\mathbf{x}.$$

Proof. By Definition 10.1.2, $(\mathbf{A}^*)^* = \mathbf{A}$, $(\mathbf{B}+\mathbf{C})^* = \mathbf{B}^* + \mathbf{C}^*$ and $(c\mathbf{B})^* = \overline{c}\mathbf{B}^*$. Hence $\mathbf{H}^* = \frac{1}{2}(\mathbf{A}^* + \mathbf{A}) = \mathbf{H}$ and $\mathbf{K}^* = \frac{1}{-2i}(\mathbf{A}^* - \mathbf{A}) = \frac{1}{2i}(\mathbf{A} - \mathbf{A}^*) = \mathbf{K}$. Also $\mathbf{H} + i\mathbf{K} = \frac{1}{2}(\mathbf{A} + \mathbf{A}^*) + \frac{1}{2}(\mathbf{A} - \mathbf{A}^*) = \mathbf{A}$. For $\mathbf{x} \in \mathbb{C}^n$, $\mathbf{x}^*\mathbf{H}\mathbf{x} = \langle \mathbf{H}\mathbf{x}, \mathbf{x}\rangle$ is real by Proposition 10.6.7 (a), applied to the self-adjoint operator $T_{\mathbf{H}}$, and likewise $\mathbf{x}^*\mathbf{K}\mathbf{x}$. So $\mathbf{x}^*\mathbf{A}\mathbf{x} = \mathbf{x}^*\mathbf{H}\mathbf{x} + i\,\mathbf{x}^*\mathbf{K}\mathbf{x}$ is the splitting of a complex number into real and imaginary parts. ∎

For example $\mathbf{J}_2(0)$ has $\mathbf{H} = \frac{1}{2}\left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$ and $\mathbf{K} = \frac{1}{2i}\left(\begin{smallmatrix} 0 & 1 \\ -1 & 0 \end{smallmatrix}\right) = \frac{1}{2}\left(\begin{smallmatrix} 0 & -i \\ i & 0 \end{smallmatrix}\right)$, both with eigenvalues $\pm\frac{1}{2}$. A Hermitian $\mathbf{A}$ has $\mathbf{K} = 0$, and then $W(\mathbf{A})$ lies on the real axis.

Theorem 19.2.4 — Toeplitz–Hausdorff Theorem

For every $\mathbf{A} \in M_n(\mathbb{C})$, the numerical range $W(\mathbf{A})$ is a convex subset of $\mathbb{C}$.

Idea. **Step roadmap.** ① By Proposition 19.2.2 (b), an affine change $z \mapsto \alpha z + \beta$ carries any two points of $W(\mathbf{A})$ to 0 and 1, and carries segments to segments; so it suffices to show that $[0,1] \subseteq W(\mathbf{B})$ whenever $0, 1 \in W(\mathbf{B})$. ② Take unit vectors $\mathbf{x}$, $\mathbf{y}$ with $\mathbf{x}^*\mathbf{B}\mathbf{x} = 0$ and $\mathbf{y}^*\mathbf{B}\mathbf{y} = 1$, and walk from $\mathbf{x}$ to $\mathbf{y}$ along the straight path $(1-t)\mathbf{x}+t\mathbf{y}$. Along the way the value of $\mathbf{B}$, normalized, moves continuously from 0 to 1, but it may wander off the real axis. ③ Its imaginary part along the path is $\mathbf{K}$ evaluated there, and expanding shows that only the cross term $\mathbf{x}^*\mathbf{K}\mathbf{y}+\mathbf{y}^*\mathbf{K}\mathbf{x} = 2\operatorname{Re}(\mathbf{x}^*\mathbf{K}\mathbf{y})$ can be non-zero. Multiplying $\mathbf{y}$ by a unimodular scalar rotates $\mathbf{x}^*\mathbf{K}\mathbf{y}$ freely without changing $\mathbf{y}^*\mathbf{B}\mathbf{y}$, so we rotate it onto the imaginary axis, where its real part is 0. ④ Then the path stays on

the real axis, and the intermediate value theorem fills in $[0,1]$.

Proof. **Step 1: reduction.** Let $w_0, w_1 \in W(\mathbf{A})$ and $0 \le s \le 1$; we must show $(1-s)w_0 + sw_1 \in W(\mathbf{A})$. If $w_0 = w_1$ there is nothing to prove. Otherwise put $\alpha = 1/(w_1 - w_0)$, $\beta = -\alpha w_0$ and $\mathbf{B} = \alpha\mathbf{A} + \beta\mathbf{I}$. By Proposition 19.2.2 (b), $W(\mathbf{B}) = \alpha W(\mathbf{A}) + \beta$, which contains $\alpha w_0 + \beta = 0$ and $\alpha w_1 + \beta = 1$. Suppose we show $s \in W(\mathbf{B})$. Then $s = \alpha w + \beta$ for some $w \in W(\mathbf{A})$, and solving, $w = w_0 + s(w_1 - w_0) = (1-s)w_0 + sw_1$. So it suffices to prove: **if $0, 1 \in W(\mathbf{B})$, then $[0,1] \subseteq W(\mathbf{B})$.**

Step 2: choosing the vectors. Let $\mathbf{B} = \mathbf{H} + i\mathbf{K}$ as in Lemma 19.2.3, and choose unit vectors $\mathbf{x}$, $\mathbf{y}_0$ with $\mathbf{x}^*\mathbf{B}\mathbf{x} = 0$ and $\mathbf{y}_0^*\mathbf{B}\mathbf{y}_0 = 1$. By Lemma 19.2.3, $\mathbf{x}^*\mathbf{H}\mathbf{x} = \mathbf{x}^*\mathbf{K}\mathbf{x} = 0$, $\mathbf{y}_0^*\mathbf{H}\mathbf{y}_0 = 1$ and $\mathbf{y}_0^*\mathbf{K}\mathbf{y}_0 = 0$. Let $c = \mathbf{x}^*\mathbf{K}\mathbf{y}_0$, and put $\gamma = 1$ if $c = 0$, and $\gamma = i\overline{c}/|c|$ otherwise. In both cases $|\gamma| = 1$ and $\gamma c = i|c|$ is purely imaginary. Set $\mathbf{y} = \gamma\mathbf{y}_0$. Then $\|\mathbf{y}\| = 1$ and $\mathbf{y}^*\mathbf{B}\mathbf{y} = |\gamma|^2\,\mathbf{y}_0^*\mathbf{B}\mathbf{y}_0 = 1$, so still $\mathbf{y}^*\mathbf{H}\mathbf{y} = 1$ and $\mathbf{y}^*\mathbf{K}\mathbf{y} = 0$. Since $\mathbf{K}$ is Hermitian, $\mathbf{y}^*\mathbf{K}\mathbf{x} = (\mathbf{x}^*\mathbf{K}\mathbf{y})^* = \overline{\mathbf{x}^*\mathbf{K}\mathbf{y}}$, and so

$$\mathbf{x}^*\mathbf{K}\mathbf{y} + \mathbf{y}^*\mathbf{K}\mathbf{x} = 2\,\mathrm{Re}(\mathbf{x}^*\mathbf{K}\mathbf{y}) = 2\,\mathrm{Re}(\gamma c) = 0.$$

Finally, $\mathbf{x}$ and $\mathbf{y}$ are linearly independent. Otherwise, both being non-zero, $\mathbf{y} = \mu\mathbf{x}$ for a scalar μ, and then $1 = \mathbf{y}^*\mathbf{B}\mathbf{y} = |\mu|^2\,\mathbf{x}^*\mathbf{B}\mathbf{x} = 0$, which is absurd.

Step 3: the path stays real. For $t \in [0,1]$ put $\mathbf{v}(t) = (1-t)\mathbf{x} + t\mathbf{y}$. The coefficients $1-t$ and t are not both zero, so $\mathbf{v}(t) \neq \mathbf{0}$ by independence. Expanding, and using $\mathbf{x}^*\mathbf{K}\mathbf{x} = \mathbf{y}^*\mathbf{K}\mathbf{y} = 0$ and Step 2,

$$\mathbf{v}(t)^*\mathbf{K}\mathbf{v}(t) = (1-t)^2\,\mathbf{x}^*\mathbf{K}\mathbf{x} + t^2\,\mathbf{y}^*\mathbf{K}\mathbf{y} + t(1-t)\big(\mathbf{x}^*\mathbf{K}\mathbf{y} + \mathbf{y}^*\mathbf{K}\mathbf{x}\big) = 0.$$

So $\mathbf{v}(t)^*\mathbf{B}\mathbf{v}(t) = \mathbf{v}(t)^*\mathbf{H}\mathbf{v}(t)$ is real for every t. The same expansion with $\mathbf{H}$ in place of $\mathbf{K}$, and with $\|\mathbf{v}(t)\|^2 = \mathbf{v}(t)^*\mathbf{v}(t)$, gives

$$\begin{aligned}\mathbf{v}(t)^*\mathbf{H}\mathbf{v}(t) &= t^2 + 2t(1-t)\,\mathrm{Re}(\mathbf{x}^*\mathbf{H}\mathbf{y}),\\ \|\mathbf{v}(t)\|^2 &= (1-t)^2 + t^2 + 2t(1-t)\,\mathrm{Re}(\mathbf{x}^*\mathbf{y}),\end{aligned}$$

two polynomials in t with real coefficients, the second positive on $[0,1]$.

Step 4: filling the segment. The function

$$f(t) = \frac{\mathbf{v}(t)^*\mathbf{H}\mathbf{v}(t)}{\|\mathbf{v}(t)\|^2}, \qquad 0 \le t \le 1,$$

is a quotient of polynomials with a denominator that never vanishes, hence continuous by the algebra of limits, and $f(0) = \mathbf{x}^*\mathbf{H}\mathbf{x} = 0$, $f(1) = \mathbf{y}^*\mathbf{H}\mathbf{y} = 1$. Let $s \in [0,1]$. By **the intermediate value theorem, fact (A5) of Chapter 15's introduction**, there is $t_s \in [0,1]$ with $f(t_s) = s$. The vector $\mathbf{u} = \mathbf{v}(t_s)/\|\mathbf{v}(t_s)\|$ is a unit vector, and by Step 3,

$$\mathbf{u}^*\mathbf{B}\mathbf{u} = \frac{\mathbf{v}(t_s)^*\mathbf{B}\mathbf{v}(t_s)}{\|\mathbf{v}(t_s)\|^2} = \frac{\mathbf{v}(t_s)^*\mathbf{H}\mathbf{v}(t_s)}{\|\mathbf{v}(t_s)\|^2} = f(t_s) = s.$$

So $s \in W(\mathbf{B})$. By Step 1, $W(\mathbf{A})$ contains the segment between any two of its points, which is Definition 17.1.1. This proves the theorem.

■

The phase choice in Step 2 is the heart of the proof. Without it the imaginary part along the

path is $2t(1-t)\,\mathrm{Re}(\mathbf{x}^*\mathbf{K}\mathbf{y}_0)/\|\mathbf{v}(t)\|^2$, which may be non-zero, and the path would leave the real axis between 0 and 1. The rotated vector $\gamma\mathbf{y}_0$ spans the same line as $\mathbf{y}_0$ and gives the same value of $\mathbf{B}$, so the rotation costs nothing. Only the path between $\mathbf{x}$ and $\mathbf{y}$ changes.

With convexity, $W(\mathbf{A})$ contains the convex hull of $\mathrm{spec}(\mathbf{A})$, by (a) and Definition 17.1.4, and it contains the diagonal entries, so it contains $\mathrm{conv}\{a_{11},\dots,a_{nn}\}$ as well.

19.2.4 Normal matrices

For a diagonal matrix the numerical range is the convex hull of the diagonal entries, and those are the eigenvalues. Unitary similarity does not change W, and a normal matrix is unitarily similar to a diagonal one. So for a normal matrix $W(\mathbf{A})$ is as small as (a) and convexity allow.

Proposition 19.2.5 — The Numerical Range of a Normal Matrix

Let $\mathbf{A} \in M_n(\mathbb{C})$ be normal, with eigenvalues $\lambda_1,\dots,\lambda_n$, listed with multiplicity. Then

$$W(\mathbf{A}) = \mathrm{conv}\{\lambda_1,\dots,\lambda_n\}.$$

Idea. Unitary similarity leaves W alone, by Proposition 19.2.2 (c), so we may replace $\mathbf{A}$ by a diagonal matrix of its eigenvalues. Then $\mathbf{x}^*\mathbf{A}\mathbf{x}$ is the average of the λ_i with weights $|x_i|^2$, and the two inclusions say exactly that the lists of admissible weights and of convex coefficients are the same.

Proof. By Corollary 11.4.3, $\mathbf{A} = \mathbf{U}\mathbf{D}\mathbf{U}^*$ with $\mathbf{U}$ unitary and $\mathbf{D} = \mathrm{diag}(\lambda_1,\dots,\lambda_n)$. So $\mathbf{U}^*\mathbf{A}\mathbf{U} = \mathbf{D}$, and $W(\mathbf{A}) = W(\mathbf{D})$ by Proposition 19.2.2 (c). For a unit $\mathbf{x}$, $\mathbf{x}^*\mathbf{D}\mathbf{x} = \sum_i |x_i|^2\lambda_i$.

($\subseteq$) The weights $|x_i|^2$ are non-negative with sum 1, so $\mathbf{x}^*\mathbf{D}\mathbf{x}$ is a convex combination of $\lambda_1,\dots,\lambda_n$, and lies in their convex hull by Theorem 17.1.3.

($\supseteq$) By Theorem 17.1.3, a point of the hull is $\sum_{k=1}^{m} t_k\mu_k$ with $t_k \geq 0$, $\sum_k t_k = 1$ and each μ_k one of the λ_i. Assign each k to one index i with $\lambda_i = \mu_k$, and let s_i be the sum of the t_k assigned to i. Then $s_i \geq 0$, $\sum_i s_i = 1$, and the point is $\sum_i s_i\lambda_i$. The unit vector with $x_i = \sqrt{s_i}$ gives $\mathbf{x}^*\mathbf{D}\mathbf{x} = \sum_i s_i\lambda_i$.

■

For a Hermitian matrix this recovers Proposition 16.1.1. For a unitary matrix, whose eigenvalues lie on the unit circle, $W(\mathbf{A})$ is the convex hull of those eigenvalues: a polygon inscribed in the circle when three or more of them are distinct, and a chord or a single point when there are two or one. For a non-normal matrix $W(\mathbf{A})$ can be much larger than $\mathrm{conv}\,\mathrm{spec}(\mathbf{A})$: by Example (The numerical range of a Jordan block), $W(\mathbf{J}_2(0))$ is a disc of radius $\frac{1}{2}$ around the single eigenvalue 0. The extra room is a measure of non-normality, and Exercise C3 turns it into a comparison with $\|\mathbf{A}\|_2$.

Quick check. Find $W(\mathbf{A})$ for the rotation $\mathbf{A} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$, regarded as a complex matrix.

Solution. $\mathbf{A}^{\top}\mathbf{A} = \mathbf{I}$, so $\mathbf{A}$ is real orthogonal, hence unitary and normal. Its characteristic polynomial is $x^2 + 1$, with roots $\pm i$. By Proposition 19.2.5, $W(\mathbf{A})$ is the segment from $-i$ to i on the imaginary axis. For real unit vectors $\mathbf{x}$ the value $\mathbf{x}^*\mathbf{A}\mathbf{x}$ is 0, which is why the real Rayleigh-type quotient of Chapter 16 §01 saw nothing; the complex unit vectors fill in the rest.

19.2.5 Bendixson's rectangle

By Lemma 19.2.3, the real part of $\mathbf{x}^*\mathbf{A}\mathbf{x}$ is a value of the Hermitian form of $\mathbf{H}$, and Proposition 16.1.1 confines those values to $[\lambda_n(\mathbf{H}), \lambda_1(\mathbf{H})]$. The same holds for the imaginary part and $\mathbf{K}$. Together they box in the whole numerical range, hence the spectrum.

Theorem 19.2.6 — Bendixson's Theorem

Let $\mathbf{A} \in M_n(\mathbb{C})$, with $\mathbf{H} = (\mathbf{A} + \mathbf{A}^*)/2$ and $\mathbf{K} = (\mathbf{A} - \mathbf{A}^*)/(2i)$. Every $w \in W(\mathbf{A})$ satisfies

$$\lambda_n(\mathbf{H}) \le \operatorname{Re} w \le \lambda_1(\mathbf{H}),$$
$$\lambda_n(\mathbf{K}) \le \operatorname{Im} w \le \lambda_1(\mathbf{K}).$$

In particular every eigenvalue λ of $\mathbf{A}$ satisfies the same inequalities with λ in place of w.

Proof. Let $w = \mathbf{x}^*\mathbf{A}\mathbf{x}$ with $\|\mathbf{x}\| = 1$. By Lemma 19.2.3, $\operatorname{Re} w = \mathbf{x}^*\mathbf{H}\mathbf{x} = \langle \mathbf{H}\mathbf{x}, \mathbf{x}\rangle$ and $\operatorname{Im} w = \mathbf{x}^*\mathbf{K}\mathbf{x}$, and $\mathbf{H}$, $\mathbf{K}$ are Hermitian. By Lemma 12.5.2, $\lambda_n(\mathbf{H}) \le \langle \mathbf{H}\mathbf{x}, \mathbf{x}\rangle \le \lambda_1(\mathbf{H})$, and likewise for $\mathbf{K}$. Every eigenvalue lies in $W(\mathbf{A})$ by Proposition 19.2.2 (a). ∎

The most used consequence concerns the sign of the real parts. If $\mathbf{A} + \mathbf{A}^* \succ 0$, then $\lambda_n(\mathbf{H}) > 0$, so every eigenvalue of $\mathbf{A}$ has positive real part, and in particular $\mathbf{A}$ is invertible. This needs nothing about the size of the off-diagonal entries, only about their symmetric part.

Example. (A rectangle beats the discs)

Let $\mathbf{A} = \begin{pmatrix} 3 & 2 \\ -4 & 1 \end{pmatrix}$. Show that every eigenvalue of $\mathbf{A}$ has positive real part, using Theorem 19.2.6, and check that the Gershgorin discs cannot show it. Compare with the eigenvalues.

Solution. Here $\mathbf{A}^* = \mathbf{A}^{\top}$, so

$$\mathbf{H} = \begin{pmatrix} 3 & -1 \\ -1 & 1 \end{pmatrix}, \qquad \mathbf{K} = \frac{1}{2i}\begin{pmatrix} 0 & 6 \\ -6 & 0 \end{pmatrix} = \begin{pmatrix} 0 & -3i \\ 3i & 0 \end{pmatrix}.$$

$\mathbf{H}$ has trace 4 and determinant 2, so $p_{\mathbf{H}}(x) = x^2 - 4x + 2$, with roots $2 \pm \sqrt{2}$. $\mathbf{K}$ has trace 0 and determinant $0 - (-3i)(3i) = -9$, so its eigenvalues are ± 3. By Theorem 19.2.6, every eigenvalue lies in the rectangle

$$2 - \sqrt{2} \le \operatorname{Re}\lambda \le 2 + \sqrt{2}, \qquad -3 \le \operatorname{Im}\lambda \le 3,$$

and in particular $\operatorname{Re}\lambda \geq 2-\sqrt{2} > 0$.

The row discs are $|z-3| \leq 2$ and $|z-1| \leq 4$, and the second contains -3. The column discs are $|z-3| \leq 4$ and $|z-1| \leq 2$, and the first contains -1. So neither union rules out an eigenvalue with negative real part.

Directly, $p_{\mathbf{A}}(x) = x^2 - 4x + 11$, so $\lambda = 2 \pm i\sqrt{7}$. The real part 2 lies in $[2-\sqrt{2}, 2+\sqrt{2}]$, and the imaginary parts $\pm\sqrt{7} \approx \pm 2.65$ lie in $[-3, 3]$.

19.2.6 What these regions do not do

Every region in this section and the last is an **inclusion region**: it contains the spectrum. None of them is a perturbation bound in the sense of the rest of this chapter, which asks how far the eigenvalues move when $\mathbf{A}$ changes by a small $\mathbf{E}$. The numerical range does give a statement of that kind. For a unit $\mathbf{x}$, $\mathbf{x}^*(\mathbf{A}+\mathbf{E})\mathbf{x} = \mathbf{x}^*\mathbf{A}\mathbf{x} + \mathbf{x}^*\mathbf{E}\mathbf{x}$, and $|\mathbf{x}^*\mathbf{E}\mathbf{x}| \leq \|\mathbf{E}\|_2$ by Proposition 19.2.2 (e). Hence

$$W(\mathbf{A}+\mathbf{E}) \subseteq W(\mathbf{A}) + W(\mathbf{E}) \subseteq \{\, w + e : w \in W(\mathbf{A}),\ |e| \leq \|\mathbf{E}\|_2 \,\},$$

and so every eigenvalue of $\mathbf{A}+\mathbf{E}$ lies within $\|\mathbf{E}\|_2$ of $W(\mathbf{A})$. This is only as good as $W(\mathbf{A})$ is small.

Warning. **$W(\mathbf{A})$ can be far larger than $\operatorname{spec}(\mathbf{A})$, so "within $\|\mathbf{E}\|_2$ of $W(\mathbf{A})$" is not "within $\|\mathbf{E}\|_2$ of an eigenvalue".** For $\mathbf{A} = M\mathbf{J}_2(0)$ with $M > 0$, Proposition 19.2.2 (b) and Example (The numerical range of a Jordan block) give $W(\mathbf{A}) = \{|z| \leq M/2\}$, while $\operatorname{spec}(\mathbf{A}) = \{0\}$. So the bound above allows the eigenvalues of $\mathbf{A}+\mathbf{E}$ to lie anywhere in $|z| \leq M/2 + \|\mathbf{E}\|_2$, and this does not shrink as $\mathbf{E} \to 0$. The eigenvalues do move a long way: $\mathbf{A} + \varepsilon \mathbf{e}_2\mathbf{e}_1^{\top}$ has characteristic polynomial $x^2 - M\varepsilon$, so for $\varepsilon > 0$ its eigenvalues $\pm\sqrt{M\varepsilon}$ have moved by $\sqrt{M\varepsilon}$, far more than ε. For a normal $\mathbf{A}$, $W(\mathbf{A}) = \operatorname{conv}\operatorname{spec}(\mathbf{A})$ is small, but it still contains points far from every eigenvalue, such as the midpoint of two distant ones.

The genuine perturbation bounds need a different mechanism: §03 proves that eigenvalues move continuously and at what rate in general, and §04 gives Bauer–Fike's bound, in which the distance to the nearest **eigenvalue** is controlled.

19.2.7 Exercises

19.2.7.1 A. Check your understanding

Exercise A1.

(a) Define the Brauer oval $O_{ij}(\mathbf{A})$ and the numerical range $W(\mathbf{A})$, and state the Toeplitz–Hausdorff theorem.

(b) True or false: $W(\mathbf{A}) = \operatorname{conv}\operatorname{spec}(\mathbf{A})$ for every $\mathbf{A} \in M_n(\mathbb{C})$. Justify your answer.

(c) True or false: $W(\mathbf{A})$ is contained in the union of the Gershgorin discs of $\mathbf{A}$. Justify your answer.

(d) True or false: if $\mathbf{A} + \mathbf{A}^* \succ 0$, then $\mathbf{A}$ is invertible. Justify your answer.

(e) Why does Theorem 19.2.1 require $n \geq 2$?

Solution.

(a) For $i \neq j$, $O_{ij}(\mathbf{A}) = \{z : |z - a_{ii}||z - a_{jj}| \leq r_i(\mathbf{A})r_j(\mathbf{A})\}$, and $W(\mathbf{A}) = \{\mathbf{x}^*\mathbf{A}\mathbf{x} : \|\mathbf{x}\| = 1\}$. Theorem 19.2.4: for every square complex $\mathbf{A}$, $W(\mathbf{A})$ is convex.

(b) False. $W(\mathbf{J}_2(0))$ is the disc $|z| \leq \frac{1}{2}$ (Example (The numerical range of a Jordan block)), while $\operatorname{conv}\operatorname{spec}(\mathbf{J}_2(0)) = \{0\}$. Equality holds for normal matrices (Proposition 19.2.5).

(c) False. For $\mathbf{A} = \operatorname{diag}(1, -1)$ the discs are the two points $\{1\}$ and $\{-1\}$, while $W(\mathbf{A}) = [-1, 1]$ contains 0. The discs contain the spectrum, not the numerical range.

(d) True. By Theorem 19.2.6 every eigenvalue has $\operatorname{Re}\lambda \geq \lambda_n(\mathbf{H}) > 0$, with $\mathbf{H} = (\mathbf{A} + \mathbf{A}^*)/2 \succ 0$. So 0 is not an eigenvalue, and $\mathbf{A}$ is invertible (Theorem 8.2.1).

(e) An oval is built from two distinct indices $i \neq j$, and the proof needs a second index $q \neq p$. For $n = 1$ there are no ovals, and the union in (a) would be empty, although the matrix has an eigenvalue.

19.2.7.2 B. Practice

Exercise B1: Invertibility from ovals.

Let $\mathbf{A} = \begin{pmatrix} 5 & 1 & 1 \\ 1 & 5 & 1 \\ 2 & 2 & 2 \end{pmatrix}$.

(a) Show that neither the row discs nor the column discs of $\mathbf{A}$ exclude 0.

(b) Use Theorem 19.2.1 to show that $\mathbf{A}$ is invertible.

(c) Check that $(1, -1, 0)$ is an eigenvector, and verify that its eigenvalue lies in $O_{12}(\mathbf{A})$.

Solution.

(a) The row radii are $2, 2, 4$, and $D_3(\mathbf{A}) = \{|z - 2| \leq 4\}$ contains 0. The column radii are $3, 3, 2$, and the third column disc $|z - 2| \leq 2$ contains 0.

(b) At $z = 0$: for O_{12}, $5 \cdot 5 = 25 > 4 = r_1 r_2$; for O_{13} and O_{23}, $5 \cdot 2 = 10 > 8 = r_1 r_3 = r_2 r_3$. So 0 lies in no oval, is not an eigenvalue by Theorem 19.2.1 (a), and $\mathbf{A}$ is invertible. (Its determinant is 32.)

(c) $\mathbf{A}(1, -1, 0) = (5 - 1, 1 - 5, 2 - 2) = (4, -4, 0)$, so the eigenvalue is 4. For O_{12}: $|4 - 5||4 - 5| = 1 \leq 4$.

Exercise B2: A Bendixson rectangle.

Let $\mathbf{A} = \begin{pmatrix} 1 & 3 \\ -1 & 1 \end{pmatrix}$. Find the rectangle of Theorem 19.2.6, and hence show that every eigenvalue of $\mathbf{A}$ satisfies $0 \leq \operatorname{Re}\lambda \leq 2$ and $|\operatorname{Im}\lambda| \leq 2$. Compare with the eigenvalues.

Solution. $\mathbf{H} = \frac{1}{2}(\mathbf{A} + \mathbf{A}^\top) = \left(\begin{smallmatrix} 1 & 1 \\ 1 & 1 \end{smallmatrix}\right)$, with $p_{\mathbf{H}}(x) = x^2 - 2x$, so its eigenvalues are 0 and 2. $\mathbf{K} = \frac{1}{2i}(\mathbf{A} - \mathbf{A}^\top) = \frac{1}{2i}\left(\begin{smallmatrix} 0 & 4 \\ -4 & 0 \end{smallmatrix}\right) = \left(\begin{smallmatrix} 0 & -2i \\ 2i & 0 \end{smallmatrix}\right)$, with trace 0 and determinant -4,

so its eigenvalues are ± 2. By Theorem 19.2.6 every eigenvalue has $0 \le \operatorname{Re}\lambda \le 2$ and $-2 \le \operatorname{Im}\lambda \le 2$. Directly, $p_{\mathbf{A}}(x) = x^2 - 2x + 4$, so $\lambda = 1 \pm i\sqrt{3}$: the real part 1 lies in $[0,2]$, and $\sqrt{3} \approx 1.73 \le 2$.

Exercise B3: Computing numerical ranges.

Determine $W(\mathbf{A})$ for each matrix. Justify your answers.

(a) $\mathbf{A} = \begin{pmatrix} 1 & 2 \\ 0 & 1 \end{pmatrix}$

(b) $\mathbf{A} = \operatorname{diag}(1, i, -1, -i)$

(c) $\mathbf{A} = \begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix}$

Solution.

(a) $\mathbf{A} = 2\mathbf{J}_2(0) + \mathbf{I}$, so by Proposition 19.2.2 (b) and Example (The numerical range of a Jordan block), $W(\mathbf{A}) = 2W(\mathbf{J}_2(0)) + 1 = \{z : |z - 1| \le 1\}$, the closed disc of radius 1 about 1.

(b) A diagonal matrix is normal, so by Proposition 19.2.5 $W(\mathbf{A}) = \operatorname{conv}\{1, i, -1, -i\}$, the filled square with these four vertices.

(c) $\mathbf{A}$ is real symmetric, with eigenvalues 3 and 1 (eigenvectors $(1,1)$ and $(1,-1)$). By Proposition 16.1.1, or Proposition 19.2.5, $W(\mathbf{A}) = [1, 3]$.

19.2.7.3 C. Going deeper

Exercise C1: Direct sums.

(a) Let $\mathbf{B} \in M_k(\mathbb{C})$ and $\mathbf{C} \in M_m(\mathbb{C})$. Prove that $W(\mathbf{B} \oplus \mathbf{C}) = \operatorname{conv}\big(W(\mathbf{B}) \cup W(\mathbf{C})\big)$.

(b) Deduce that $\mathbf{A} = \operatorname{diag}(2, -2, 2i, -2i) \oplus \mathbf{J}_2(0)$ is not normal, but satisfies $W(\mathbf{A}) = \operatorname{conv}\operatorname{spec}(\mathbf{A})$.

Hint for (a): one inclusion needs Theorem 19.2.4.

Solution.

(a) ($\subseteq$) Write a unit vector of $\mathbb{C}^{k+m}$ as $\mathbf{x} = (\mathbf{y}, \mathbf{z})$, with $\|\mathbf{y}\|^2 + \|\mathbf{z}\|^2 = 1$. Then $\mathbf{x}^*(\mathbf{B} \oplus \mathbf{C})\mathbf{x} = \mathbf{y}^*\mathbf{B}\mathbf{y} + \mathbf{z}^*\mathbf{C}\mathbf{z}$. If $\mathbf{z} = \mathbf{0}$ this is a point of $W(\mathbf{B})$, and if $\mathbf{y} = \mathbf{0}$ a point of $W(\mathbf{C})$. Otherwise, with $s = \|\mathbf{y}\|^2 \in (0,1)$,

$$\mathbf{x}^*(\mathbf{B} \oplus \mathbf{C})\mathbf{x} = s\,\frac{\mathbf{y}^*\mathbf{B}\mathbf{y}}{\|\mathbf{y}\|^2} + (1-s)\,\frac{\mathbf{z}^*\mathbf{C}\mathbf{z}}{\|\mathbf{z}\|^2},$$

a convex combination of a point of $W(\mathbf{B})$, at the unit vector $\mathbf{y}/\|\mathbf{y}\|$, and a point of $W(\mathbf{C})$. In every case the value lies in $\operatorname{conv}(W(\mathbf{B}) \cup W(\mathbf{C}))$, by Theorem 17.1.3. ($\supseteq$) Taking $\mathbf{x} = (\mathbf{y}, \mathbf{0})$ with $\mathbf{y}$ a unit vector shows $W(\mathbf{B}) \subseteq W(\mathbf{B} \oplus \mathbf{C})$, and likewise $W(\mathbf{C}) \subseteq W(\mathbf{B} \oplus \mathbf{C})$. By Theorem 19.2.4, $W(\mathbf{B} \oplus \mathbf{C})$ is convex, so it contains the smallest convex set containing $W(\mathbf{B}) \cup W(\mathbf{C})$ (Definition 17.1.4).

(b) $\mathbf{A}$ is not normal: its lower-right block is $\mathbf{J}_2(0)$, and $\mathbf{A}^*\mathbf{A}$ and $\mathbf{A}\mathbf{A}^*$ differ in that

block, since $\mathbf{J}_2(0)^*\mathbf{J}_2(0) = \operatorname{diag}(0,1)$ and $\mathbf{J}_2(0)\mathbf{J}_2(0)^* = \operatorname{diag}(1,0)$. By (a), Proposition 19.2.5 and Example (The numerical range of a Jordan block), $W(\mathbf{A})$ is the convex hull of the square $Q = \operatorname{conv}\{\pm 2, \pm 2i\}$ and the disc $\{|z| \le \frac{1}{2}\}$. The square contains the disc: $Q = \{z : |\operatorname{Re} z| + |\operatorname{Im} z| \le 2\}$, and $|\operatorname{Re} z| + |\operatorname{Im} z| \le 2|z| \le 1$ on the disc. So $W(\mathbf{A}) = Q$. The spectrum is $\{\pm 2, \pm 2i, 0\}$, whose hull is also Q, since $0 \in Q$. Hence $W(\mathbf{A}) = \operatorname{conv}\operatorname{spec}(\mathbf{A})$, although $\mathbf{A}$ is not normal: the converse of Proposition 19.2.5 fails.

Exercise C2: When the numerical range is real, or a point.

Let $\mathbf{A} \in M_n(\mathbb{C})$.

(a) Prove that $W(\mathbf{A}) \subseteq \mathbb{R}$ if and only if $\mathbf{A}$ is Hermitian.

(b) Deduce that $W(\mathbf{A}) = \{c\}$ for a single $c \in \mathbb{C}$ if and only if $\mathbf{A} = c\mathbf{I}$.

Solution.

(a) ($\Leftarrow$) If $\mathbf{A}$ is Hermitian, $\mathbf{x}^*\mathbf{A}\mathbf{x} = \langle \mathbf{A}\mathbf{x}, \mathbf{x}\rangle$ is real by Proposition 10.6.7 (a). ($\Rightarrow$) Write $\mathbf{A} = \mathbf{H} + i\mathbf{K}$ as in Lemma 19.2.3. If $W(\mathbf{A}) \subseteq \mathbb{R}$, then $\mathbf{x}^*\mathbf{K}\mathbf{x} = \operatorname{Im}(\mathbf{x}^*\mathbf{A}\mathbf{x}) = 0$ for every unit $\mathbf{x}$. By Proposition 16.1.1, $\lambda_1(\mathbf{K})$ and $\lambda_n(\mathbf{K})$ are values of $\mathbf{x}^*\mathbf{K}\mathbf{x}$ on unit vectors, so both are 0, and every eigenvalue of $\mathbf{K}$ is 0. By Corollary 11.4.3, $\mathbf{K} = \mathbf{U}\,0\,\mathbf{U}^* = 0$. Hence $\mathbf{A} = \mathbf{H}$ is Hermitian.

(b) ($\Leftarrow$) is the example $W(c\mathbf{I}) = \{c\}$. ($\Rightarrow$) By Proposition 19.2.2 (b), $W(\mathbf{A} - c\mathbf{I}) = W(\mathbf{A}) - c = \{0\} \subseteq \mathbb{R}$, so $\mathbf{A} - c\mathbf{I}$ is Hermitian by (a). By Proposition 16.1.1 its extreme eigenvalues are values of the form on unit vectors, hence both 0, and as in (a) the Hermitian matrix $\mathbf{A} - c\mathbf{I}$ with all eigenvalues 0 is 0.

Exercise C3: The numerical radius.

For $\mathbf{A} \in M_n(\mathbb{C})$, the **numerical radius** is $w(\mathbf{A}) = \max\{|z| : z \in W(\mathbf{A})\}$.

(a) Explain why the maximum exists, and prove that $\rho(\mathbf{A}) \le w(\mathbf{A}) \le \|\mathbf{A}\|_2$.

(b) Prove that $\|\mathbf{A}\|_2 \le 2\,w(\mathbf{A})$.

(c) Show that both constants are attained: $w(\mathbf{A}) = \|\mathbf{A}\|_2$ for every normal $\mathbf{A}$, and $\|\mathbf{A}\|_2 = 2\,w(\mathbf{A})$ for $\mathbf{A} = \mathbf{J}_2(0)$.

Hint for (b): bound $\|\mathbf{H}\|_2$ and $\|\mathbf{K}\|_2$ separately.

Solution.

(a) $W(\mathbf{A})$ is non-empty and compact (Proposition 19.2.2 (d)), and $z \mapsto |z|$ is continuous, so the maximum is attained by **the extreme value theorem, fact (A4) of Chapter 15's introduction**. Every eigenvalue lies in $W(\mathbf{A})$, by Proposition 19.2.2 (a), so $\rho(\mathbf{A}) \le w(\mathbf{A})$; and $w(\mathbf{A}) \le \|\mathbf{A}\|_2$ by Proposition 19.2.2 (e).

(b) Let $\mathbf{A} = \mathbf{H} + i\mathbf{K}$ as in Lemma 19.2.3. By Lemma 16.3.5, $\|\mathbf{H}\|_2$ is the larger of $\lambda_1(\mathbf{H})$ and $-\lambda_n(\mathbf{H})$. By Proposition 16.1.1 there is a unit $\mathbf{x}$ with

$$\lambda_1(\mathbf{H}) = \mathbf{x}^*\mathbf{H}\mathbf{x} = \operatorname{Re}(\mathbf{x}^*\mathbf{A}\mathbf{x}) \le |\mathbf{x}^*\mathbf{A}\mathbf{x}| \le w(\mathbf{A}),$$

and a unit $\mathbf{y}$ with $-\lambda_n(\mathbf{H}) = -\operatorname{Re}(\mathbf{y}^*\mathbf{A}\mathbf{y}) \le w(\mathbf{A})$. So $\|\mathbf{H}\|_2 \le w(\mathbf{A})$, and the same argument with imaginary parts gives $\|\mathbf{K}\|_2 \le w(\mathbf{A})$. As the operator norm is a norm (Theorem 15.3.2 (b)), $\|\mathbf{A}\|_2 \le \|\mathbf{H}\|_2 + \|i\mathbf{K}\|_2 \le 2\,w(\mathbf{A})$.

(c) For normal $\mathbf{A}$, $\rho(\mathbf{A}) = \|\mathbf{A}\|_2$, as Chapter 15 §04 showed after Definition 15.4.1, so the chain in (a) collapses to equalities. For $\mathbf{J}_2(0)$, Example (The numerical range of a Jordan block) gives $w(\mathbf{J}_2(0)) = \frac{1}{2}$, and $\|\mathbf{J}_2(0)\|_2 = 1$, since $\|\mathbf{J}_2(0)\mathbf{x}\| = |x_2| \le \|\mathbf{x}\|$ with equality at $\mathbf{x} = \mathbf{e}_2$. So $\|\mathbf{J}_2(0)\|_2 = 2\,w(\mathbf{J}_2(0))$.

19.3 Continuity of Roots

Chapter 15 §07 proved that the eigenvalues of a matrix move continuously with the matrix, but only after quoting a theorem it did not prove: the roots of a monic polynomial move continuously with its coefficients (Theorem 15.7.3). This section proves that theorem, with nothing more than the compactness of closed bounded sets. It then asks two quantitative questions the qualitative theorem cannot answer. How far can an eigenvalue move when the matrix moves by a given amount, with no hypothesis on the matrix at all? And how many eigenvalues does a region of the plane hold? The second question finishes the story of Gershgorin's discs begun in Section 1: an isolated disc holds **exactly one** eigenvalue.

Throughout, matrices are complex and eigenvalues are listed with algebraic multiplicity, so that $\mathbf{A} \in M_n(\mathbb{C})$ has exactly n of them (Corollary 5.5.5). Two imported facts of analysis are used, and each is named where it acts: compactness, fact (A3) of Chapter 15's introduction, and the intermediate value theorem, fact (A5).

19.3.1 A bound for the roots

The proof of continuity will take a sequence of polynomials and follow their roots. For that to work, the roots must not escape to infinity, and the first step is a bound on the roots in terms of the coefficients.

Lemma 19.3.1 — Cauchy's Bound for the Roots

Let $n \ge 1$ and let $p(x) = x^n + c_{n-1}x^{n-1} + \cdots + c_1 x + c_0 \in \mathbb{C}[x]$ be monic. Put $M = \max_{0 \le j \le n-1} |c_j|$. Then every root $z \in \mathbb{C}$ of p satisfies

$$|z| \le 1 + M.$$

Idea. A root satisfies $z^n = -(c_{n-1}z^{n-1} + \cdots + c_0)$. If $|z|$ is large, the left side is much bigger than every single term on the right, and there are only n terms; summing the geometric series on the right makes this precise.

Proof. If $|z| \le 1$ there is nothing to prove, so suppose $|z| > 1$. Since $p(z) = 0$, we have $z^n = -\sum_{j=0}^{n-1} c_j z^j$, and the triangle inequality (Theorem 0.6.4) gives

$$|z|^n \le M \sum_{j=0}^{n-1} |z|^j = M\,\frac{|z|^n - 1}{|z| - 1} \le M\,\frac{|z|^n}{|z| - 1},$$

where the equality sums a geometric series with ratio $|z| \neq 1$. Dividing by $|z|^n > 0$ and multiplying by $|z| - 1 > 0$ gives $|z| - 1 \leq M$, as claimed.

■

The bound depends only on the size of the coefficients, and that is what the next proof needs. Polynomials whose coefficients stay bounded have roots that stay bounded.

Quick check. Show that the 1 in the bound cannot be dropped: find a monic polynomial with a root of modulus larger than $M = \max_j |c_j|$.

Solution. Take $p(x) = x^2 - x - 1$, with $M = 1$. Its roots are $(1 \pm \sqrt{5})/2$, and $(1+\sqrt{5})/2 \approx 1.618 > 1$. The bound $1 + M = 2$ does hold.

19.3.2 The roots move continuously

Here is the theorem of Chapter 15, restated in full under its own label, since from now on it is a proved result.

Theorem 19.3.2 — Continuous Dependence of the Roots on the Coefficients

Let $n \geq 1$ and let

$$p(x) = x^n + c_{n-1}x^{n-1} + \cdots + c_1 x + c_0 \in \mathbb{C}[x]$$

be monic, with roots $\mu_1, \ldots, \mu_n \in \mathbb{C}$ listed with multiplicity. Let $\varepsilon > 0$. Then there is $\delta > 0$ with the following property. If

$$q(x) = x^n + b_{n-1}x^{n-1} + \cdots + b_1 x + b_0$$

is monic of the **same degree** n and $|b_j - c_j| < \delta$ for every j, then the roots $\nu_1, \ldots, \nu_n$ of q, listed with multiplicity, can be **numbered** so that $|\nu_i - \mu_i| < \varepsilon$ for $i = 1, \ldots, n$.

Idea. The hard direction, from coefficients to roots, has no formula. The easy direction does: expanding $(x - \nu_1) \cdots (x - \nu_n)$ writes each coefficient as a polynomial in the roots. So argue by contradiction and let compactness supply the missing formula.

① A bad sequence $q_k \to p$ has root vectors that stay bounded, by Cauchy's bound. ② By compactness, a subsequence of root vectors converges to some $\boldsymbol{\nu} \in \mathbb{C}^n$. ③ Coefficients are polynomials in roots, so $(x - \nu_1) \cdots (x - \nu_n)$ has the limiting coefficients, which are those of p. ④ Unique factorization says $\boldsymbol{\nu}$ is a rearrangement of $(\mu_1, \ldots, \mu_n)$. ⑤ That rearrangement is a good numbering for the late q_k, which were supposed to have none.

Proof. Suppose the conclusion fails for some $\varepsilon > 0$. Then no δ works; in particular $\delta = 1/k$ fails for every integer $k \geq 1$. So there is a monic $q_k(x) = x^n + \sum_{j<n} b_j^{(k)} x^j$ with $|b_j^{(k)} - c_j| < 1/k$ for every j, whose roots admit **no** numbering within ε of $\mu_1, \ldots, \mu_n$. By Corollary 5.5.5 (a), $q_k = (x - \nu_1^{(k)}) \cdots (x - \nu_n^{(k)})$ for some $\boldsymbol{\nu}^{(k)} = (\nu_1^{(k)}, \ldots, \nu_n^{(k)}) \in \mathbb{C}^n$, which lists the roots of q_k with multiplicity.

The root vectors are bounded. Put $M = \max_j |c_j|$. Then $|b_j^{(k)}| < M + 1$, so by Lemma 19.3.1 every $|\nu_i^{(k)}| \le M + 2$, and $\|\boldsymbol{\nu}^{(k)}\|_2 \le \sqrt{n}\,(M + 2)$. By compactness, fact (A3), the sequence $(\boldsymbol{\nu}^{(k)})$ has a subsequence $(\boldsymbol{\nu}^{(k_l)})_{l \ge 1}$ converging in $\mathbb{C}^n$ to some $\boldsymbol{\nu} = (\nu_1, \dots, \nu_n)$. Since $|\nu_i^{(k_l)} - \nu_i| \le \|\boldsymbol{\nu}^{(k_l)} - \boldsymbol{\nu}\|_2$, each coordinate converges: $\nu_i^{(k_l)} \to \nu_i$.

The limit is a root vector of p. Expanding the product $(x - z_1) \cdots (x - z_n)$ gives $x^n + \sum_{j<n} s_j(z_1, \dots, z_n) x^j$, where each s_j is a fixed polynomial with integer coefficients in $z_1, \dots, z_n$ (it is $\pm$ the sum of all products of $n - j$ of the z_i with distinct indices). Hence $b_j^{(k)} = s_j(\boldsymbol{\nu}^{(k)})$. Along the subsequence, the algebra of limits gives $s_j(\boldsymbol{\nu}^{(k_l)}) \to s_j(\boldsymbol{\nu})$, while $b_j^{(k_l)} \to c_j$ by the choice of q_k. Limits are unique, so $s_j(\boldsymbol{\nu}) = c_j$ for every j, that is,

$$(x - \nu_1)(x - \nu_2) \cdots (x - \nu_n) = p(x) = (x - \mu_1)(x - \mu_2) \cdots (x - \mu_n).$$

Each factor $x - a$ is monic of degree 1, hence irreducible, so both sides are factorizations of p into monic irreducibles. By the uniqueness in Theorem 5.3.5 (b), there is a permutation π of $\{1, \dots, n\}$ with $\nu_{\pi(i)} = \mu_i$ for every i.

The contradiction. For each i, $\nu_{\pi(i)}^{(k_l)} \to \nu_{\pi(i)} = \mu_i$, so there is L_i with $|\nu_{\pi(i)}^{(k_l)} - \mu_i| < \varepsilon$ for all $l \ge L_i$. Take $l \ge \max_i L_i$. Then the list $\nu_{\pi(1)}^{(k_l)}, \dots, \nu_{\pi(n)}^{(k_l)}$ is a numbering of the roots of q_{k_l}, with multiplicity, within ε of $\mu_1, \dots, \mu_n$. This contradicts the choice of q_{k_l}, and proves the theorem.

■

Chapter 15 quoted this statement as Theorem 15.7.3 and left its proof to this section. The proof needed nothing beyond compactness and unique factorization, and Corollary 15.7.4, with everything Chapter 15 built on it, now rests on a proved theorem.

Each hypothesis of the theorem did a job in the proof. **Monic of the same degree** gave both the bound on the roots and the factorization of q_k with exactly n linear factors. **Numbered so that** is where the permutation π went. It was produced by unique factorization and depends on the subsequence, which is exactly the freedom that Proposition 15.7.2 says cannot be removed.

Remark. The proof is an instance of a move worth naming: **compactness plus uniqueness**. To show that x depends continuously on y when only the inverse relation $y = F(x)$ is explicit, take a sequence, extract a convergent subsequence by compactness, and use the uniqueness of the solution of $y = F(x)$ to identify its limit. Here F sends a root vector to the coefficients, and "unique" means unique up to order.

19.3.3 How far: Elsner's bound

The theorem says that a small enough perturbation moves the roots a little, and it gives no rate. Chapter 15's example Example (A Jordan block's eigenvalues move like $\varepsilon^{1/k}$) showed that no bound of the form $L\|\mathbf{E}\|$ can hold. What *does* hold, for every matrix, is a bound by the n-th root of $\|\mathbf{E}\|$. The proof bounds one determinant in two ways: from below by the eigenvalues, and from above by Hadamard's inequality.

Theorem 19.3.3 — Elsner's Spectral Variation Bound

Let $\mathbf{A}, \mathbf{B} \in M_n(\mathbb{C})$, and let $\lambda_1, \dots, \lambda_n$ be the eigenvalues of $\mathbf{A}$. Then every eigenvalue μ of $\mathbf{B}$ satisfies

$$\min_{1 \le i \le n} |\lambda_i - \mu| \le \big(\|\mathbf{A}\|_2 + \|\mathbf{B}\|_2\big)^{1 - 1/n} \, \|\mathbf{A} - \mathbf{B}\|_2^{1/n}.$$

(For $n = 1$ the first factor is 1.)

Idea. The quantity $\prod_i |\lambda_i - \mu|$ is $|\det(\mathbf{A} - \mu \mathbf{I})|$, and it is at least the n-th power of the smallest factor. Bound the determinant above by Hadamard's inequality, after rotating to an orthonormal basis whose first vector is an eigenvector $\mathbf{x}$ of $\mathbf{B}$. The first column is then $(\mathbf{A} - \mu \mathbf{I})\mathbf{x} = (\mathbf{A} - \mathbf{B})\mathbf{x}$, which is small. The other $n - 1$ columns are merely bounded. So one small factor meets $n - 1$ bounded ones, and taking n-th roots produces the exponent $1/n$.

Proof. Let $\mathbf{x}$ be an eigenvector of $\mathbf{B}$ for μ with $\|\mathbf{x}\|_2 = 1$. By Corollary 10.2.3, extend $(\mathbf{x})$ to an orthonormal basis $(\mathbf{u}_1, \dots, \mathbf{u}_n)$ of $\mathbb{C}^n$ with $\mathbf{u}_1 = \mathbf{x}$, and let $\mathbf{U}$ be the unitary matrix with these columns. Then $\mathbf{U}^* \mathbf{U} = \mathbf{I}$, so $|\det \mathbf{U}|^2 = \det \mathbf{U}^* \det \mathbf{U} = 1$ by Theorem 6.5.4 and Theorem 6.4.5.

By Corollary 11.1.5 applied to $\mathbf{A} - \mu \mathbf{I}$, whose eigenvalues are the $\lambda_i - \mu$, listed with the same multiplicities (Theorem 8.10.1, with $q(x) = x - \mu$), and by Theorem 6.5.4,

$$\prod_{i=1}^{n} |\lambda_i - \mu| = |\det(\mathbf{A} - \mu \mathbf{I})| = |\det\big((\mathbf{A} - \mu \mathbf{I})\mathbf{U}\big)|.$$

The j-th column of $(\mathbf{A} - \mu \mathbf{I})\mathbf{U}$ is $(\mathbf{A} - \mu \mathbf{I})\mathbf{u}_j$. Hadamard's inequality Theorem 12.6.4 (b) bounds the determinant by the product of the column lengths.

For $j = 1$, $(\mathbf{A} - \mu \mathbf{I})\mathbf{x} = \mathbf{A}\mathbf{x} - \mathbf{B}\mathbf{x} = (\mathbf{A} - \mathbf{B})\mathbf{x}$, so $\|(\mathbf{A} - \mu \mathbf{I})\mathbf{u}_1\|_2 \le \|\mathbf{A} - \mathbf{B}\|_2$ by Theorem 15.3.2 (a). For $j \ge 2$, the triangle inequality gives $\|(\mathbf{A} - \mu \mathbf{I})\mathbf{u}_j\|_2 \le \|\mathbf{A}\|_2 + |\mu|$, and $|\mu| \le \rho(\mathbf{B}) \le \|\mathbf{B}\|_2$ by Theorem 15.4.1. Writing $\delta = \min_i |\lambda_i - \mu|$, each factor on the left is at least δ, so

$$\delta^n \le \prod_{i=1}^{n} |\lambda_i - \mu| \le \|\mathbf{A} - \mathbf{B}\|_2 \, \big(\|\mathbf{A}\|_2 + \|\mathbf{B}\|_2\big)^{n-1}.$$

Taking non-negative n-th roots, which preserves inequalities between non-negative reals, gives the claim.

■

The bound needs no hypothesis on $\mathbf{A}$: no diagonalizability, no normality. It is a **Hölder modulus of continuity with exponent** $1/n$. The next example shows that the exponent cannot be improved, and that is the quantitative form of the instability that Chapter 9 §03 warned about.

Example. (The Jordan block meets Elsner's bound)

Let $n \ge 2$ and $0 < \varepsilon \le 1$, and put $\mathbf{A} = \mathbf{J}_n(0)$ and $\mathbf{B} = \mathbf{J}_n(0) + \varepsilon \, \mathbf{e}_n \mathbf{e}_1^{\top}$. Compare the movement of the eigenvalues with Elsner's bound, and show that no bound of the form $C(\|\mathbf{A}\|_2 + \|\mathbf{B}\|_2)^{1-\alpha} \|\mathbf{A} - \mathbf{B}\|_2^{\alpha}$ with $\alpha > 1/n$ can hold for all $\mathbf{A}, \mathbf{B} \in M_n(\mathbb{C})$.

Solution. The eigenvalues. The matrix $\mathbf{B}$ is the one of Example (A Jordan block's eigenvalues move like $\varepsilon^{1/k}$) with $k = n$, where $p_{\mathbf{B}}(x) = x^n - \varepsilon$ was computed. So the eigenvalues of $\mathbf{B}$ are the n complex n-th roots of ε, each of modulus $\varepsilon^{1/n}$, while $\mathbf{A}$ has the single eigenvalue 0. Every eigenvalue has moved exactly $\varepsilon^{1/n}$.

The norms. $\mathbf{A} - \mathbf{B} = -\varepsilon\, \mathbf{e}_n \mathbf{e}_1^{\top}$ has the single non-zero entry $-\varepsilon$, so $\|\mathbf{A} - \mathbf{B}\|_2 = \varepsilon$ (Theorem 15.3.3 (c)). Next, $\mathbf{B}\mathbf{e}_1 = \varepsilon \mathbf{e}_n$ and $\mathbf{B}\mathbf{e}_j = \mathbf{e}_{j-1}$ for $j \geq 2$, so for $\mathbf{x} = (x_1, \ldots, x_n)$

$$\|\mathbf{B}\mathbf{x}\|_2^2 = \varepsilon^2 |x_1|^2 + \sum_{j=2}^{n} |x_j|^2 \leq \|\mathbf{x}\|_2^2,$$

with equality at $\mathbf{x} = \mathbf{e}_2$. Hence $\|\mathbf{B}\|_2 = 1$, and the same computation with $\varepsilon = 0$ gives $\|\mathbf{A}\|_2 = 1$.

The comparison. Elsner's bound is $2^{1-1/n}\varepsilon^{1/n}$, and the actual movement is $\varepsilon^{1/n}$. The bound is attained up to a factor $2^{1-1/n} < 2$.

The exponent is optimal. If a bound $C\, 2^{1-\alpha}\varepsilon^{\alpha}$ held for these pairs with $\alpha > 1/n$, then $\varepsilon^{1/n} \leq C\, 2^{1-\alpha}\varepsilon^{\alpha}$, that is, $\varepsilon^{1/n-\alpha} \leq 2^{1-\alpha} C$, for every $\varepsilon \in (0, 1]$. But $1/n - \alpha < 0$, so the left side tends to ∞ as $\varepsilon \to 0^+$. No such C exists.

Put numbers on it. For $n = 16$ and $\varepsilon = 10^{-16}$, a change in the sixteenth decimal place of one entry, the eigenvalues of $\mathbf{J}_{16}(0)$ move to the circle of radius $(10^{-16})^{1/16} = 10^{-1}$. This pays the debt of Chapter 9 §03, whose warning said that the Jordan form is not stable under small changes of the matrix and that Chapter 19 returns to this point. Elsner's theorem says how unstable the eigenvalues can be: never worse than $\|\mathbf{E}\|^{1/n}$. The Jordan block says that this worst case happens. Arithmetic that keeps about sixteen significant digits commits errors of about this relative size at every step. So what such a computation returns are, at best, the eigenvalues of some matrix within about 10^{-16} of $\mathbf{J}_{16}(0)$, and these may be spread around a circle of radius 0.1. The computation cannot tell a nilpotent Jordan block from a diagonalizable matrix with sixteen distinct eigenvalues. This is the numerical reason the Jordan form is not computed in floating-point arithmetic.

19.3.4 Counting eigenvalues in a region

Section 1 showed that every eigenvalue lies in the union of the Gershgorin discs (Theorem 19.1.1), and left open how many lie in each part of that union. The tool for counting is a principle in the spirit of one the proof of Proposition 15.7.2 already used: **an integer-valued function that varies continuously cannot change**. We apply it to the number of eigenvalues in a region, while the matrix moves along a segment.

Lemma 19.3.4 — Eigenvalue Counts Are Constant Along a Path

Let $\mathbf{A}_0, \mathbf{A}_1 \in M_n(\mathbb{C})$, and put $\mathbf{A}(t) = (1-t)\mathbf{A}_0 + t\mathbf{A}_1$ for $t \in [0, 1]$. Let $K, L \subseteq \mathbb{C}$ be sets at **positive distance**: there is $d > 0$ with $|z - w| \geq d$ for all $z \in K$ and $w \in L$. Suppose that for **every** $t \in [0, 1]$, every eigenvalue of $\mathbf{A}(t)$ lies in $K \cup L$. Then the number $N(t)$ of eigenvalues of $\mathbf{A}(t)$ in K, counted with algebraic multiplicity, does not depend on t. In particular $N(0) = N(1)$.

Idea. The eigenvalues cannot jump across the gap between K and L, because they move continuously and are never allowed inside the gap. So near each t_0 the count is unchanged, and a function that is locally constant on an interval is constant. The last step is the intermediate value theorem: a continuous function with integer values cannot pass from one integer to another without taking the values in between.

Proof. Fix $t_0 \in [0,1]$. By Corollary 15.7.4, applied to $\mathbf{A}(t_0)$ with the tolerance d and the norm $\|\cdot\|_2$, there is $\delta > 0$ such that every $\mathbf{B}$ with $\|\mathbf{B} - \mathbf{A}(t_0)\|_2 < \delta$ has its eigenvalues μ_i numbered so that $|\mu_i - \lambda_i| < d$, where $\lambda_1, \dots, \lambda_n$ are the eigenvalues of $\mathbf{A}(t_0)$. Now $\mathbf{A}(t) - \mathbf{A}(t_0) = (t - t_0)(\mathbf{A}_1 - \mathbf{A}_0)$, so $\|\mathbf{A}(t) - \mathbf{A}(t_0)\|_2 < \delta$ whenever $|t - t_0|\,\|\mathbf{A}_1 - \mathbf{A}_0\|_2 < \delta$, which holds for all t close enough to t_0.

For such t, number the eigenvalues μ_i of $\mathbf{A}(t)$ in this way. Both λ_i and μ_i lie in $K \cup L$, and a point of K is at distance at least d from every point of L. Since $|\mu_i - \lambda_i| < d$, the two lie in the same one of the two sets: $\mu_i \in K$ if and only if $\lambda_i \in K$. Counting indices, $N(t) = N(t_0)$.

So N is constant on a neighborhood of each point of $[0,1]$. In particular N is continuous: if $t_k \to t_0$, then $N(t_k) = N(t_0)$ for all large k. Suppose $N(s) \neq N(0)$ for some $s \in (0,1]$, say $N(s) > N(0)$; the other case is symmetric. By the intermediate value theorem, fact (A5), applied to N on $[0,s]$, there is t with $N(t) = N(0) + \tfrac{1}{2}$, which is not an integer. This contradiction shows $N(s) = N(0)$ for every $s \in [0,1]$, and proves the lemma. ∎

Now the counting theorem. The trick is to shrink the off-diagonal part of $\mathbf{A}$ to zero. At the start of the path the matrix is diagonal and its eigenvalues are the disc centers, which we can count by looking.

Theorem 19.3.5 — Gershgorin's Counting Theorem

Let $\mathbf{A} \in M_n(\mathbb{C})$, let $S \subseteq \{1, \dots, n\}$ have k elements with $1 \le k \le n-1$, and put

$$U = \bigcup_{i \in S} D_i(\mathbf{A}), \qquad V = \bigcup_{i \notin S} D_i(\mathbf{A}).$$

If $U \cap V = \emptyset$, then U contains exactly k eigenvalues of $\mathbf{A}$ and V contains exactly $n - k$, counted with algebraic multiplicity.

Idea. Let $\mathbf{D} = \operatorname{diag}(a_{11}, \dots, a_{nn})$ and slide from $\mathbf{D}$ to $\mathbf{A}$ along $\mathbf{A}(t) = (1-t)\mathbf{D} + t\mathbf{A}$. The discs of $\mathbf{A}(t)$ have the same centers and radii $t\,r_i(\mathbf{A})$, so they grow from points into the discs of $\mathbf{A}$ and never leave $U \cup V$. By Theorem 19.1.1 the eigenvalues never leave either, and Lemma 19.3.4 carries the count from $t = 0$, where it is k, to $t = 1$.

Proof. *The two unions are at positive distance.* Let $i \in S$ and $j \notin S$. The discs $D_i(\mathbf{A})$ and $D_j(\mathbf{A})$ are disjoint, so $|a_{ii} - a_{jj}| > r_i(\mathbf{A}) + r_j(\mathbf{A})$; otherwise the point on the segment from a_{ii} to a_{jj} at distance $\min\{r_i(\mathbf{A}), |a_{ii} - a_{jj}|\}$ from a_{ii} would lie in both. For $z \in D_i(\mathbf{A})$ and $w \in D_j(\mathbf{A})$, the triangle inequality gives

$$|z - w| \ge |a_{ii} - a_{jj}| - r_i(\mathbf{A}) - r_j(\mathbf{A}) > 0.$$

Call the middle quantity d_{ij}. The minimum d of the finitely many d_{ij} is positive, and every point of U is at distance at least d from every point of V.

The path. Let $\mathbf{D} = \operatorname{diag}(a_{11}, \dots, a_{nn})$ and $\mathbf{A}(t) = (1-t)\mathbf{D} + t\mathbf{A}$ for $t \in [0,1]$. The diagonal entries of $\mathbf{A}(t)$ are the a_{ii}, and its off-diagonal entries are $t\,a_{ij}$, so $r_i(\mathbf{A}(t)) = t\,r_i(\mathbf{A}) \le r_i(\mathbf{A})$ and $D_i(\mathbf{A}(t)) \subseteq D_i(\mathbf{A})$. By Theorem 19.1.1 applied to $\mathbf{A}(t)$, every eigenvalue of $\mathbf{A}(t)$ lies in $\bigcup_i D_i(\mathbf{A}(t)) \subseteq U \cup V$. By Lemma 19.3.4 with $K = U$ and $L = V$, the number of eigenvalues of $\mathbf{A}(t)$ in U is the same at $t = 0$ and at $t = 1$.

The count at $t = 0$. $\mathbf{A}(0) = \mathbf{D}$ is diagonal, so $p_{\mathbf{D}}(x) = \prod_i (x - a_{ii})$ by Theorem 6.4.6, and its eigenvalue list is $a_{11}, \dots, a_{nn}$. For $i \in S$, a_{ii} is the center of $D_i(\mathbf{A})$, so $a_{ii} \in U$. For $i \notin S$, $a_{ii} \in V$, hence $a_{ii} \notin U$. So exactly k entries of the list lie in U.

Therefore $\mathbf{A}(1) = \mathbf{A}$ has exactly k eigenvalues in U. All n eigenvalues lie in $U \cup V$, and $U \cap V = \emptyset$, so the other $n - k$ lie in V. This proves the theorem.

■

The case $k = 1$ is the one used most, and for a real matrix it says something about reality as well.

Corollary 19.3.6 — An Isolated Disc Holds One Eigenvalue

Let $\mathbf{A} \in M_n(\mathbb{C})$ with $n \ge 2$, and suppose $D_i(\mathbf{A})$ is disjoint from $D_j(\mathbf{A})$ for every $j \ne i$.

(a) $D_i(\mathbf{A})$ contains exactly one eigenvalue of $\mathbf{A}$, and it is **algebraically simple**.

(b) If $\mathbf{A}$ is **real**, that eigenvalue is real, and it lies in the interval $[a_{ii} - r_i(\mathbf{A}),\, a_{ii} + r_i(\mathbf{A})]$.

Proof.

(a) Take $S = \{i\}$. Then $U = D_i(\mathbf{A})$ is disjoint from the union V of the other discs, because it is disjoint from each of them. By Theorem 19.3.5, $D_i(\mathbf{A})$ contains exactly one eigenvalue counted with algebraic multiplicity, so that eigenvalue λ has algebraic multiplicity 1.

(b) Suppose $\lambda \notin \mathbb{R}$. By Theorem 8.2.5, $\overline{\lambda} \ne \lambda$ is also an eigenvalue of $\mathbf{A}$. The center a_{ii} is real, so $|\overline{\lambda} - a_{ii}| = |\overline{\lambda - a_{ii}}| = |\lambda - a_{ii}| \le r_i(\mathbf{A})$, and $\overline{\lambda} \in D_i(\mathbf{A})$ too. Then $D_i(\mathbf{A})$ contains two distinct eigenvalues, contradicting (a). So λ is real, and a real number within $r_i(\mathbf{A})$ of a_{ii} lies in the stated interval.

■

Scaling (Proposition 19.1.3) and counting work together. Scaling moves the radii around without changing the eigenvalues, and a disc that scaling manages to isolate then holds exactly one eigenvalue.

Example. (Isolating a real eigenvalue by scaling)

Let

$$\mathbf{A} = \begin{pmatrix} 7 & 3 & -1 \\ 0 & -1 & -3 \\ 1 & 1 & 1 \end{pmatrix}.$$

Show that $\mathbf{A}$ has exactly one eigenvalue λ with $|\lambda - 7| \leq 2$, and that it is real.

Solution. The unscaled discs do not decide it. The row radii are $r_1 = 4$, $r_2 = 3$, $r_3 = 2$, so the discs are $|z - 7| \leq 4$, $|z + 1| \leq 3$ and $|z - 1| \leq 2$. The first and the third meet at $z = 3$, since $7 - 1 = 4 + 2$. So no disc is isolated, and Theorem 19.3.5 does not apply.

Scale. Take $\mathbf{D} = \operatorname{diag}(2, 1, 1)$. By Proposition 19.1.3, $\mathbf{D}^{-1}\mathbf{A}\mathbf{D}$ has the same eigenvalues as $\mathbf{A}$, and its (i, j) entry is $a_{ij}d_j/d_i$:

$$\mathbf{D}^{-1}\mathbf{A}\mathbf{D} = \begin{pmatrix} 7 & 3/2 & -1/2 \\ 0 & -1 & -3 \\ 2 & 1 & 1 \end{pmatrix}.$$

Its discs are $|z - 7| \leq 2$, $|z + 1| \leq 3$ and $|z - 1| \leq 3$. The first is disjoint from the other two, because $7 - (-1) = 8 > 2 + 3$ and $7 - 1 = 6 > 2 + 3$.

Count. By Corollary 19.3.6, applied to the real matrix $\mathbf{D}^{-1}\mathbf{A}\mathbf{D}$, the disc $|z - 7| \leq 2$ contains exactly one eigenvalue, it is simple and real, and it lies in $[5, 9]$. The other two eigenvalues lie in $|z + 1| \leq 3$ or $|z - 1| \leq 3$, outside $[5, 9]$.

A check by hand. Expanding along the first column, $p_{\mathbf{A}}(x) = x^3 - 7x^2 + 3x - 4$. Then $p_{\mathbf{A}}(5) = -39 < 0$ and $p_{\mathbf{A}}(9) = 185 > 0$, consistent with a real root in $(5, 9)$. (It is about 6.64. The other two roots are the non-real pair $0.18 \pm 0.75i$, approximately, so here Gershgorin has isolated the only real eigenvalue.)

Quick check. A real 3×3 matrix has three pairwise disjoint Gershgorin discs. What can you say about its eigenvalues, and is it diagonalizable?

Solution. By Corollary 19.3.6, each disc contains exactly one eigenvalue, which is real. The discs are disjoint, so the three eigenvalues are distinct and real, and the matrix is diagonalizable over $\mathbb{R}$ by Corollary 8.4.2.

Warning. **The count is for the union, not for each disc in it.** Take $\mathbf{A} = \left(\begin{smallmatrix} 0 & 1 & 0 \\ 4 & 0 & 0 \\ 0 & 0 & 10 \end{smallmatrix}\right)$. Its discs are $|z| \leq 1$, $|z| \leq 4$ and the single point $\{10\}$. The union of the first two is disjoint from the third, and it does contain two eigenvalues, ± 2. But both lie in the second disc, and the first disc contains none. Inside a cluster of overlapping discs, the counting theorem says nothing about the individual discs.

19.3.5 From one-sided to matched

Elsner's bound is **one-sided**. It says that every eigenvalue of $\mathbf{B}$ is near **some** eigenvalue of $\mathbf{A}$, and it does not forbid two eigenvalues of $\mathbf{B}$ from crowding near the same eigenvalue of $\mathbf{A}$ while another eigenvalue of $\mathbf{A}$ is left alone. The counting lemma turns it into a statement about a **numbering**. The price is a factor that grows with n.

Theorem 19.3.7 — Elsner's Matching Bound

Let $\mathbf{A}, \mathbf{B} \in M_n(\mathbb{C})$ have eigenvalues $\lambda_1, \dots, \lambda_n$ and $\mu_1, \dots, \mu_n$, and put

$$R = \big(\|\mathbf{A}\|_2 + \|\mathbf{B}\|_2\big)^{1-1/n} \, \|\mathbf{A} - \mathbf{B}\|_2^{1/n}.$$

Then the μ_i can be numbered so that $|\lambda_i - \mu_i| \le (2n-1)R$ for every i.

Idea. Slide from $\mathbf{A}$ to $\mathbf{B}$ along a segment. By Theorem 19.3.3, every matrix on the way has its eigenvalues in the discs of radius R about the λ_i. Group those discs into clusters that do not touch one another. By Lemma 19.3.4 a cluster built from m of the λ_i holds exactly m eigenvalues of $\mathbf{B}$, so we can pair within clusters. A cluster of m discs has diameter at most $2mR$, which gives the factor $2n-1$.

Proof. The conclusion is symmetric in $\mathbf{A}$ and $\mathbf{B}$, and so is R, so we may assume $\|\mathbf{A}\|_2 \le \|\mathbf{B}\|_2$. For $t \in [0,1]$ put $\mathbf{A}(t) = (1-t)\mathbf{A} + t\mathbf{B}$. Then $\|\mathbf{A}(t)\|_2 \le (1-t)\|\mathbf{A}\|_2 + t\|\mathbf{B}\|_2 \le \|\mathbf{B}\|_2$ and $\|\mathbf{A} - \mathbf{A}(t)\|_2 = t\|\mathbf{A} - \mathbf{B}\|_2 \le \|\mathbf{A} - \mathbf{B}\|_2$. By Theorem 19.3.3 applied to $\mathbf{A}$ and $\mathbf{A}(t)$, and since the exponents $1 - 1/n$ and $1/n$ are non-negative, every eigenvalue of $\mathbf{A}(t)$ lies within R of some λ_i.

Clusters. Call indices i and j **linked** if $|\lambda_i - \lambda_j| \le 2R$, and put two indices in the same **cluster** if a chain of links joins them. The clusters partition $\{1, \dots, n\}$. For a cluster C let K_C be the set of z with $|z - \lambda_i| \le R$ for some $i \in C$, and let L_C be the union of the $K_{C'}$ for the other clusters C'. If $i \in C$ and $j \notin C$, then i and j are not linked, so for z within R of λ_i and w within R of λ_j,

$$|z - w| \ge |\lambda_i - \lambda_j| - 2R > 0.$$

Taking the minimum over the finitely many such pairs, K_C and L_C are at positive distance; and if C is the only cluster, L_C is empty, there is no pair to check, and the requirement holds with any $d > 0$. Every eigenvalue of every $\mathbf{A}(t)$ lies in $K_C \cup L_C$.

Counting. At $t = 0$ the eigenvalues are the λ_j. Those with $j \in C$ lie in K_C, and the others lie in L_C, hence not in K_C; so $\mathbf{A}(0)$ has exactly $|C|$ eigenvalues in K_C. By Lemma 19.3.4, so does $\mathbf{A}(1) = \mathbf{B}$. Each μ lies in exactly one K_C, since the K_C are pairwise disjoint and cover every eigenvalue. So we may number the μ's so that, for each cluster C, those in K_C receive the indices in C.

Distances. Let $i \in C$, with $m = |C|$. Since $\mu_i \in K_C$, there is $j \in C$ with $|\mu_i - \lambda_j| \le R$. A chain of links from j to i inside C can be chosen without repeating an index, so it has at most $m - 1$ links, each of length at most $2R$, and $|\lambda_j - \lambda_i| \le 2(m-1)R$. Hence

$$|\mu_i - \lambda_i| \le R + 2(m-1)R = (2m-1)R \le (2n-1)R.$$

This proves the theorem. ∎

The factor $2n-1$ is not the best possible, and bounds with a factor independent of n are known; we will not need them. What matters is the shape: a matching distance of order $\|\mathbf{A} - \mathbf{B}\|^{1/n}$, with no hypothesis on either matrix. Sections 4 and 5 replace the exponent $1/n$ by 1, and the price is a hypothesis on $\mathbf{A}$: diagonalizable in Section 4, and normal in Section 5.

19.3.6 Exercises

19.3.6.1 A. Check your understanding

Exercise A1.

(a) State Theorem 19.3.2, including both hypotheses on q.

(b) Which imported fact of analysis does the proof of Theorem 19.3.2 use, and at which step? Which one does Lemma 19.3.4 use?

(c) True or false: if $\|\mathbf{B}-\mathbf{A}\|_2 \le 10^{-8}$, then every eigenvalue of $\mathbf{B}$ lies within 10^{-8} of an eigenvalue of $\mathbf{A}$. Justify your answer.

(d) True or false: if $\mathbf{A} \in M_3(\mathbb{C})$ and $D_1(\mathbf{A}) \cup D_2(\mathbf{A})$ is disjoint from $D_3(\mathbf{A})$, then $D_1(\mathbf{A})$ contains exactly one eigenvalue. Justify your answer.

(e) What is the difference between the conclusions of Theorem 19.3.3 and Theorem 19.3.7?

Solution.

(a) See Theorem 19.3.2. The polynomial q must be **monic** and of the **same degree** n as p.

(b) Compactness, fact (A3), supplies a convergent subsequence of the bounded root vectors $\boldsymbol{\nu}^{(k)}$. The lemma uses the intermediate value theorem, fact (A5), to show that a locally constant integer-valued function on $[0,1]$ is constant.

(c) False. Take $\mathbf{A} = \mathbf{J}_2(0)$ and $\mathbf{B} = \mathbf{J}_2(0) + 10^{-8}\mathbf{e}_2\mathbf{e}_1^{\top}$, so $\|\mathbf{B}-\mathbf{A}\|_2 = 10^{-8}$. By Example (The Jordan block meets Elsner's bound) with $n=2$, the eigenvalues of $\mathbf{B}$ are $\pm 10^{-4}$, at distance 10^{-4} from the only eigenvalue 0 of $\mathbf{A}$.

(d) False. In the warning after Corollary 19.3.6, $D_1 \cup D_2$ is disjoint from $D_3 = \{10\}$, yet $D_1 = \{|z| \le 1\}$ contains neither eigenvalue ± 2. The counting theorem counts in the union.

(e) The first is one-sided: every eigenvalue of $\mathbf{B}$ is within R of **some** eigenvalue of $\mathbf{A}$, and several may be near the same one. The second gives a **numbering** pairing each μ_i with its own λ_i, within $(2n-1)R$.

19.3.6.2 B. Practice

Exercise B1: Cauchy's bound.

Let $p(x) = x^3 - 3x^2 + 4x - 12$.

(a) Use Lemma 19.3.1 to bound the moduli of the roots of p.

(b) Find the roots exactly, and compare.

Solution.

(a) Here $M = \max\{3,4,12\} = 12$, so every root has $|z| \le 13$.

(b) $p(x) = x^2(x-3) + 4(x-3) = (x-3)(x^2+4)$, so the roots are 3 and $\pm 2i$, of moduli 3 and 2. The bound 13 is true but crude, because the constant term 12 dominates M.

Exercise B2: Counting with discs.

Let

$$\mathbf{A} = \begin{pmatrix} 10 & 1 & -1 \\ 1 & 2 & 2 \\ 0 & -2 & 1 \end{pmatrix}.$$

(a) Show that $\mathbf{A}$ has exactly one eigenvalue λ_1 with $|\lambda_1 - 10| \le 2$, and that it is real.

(b) Explain why the Gershgorin discs cannot decide whether the other two eigenvalues are real.

(c) Use the trace to locate the sum of the other two eigenvalues in an interval.

Solution.

(a) The row radii are $r_1 = 2$, $r_2 = 3$, $r_3 = 2$, so the discs are $|z - 10| \le 2$, $|z - 2| \le 3$ and $|z - 1| \le 2$. The first is disjoint from the other two, since $10 - 2 = 8 > 2 + 3$ and $10 - 1 = 9 > 2 + 2$. By Corollary 19.3.6, it contains exactly one eigenvalue, which is simple, real, and in $[8, 12]$.

(b) The other two eigenvalues lie in $\{|z - 2| \le 3\} \cup \{|z - 1| \le 2\}$, a union of two overlapping discs that contains both real and non-real points. The counting theorem only says that this union holds two eigenvalues. A conjugate pair and two real numbers are both consistent with that. (In fact they are the non-real pair $1.43 \pm 1.99i$, approximately.)

(c) By Corollary 11.1.4, $\lambda_1 + \lambda_2 + \lambda_3 = \operatorname{tr} \mathbf{A} = 13$. Since $8 \le \lambda_1 \le 12$, the sum $\lambda_2 + \lambda_3 = 13 - \lambda_1$ is real and lies in $[1, 5]$.

19.3.6.3 C. Going deeper

Exercise C1: Stability is an open condition.

(a) Let p be monic of degree n with every root in the open disc $\{|z| < 1\}$. Prove that there is $\delta > 0$ such that every monic q of degree n whose coefficients are within δ of those of p also has every root in $\{|z| < 1\}$.

(b) Deduce that the set of $\mathbf{A} \in M_n(\mathbb{C})$ with $\rho(\mathbf{A}) < 1$ is **open**: for each such $\mathbf{A}$ there is $\eta > 0$ with $\rho(\mathbf{B}) < 1$ whenever $\|\mathbf{B} - \mathbf{A}\|_2 < \eta$.

Solution.

(a) Let $\mu_1, \dots, \mu_n$ be the roots of p and put $\varepsilon = 1 - \max_i |\mu_i|$, which is positive since there are finitely many roots, each of modulus less than 1. Let δ be given by Theorem 19.3.2 for this ε. If q is within δ, number its roots so that $|\nu_i - \mu_i| < \varepsilon$. Then $|\nu_i| < |\mu_i| + \varepsilon \le 1$ for every i.

(b) Let $\rho(\mathbf{A}) < 1$, so every root of $p_{\mathbf{A}}$ lies in $\{|z| < 1\}$ (Definition 15.4.1). Take δ from (a) for $p = p_{\mathbf{A}}$. The coefficients of $p_{\mathbf{B}}$ are polynomials in the entries of $\mathbf{B}$, as noted after Lemma 15.7.1, so that lemma gives $\eta > 0$ such that $\|\mathbf{B} - \mathbf{A}\|_2 < \eta$ makes every coefficient of $p_{\mathbf{B}}$ within δ of the corresponding coefficient of $p_{\mathbf{A}}$. For such $\mathbf{B}$, (a) puts every eigenvalue of $\mathbf{B}$ in the open unit disc, and $\rho(\mathbf{B}) < 1$ because there are finitely many of them.

Exercise C2: Why one-sided bounds do not give a matching.

For lists $(\lambda_1, \dots, \lambda_n)$ and $(\mu_1, \dots, \mu_n)$ of complex numbers and $r \geq 0$, say that the list of μ's is r**-close to** the list of λ's if every μ_j is within r of some λ_i.

(a) Let $n = 2$. Prove that if each list is r-close to the other, then the μ_j can be numbered so that $|\lambda_i - \mu_i| \leq r$ for $i = 1, 2$.

(b) Show that (a) fails for $n = 3$: give two lists of length 3, each 0-close to the other, such that every numbering has $\max_i |\lambda_i - \mu_i| = 2$.

(c) Explain why the proof of Theorem 19.3.7 needs Lemma 19.3.4, and cannot simply apply Theorem 19.3.3 twice, once in each direction.

Solution.

(a) By hypothesis, λ_2 is within r of some μ_j; number the μ's so that this one is μ_2, so $|\lambda_2 - \mu_2| \leq r$. The other one, μ_1, is within r of λ_1 or of λ_2. If of λ_1, we are done. If not, then $|\mu_1 - \lambda_2| \leq r$ and $|\mu_1 - \lambda_1| > r$. Now λ_1 is within r of some μ_j, and not of μ_1, so $|\lambda_1 - \mu_2| \leq r$. Renumber by swapping μ_1 and μ_2. Then $|\lambda_1 - \mu_1| \leq r$ and $|\lambda_2 - \mu_2| \leq r$.

(b) Take $(\lambda_1, \lambda_2, \lambda_3) = (0, 2, 2)$ and $(\mu_1, \mu_2, \mu_3) = (0, 0, 2)$. Every entry of each list occurs in the other, so each is 0-close to the other. But the μ's contain 0 twice and the λ's only once, so every numbering pairs some $\mu_i = 0$ with some $\lambda_i = 2$, and $\max_i |\lambda_i - \mu_i| = 2$.

(c) Applying Theorem 19.3.3 to $(\mathbf{A}, \mathbf{B})$ and to $(\mathbf{B}, \mathbf{A})$ gives exactly the two-sided closeness of (a) with $r = R$, since R is symmetric in $\mathbf{A}$ and $\mathbf{B}$. By (b), two-sided closeness does not produce a numbering once $n \geq 3$, because it ignores multiplicities. The counting lemma supplies the missing information: each cluster of discs holds as many eigenvalues of $\mathbf{B}$, counted with multiplicity, as it holds eigenvalues of $\mathbf{A}$.

Exercise C3: Sharpening Cauchy's bound by rescaling.

Let $n \geq 1$, let $p(x) = x^n + c_{n-1}x^{n-1} + \cdots + c_1 x + c_0 \in \mathbb{C}[x]$ be monic, and let $s > 0$.

(a) Prove that $q(y) := p(sy)/s^n$ is monic of degree n, with coefficients c_j / s^{n-j}, and that z is a root of p if and only if z/s is a root of q. Hence deduce that every root z of p satisfies

$$|z| \leq s\Big(1 + \max_{0 \leq j \leq n-1} \frac{|c_j|}{s^{n-j}}\Big).$$

(b) Apply (a) with $s = 3$ to $p(x) = x^3 - 3x^2 + 4x - 12$, and compare the bound with the one Lemma 19.3.1 gives directly and with the roots found in Exercise (B1: Cauchy's bound).

Solution.

(a) Substituting $x = sy$ and dividing by $s^n > 0$,

$$q(y) = \frac{p(sy)}{s^n} = \frac{s^n y^n + \sum_{j<n} c_j s^j y^j}{s^n} = y^n + \sum_{j<n} \frac{c_j}{s^{n-j}}\, y^j,$$

which is monic of degree n with the stated coefficients. Since $s^n \neq 0$, the identity $q(z/s) = p(z)/s^n$ shows that $q(z/s) = 0$ if and only if $p(z) = 0$. Now let z be a root of p. Then z/s is a root of q, so by Lemma 19.3.1 applied to q, whose coefficient maximum is $M_s = \max_j |c_j|/s^{n-j}$, we get $|z|/s = |z/s| \leq 1 + M_s$. Multiplying by $s > 0$ gives the bound.

(b) For $s = 3$ the coefficients of q are $-3/3 = -1$, $4/9$ and $-12/27 = -4/9$, so $M_3 = 1$ and every root of p has $|z| \leq 3(1 + 1) = 6$. Applied to p itself, Lemma 19.3.1 gives only $|z| \leq 13$, as in Exercise (B1: Cauchy's bound) (a). The true moduli are 3 and 2, so the rescaled bound is closer, and the trade-off is visible in the formula: enlarging s shrinks every $|c_j|/s^{n-j}$ but multiplies the whole bound by s.

19.4 The Bauer–Fike Theorem

Section 3 bounded the movement of the eigenvalues of an arbitrary matrix by a constant times $\|\mathbf{E}\|_2^{1/n}$, and the Jordan block showed that nothing better holds in general. The culprit was the Jordan block itself. This section removes it by assuming that $\mathbf{A}$ is diagonalizable, and the exponent $1/n$ becomes 1: every eigenvalue of $\mathbf{A} + \mathbf{E}$ lies within $\kappa_2(\mathbf{X})\|\mathbf{E}\|_2$ of some eigenvalue of $\mathbf{A}$, where $\mathbf{X}$ is a matrix of eigenvectors.

This is the theorem several earlier chapters pointed to. Chapter 11 §11 described it as the statement "that for a diagonalizable $\mathbf{A}$ every eigenvalue of a perturbed $\mathbf{A} + \mathbf{E}$ lies within $\kappa\|\mathbf{E}\|$ of some eigenvalue of $\mathbf{A}$, where κ measures how far from unitary the diagonalizing matrix is, and that $\kappa = 1$ exactly in the normal case", and said that it "needs matrix norms and a little analysis, and Chapter 19 develops both and proves it". Chapter 15 §07 and Chapter 16 §03 promised a bound "for a diagonalizable matrix" carrying "an extra factor that measures how far the eigenvector basis of $\mathbf{A}$ is from orthonormal". Chapter 16 §11 left the bounds for non-Hermitian matrices, "beginning with Bauer–Fike", to this chapter, and Chapter 15 §08 recorded that "the bounds that do exist, Weyl's and Bauer–Fike's, are Chapters 16 and 19". We prove the theorem, identify the factor, prove the "exactly", and then return to the defective case. There the m-th root comes back, where m is the size of the largest Jordan block.

Throughout, $\mathbf{A} \in M_n(\mathbb{C})$, the perturbation is $\mathbf{E} \in M_n(\mathbb{C})$, and $\kappa_p(\mathbf{X}) = \|\mathbf{X}\|_p\|\mathbf{X}^{-1}\|_p$ is the condition number of Definition 15.8.1. No fact of analysis is imported in this section beyond those already used by the results it cites.

19.4.1 Factoring out the inverse

The whole section runs on one estimate. If μ is an eigenvalue of $\mathbf{A}+\mathbf{E}$ but not of $\mathbf{A}$, then $\mathbf{A}-\mu\mathbf{I}$ is invertible while $\mathbf{A} + \mathbf{E} - \mu\mathbf{I}$ is not. A small $\mathbf{E}$ cannot destroy invertibility (Corollary 15.5.2), so $\mathbf{E}$ must be large compared with the inverse of $\mathbf{A} - \mu\mathbf{I}$. The matrix $(\mathbf{A} - \mu\mathbf{I})^{-1}$, a function of μ, is called the **resolvent** of $\mathbf{A}$, up to a sign convention. Chapter 15 asked for this estimate in Exercise (C1: How close to singular a nearby eigenvalue forces you to be). Since the theorems below rest on it, we prove it here in full.

Lemma 19.4.1 — A Perturbed Eigenvalue Forces a Large Resolvent

Let $\mathbf{A}, \mathbf{E} \in M_n(\mathbb{C})$, let $\|\cdot\|$ be an operator norm on $M_n(\mathbb{C})$ (Definition 15.3.2), and let μ be an eigenvalue of $\mathbf{A}+\mathbf{E}$ that is **not** an eigenvalue of $\mathbf{A}$. Then

$$1 \le \|(\mathbf{A}-\mu\mathbf{I})^{-1}\mathbf{E}\| \le \|(\mathbf{A}-\mu\mathbf{I})^{-1}\|\,\|\mathbf{E}\|.$$

Proof. Since $\mu \notin \operatorname{spec}(\mathbf{A})$, the matrix $\mathbf{A}-\mu\mathbf{I}$ is invertible (Theorem 8.2.1), and

$$\mathbf{A}+\mathbf{E}-\mu\mathbf{I} = (\mathbf{A}-\mu\mathbf{I})\big(\mathbf{I}+(\mathbf{A}-\mu\mathbf{I})^{-1}\mathbf{E}\big).$$

The left side is singular, because μ is an eigenvalue of $\mathbf{A}+\mathbf{E}$. If the second factor on the right were invertible, the product of two invertible matrices would be invertible. So $\mathbf{I}-\mathbf{F}$ is singular, where $\mathbf{F} = -(\mathbf{A}-\mu\mathbf{I})^{-1}\mathbf{E}$. By Theorem 15.5.1 (a), $\|\mathbf{F}\| < 1$ would make $\mathbf{I}-\mathbf{F}$ invertible, hence $\|\mathbf{F}\| \ge 1$. Since $\|\mathbf{F}\| = \|(\mathbf{A}-\mu\mathbf{I})^{-1}\mathbf{E}\|$, this is the first inequality, and the second is submultiplicativity (Theorem 15.3.2 (d)).

■

The lemma holds for every matrix and needs no eigenvectors. To turn it into a bound on $|\lambda_i - \mu|$, we need to compute $\|(\mathbf{A}-\mu\mathbf{I})^{-1}\|$ in terms of the distances from μ to the eigenvalues. For a diagonal matrix that is immediate, and diagonalizable matrices are diagonal in the right coordinates.

19.4.2 The theorem

We need one fact about diagonal matrices. Let $\mathbf{D} = \operatorname{diag}(d_1, \dots, d_n)$ and $p \in \{1, 2, \infty\}$. For every $\mathbf{x}$, each coordinate of $\mathbf{Dx}$ is $d_i x_i$, with $|d_i x_i| \le (\max_j |d_j|)|x_i|$, so $\|\mathbf{Dx}\|_p \le (\max_j |d_j|)\|\mathbf{x}\|_p$. Equality holds at $\mathbf{x} = \mathbf{e}_k$, where k is an index with $|d_k| = \max_j |d_j|$. Hence

$$\|\operatorname{diag}(d_1, \dots, d_n)\|_p = \max_j |d_j| \qquad (p = 1, 2, \infty). \tag{19.4.1}$$

Theorem 19.4.2 — Bauer–Fike Theorem

Let $\mathbf{A} \in M_n(\mathbb{C})$ be diagonalizable. Write $\mathbf{A} = \mathbf{X}\mathbf{\Lambda}\mathbf{X}^{-1}$, where $\mathbf{X}$ is invertible and $\mathbf{\Lambda}$ is the diagonal matrix with diagonal entries $\lambda_1, \dots, \lambda_n$. Let $\mathbf{E} \in M_n(\mathbb{C})$ be arbitrary, and let $p \in \{1, 2, \infty\}$. Then every eigenvalue μ of $\mathbf{A}+\mathbf{E}$ satisfies

$$\min_{1 \le i \le n} |\lambda_i - \mu| \le \kappa_p(\mathbf{X})\,\|\mathbf{E}\|_p.$$

Idea. Change coordinates so that $\mathbf{A}$ becomes $\mathbf{\Lambda}$. Then $\mathbf{A}+\mathbf{E}$ becomes $\mathbf{\Lambda} + \mathbf{X}^{-1}\mathbf{E}\mathbf{X}$, with the same eigenvalues, and the perturbation has grown by at most the factor $\kappa_p(\mathbf{X})$. For the diagonal matrix $\mathbf{\Lambda}$, the resolvent $(\mathbf{\Lambda}-\mu\mathbf{I})^{-1}$ has norm exactly $1/\min_i|\lambda_i-\mu|$, and Lemma 19.4.1 finishes the proof.

Proof. If $\mu = \lambda_i$ for some i, the left side is 0 and there is nothing to prove. So suppose $\mu \ne \lambda_i$ for every i, and put $\delta = \min_i |\lambda_i - \mu| > 0$.

Since $\mathbf{X}^{-1}(\mathbf{A}+\mathbf{E})\mathbf{X} = \mathbf{\Lambda} + \mathbf{F}$ with $\mathbf{F} = \mathbf{X}^{-1}\mathbf{E}\mathbf{X}$, the matrices $\mathbf{A}+\mathbf{E}$ and $\mathbf{\Lambda}+\mathbf{F}$ are

similar, so μ is an eigenvalue of $\mathbf{\Lambda}+\mathbf{F}$ (Theorem 6.10.3). The eigenvalues of $\mathbf{\Lambda}$ are the λ_i, so $\mu \notin \operatorname{spec}(\mathbf{\Lambda})$. By Lemma 19.4.1 with the operator norm $\|\cdot\|_p$,

$$1 \le \|(\mathbf{\Lambda}-\mu\mathbf{I})^{-1}\|_p \, \|\mathbf{F}\|_p.$$

Now $(\mathbf{\Lambda}-\mu\mathbf{I})^{-1} = \operatorname{diag}\big(1/(\lambda_1-\mu),\dots,1/(\lambda_n-\mu)\big)$, whose norm is $\max_i 1/|\lambda_i-\mu| = 1/\delta$ by Eq. 19.4.1. By submultiplicativity (Theorem 15.3.2 (d)), $\|\mathbf{F}\|_p \le \|\mathbf{X}^{-1}\|_p\|\mathbf{E}\|_p\|\mathbf{X}\|_p = \kappa_p(\mathbf{X})\|\mathbf{E}\|_p$. Therefore $1 \le \kappa_p(\mathbf{X})\|\mathbf{E}\|_p/\delta$, that is, $\delta \le \kappa_p(\mathbf{X})\|\mathbf{E}\|_p$. This proves the theorem.

■

The proof used only two properties of $\|\cdot\|_p$: it is an operator norm, and it gives a diagonal matrix the norm $\max_j|d_j|$. So the theorem holds for every operator norm with that second property. The spectral norm is the one used in practice, and $\kappa_2(\mathbf{X})$ is the headline constant.

Read the theorem as a picture. Draw the closed disc of radius $\kappa_p(\mathbf{X})\|\mathbf{E}\|_p$ about each λ_i; every eigenvalue of $\mathbf{A}+\mathbf{E}$ lies in the union. The bound is **one-sided**, like Elsner's (Theorem 19.3.3). It does not say that each disc holds one perturbed eigenvalue. When the discs are disjoint, Lemma 19.3.4 adds that, and Exercise C1 does it.

Quick check. Let $\mathbf{A} = \operatorname{diag}(1,2)$. Which matrices $\mathbf{X}$ satisfy $\mathbf{X}^{-1}\mathbf{A}\mathbf{X}$ diagonal, and what does Theorem 19.4.2 give for each of them?

Solution. The eigenvalues $1,2$ are distinct and each eigenspace is a line: $E_1(\mathbf{A}) = \operatorname{span}(\mathbf{e}_1)$ and $E_2(\mathbf{A}) = \operatorname{span}(\mathbf{e}_2)$. The columns of $\mathbf{X}$ must be eigenvectors (Theorem 8.4.1), so $\mathbf{X} = \operatorname{diag}(a,b)$ or $\mathbf{X} = \left(\begin{smallmatrix} 0 & a \\ b & 0 \end{smallmatrix}\right)$ with $a,b \neq 0$. In both cases the singular values of $\mathbf{X}$ are $|a|$ and $|b|$, so $\kappa_2(\mathbf{X}) = \max(|a|,|b|)/\min(|a|,|b|)$ (Proposition 15.8.2 (d)). The theorem gives $\min_i|\lambda_i-\mu| \le \kappa_2(\mathbf{X})\|\mathbf{E}\|_2$. This is $\|\mathbf{E}\|_2$ when $|a| = |b|$, and arbitrarily weak as $|a|/|b|$ grows. The theorem is true for every choice, and one uses the best.

19.4.3 Normal matrices

For a normal matrix the eigenvectors can be chosen orthonormal, and then the factor is 1. The second half of the next result proves the converse, in the form Chapter 11 §11 stated it: $\kappa = 1$ **exactly** in the normal case.

Corollary 19.4.3 — Bauer–Fike for Normal Matrices (a) Let $\mathbf{A} \in M_n(\mathbb{C})$ be normal with eigenvalues $\lambda_1,\dots,\lambda_n$, and let $\mathbf{E} \in M_n(\mathbb{C})$. Then every eigenvalue μ of $\mathbf{A}+\mathbf{E}$ satisfies $\min_i|\lambda_i-\mu| \le \|\mathbf{E}\|_2$.

(b) Let $\mathbf{A} \in M_n(\mathbb{C})$ be diagonalizable. Then

$$\inf\big\{\kappa_2(\mathbf{X}) : \mathbf{X}^{-1}\mathbf{A}\mathbf{X} \text{ is diagonal}\big\} = 1,$$

the infimum over invertible $\mathbf{X}$, if and only if $\mathbf{A}$ is normal.

Idea. Part (a) is the theorem with a unitary $\mathbf{X}$. For (b), write $\mathbf{X} = \mathbf{W}\mathbf{\Sigma}\mathbf{V}^*$ by the singular value decomposition. Then $\mathbf{A}$ is $\mathbf{W}\mathbf{\Sigma}\mathbf{M}\mathbf{\Sigma}^{-1}\mathbf{W}^*$ with $\mathbf{M}$ normal. If all the singular values of $\mathbf{X}$ are nearly equal, $\mathbf{\Sigma}\mathbf{M}\mathbf{\Sigma}^{-1}$ is nearly $\mathbf{M}$, so $\mathbf{A}$ is nearly the normal

matrix $\mathbf{WMW}^*$, and its commutator $\mathbf{A}^*\mathbf{A} - \mathbf{AA}^*$ is nearly $\mathbf{0}$. A commutator that is arbitrarily small is zero.

Proof.

(a) By Corollary 11.4.3, $\mathbf{A} = \mathbf{U\Lambda U}^*$ with $\mathbf{U}$ unitary and $\mathbf{\Lambda} = \operatorname{diag}(\lambda_1, \dots, \lambda_n)$, so $\mathbf{U}^{-1} = \mathbf{U}^*$. A unitary matrix preserves $\|\cdot\|_2$ (Theorem 10.7.3), so $\|\mathbf{U}\|_2 = \|\mathbf{U}^*\|_2 = 1$ and $\kappa_2(\mathbf{U}) = 1$. Now apply Theorem 19.4.2 with $\mathbf{X} = \mathbf{U}$ and $p = 2$.

(b) ($\Leftarrow$) If $\mathbf{A}$ is normal, the $\mathbf{U}$ of (a) diagonalizes $\mathbf{A}$ with $\kappa_2(\mathbf{U}) = 1$, and every $\kappa_2(\mathbf{X}) \geq 1$ by Proposition 15.8.2 (a). So the infimum is 1.

($\Rightarrow$) First we prove that every invertible $\mathbf{X}$ with $\mathbf{X}^{-1}\mathbf{AX} = \mathbf{\Lambda}$ diagonal satisfies

$$\begin{aligned}\|\mathbf{A}^*\mathbf{A} - \mathbf{AA}^*\|_F \leq 2\big(\kappa_2(\mathbf{X}) - 1\big)\|\mathbf{\Lambda}\|_F \\ \cdot \big(\|\mathbf{A}\|_F + \|\mathbf{\Lambda}\|_F\big).\end{aligned} \tag{19.4.2}$$

Write $\mathbf{X} = \mathbf{W\Sigma V}^*$ (Theorem 12.8.1), with $\mathbf{W}, \mathbf{V}$ unitary and $\mathbf{\Sigma} = \operatorname{diag}(\sigma_1, \dots, \sigma_n)$. Here $\sigma_n > 0$, because $\mathbf{X}$ is invertible and so has rank n. Then $\mathbf{X}^{-1} = \mathbf{V\Sigma}^{-1}\mathbf{W}^*$, and

$$\mathbf{A} = \mathbf{X\Lambda X}^{-1} = \mathbf{W\Sigma M\Sigma}^{-1}\mathbf{W}^*, \qquad \mathbf{M} = \mathbf{V}^*\mathbf{\Lambda V}.$$

Put $\mathbf{N} = \mathbf{WMW}^* = (\mathbf{WV}^*)\mathbf{\Lambda}(\mathbf{WV}^*)^*$. It is unitarily diagonalizable, hence normal by Corollary 11.4.3. The (i, j) entry of $\mathbf{\Sigma M\Sigma}^{-1} - \mathbf{M}$ is $m_{ij}(\sigma_i/\sigma_j - 1)$. Write $\kappa = \kappa_2(\mathbf{X}) = \sigma_1/\sigma_n$ (Proposition 15.8.2 (d)). If $\sigma_i \geq \sigma_j$, then $0 \leq \sigma_i/\sigma_j - 1 \leq \kappa - 1$. If $\sigma_i < \sigma_j$, then $0 < 1 - \sigma_i/\sigma_j \leq 1 - 1/\kappa \leq \kappa - 1$, the last step because $(\kappa - 1) - (1 - 1/\kappa) = (\kappa - 1)^2/\kappa \geq 0$. So every entry is at most $(\kappa - 1)|m_{ij}|$ in modulus. In the display below, the first equality is Lemma 11.11.1 applied to $\mathbf{A} - \mathbf{N} = \mathbf{W}(\mathbf{\Sigma M\Sigma}^{-1} - \mathbf{M})\mathbf{W}^*$; the inequality is the entrywise bound just proved, summed over the entries; and the last equality is the same lemma again, applied to $\mathbf{M} = \mathbf{V}^*\mathbf{\Lambda V}$. So

$$\|\mathbf{A} - \mathbf{N}\|_F = \|\mathbf{\Sigma M\Sigma}^{-1} - \mathbf{M}\|_F \leq (\kappa - 1)\|\mathbf{M}\|_F = (\kappa - 1)\|\mathbf{\Lambda}\|_F.$$

Now $\mathbf{N}^*\mathbf{N} = \mathbf{NN}^*$, and a direct expansion gives

$$\begin{aligned}\mathbf{A}^*\mathbf{A} - \mathbf{AA}^* &= \big(\mathbf{A}^*\mathbf{A} - \mathbf{N}^*\mathbf{N}\big) - \big(\mathbf{AA}^* - \mathbf{NN}^*\big) \\ &= \mathbf{A}^*(\mathbf{A} - \mathbf{N}) + (\mathbf{A} - \mathbf{N})^*\mathbf{N} \\ &\quad - \mathbf{A}(\mathbf{A} - \mathbf{N})^* - (\mathbf{A} - \mathbf{N})\mathbf{N}^*.\end{aligned}$$

The Frobenius norm is submultiplicative (Example (The Frobenius norm is submultiplicative)), $\|\mathbf{Y}^*\|_F = \|\mathbf{Y}\|_F$ for every $\mathbf{Y}$, since the entries of $\mathbf{Y}^*$ are the conjugates of those of $\mathbf{Y}$ and conjugation preserves the modulus, and $\|\mathbf{N}\|_F = \|\mathbf{\Lambda}\|_F$ by Lemma 11.11.1. So each of the four terms has norm at most $\|\mathbf{A} - \mathbf{N}\|_F$ times $\|\mathbf{A}\|_F$ or $\|\mathbf{\Lambda}\|_F$, and

$$\|\mathbf{A}^*\mathbf{A} - \mathbf{AA}^*\|_F \leq 2\|\mathbf{A} - \mathbf{N}\|_F\big(\|\mathbf{A}\|_F + \|\mathbf{\Lambda}\|_F\big),$$

which with the previous display gives Eq. 19.4.2.

Now suppose the infimum is 1. Every diagonalizing $\mathbf{X}$ produces the same $\|\mathbf{\Lambda}\|_F = (\sum_i |\lambda_i|^2)^{1/2}$, since $\mathbf{\Lambda}$ lists the eigenvalues of $\mathbf{A}$ in some order. So the right side of Eq. 19.4.2 can be made smaller than any positive number, while the left side does not

depend on $\mathbf{X}$. Hence $\|\mathbf{A}^*\mathbf{A} - \mathbf{A}\mathbf{A}^*\|_F = 0$, so $\mathbf{A}^*\mathbf{A} = \mathbf{A}\mathbf{A}^*$ and $\mathbf{A}$ is normal. This proves the corollary.

■

Part (b) says more than the bare equivalence. By Eq. 19.4.2, a diagonalizable matrix whose eigenvector matrix is **nearly** unitary is **nearly** normal. It also shows that $\kappa_2(\mathbf{X}) = 1$ forces $\mathbf{A}$ to be normal. In fact $\kappa_2(\mathbf{X}) = 1$ says that $\sigma_1 = \sigma_n$, so $\mathbf{\Sigma} = \sigma_1\mathbf{I}$ and $\mathbf{X} = \sigma_1\mathbf{W}\mathbf{V}^*$, a non-zero multiple of a unitary matrix.

Part (a) is sharp, and the example that shows it is the one Chapter 16 §03 used to warn that Weyl's inequality needs Hermitian matrices. Take $\mathbf{A} = \mathbf{0}$, which is normal with the single eigenvalue 0, and $\mathbf{E} = \left(\begin{smallmatrix} 0 & -1 \\ 1 & 0 \end{smallmatrix}\right)$, with $\|\mathbf{E}\|_2 = 1$ because $\mathbf{E}$ is unitary. The eigenvalues of $\mathbf{A} + \mathbf{E}$ are $\pm i$, since $p_{\mathbf{E}}(x) = x^2 + 1$. Weyl's comparison of the i-th eigenvalues cannot even be stated, because $\pm i$ are not real. The Bauer–Fike bound can: each of $\pm i$ is within $\|\mathbf{E}\|_2 = 1$ of 0, and the distance is exactly 1. So the constant 1 in (a) cannot be lowered.

19.4.4 Residuals

In practice one rarely knows $\mathbf{E}$. What one has is an approximate eigenpair $(\mu, \widehat{\mathbf{x}})$, computed somehow, and the **residual** $\mathbf{r} = \mathbf{A}\widehat{\mathbf{x}} - \mu\widehat{\mathbf{x}}$, which can be evaluated. The residual turns into a perturbation: a small residual means that $(\mu, \widehat{\mathbf{x}})$ is an exact eigenpair of a nearby matrix.

Theorem 19.4.4 — Residual Bound

Let $\mathbf{A} = \mathbf{X}\mathbf{\Lambda}\mathbf{X}^{-1} \in M_n(\mathbb{C})$ be diagonalizable, with $\mathbf{\Lambda} = \operatorname{diag}(\lambda_1, \dots, \lambda_n)$. Let $\mu \in \mathbb{C}$ and $\widehat{\mathbf{x}} \in \mathbb{C}^n$ with $\widehat{\mathbf{x}} \neq \mathbf{0}$, and let $\eta \geq 0$ satisfy

$$\|\mathbf{A}\widehat{\mathbf{x}} - \mu\widehat{\mathbf{x}}\|_2 \leq \eta\, \|\widehat{\mathbf{x}}\|_2.$$

Then some eigenvalue λ_i of $\mathbf{A}$ satisfies $|\lambda_i - \mu| \leq \kappa_2(\mathbf{X})\, \eta$. If $\mathbf{A}$ is normal, some eigenvalue satisfies $|\lambda_i - \mu| \leq \eta$.

Proof. Put $\mathbf{r} = \mathbf{A}\widehat{\mathbf{x}} - \mu\widehat{\mathbf{x}}$ and $\mathbf{E} = -\mathbf{r}\widehat{\mathbf{x}}^*/\|\widehat{\mathbf{x}}\|_2^2$. Then

$$(\mathbf{A} + \mathbf{E})\widehat{\mathbf{x}} = \mathbf{A}\widehat{\mathbf{x}} - \mathbf{r}\,\frac{\widehat{\mathbf{x}}^*\widehat{\mathbf{x}}}{\|\widehat{\mathbf{x}}\|_2^2} = \mathbf{A}\widehat{\mathbf{x}} - \mathbf{r} = \mu\widehat{\mathbf{x}},$$

so μ is an eigenvalue of $\mathbf{A} + \mathbf{E}$ with eigenvector $\widehat{\mathbf{x}}$. For every $\mathbf{z}$, the Cauchy–Schwarz inequality (Theorem 10.1.5) gives $|\widehat{\mathbf{x}}^*\mathbf{z}| \leq \|\widehat{\mathbf{x}}\|_2\|\mathbf{z}\|_2$, hence

$$\|\mathbf{E}\mathbf{z}\|_2 = \frac{|\widehat{\mathbf{x}}^*\mathbf{z}|\,\|\mathbf{r}\|_2}{\|\widehat{\mathbf{x}}\|_2^2} \leq \frac{\|\mathbf{r}\|_2}{\|\widehat{\mathbf{x}}\|_2}\,\|\mathbf{z}\|_2,$$

so $\|\mathbf{E}\|_2 \leq \|\mathbf{r}\|_2/\|\widehat{\mathbf{x}}\|_2 \leq \eta$. (The first inequality is an equality, since $\mathbf{E}\widehat{\mathbf{x}} = -\mathbf{r}$.) By Theorem 19.4.2 with $p = 2$, some λ_i satisfies $|\lambda_i - \mu| \leq \kappa_2(\mathbf{X})\|\mathbf{E}\|_2 \leq \kappa_2(\mathbf{X})\eta$. If $\mathbf{A}$ is normal, use Corollary 19.4.3 (a) instead.

■

The theorem reverses the usual question. Instead of asking how far the eigenvalues of a given perturbed matrix have moved, it asks: of which nearby matrix is my computed answer exactly right? The answer is $\mathbf{A}+\mathbf{E}$ with $\|\mathbf{E}\|_2 = \|\mathbf{r}\|_2/\|\widehat{\mathbf{x}}\|_2$. An error analysis of this kind, which measures an answer by a change in the data that makes it exact, is a **backward error analysis**. Chapter 23 builds on it. For a normal matrix, the scaled residual norm $\|\mathbf{r}\|_2/\|\widehat{\mathbf{x}}\|_2$ is itself a certified error bar for μ.

Example. (An error bar from one product)

Let $\mathbf{A} = \begin{pmatrix} 2 & 1 \\ 1 & 3 \end{pmatrix}$, $\widehat{\mathbf{x}} = (1,2)$ and $\mu = \frac{7}{2}$. Compute the residual, and say what interval Theorem 19.4.4 certifies around μ. Then compare it with the truth.

Solution. $\mathbf{A}\widehat{\mathbf{x}} = (4,7)$ and $\mu\widehat{\mathbf{x}} = (\frac{7}{2},7)$, so $\mathbf{r} = (\frac{1}{2},0)$, with $\|\mathbf{r}\|_2 = \frac{1}{2}$ and $\|\widehat{\mathbf{x}}\|_2 = \sqrt{5}$. Take $\eta = \|\mathbf{r}\|_2/\|\widehat{\mathbf{x}}\|_2 = \sqrt{5}/10 \approx 0.2236$. The matrix $\mathbf{A}$ is real symmetric, hence normal, so Theorem 19.4.4 gives an eigenvalue of $\mathbf{A}$ within η of $\frac{7}{2}$, and that eigenvalue is real (Theorem 11.2.1). So $\mathbf{A}$ has an eigenvalue in $[\frac{7}{2}-\eta, \frac{7}{2}+\eta] \approx [3.276, 3.724]$, and no eigenvalue was computed to say so: one matrix–vector product did it.

The truth. $p_{\mathbf{A}}(x) = (x-2)(x-3)-1 = x^2-5x+5$, with roots $(5 \pm \sqrt{5})/2$. The larger is ≈ 3.618, which does lie in the interval, at distance ≈ 0.118 from $\frac{7}{2}$ — about half of η, so the certificate costs a factor of 2 in sharpness.

19.4.5 A worked example

Chapter 11 §11 perturbed a corner of $\left(\begin{smallmatrix} 1 & M \\ 0 & 1 \end{smallmatrix}\right)$, with a double eigenvalue, and found the eigenvalues moving by $\sqrt{M\varepsilon}$ (Example (A perturbation that moves the eigenvalues a thousand times as far)). Its closing remark said that "a matrix with well-separated eigenvalues and a large defect behaves less dramatically". Bauer–Fike says how much less.

Example. (A large corner, separated eigenvalues)

Let $M > 0$, $\mathbf{A} = \begin{pmatrix} 1 & M \\ 0 & 2 \end{pmatrix}$, and $\mathbf{E} = \varepsilon\, \mathbf{e}_2\mathbf{e}_1^{\top}$ with $0 < \varepsilon \le 1$. Diagonalize $\mathbf{A}$ in two ways, compute κ_2 of each eigenvector matrix, and compare the Bauer–Fike bound with the exact movement of the eigenvalues.

Solution. Eigenvectors. $\mathbf{A}$ is upper triangular with distinct diagonal entries $1, 2$, which are its eigenvalues. For 1, $\mathbf{A}-\mathbf{I} = \left(\begin{smallmatrix} 0 & M \\ 0 & 1 \end{smallmatrix}\right)$ has kernel $\operatorname{span}(\mathbf{e}_1)$. For 2, $\mathbf{A}-2\mathbf{I} = \left(\begin{smallmatrix} -1 & M \\ 0 & 0 \end{smallmatrix}\right)$ has kernel spanned by $(M,1)$. Two natural choices are

$$\mathbf{X}_1 = \begin{pmatrix} 1 & M \\ 0 & 1 \end{pmatrix}, \qquad \mathbf{X}_2 = \begin{pmatrix} 1 & M/s \\ 0 & 1/s \end{pmatrix}, \quad s = \sqrt{1+M^2}.$$

The second has columns of length 1. Both satisfy $\mathbf{X}^{-1}\mathbf{A}\mathbf{X} = \operatorname{diag}(1,2)$.

$\kappa_2(\mathbf{X}_1)$. $\mathbf{X}_1^{*}\mathbf{X}_1 = \left(\begin{smallmatrix} 1 & M \\ M & 1+M^2 \end{smallmatrix}\right)$ has trace $2+M^2$ and determinant 1. Its eigenvalues $\sigma_1^2 \ge \sigma_2^2$

therefore have product 1, and $\kappa_2(\mathbf{X}_1) = \sigma_1/\sigma_2 = \sigma_1^2$. Solving the quadratic,

$$\kappa_2(\mathbf{X}_1) = \frac{2 + M^2 + M\sqrt{M^2+4}}{2},$$

which exceeds M^2.

$\kappa_2(\mathbf{X}_2)$. $\mathbf{X}_2^*\mathbf{X}_2 = \left(\begin{smallmatrix} 1 & q \\ q & 1 \end{smallmatrix}\right)$ with $q = M/s$, since the columns are unit vectors whose inner product is M/s. Its eigenvalues are $1 \pm q$, so

$$\kappa_2(\mathbf{X}_2)^2 = \frac{1+q}{1-q} = \frac{s+M}{s-M} = (s+M)^2,$$

using $(s+M)(s-M) = s^2 - M^2 = 1$. Hence $\kappa_2(\mathbf{X}_2) = M + \sqrt{1+M^2}$, which lies between $2M$ and $2M+1$.

The bound. $\|\mathbf{E}\|_2 = \varepsilon$, since $\mathbf{E}$ has a single non-zero entry. With $\mathbf{X}_2$, Theorem 19.4.2 gives movement at most $(M + \sqrt{1+M^2})\varepsilon$, about $2M\varepsilon$. With $\mathbf{X}_1$ it gives about $M^2\varepsilon$.

The truth. $p_{\mathbf{A}+\mathbf{E}}(x) = (x-1)(x-2) - M\varepsilon = x^2 - 3x + 2 - M\varepsilon$, with roots $\big(3 \pm \sqrt{1+4M\varepsilon}\big)/2$. Each eigenvalue has moved by

$$\frac{\sqrt{1+4M\varepsilon} - 1}{2} = \frac{2M\varepsilon}{1 + \sqrt{1+4M\varepsilon}},$$

multiplying top and bottom by $\sqrt{1+4M\varepsilon}+1$. The denominator is at least 2, and at most $2 + 2M\varepsilon$ because $\sqrt{1+4M\varepsilon} \le 1 + 2M\varepsilon$. So the movement lies between $M\varepsilon/(1+M\varepsilon)$ and $M\varepsilon$.

Numbers. For $M = 100$ and $\varepsilon = 10^{-6}$, the eigenvalues move by about 0.9999×10^{-4}, and the bound with $\mathbf{X}_2$ is about 2.0×10^{-4}. The bound with $\mathbf{X}_1$ is about 10^{-2}. By comparison, in Example (A perturbation that moves the eigenvalues a thousand times as far), the same corner and the same ε moved a **double** eigenvalue by $\sqrt{M\varepsilon} = 10^{-2}$. Separating the eigenvalues turns a square-root amplification into a linear one, with a constant of about M. The constant is still large, and $\kappa_2(\mathbf{X}_2)$ predicts it correctly to within a factor of about 2.

Warning. $\kappa_2(\mathbf{X})$ **belongs to the choice of X, not to A.** Eigenvectors can be rescaled, and rescaling changes κ_2: in Example (A large corner, separated eigenvalues) the same matrix gave $\kappa_2(\mathbf{X}_1) \approx 10^4$ and $\kappa_2(\mathbf{X}_2) \approx 200$ at $M = 100$. The theorem holds for every choice, so use the best one you can find; normalizing the columns is a reasonable first step. And even the best $\mathbf{X}$ measures all the eigenvalues at once. Section 11 attaches a separate condition number to each simple eigenvalue, and one eigenvalue can be well conditioned while $\mathbf{X}$ is badly conditioned.

19.4.6 Defective matrices

When $\mathbf{A}$ is not diagonalizable, write $\mathbf{A} = \mathbf{X}\mathbf{J}\mathbf{X}^{-1}$ with $\mathbf{J}$ a Jordan form (Theorem 9.3.1). The letter $\mathbf{J}$ is local to this subsection; elsewhere in the book $\mathbf{J}$ is the all-ones matrix, which does not appear here. The proof of Theorem 19.4.2 goes through verbatim, except that $(\mathbf{J} - \mu\mathbf{I})^{-1}$ is no longer diagonal. Its norm is no longer $1/\delta$; it grows like $1/\delta^m$ as $\delta \to 0$, where m is the size of the largest Jordan block. Taking m-th roots brings back the exponent of Section 3.

Theorem 19.4.5 — Bauer–Fike for a Jordan Form

Let $\mathbf{A} = \mathbf{X}\mathbf{J}\mathbf{X}^{-1} \in M_n(\mathbb{C})$, where $\mathbf{X}$ is invertible and $\mathbf{J}$ is a Jordan form of $\mathbf{A}$ whose largest block has size m. Let $\lambda_1, \dots, \lambda_n$ be the eigenvalues of $\mathbf{A}$, let $\mathbf{E} \in M_n(\mathbb{C})$, and put $\theta = m\,\kappa_2(\mathbf{X})\|\mathbf{E}\|_2$. Then every eigenvalue μ of $\mathbf{A} + \mathbf{E}$ satisfies

$$\min_{1 \le i \le n} |\lambda_i - \mu| \le \max\bigl(\theta, \theta^{1/m}\bigr).$$

Idea. Run the proof of Theorem 19.4.2 with $\mathbf{J}$ in place of $\mathbf{\Lambda}$. The only new work is to bound $\|(\mathbf{J}_k(\lambda) - \mu\mathbf{I})^{-1}\|_2$ for one block. The block is $(\lambda - \mu)\mathbf{I} + \mathbf{N}$, with $\mathbf{N}$ nilpotent of norm at most 1, so its inverse is a **finite** Neumann series $\sum_{j<k} (-1)^j \mathbf{N}^j / (\lambda - \mu)^{j+1}$ with at most m terms. Bound it by $m\delta^{-1}$ when $\delta \ge 1$ and by $m\delta^{-m}$ when $\delta < 1$.

Proof. Put $\delta = \min_i |\lambda_i - \mu|$. If $\delta = 0$ there is nothing to prove, so suppose $\delta > 0$. The upper triangular $\mathbf{J}$ has its diagonal entries as eigenvalues (Theorem 8.7.4 (b)), and these are the λ_i because $\mathbf{J}$ and $\mathbf{A}$ are similar (Theorem 6.10.3); so $\mu \notin \operatorname{spec}(\mathbf{J})$. As in the proof of Theorem 19.4.2, μ is an eigenvalue of $\mathbf{J} + \mathbf{X}^{-1}\mathbf{E}\mathbf{X}$, and Lemma 19.4.1 with submultiplicativity gives

$$1 \le \|(\mathbf{J} - \mu\mathbf{I})^{-1}\|_2 \, \kappa_2(\mathbf{X}) \, \|\mathbf{E}\|_2.$$

One block. Let $\mathbf{J}_k(\lambda)$ be a block of $\mathbf{J}$, so $k \le m$ and $|\lambda - \mu| \ge \delta$, and write $\mathbf{J}_k(\lambda) - \mu\mathbf{I} = a\mathbf{I} + \mathbf{N}$ with $a = \lambda - \mu \ne 0$ and $\mathbf{N} = \mathbf{J}_k(0)$. The matrix $\mathbf{N}$ sends $\mathbf{e}_1$ to $\mathbf{0}$ and $\mathbf{e}_j$ to $\mathbf{e}_{j-1}$ for $j \ge 2$, so $\mathbf{N}^k$ sends every $\mathbf{e}_j$ to $\mathbf{0}$ and $\mathbf{N}^k = \mathbf{0}$. Then

$$(a\mathbf{I} + \mathbf{N}) \sum_{j=0}^{k-1} \frac{(-1)^j \mathbf{N}^j}{a^{j+1}} = \sum_{j=0}^{k-1} \frac{(-1)^j \mathbf{N}^j}{a^j} - \sum_{j=1}^{k} \frac{(-1)^j \mathbf{N}^j}{a^j} = \mathbf{I} - \frac{(-1)^k \mathbf{N}^k}{a^k} = \mathbf{I},$$

so the sum is the inverse of $a\mathbf{I} + \mathbf{N}$. The same description of $\mathbf{N}$ gives $\|\mathbf{N}\mathbf{x}\|_2^2 = \sum_{j \ge 2} |x_j|^2 \le \|\mathbf{x}\|_2^2$, so $\|\mathbf{N}\|_2 \le 1$. Hence $\|\mathbf{N}^j\|_2 \le 1$ for every $j \ge 0$ by submultiplicativity, and the triangle inequality gives

$$\|(\mathbf{J}_k(\lambda) - \mu\mathbf{I})^{-1}\|_2 \le \sum_{j=1}^{k} |a|^{-j} \le \sum_{j=1}^{m} \delta^{-j},$$

using $|a| \ge \delta$ and $k \le m$.

All blocks. $(\mathbf{J} - \mu\mathbf{I})^{-1}$ is block diagonal, with the inverses of the blocks $\mathbf{J}_k(\lambda) - \mu\mathbf{I}$ on its diagonal. Split $\mathbf{x}$ into the matching pieces $\mathbf{x}_1, \dots, \mathbf{x}_r$ and let $\mathbf{C}_1, \dots, \mathbf{C}_r$ be the diagonal blocks. Then $\|(\mathbf{J} - \mu\mathbf{I})^{-1}\mathbf{x}\|_2^2 = \sum_l \|\mathbf{C}_l \mathbf{x}_l\|_2^2 \le (\max_l \|\mathbf{C}_l\|_2)^2 \|\mathbf{x}\|_2^2$. So $\|(\mathbf{J} - \mu\mathbf{I})^{-1}\|_2 \le \sum_{j=1}^{m} \delta^{-j}$, and

$$1 \le \frac{\theta}{m} \sum_{j=1}^{m} \delta^{-j}.$$

Two cases. If $\delta \ge 1$, each $\delta^{-j} \le \delta^{-1}$, so $1 \le \theta/\delta$ and $\delta \le \theta$. If $\delta < 1$, each $\delta^{-j} \le \delta^{-m}$, so $1 \le \theta\delta^{-m}$, that is $\delta^m \le \theta$ and $\delta \le \theta^{1/m}$. In both cases $\delta \le \max(\theta, \theta^{1/m})$. This proves the theorem.

■

For $m = 1$, $\mathbf{J}$ is diagonal, $\theta = \kappa_2(\mathbf{X})\|\mathbf{E}\|_2$, and the theorem is Theorem 19.4.2 with $p = 2$. For $m \geq 2$ and small $\mathbf{E}$, the term $\theta^{1/m}$ dominates, and the eigenvalues move like the m-th root of the perturbation. That exponent is the Jordan block's signature, and it is the answer to Chapter 9 §03's warning that the Jordan form is not stable. Section 3's Example (The Jordan block meets Elsner's bound) shows it cannot be improved. There $\mathbf{A} = \mathbf{J}_n(0)$, $\mathbf{X} = \mathbf{I}$, $m = n$ and $\|\mathbf{E}\|_2 = \varepsilon \leq 1/n$, so $\theta = n\varepsilon \leq 1$ and the theorem gives $\max(\theta, \theta^{1/n}) = (n\varepsilon)^{1/n}$ while the eigenvalues actually move $\varepsilon^{1/n}$. The two differ by the factor $n^{1/n}$, which never exceeds $3^{1/3} < 1.45$.

Only the size of the largest block enters, and a diagonalizable part of $\mathbf{A}$ is charged the same m-th root as the defective part. Section 11 separates the eigenvalues. There a simple eigenvalue gets its own first-order condition number, and that number becomes infinite exactly when two eigenvalues merge into a Jordan block.

19.4.7 Exercises

19.4.7.1 A. Check your understanding

Exercise A1.

(a) State Theorem 19.4.2 with all its hypotheses.

(b) True or false: the constant $\kappa_2(\mathbf{X})$ in Theorem 19.4.2 is determined by $\mathbf{A}$. Justify your answer.

(c) True or false: for every $\mathbf{A}, \mathbf{E} \in M_n(\mathbb{C})$, every eigenvalue of $\mathbf{A} + \mathbf{E}$ lies within $\|\mathbf{E}\|_2$ of an eigenvalue of $\mathbf{A}$. Justify your answer.

(d) What does Corollary 19.4.3 (a) give when $\mathbf{A}$ is normal, and which example shows that its constant cannot be lowered?

(e) In Theorem 19.4.5, what exponent appears for small $\|\mathbf{E}\|_2$, and what decides it?

Solution.

(a) See Theorem 19.4.2: $\mathbf{A} = \mathbf{X}\mathbf{\Lambda}\mathbf{X}^{-1}$ diagonalizable, $\mathbf{E}$ arbitrary, $p \in \{1, 2, \infty\}$; every eigenvalue μ of $\mathbf{A} + \mathbf{E}$ is within $\kappa_p(\mathbf{X})\|\mathbf{E}\|_p$ of some λ_i.

(b) False. The columns of $\mathbf{X}$ can be rescaled, and κ_2 changes. The Quick check gave $\mathbf{X} = \operatorname{diag}(a, b)$ for $\mathbf{A} = \operatorname{diag}(1, 2)$, with $\kappa_2(\mathbf{X}) = \max(|a|, |b|)/\min(|a|, |b|)$, any number ≥ 1.

(c) False. By Example (The Jordan block meets Elsner's bound) with $n = 2$, $\mathbf{A} = \mathbf{J}_2(0)$ and $\mathbf{E} = \varepsilon \mathbf{e}_2 \mathbf{e}_1^{\top}$ with $0 < \varepsilon < 1$ give eigenvalues $\pm\sqrt{\varepsilon}$ of $\mathbf{A} + \mathbf{E}$, at distance $\sqrt{\varepsilon} > \varepsilon = \|\mathbf{E}\|_2$ from 0. The hypothesis that fails is diagonalizability.

(d) Every eigenvalue of $\mathbf{A} + \mathbf{E}$ is within $\|\mathbf{E}\|_2$ of an eigenvalue of $\mathbf{A}$. The example $\mathbf{A} = \mathbf{0}$, $\mathbf{E} = \left(\begin{smallmatrix} 0 & -1 \\ 1 & 0 \end{smallmatrix}\right)$ has perturbed eigenvalues $\pm i$ at distance exactly $1 = \|\mathbf{E}\|_2$.

(e) The exponent $1/m$, where m is the size of the largest Jordan block of $\mathbf{A}$.

19.4.7.2 B. Practice

Exercise B1: A Bauer–Fike region.

Let $\mathbf{A} = \begin{pmatrix} 1 & 2 \\ 0 & 3 \end{pmatrix}$.

(a) Find an eigenvector matrix $\mathbf{X}$ with columns of length 1, and compute $\kappa_2(\mathbf{X})$.

(b) Hence find r such that every eigenvalue of $\mathbf{A}+\mathbf{E}$ lies within r of 1 or of 3 whenever $\|\mathbf{E}\|_2 \le 0.01$.

(c) Compute the eigenvalues of $\mathbf{A} + 0.01\,\mathbf{e}_2\mathbf{e}_1^{\top}$ exactly, and compare their movement with r.

Solution.

(a) The eigenvalues are 1 and 3, with eigenvectors $\mathbf{e}_1$ and $(1,1)$, since $(\mathbf{A}-3\mathbf{I})(1,1) = (-2+2, 0) = \mathbf{0}$. So $\mathbf{X} = \begin{pmatrix} 1 & 1/\sqrt{2} \\ 0 & 1/\sqrt{2} \end{pmatrix}$. Then $\mathbf{X}^*\mathbf{X} = \begin{pmatrix} 1 & q \\ q & 1 \end{pmatrix}$ with $q = 1/\sqrt{2}$, with eigenvalues $1 \pm q$, so

$$\kappa_2(\mathbf{X})^2 = \frac{1+q}{1-q} = \frac{\sqrt{2}+1}{\sqrt{2}-1} = (\sqrt{2}+1)^2,$$

and $\kappa_2(\mathbf{X}) = 1+\sqrt{2} \approx 2.414$.

(b) By Theorem 19.4.2 with $p=2$, $r = (1+\sqrt{2})(0.01) \approx 0.0241$ works.

(c) $p(x) = (x-1)(x-3) - 0.02 = x^2 - 4x + 2.98$, with roots $2 \pm \sqrt{1.02}$. Each eigenvalue has moved by $\sqrt{1.02} - 1 \approx 0.00995$, well within $r \approx 0.0241$.

Exercise B2: A residual certificate.

Let $\mathbf{A} = \begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix}$, $\widehat{\mathbf{x}} = (10, 9)$ and $\mu = 3$.

(a) Compute the residual $\mathbf{r} = \mathbf{A}\widehat{\mathbf{x}} - \mu\widehat{\mathbf{x}}$ and $\eta = \|\mathbf{r}\|_2 / \|\widehat{\mathbf{x}}\|_2$.

(b) Hence show that $\mathbf{A}$ has an eigenvalue in the interval $[3-\eta, 3+\eta]$, without computing the eigenvalues of $\mathbf{A}$.

Solution.

(a) $\mathbf{A}\widehat{\mathbf{x}} = (29, 28)$ and $3\widehat{\mathbf{x}} = (30, 27)$, so $\mathbf{r} = (-1, 1)$, $\|\mathbf{r}\|_2 = \sqrt{2}$, $\|\widehat{\mathbf{x}}\|_2 = \sqrt{181}$, and $\eta = \sqrt{2/181} \approx 0.105$.

(b) $\mathbf{A}$ is real symmetric, hence normal. By Theorem 19.4.4, some eigenvalue λ satisfies $|\lambda - 3| \le \eta$. The eigenvalues of a real symmetric matrix are real (Theorem 11.2.1), so $\lambda \in [3-\eta, 3+\eta]$. (In fact $\lambda = 3$, with eigenvector $(1,1)$.)

Exercise B3: A defective bound.

Let $\mathbf{A} = \mathbf{J}_2(3)$.

(a) Explain why Theorem 19.4.2 does not apply to $\mathbf{A}$.

(b) Use Theorem 19.4.5 to find r such that every eigenvalue of $\mathbf{A}+\mathbf{E}$ lies within r of 3 whenever $\|\mathbf{E}\|_2 \le 10^{-4}$.

(c) Compute the eigenvalues of $\mathbf{A} + 10^{-4}\mathbf{e}_2\mathbf{e}_1^{\top}$, and compare.

Solution.

(a) $\mathbf{A}$ has the single eigenvalue 3 with algebraic multiplicity 2, and $\mathbf{A} - 3\mathbf{I} = \mathbf{J}_2(0)$ has rank 1, so the eigenspace has dimension 1. Hence $\mathbf{A}$ is not diagonalizable (Theorem 8.4.1), and there is no $\mathbf{X}$ to put in Theorem 19.4.2.

(b) $\mathbf{A}$ is its own Jordan form, so take $\mathbf{X} = \mathbf{I}$, with $\kappa_2(\mathbf{I}) = 1$, and $m = 2$. Then $\theta = 2 \cdot 1 \cdot 10^{-4} = 2 \times 10^{-4}$, and $\max(\theta, \theta^{1/2}) = \sqrt{2} \times 10^{-2} \approx 0.0141$. So $r = \sqrt{2} \times 10^{-2}$ works.

(c) $p(x) = (x-3)^2 - 10^{-4}$, with roots 3 ± 10^{-2}. The movement 0.01 is below $r \approx 0.0141$, and it is a hundred times the size 10^{-4} of the perturbation: the square root at work.

19.4.7.3 C. Going deeper

Exercise C1: One eigenvalue in each disc.

Let $\mathbf{A} = \mathbf{X}\mathbf{\Lambda}\mathbf{X}^{-1}$ have n distinct eigenvalues $\lambda_1, \ldots, \lambda_n$, put $g = \min_{i \neq j} |\lambda_i - \lambda_j|$, and let $\mathbf{E}$ satisfy $r = \kappa_2(\mathbf{X})\|\mathbf{E}\|_2 < g/2$.

(a) Prove that for each i, $\mathbf{A}+\mathbf{E}$ has exactly one eigenvalue in the disc $\{z : |z-\lambda_i| \leq r\}$, and that $\mathbf{A} + \mathbf{E}$ is diagonalizable.

(b) Deduce that if $\mathbf{A}$ and $\mathbf{E}$ are real and every λ_i is real, then every eigenvalue of $\mathbf{A} + \mathbf{E}$ is real.

Hint: apply Lemma 19.3.4 to the path $\mathbf{A} + t\mathbf{E}$.

Solution.

(a) Let $Q_i = \{z : |z - \lambda_i| \leq r\}$. For $i \neq j$, $z \in Q_i$ and $w \in Q_j$, the triangle inequality gives $|z - w| \geq |\lambda_i - \lambda_j| - 2r \geq g - 2r > 0$. So Q_i and the union L_i of the other Q_j are at distance at least $g - 2r > 0$. For $t \in [0, 1]$, Theorem 19.4.2 applied to $\mathbf{A}$ and $t\mathbf{E}$ puts every eigenvalue of $\mathbf{A} + t\mathbf{E}$ within $\kappa_2(\mathbf{X})\|t\mathbf{E}\|_2 \leq r$ of some λ_j, that is, in $Q_i \cup L_i$. The path $\mathbf{A} + t\mathbf{E} = (1 - t)\mathbf{A} + t(\mathbf{A} + \mathbf{E})$ is of the form in Lemma 19.3.4, so the number of eigenvalues in Q_i is the same at $t = 0$ and $t = 1$. At $t = 0$ it is 1: $\lambda_i \in Q_i$, and $\lambda_j \in Q_j \subseteq L_i$ is not in Q_i for $j \neq i$. So $\mathbf{A} + \mathbf{E}$ has exactly one eigenvalue in each Q_i. The Q_i are pairwise disjoint, so these n eigenvalues are distinct, and $\mathbf{A} + \mathbf{E}$ is diagonalizable by Corollary 8.4.2.

(b) Let μ be the eigenvalue of $\mathbf{A} + \mathbf{E}$ in Q_i. Since λ_i is real, $|\overline{\mu} - \lambda_i| = |\mu - \lambda_i| \leq r$, so $\overline{\mu} \in Q_i$. Since $\mathbf{A} + \mathbf{E}$ is real, $\overline{\mu}$ is also an eigenvalue (Theorem 8.2.5). By (a), Q_i holds only one eigenvalue, so $\overline{\mu} = \mu$, and μ is real. Every eigenvalue of $\mathbf{A} + \mathbf{E}$ lies in some Q_i, so all of them are real.

Exercise C2: The best shift for a residual.

Let $\mathbf{A} \in M_n(\mathbb{C})$ and $\widehat{\mathbf{x}} \in \mathbb{C}^n$ with $\widehat{\mathbf{x}} \neq \mathbf{0}$, and put $\rho = \widehat{\mathbf{x}}^* \mathbf{A} \widehat{\mathbf{x}} / \widehat{\mathbf{x}}^* \widehat{\mathbf{x}}$.

(a) Prove that $\|\mathbf{A}\widehat{\mathbf{x}} - \mu\widehat{\mathbf{x}}\|_2 \geq \|\mathbf{A}\widehat{\mathbf{x}} - \rho\widehat{\mathbf{x}}\|_2$ for every $\mu \in \mathbb{C}$, with equality only for $\mu = \rho$.

(b) Deduce that if $\mathbf{A}$ is normal, then $\mathbf{A}$ has an eigenvalue λ with $|\lambda - \rho| \leq \|\mathbf{A}\widehat{\mathbf{x}} -$

$\mu\widehat{\mathbf{x}}\|_2/\|\widehat{\mathbf{x}}\|_2$ for **every** $\mu \in \mathbb{C}$.

Solution.

(a) Put $\mathbf{w} = \mathbf{A}\widehat{\mathbf{x}} - \rho\widehat{\mathbf{x}}$. Then $\langle \mathbf{w}, \widehat{\mathbf{x}} \rangle = \widehat{\mathbf{x}}^*\mathbf{w} = \widehat{\mathbf{x}}^*\mathbf{A}\widehat{\mathbf{x}} - \rho\,\widehat{\mathbf{x}}^*\widehat{\mathbf{x}} = 0$ by the choice of ρ. For any μ, $\mathbf{A}\widehat{\mathbf{x}} - \mu\widehat{\mathbf{x}} = \mathbf{w} + (\rho - \mu)\widehat{\mathbf{x}}$ is a sum of two orthogonal vectors, so by the Pythagorean theorem (Theorem 10.1.3)

$$\|\mathbf{A}\widehat{\mathbf{x}} - \mu\widehat{\mathbf{x}}\|_2^2 = \|\mathbf{w}\|_2^2 + |\rho - \mu|^2\|\widehat{\mathbf{x}}\|_2^2.$$

This is at least $\|\mathbf{w}\|_2^2$, with equality exactly when $|\rho - \mu|\,\|\widehat{\mathbf{x}}\|_2 = 0$, that is, when $\mu = \rho$, since $\widehat{\mathbf{x}} \neq \mathbf{0}$.

(b) Apply Theorem 19.4.4 for normal $\mathbf{A}$ with the shift ρ and $\eta = \|\mathbf{A}\widehat{\mathbf{x}} - \rho\widehat{\mathbf{x}}\|_2/\|\widehat{\mathbf{x}}\|_2$. It gives an eigenvalue λ with $|\lambda - \rho| \le \eta$, and $\eta \le \|\mathbf{A}\widehat{\mathbf{x}} - \mu\widehat{\mathbf{x}}\|_2/\|\widehat{\mathbf{x}}\|_2$ for every μ by (a).

19.5 The Hoffman–Wielandt Theorem

Section 04 showed that for a normal $\mathbf{A}$, every eigenvalue of $\mathbf{A} + \mathbf{E}$ lies within $\|\mathbf{E}\|_2$ of **some** eigenvalue of $\mathbf{A}$. That answers "how far", one perturbed eigenvalue at a time. It does not answer "which goes where": it never says that the eigenvalues of the two matrices can be **paired off**, each with a partner of its own. This section proves that for two normal matrices they can, with the total squared distance of the pairs bounded by $\|\mathbf{A} - \mathbf{B}\|_F^2$. The proof is short once the right tool is in hand, and the tool is Birkhoff's theorem from Chapter 18 §07. We then sharpen the result for Hermitian matrices, where the pairing is simply the decreasing order, and show that without normality the inequality fails for every pairing.

Throughout, the field is $\mathbb{C}$, and eigenvalues are listed **with algebraic multiplicity**. For a Hermitian matrix, $\lambda_1(\mathbf{A}) \ge \cdots \ge \lambda_n(\mathbf{A})$ is the decreasing list, as in Chapter 16.

19.5.1 One-sided bounds do not pair eigenvalues

Recall Corollary 19.4.3 (a): if $\mathbf{A} \in M_n(\mathbb{C})$ is normal and $\mathbf{E} \in M_n(\mathbb{C})$ is arbitrary, then every eigenvalue μ of $\mathbf{A} + \mathbf{E}$ satisfies $\min_i|\lambda_i - \mu| \le \|\mathbf{E}\|_2$, where $\lambda_1, \dots, \lambda_n$ are the eigenvalues of $\mathbf{A}$. The statement starts from a perturbed eigenvalue and finds a partner for it. Nothing in it stops two perturbed eigenvalues from choosing the **same** partner.

Here is the smallest case. Let

$$\mathbf{A} = \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix}, \qquad \mathbf{A} + \mathbf{E} = \begin{pmatrix} \frac{1}{5} & 0 \\ 0 & \frac{2}{5} \end{pmatrix}, \qquad \mathbf{E} = \begin{pmatrix} \frac{1}{5} & 0 \\ 0 & -\frac{3}{5} \end{pmatrix}.$$

Then $\|\mathbf{E}\|_2 = \frac{3}{5}$, and both perturbed eigenvalues are within $\frac{3}{5}$ of an eigenvalue of $\mathbf{A}$, as the corollary promises. But if each one goes to its **nearest** eigenvalue of $\mathbf{A}$, both go to 0: the distances are $\frac{1}{5}$ and $\frac{2}{5}$ to 0, against $\frac{4}{5}$ and $\frac{3}{5}$ to 1. The nearest-eigenvalue map is not a bijection, and the eigenvalue 1 is left without a partner. A pairing does exist here, $0 \leftrightarrow \frac{1}{5}$ and $1 \leftrightarrow \frac{2}{5}$, with distances $\frac{1}{5}$ and $\frac{3}{5}$, but finding it was not the corollary's doing.

Why ask for a pairing at all? Because it is what "the eigenvalues move a little" should mean.

Chapter 15's Corollary 15.7.4 is a pairing statement: the eigenvalues of a nearby matrix **can be numbered** so that each is close to its counterpart. It gives no rate. For Hermitian matrices, Weyl's Corollary 16.3.6 gives a pairing with a rate, and the pairing is the decreasing order. For normal matrices with complex eigenvalues there is no decreasing order, and the pairing has to be found.

To say this precisely, let $\lambda_1, \dots, \lambda_n$ and $\mu_1, \dots, \mu_n$ be two lists of complex numbers. A **pairing** of them is a permutation $\sigma \in S_n$, which matches λ_i with $\mu_{\sigma(i)}$. Its cost, in the sense of this section, is the sum of squared distances

$$\sum_{i=1}^{n} |\lambda_i - \mu_{\sigma(i)}|^2.$$

A one-sided statement, "every μ_j is within r of some λ_i", is a statement about sets. A pairing is a statement about lists with multiplicity, and it is strictly stronger.

> *Quick check.* Let $\mathbf{A} = \operatorname{diag}(0, 0, 1)$ and $\mathbf{B} = \operatorname{diag}(0, 1, 1)$. Show that every eigenvalue of $\mathbf{B}$ is an eigenvalue of $\mathbf{A}$ and conversely, so each one-sided distance is 0. What is the smallest possible largest distance $\max_i |\lambda_i - \mu_{\sigma(i)}|$ over all pairings σ?

> *Solution.* Both matrices have the eigenvalue set $\{0, 1\}$, so every eigenvalue of either one is at distance 0 from an eigenvalue of the other. As lists, $\mathbf{A}$ has $(0, 0, 1)$ and $\mathbf{B}$ has $(0, 1, 1)$. Any pairing must send one of the two 0's of $\mathbf{A}$ to a 1 of $\mathbf{B}$, since $\mathbf{B}$ has only one 0. So every pairing has largest distance at least 1, and the identity pairing attains 1. Sets that agree can still be far apart as lists.

19.5.2 Birkhoff turns weights into a permutation

The proof below will produce a sum of the form $\sum_{i,j} s_{ij} c_{ij}$, in which $c_{ij} = |\lambda_i - \mu_j|^2$ is the cost of pairing λ_i with μ_j, and the weights s_{ij} form a doubly stochastic matrix. Such a sum is a **fractional pairing**: every λ_i spreads a total weight 1 over the μ_j, and every μ_j receives a total weight 1. A genuine pairing is the special case where each weight is 0 or 1, that is, where (s_{ij}) is a permutation matrix. The lemma says that fractional pairings never beat the best genuine one.

Recall Definition 17.8.4: $\mathbf{S} \in M_n(\mathbb{R})$ is doubly stochastic if its entries are non-negative and every row and every column adds up to 1; the set of such matrices is Ω_n. Recall also Definition 2.6.2: $\mathbf{P}_\sigma$ is the matrix whose j-th column is $\mathbf{e}_{\sigma(j)}$, so its entry in position $(\sigma(j), j)$ is 1 for each j, and all its other entries are 0.

Lemma 19.5.1 — A Fractional Pairing Is Never Cheaper

Let $\mathbf{C} = (c_{ij}) \in M_n(\mathbb{R})$ and $\mathbf{S} = (s_{ij}) \in \Omega_n$. Then there is a permutation $\sigma \in S_n$ with

$$\sum_{j=1}^{n} c_{\sigma(j)j} \;\le\; \sum_{i,j=1}^{n} s_{ij} c_{ij}.$$

> *Idea.* Write $f(\mathbf{X}) = \sum_{i,j} x_{ij} c_{ij}$, a linear function of $\mathbf{X}$. Birkhoff's theorem writes $\mathbf{S}$ as

an average of permutation matrices, so $f(\mathbf{S})$ is the same average of the numbers $f(\mathbf{P}_\sigma)$, and an average is at least its smallest term.

Proof. Let $f(\mathbf{X}) = \sum_{i,j} x_{ij} c_{ij}$ for $\mathbf{X} \in M_n(\mathbb{R})$; it is linear in $\mathbf{X}$. By Theorem 18.7.2, $\mathbf{S} = \sum_{k=1}^{m} t_k \mathbf{P}_{\sigma_k}$ for some permutations $\sigma_1, \dots, \sigma_m$ and weights $t_k \geq 0$ with $\sum_k t_k = 1$. By linearity,

$$f(\mathbf{S}) = \sum_{k=1}^{m} t_k \, f(\mathbf{P}_{\sigma_k}) \;\geq\; \Big(\sum_{k=1}^{m} t_k\Big) \min_k f(\mathbf{P}_{\sigma_k}) = \min_k f(\mathbf{P}_{\sigma_k}),$$

where the inequality uses $t_k \geq 0$. Let σ be a σ_k attaining the minimum. The only non-zero entries of $\mathbf{P}_\sigma$ are the 1's in positions $(\sigma(j), j)$, so $f(\mathbf{P}_\sigma) = \sum_j c_{\sigma(j)j}$. Hence $\sum_j c_{\sigma(j)j} \leq f(\mathbf{S})$, as claimed. ∎

In the language of Chapter 17, this is Corollary 17.8.6 applied to Ω_n. With the Frobenius inner product $\langle \mathbf{X}, \mathbf{C} \rangle = \operatorname{tr}(\mathbf{C}^\top \mathbf{X}) = \sum_{i,j} x_{ij} c_{ij}$, the function f is $\mathbf{X} \mapsto \langle \mathbf{X}, \mathbf{C} \rangle$. The set Ω_n is non-empty, compact and convex (Chapter 17 §08), so the minimum of f over it is attained at an extreme point, and by Theorem 18.7.2 the extreme points are the permutation matrices. The proof above uses the second form of Birkhoff's theorem instead, so no compactness argument appears in it.

19.5.3 The theorem

We can now prove that two normal matrices have a pairing of their eigenvalues whose cost is at most the squared Frobenius distance between the matrices.

Theorem 19.5.2 — Hoffman–Wielandt Theorem

Let $\mathbf{A}, \mathbf{B} \in M_n(\mathbb{C})$ be **normal**, with eigenvalues $\lambda_1, \dots, \lambda_n$ and $\mu_1, \dots, \mu_n$ respectively, each listed with algebraic multiplicity in any order. Then there is a permutation $\sigma \in S_n$ with

$$\sum_{i=1}^{n} \left|\lambda_i - \mu_{\sigma(i)}\right|^2 \;\leq\; \|\mathbf{A} - \mathbf{B}\|_F^2.$$

Idea. **Step roadmap.**

① **Diagonalize both.** The spectral theorem gives $\mathbf{A} = \mathbf{U}\mathbf{\Lambda}\mathbf{U}^*$ and $\mathbf{B} = \mathbf{V}\mathbf{M}\mathbf{V}^*$ with $\mathbf{U}, \mathbf{V}$ unitary and $\mathbf{\Lambda}, \mathbf{M}$ diagonal. The two orthonormal bases of eigenvectors are different, and the unitary $\mathbf{W} = \mathbf{U}^*\mathbf{V}$ records how they sit relative to each other.

② **Compute the distance.** The Frobenius norm does not see unitary factors, so $\|\mathbf{A} - \mathbf{B}\|_F = \|\mathbf{\Lambda}\mathbf{W} - \mathbf{W}\mathbf{M}\|_F$. The (i,j) entry of $\mathbf{\Lambda}\mathbf{W} - \mathbf{W}\mathbf{M}$ is $(\lambda_i - \mu_j) w_{ij}$, so $\|\mathbf{A} - \mathbf{B}\|_F^2 = \sum_{i,j} |w_{ij}|^2 |\lambda_i - \mu_j|^2$. This is a fractional pairing with weights $|w_{ij}|^2$.

③ **Round it.** The weights form a doubly stochastic matrix, because the rows and the columns of a unitary matrix are unit vectors. The lemma replaces the fractional pairing by a genuine one that costs no more.

Proof. By Corollary 11.4.3, since $\mathbf{A}$ and $\mathbf{B}$ are normal, there are unitary $\mathbf{U}, \mathbf{V} \in \mathrm{U}(n)$ with

$$\mathbf{A} = \mathbf{U}\mathbf{\Lambda}\mathbf{U}^*, \qquad \mathbf{B} = \mathbf{V}\mathbf{M}\mathbf{V}^*,$$

where $\mathbf{\Lambda} = \operatorname{diag}(\lambda_1, \dots, \lambda_n)$ and $\mathbf{M} = \operatorname{diag}(\mu_1, \dots, \mu_n)$ in the given orders. Put $\mathbf{W} = \mathbf{U}^*\mathbf{V}$, which is unitary as a product of unitary matrices. Since $\mathbf{U}^*\mathbf{U} = \mathbf{I}$ and $\mathbf{V}^*\mathbf{V} = \mathbf{I}$,

$$\mathbf{U}^*(\mathbf{A} - \mathbf{B})\mathbf{V} = \mathbf{\Lambda}\mathbf{U}^*\mathbf{V} - \mathbf{U}^*\mathbf{V}\mathbf{M} = \mathbf{\Lambda}\mathbf{W} - \mathbf{W}\mathbf{M}.$$

By Lemma 11.11.1, applied with the unitary factors $\mathbf{U}^*$ on the left and $\mathbf{V}$ on the right, $\|\mathbf{A} - \mathbf{B}\|_F = \|\mathbf{\Lambda}\mathbf{W} - \mathbf{W}\mathbf{M}\|_F$. The (i, j) entry of $\mathbf{\Lambda}\mathbf{W}$ is $\lambda_i w_{ij}$ and that of $\mathbf{W}\mathbf{M}$ is $w_{ij}\mu_j$, since multiplying by a diagonal matrix on the left scales rows and on the right scales columns. Hence

$$\|\mathbf{A} - \mathbf{B}\|_F^2 = \sum_{i,j=1}^{n} |w_{ij}|^2 \, |\lambda_i - \mu_j|^2. \tag{19.5.1}$$

Let $\mathbf{S} = (s_{ij})$ with $s_{ij} = |w_{ij}|^2$. Its entries are non-negative. Row i adds up to $\sum_j |w_{ij}|^2 = (\mathbf{W}\mathbf{W}^*)_{ii} = 1$, and column j adds up to $\sum_i |w_{ij}|^2 = (\mathbf{W}^*\mathbf{W})_{jj} = 1$, since $\mathbf{W}$ is unitary. So $\mathbf{S} \in \Omega_n$. Apply Lemma 19.5.1 to $\mathbf{S}$ and the real matrix $\mathbf{C}$ with $c_{ij} = |\lambda_i - \mu_j|^2$. It gives $\tau \in S_n$ with

$$\sum_{j=1}^{n} |\lambda_{\tau(j)} - \mu_j|^2 \;\le\; \sum_{i,j} s_{ij} c_{ij} = \|\mathbf{A} - \mathbf{B}\|_F^2,$$

the equality being Eq. 19.5.1. Put $\sigma = \tau^{-1}$. As j runs over $1, \dots, n$, so does $i = \tau(j)$, and $j = \sigma(i)$; so the left-hand side is $\sum_i |\lambda_i - \mu_{\sigma(i)}|^2$. This proves the theorem.

■

Both hypotheses were used in the first line and nowhere else: normality is what makes the diagonalizing matrices unitary. The rest of the proof is bookkeeping and Birkhoff's theorem, which is where Chapter 18 §07's theorem earns its keep.

In words: *the eigenvalues of a normal matrix, as a list with multiplicity, are a* 1*-Lipschitz function of the matrix, when matrices are measured in the Frobenius norm and lists by their best pairing.* In particular every pair in the best pairing is within $\|\mathbf{A} - \mathbf{B}\|_F$, so each eigenvalue of $\mathbf{B}$ has its own partner among those of $\mathbf{A}$ within that distance. This is a matching bound, with a constant, valid for all normal matrices at once. Compare Corollary 15.7.4, which gives a matching with no constant for all matrices, and Corollary 19.4.3, which gives a constant with no matching.

The theorem asserts that **some** pairing is cheap. The proof does not say which, beyond what the lemma gives, but the cheapest of the $n!$ pairings certainly works, since it costs no more than any other. The next example shows that a pairing chosen by any other rule can fail.

Example. (A Hermitian and a diagonal matrix)

Let

$$\mathbf{A} = \begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix}, \qquad \mathbf{B} = \begin{pmatrix} i & 0 \\ 0 & 2+i \end{pmatrix}.$$

Both are normal. Compute $\|\mathbf{A} - \mathbf{B}\|_F^2$, the cost of both pairings of the eigenvalues, and

the matrix $\mathbf{S}$ of the proof. Which pairings satisfy the conclusion of Theorem 19.5.2?

Solution. $\mathbf{A}$ is real symmetric, hence Hermitian and normal, and $\mathbf{B}$ is diagonal, hence normal. The eigenvalues of $\mathbf{A}$ are $\lambda_1 = 3$ and $\lambda_2 = 1$, with unit eigenvectors $\frac{1}{\sqrt{2}}(1,1)$ and $\frac{1}{\sqrt{2}}(1,-1)$: indeed $\mathbf{A}(1,1) = (3,3)$ and $\mathbf{A}(1,-1) = (1,-1)$. Those of $\mathbf{B}$ are $\mu_1 = i$ and $\mu_2 = 2+i$, with eigenvectors $\mathbf{e}_1, \mathbf{e}_2$.

The distance. $\mathbf{A} - \mathbf{B} = \left(\begin{smallmatrix} 2-i & 1 \\ 1 & -i \end{smallmatrix}\right)$, so

$$\|\mathbf{A} - \mathbf{B}\|_F^2 = |2-i|^2 + 1 + 1 + |-i|^2 = 5 + 1 + 1 + 1 = 8.$$

The costs. The four squared distances $c_{ij} = |\lambda_i - \mu_j|^2$ are

$$c_{11} = |3-i|^2 = 10, \qquad c_{12} = |1-i|^2 = 2,$$
$$c_{21} = |1-i|^2 = 2, \qquad c_{22} = |-1-i|^2 = 2.$$

The identity pairing $3 \leftrightarrow i$, $1 \leftrightarrow 2+i$ costs $c_{11} + c_{22} = 12$. The swap $3 \leftrightarrow 2+i$, $1 \leftrightarrow i$ costs $c_{12} + c_{21} = 4$.

The weights. With $\mathbf{U} = \frac{1}{\sqrt{2}}\left(\begin{smallmatrix} 1 & 1 \\ 1 & -1 \end{smallmatrix}\right)$ and $\mathbf{V} = \mathbf{I}$, $\mathbf{W} = \mathbf{U}^*$, and every entry of $\mathbf{W}$ has modulus $\frac{1}{\sqrt{2}}$. So $\mathbf{S} = \frac{1}{2}\mathbf{J}$, and Eq. 19.5.1 reads

$$\|\mathbf{A} - \mathbf{B}\|_F^2 = \tfrac{1}{2}(10 + 2 + 2 + 2) = 8,$$

the average of the two costs, $\frac{1}{2}(12+4)$. An average lies between its terms, so the cheaper pairing, the swap with cost 4, satisfies $4 \le 8$. The identity pairing, with cost $12 > 8$, does not.

Warning. **The theorem does not say that the given numbering works.** In the example, the lists $(3,1)$ and $(i, 2+i)$, paired in the order written, cost $12 > 8 = \|\mathbf{A}-\mathbf{B}\|_F^2$. Complex numbers have no natural order to sort by, so, unlike the Hermitian case below, there is no rule fixed in advance that always picks a good pairing. The safe reading is: the **cheapest** pairing satisfies the inequality.

19.5.4 Normality cannot be dropped

The proof used normality once, in its first line, to make the diagonalizing matrices unitary. For diagonalizable matrices $\mathbf{A} = \mathbf{X}\mathbf{\Lambda}\mathbf{X}^{-1}$ and $\mathbf{B} = \mathbf{Y}\mathbf{M}\mathbf{Y}^{-1}$ with $\mathbf{X}$, $\mathbf{Y}$ not unitary, Lemma 11.11.1 no longer applies, and $\|\mathbf{A} - \mathbf{B}\|_F$ is no longer the norm of $\mathbf{\Lambda}\mathbf{W} - \mathbf{W}\mathbf{M}$ with $\mathbf{W} = \mathbf{X}^{-1}\mathbf{Y}$. The failure is real, not an artifact of the proof.

Example. (Every pairing fails)

Let

$$\mathbf{A} = \begin{pmatrix} 1 & 3 \\ 0 & -1 \end{pmatrix}, \qquad \mathbf{B} = \begin{pmatrix} 1 & 3 \\ 1 & -1 \end{pmatrix}.$$

Show that $\mathbf{A}$ and $\mathbf{B}$ are diagonalizable but not normal, and that the inequality of Theorem 19.5.2 fails for **every** pairing of their eigenvalues.

Solution. $\mathbf{A}$ is triangular with eigenvalues 1 and -1. The matrix $\mathbf{B}$ has trace 0 and determinant $-1-3=-4$, so its characteristic polynomial is x^2-4 and its eigenvalues are 2 and -2. Each has two distinct eigenvalues, so each is diagonalizable (Theorem 8.4.1). Neither is normal:

$$\mathbf{A}^*\mathbf{A}=\begin{pmatrix}1&3\\3&10\end{pmatrix}\neq\begin{pmatrix}10&-3\\-3&1\end{pmatrix}=\mathbf{A}\mathbf{A}^*,$$

$$\mathbf{B}^*\mathbf{B}=\begin{pmatrix}2&2\\2&10\end{pmatrix}\neq\begin{pmatrix}10&-2\\-2&2\end{pmatrix}=\mathbf{B}\mathbf{B}^*.$$

The difference $\mathbf{A}-\mathbf{B}$ has a single non-zero entry, -1 in position $(2,1)$, so $\|\mathbf{A}-\mathbf{B}\|_F^2=1$.

There are two pairings. The one that matches signs, $1\leftrightarrow 2$ and $-1\leftrightarrow -2$, costs $1^2+1^2=2$. The other, $1\leftrightarrow -2$ and $-1\leftrightarrow 2$, costs $3^2+3^2=18$. Both exceed 1, so no pairing satisfies the inequality.

The entry 3 is what makes this work, and the failure is not confined to a perturbation as large as 1. Put $\delta>0$ in the corner instead: $\mathbf{B}_\delta=\left(\begin{smallmatrix}1&3\\\delta&-1\end{smallmatrix}\right)$ has determinant $-1-3\delta$ and eigenvalues $\pm\sqrt{1+3\delta}$, each of which moves by $\sqrt{1+3\delta}-1$, about $\frac{3}{2}\delta$ for small δ. So the cheaper pairing costs about $2\left(\frac{3}{2}\delta\right)^2=\frac{9}{2}\delta^2$, well above $\|\mathbf{A}-\mathbf{B}_\delta\|_F^2=\delta^2$. With an entry m in place of 3 the cost is about $\frac{1}{2}m^2\delta^2$, so the inequality fails for small δ as soon as $m>\sqrt{2}$. A large entry above the diagonal is exactly what Chapter 11 §11 measured as departure from normality, and it is what makes the eigenvalues sensitive.

A Jordan block shows that no constant can repair the inequality. Let $\mathbf{A}=\mathbf{J}_2(0)$ and, for $\varepsilon>0$, $\mathbf{B}_\varepsilon=\left(\begin{smallmatrix}0&1\\\varepsilon&0\end{smallmatrix}\right)$. Then $\mathbf{A}$ has the eigenvalue 0 twice, $\mathbf{B}_\varepsilon$ has characteristic polynomial $x^2-\varepsilon$ and eigenvalues $\pm\sqrt{\varepsilon}$, and $\|\mathbf{A}-\mathbf{B}_\varepsilon\|_F^2=\varepsilon^2$. Both pairings cost the same, $(\sqrt{\varepsilon})^2+(\sqrt{\varepsilon})^2=2\varepsilon$, and

$$\frac{2\varepsilon}{\varepsilon^2}=\frac{2}{\varepsilon}\longrightarrow\infty\qquad(\varepsilon\to 0^+).$$

So there is no constant K with $\min_\sigma\sum_i|\lambda_i-\mu_{\sigma(i)}|^2\le K\|\mathbf{A}-\mathbf{B}\|_F^2$ for all pairs of matrices. This is Example (A Jordan block's eigenvalues move like $\varepsilon^{1/k}$) of Chapter 15 read in the language of pairings: the eigenvalues move like $\sqrt{\varepsilon}$ while the matrix moves by ε.

Warning. **Diagonalizable is not enough, and one normal matrix is not enough.** In Example (Every pairing fails) both matrices are diagonalizable, and every pairing fails. Nor does it help to make just one of the two matrices normal: for $\mathbf{A}=\mathbf{J}_2(0)$ and the Hermitian $\mathbf{B}=\left(\begin{smallmatrix}0&1\\1&0\end{smallmatrix}\right)$, with eigenvalues ±1, both pairings cost $1+1=2$, while $\|\mathbf{A}-\mathbf{B}\|_F^2=1$. The theorem needs **both** matrices normal.

19.5.5 Hermitian matrices: the pairing is the order

When both matrices are Hermitian, the eigenvalues are real, and there is a natural guess for the best pairing: largest with largest, second with second, and so on. The guess is right, and the reason is a fact about real numbers alone.

Lemma 19.5.3 — The Sorted Pairing Is Cheapest

Let $a_1 \geq a_2 \geq \cdots \geq a_n$ and $b_1 \geq b_2 \geq \cdots \geq b_n$ be real numbers. Then for every $\sigma \in S_n$,

$$\sum_{i=1}^{n}(a_i - b_i)^2 \;\leq\; \sum_{i=1}^{n}(a_i - b_{\sigma(i)})^2.$$

Idea. Expanding the squares, $\sum_i a_i^2$ and $\sum_i b_{\sigma(i)}^2 = \sum_j b_j^2$ do not depend on σ, so the claim is that the cross term $\sum_i a_i b_{\sigma(i)}$ is largest at the identity. If σ puts a smaller b before a larger one in two neighboring positions, swapping those two values can only increase the cross term, and it removes one inversion. Repeating the swap sorts σ into the identity.

Proof. For every σ, since σ is a bijection, $\sum_i b_{\sigma(i)}^2 = \sum_j b_j^2$, and so

$$\sum_{i=1}^{n}(a_i - b_{\sigma(i)})^2 = \sum_i a_i^2 + \sum_j b_j^2 - 2g(\sigma),$$
$$g(\sigma) = \sum_{i=1}^{n} a_i b_{\sigma(i)}.$$

It therefore suffices to show $g(\sigma) \leq g(\mathrm{id})$ for every σ. The set S_n is finite, so g attains a maximum on it; among the permutations where it does, choose one, σ, with the fewest inversions (Definition 6.3.1). Suppose $\sigma \neq \mathrm{id}$. Then $\sigma(i) > \sigma(i+1)$ for some i, since a permutation with $\sigma(1) < \sigma(2) < \cdots < \sigma(n)$ is the identity. Let σ' agree with σ except that $\sigma'(i) = \sigma(i+1)$ and $\sigma'(i+1) = \sigma(i)$. Then

$$g(\sigma') - g(\sigma) = (a_i - a_{i+1})\big(b_{\sigma(i+1)} - b_{\sigma(i)}\big) \;\geq\; 0,$$

because $a_i \geq a_{i+1}$, and $\sigma(i+1) < \sigma(i)$ gives $b_{\sigma(i+1)} \geq b_{\sigma(i)}$. So σ' also maximizes g. Now count inversions. The pair of positions $(i, i+1)$ is an inversion of σ and not of σ'. A pair involving neither i nor $i+1$ sees the same values under both. For a position $p \notin \{i, i+1\}$, the two pairs joining p to i and to $i+1$ compare $\sigma(p)$ with the same two values $\sigma(i), \sigma(i+1)$ under σ and under σ', from the same side, so together they contain the same number of inversions. Hence σ' has one inversion fewer than σ, contradicting the choice of σ. So $\sigma = \mathrm{id}$ maximizes g, and $g(\sigma) \leq g(\mathrm{id})$ for every σ. This proves the lemma.

■

The move is an **exchange argument**: to show that an arrangement is optimal, show that repairing one local defect never makes things worse. The inequality $\sum_i a_i b_{\sigma(i)} \leq \sum_i a_i b_i$ is known as the rearrangement inequality.

Example. (Three numbers, six pairings)

Let $\mathbf{a} = (4, 2, 1)$ and $\mathbf{b} = (3, 0, -1)$, both decreasing. Compute $\sum_i (a_i - b_{\sigma(i)})^2$ for all six $\sigma \in S_3$, and find the cheapest and the dearest.

Solution. The nine squared distances $(a_i - b_j)^2$, with i the row and j the column, are

$$\begin{pmatrix} 1 & 16 & 25 \\ 1 & 4 & 9 \\ 4 & 1 & 4 \end{pmatrix}.$$

A pairing picks one entry from each row and each column. Writing σ by its values $(\sigma(1), \sigma(2), \sigma(3))$,

$$\begin{aligned} &(1,2,3) : 1+4+4 = 9, \qquad &&(1,3,2) : 1+9+1 = 11, \\ &(2,1,3) : 16+1+4 = 21, \qquad &&(2,3,1) : 16+9+4 = 29, \\ &(3,1,2) : 25+1+1 = 27, \qquad &&(3,2,1) : 25+4+4 = 33. \end{aligned}$$

The identity, which pairs the two sorted lists in order, costs 9, the least of the six, as Lemma 19.5.3 says. The dearest is the reversed pairing $(3,2,1)$, at 33.

One exchange step of the proof is visible here. The permutation $(1,3,2)$ has the single inversion $\sigma(2) > \sigma(3)$; undoing it gives the identity and lowers the cost by 2, which is $2(a_2 - a_3)(b_2 - b_3) = 2 \cdot 1 \cdot 1$.

Corollary 19.5.4 — Hoffman–Wielandt for Hermitian Matrices

Let $\mathbf{A}, \mathbf{B} \in M_n(\mathbb{C})$ be Hermitian. Then

$$\sum_{i=1}^{n} \big(\lambda_i(\mathbf{A}) - \lambda_i(\mathbf{B})\big)^2 \;\le\; \|\mathbf{A} - \mathbf{B}\|_F^2.$$

Proof. Hermitian matrices are normal (Proposition 10.6.7 (c)) and have real eigenvalues. By Theorem 19.5.2 applied to the lists $\lambda_1(\mathbf{A}), \dots, \lambda_n(\mathbf{A})$ and $\lambda_1(\mathbf{B}), \dots, \lambda_n(\mathbf{B})$, there is $\sigma \in S_n$ with $\sum_i \big(\lambda_i(\mathbf{A}) - \lambda_{\sigma(i)}(\mathbf{B})\big)^2 \le \|\mathbf{A} - \mathbf{B}\|_F^2$, where $|t|^2 = t^2$ for real t. Both lists are decreasing, so by Lemma 19.5.3 the sorted pairing costs no more than σ. This proves the corollary. ∎

This is the Frobenius-norm companion of Weyl's bound. Put $\mathbf{E} = \mathbf{A} - \mathbf{B}$, Hermitian. By the spectral theorem $\mathbf{E} = \mathbf{U}\mathbf{D}\mathbf{U}^*$ with $\mathbf{U}$ unitary and $\mathbf{D} = \operatorname{diag}(\lambda_1(\mathbf{E}), \dots, \lambda_n(\mathbf{E}))$, so Lemma 11.11.1 gives $\|\mathbf{E}\|_F^2 = \|\mathbf{D}\|_F^2 = \sum_i \lambda_i(\mathbf{E})^2$, while $\|\mathbf{E}\|_2 = \max_i |\lambda_i(\mathbf{E})|$ by Lemma 16.3.5. So Weyl's Corollary 16.3.6 says

$$\max_i \big|\lambda_i(\mathbf{A}) - \lambda_i(\mathbf{B})\big| \;\le\; \max_i |\lambda_i(\mathbf{E})|,$$

and Corollary 19.5.4 says

$$\sum_i \big(\lambda_i(\mathbf{A}) - \lambda_i(\mathbf{B})\big)^2 \;\le\; \sum_i \lambda_i(\mathbf{E})^2.$$

In both, a norm of the vector of shifts $\boldsymbol{\lambda}(\mathbf{A}) - \boldsymbol{\lambda}(\mathbf{B})$ is bounded by the same norm of $\boldsymbol{\lambda}(\mathbf{E})$: the ∞-norm for Weyl, the 2-norm for Hoffman–Wielandt.

Neither implies the other. For $\mathbf{E} = t\mathbf{I}$ with $t > 0$, every eigenvalue shifts by t; Weyl's bound t is exact for each shift, while Hoffman–Wielandt alone allows a single shift as large as $\|\mathbf{E}\|_F = \sqrt{n}\, t$. For a rank-one $\mathbf{E} = t\,\mathbf{x}\mathbf{x}^*$ with $\|\mathbf{x}\|_2 = 1$, $\|\mathbf{E}\|_F = \|\mathbf{E}\|_2 = t$; Weyl lets **every** eigenvalue move

by up to t, while Hoffman–Wielandt says that the squared shifts together use up at most t^2, so if one eigenvalue moves by t, none of the others moves at all.

Remark. Lidskii's inequality contains both. Chapter 16 §07 proved $\boldsymbol{\lambda}(\mathbf{A})-\boldsymbol{\lambda}(\mathbf{B}) \prec \boldsymbol{\lambda}(\mathbf{A}-\mathbf{B})$ (the remark after Theorem 16.7.2), and Weyl's bound follows from it there, as Corollary 16.7.3 (a). Chapter 20 shows that a majorization $\mathbf{x} \prec \mathbf{y}$ gives $\sum_i \phi(x_i) \le \sum_i \phi(y_i)$ for every convex ϕ; with $\phi(t) = t^2$ this is Corollary 19.5.4 again, and Chapter 20 turns the same majorization into one bound for every unitarily invariant norm. Nothing here depends on that route; the proof above goes through Birkhoff's theorem, Theorem 18.7.2.

Quick check. Let $\mathbf{A} = \operatorname{diag}(3,1)$ and $\mathbf{B} = \left(\begin{smallmatrix} 2 & 1 \\ 1 & 2 \end{smallmatrix}\right)$. Compute $\|\mathbf{A}-\mathbf{B}\|_F^2$ and both sides of Corollary 19.5.4. What does the reversed pairing $\lambda_1(\mathbf{A}) \leftrightarrow \lambda_2(\mathbf{B})$, $\lambda_2(\mathbf{A}) \leftrightarrow \lambda_1(\mathbf{B})$ cost?

Solution. $\mathbf{A}-\mathbf{B} = \left(\begin{smallmatrix} 1 & -1 \\ -1 & -1 \end{smallmatrix}\right)$, so $\|\mathbf{A}-\mathbf{B}\|_F^2 = 4$. The eigenvalues of $\mathbf{B}$ are 3 and 1 (as in Example (A Hermitian and a diagonal matrix)), the same as those of $\mathbf{A}$. So the left side of the corollary is $0 \le 4$: two matrices at Frobenius distance 2 can have identical spectra, and the inequality is only an upper bound. The reversed pairing costs $(3-1)^2+(1-3)^2 = 8 > 4$. Even for Hermitian matrices, the pairing matters.

19.5.6 Exercises

19.5.6.1 A. Check your understanding

Exercise A1.

(a) State the Hoffman–Wielandt theorem, with its hypotheses.

(b) True or false: if $\mathbf{A}$ and $\mathbf{B}$ are normal, the eigenvalues of $\mathbf{B}$ listed in any order satisfy $\sum_i |\lambda_i - \mu_i|^2 \le \|\mathbf{A}-\mathbf{B}\|_F^2$. Justify your answer.

(c) True or false: the Hoffman–Wielandt inequality holds for every pair of diagonalizable matrices. Justify your answer.

(d) For normal $\mathbf{A}$ and $\mathbf{B}$, what bound does the theorem give on the distance between an eigenvalue of $\mathbf{B}$ and its partner?

(e) Where exactly does Birkhoff's theorem (Theorem 18.7.2) enter the proof, and what would be missing without it?

(f) For Hermitian $\mathbf{A}$, $\mathbf{B}$ with $\mathbf{E} = \mathbf{A}-\mathbf{B}$ of rank one, explain why at most one eigenvalue can move by the full amount $\|\mathbf{E}\|_2$.

Solution.

(a) If $\mathbf{A}, \mathbf{B} \in M_n(\mathbb{C})$ are normal, with eigenvalues $\lambda_1, \dots, \lambda_n$ and $\mu_1, \dots, \mu_n$ listed with multiplicity, then there is a permutation σ with $\sum_i |\lambda_i - \mu_{\sigma(i)}|^2 \le \|\mathbf{A}-\mathbf{B}\|_F^2$.

(b) False. In Example (A Hermitian and a diagonal matrix), the order $(3,1)$ and $(i, 2+i)$ costs $12 > 8$. Only a suitable pairing, for instance the cheapest one, is guaranteed.

(c) False. In Example (Every pairing fails) both matrices have two distinct eigenvalues, hence are diagonalizable, and both pairings cost more than $\|\mathbf{A}-\mathbf{B}\|_F^2 = 1$.

(d) Each summand is at most the whole sum, so $|\lambda_i - \mu_{\sigma(i)}| \le \|\mathbf{A}-\mathbf{B}\|_F$ for every i,

for the pairing σ of the theorem.

(e) The proof writes $\|\mathbf{A}-\mathbf{B}\|_F^2$ as $\sum_{i,j} s_{ij}|\lambda_i-\mu_j|^2$ with (s_{ij}) doubly stochastic, a fractional pairing. Birkhoff's theorem, through Lemma 19.5.1, replaces it by a genuine pairing that costs no more. Without it, we would know only that a weighted average of the costs $|\lambda_i-\mu_j|^2$ is small, which does not produce a permutation.

(f) For Hermitian $\mathbf{E}$ of rank one, $\mathbf{E}$ has at most one non-zero eigenvalue, so $\|\mathbf{E}\|_F^2 = \sum_i \lambda_i(\mathbf{E})^2 = \|\mathbf{E}\|_2^2$. By Corollary 19.5.4 the squared shifts add up to at most $\|\mathbf{E}\|_2^2$. If one shift equals $\|\mathbf{E}\|_2$ in absolute value, the others are 0.

19.5.6.2 B. Practice

Exercise B1: A pair of normal matrices.

Let

$$\mathbf{A} = \begin{pmatrix} 0 & 2 \\ 2 & 0 \end{pmatrix}, \qquad \mathbf{B} = \begin{pmatrix} 1 & 0 \\ 0 & -1+2i \end{pmatrix}.$$

Check that both are normal, compute $\|\mathbf{A}-\mathbf{B}\|_F^2$ and the costs of both pairings of the eigenvalues, and compute the matrix $\mathbf{S}$ of the proof of Theorem 19.5.2. Hence decide which pairings satisfy the Hoffman–Wielandt inequality.

Solution. $\mathbf{A}$ is real symmetric, hence normal, and $\mathbf{B}$ is diagonal, hence normal. $\mathbf{A}(1,1) = (2,2)$ and $\mathbf{A}(1,-1) = (-2,2)$, so $\mathbf{A}$ has eigenvalues $\lambda_1 = 2$, $\lambda_2 = -2$ with unit eigenvectors $\frac{1}{\sqrt{2}}(1,\pm 1)$. $\mathbf{B}$ has eigenvalues $\mu_1 = 1$, $\mu_2 = -1+2i$.

$\mathbf{A}-\mathbf{B} = \left(\begin{smallmatrix} -1 & 2 \\ 2 & 1-2i \end{smallmatrix}\right)$, so $\|\mathbf{A}-\mathbf{B}\|_F^2 = 1+4+4+5 = 14$.

The squared distances are $c_{11} = |2-1|^2 = 1$, $c_{12} = |3-2i|^2 = 13$, $c_{21} = |-3|^2 = 9$, $c_{22} = |-1-2i|^2 = 5$. The identity pairing costs $1+5 = 6$, and the swap costs $13+9 = 22$.

With $\mathbf{U} = \frac{1}{\sqrt{2}}\left(\begin{smallmatrix} 1 & 1 \\ 1 & -1 \end{smallmatrix}\right)$ and $\mathbf{V} = \mathbf{I}$, $\mathbf{W} = \mathbf{U}^*$ has all entries of modulus $\frac{1}{\sqrt{2}}$, so $\mathbf{S} = \frac{1}{2}\mathbf{J}$, and indeed $\frac{1}{2}(1+13+9+5) = 14$. Hence the identity pairing satisfies the inequality, $6 \le 14$, and the swap does not, $22 > 14$.

Exercise B2: Hermitian, compared with Weyl.

Let

$$\mathbf{A} = \begin{pmatrix} 2 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \qquad \mathbf{B} = \begin{pmatrix} 2 & 1 & 0 \\ 1 & 2 & 0 \\ 0 & 0 & -1 \end{pmatrix}.$$

Compute $\boldsymbol{\lambda}(\mathbf{A})$, $\boldsymbol{\lambda}(\mathbf{B})$, $\|\mathbf{A}-\mathbf{B}\|_F$ and $\|\mathbf{A}-\mathbf{B}\|_2$. Verify Corollary 19.5.4 and Corollary 16.3.6 for this pair. Hence say which of the two bounds is closer to the truth here.

Solution. $\boldsymbol{\lambda}(\mathbf{A}) = (2,1,0)$. The top-left block of $\mathbf{B}$ has eigenvalues 3 and 1 (with eigenvectors $(1,1)$ and $(1,-1)$), and the last entry is -1, so $\boldsymbol{\lambda}(\mathbf{B}) = (3,1,-1)$. The shifts are $\lambda_i(\mathbf{B}) - \lambda_i(\mathbf{A}) = 1, 0, -1$.

$\mathbf{E} = \mathbf{B}-\mathbf{A} = \left(\begin{smallmatrix} 0 & 1 & 0 \\ 1 & 1 & 0 \\ 0 & 0 & -1 \end{smallmatrix}\right)$, so $\|\mathbf{E}\|_F^2 = 1+1+1+1 = 4$ and $\|\mathbf{E}\|_F = 2$. Its top-left block has characteristic polynomial $x^2 - x - 1$, with roots $\frac{1\pm\sqrt{5}}{2}$, and its last eigenvalue is -1.

By Lemma 16.3.5, $\|\mathbf{E}\|_2 = \frac{1+\sqrt{5}}{2} \approx 1.618$.

Hoffman–Wielandt: $1^2+0^2+(-1)^2 = 2 \le 4$. Weyl: each $|\text{shift}| \le 1 \le 1.618$. Hence both hold. Weyl overestimates the largest shift by a factor of about 1.6; Hoffman–Wielandt overestimates the sum of squares by a factor of 2. Neither is sharp here, and neither dominates.

Exercise B3: Sorting.

Let $\mathbf{a} = (5, 2, -1)$ and $\mathbf{b} = (4, 3, 0)$. Compute $\sum_i (a_i - b_{\sigma(i)})^2$ for all six $\sigma \in S_3$. Hence confirm Lemma 19.5.3, and say which pairing is the most expensive.

Solution. Write σ by its values $(\sigma(1), \sigma(2), \sigma(3))$. Then

$$\begin{aligned} &(1,2,3) : 1+1+1 = 3, && (1,3,2) : 1+4+16 = 21, \\ &(2,1,3) : 4+4+1 = 9, && (2,3,1) : 4+4+25 = 33, \\ &(3,1,2) : 25+4+16 = 45, && (3,2,1) : 25+1+25 = 51. \end{aligned}$$

The identity, which pairs the sorted lists in order, costs 3, the least of the six, as the lemma says. The most expensive is $(3, 2, 1)$, which pairs the largest a with the smallest b and so on: the reversed order. Exercise C1 (b) shows this is no accident.

19.5.6.3 C. Going deeper

Exercise C1: The most expensive pairing.

(a) Let $\mathbf{A}, \mathbf{B} \in M_n(\mathbb{C})$ be normal, with eigenvalues λ_i and μ_i. Prove that there is also a permutation σ with $\sum_i |\lambda_i - \mu_{\sigma(i)}|^2 \ge \|\mathbf{A} - \mathbf{B}\|_F^2$.

(b) Deduce that for Hermitian $\mathbf{A}, \mathbf{B}$,

$$\sum_{i=1}^{n} \big(\lambda_i(\mathbf{A}) - \lambda_{n+1-i}(\mathbf{B})\big)^2 \;\ge\; \|\mathbf{A} - \mathbf{B}\|_F^2.$$

Hint for (b): apply Lemma 19.5.3 to the list $-\lambda_{n+1-i}(\mathbf{B})$.

Solution.

(a) Apply Lemma 19.5.1 to the same $\mathbf{S} \in \Omega_n$ as in the proof of Theorem 19.5.2 and to the matrix $-\mathbf{C}$, where $c_{ij} = |\lambda_i - \mu_j|^2$. It gives τ with $-\sum_j c_{\tau(j)j} \le -\sum_{i,j} s_{ij} c_{ij} = -\|\mathbf{A} - \mathbf{B}\|_F^2$, by Eq. 19.5.1. Multiplying by -1 and putting $\sigma = \tau^{-1}$, as in that proof, gives $\sum_i |\lambda_i - \mu_{\sigma(i)}|^2 \ge \|\mathbf{A} - \mathbf{B}\|_F^2$.

(b) Write $a_i = \lambda_i(\mathbf{A})$ and $c_i = \lambda_i(\mathbf{B})$, and let $b_i = -c_{n+1-i}$. Both (a_i) and (b_i) are decreasing, the second because c_{n+1-i} increases with i. Let $\pi \in S_n$, and let $\sigma(i) = n + 1 - \pi(i)$, which is again a permutation, with $b_{\sigma(i)} = -c_{\pi(i)}$. By Lemma 19.5.3, $\sum_i (a_i - b_i)^2 \le \sum_i (a_i - b_{\sigma(i)})^2$, that is,

$$\sum_i (a_i + c_{n+1-i})^2 \;\le\; \sum_i (a_i + c_{\pi(i)})^2.$$

Expanding both sides, the squares $\sum_i a_i^2$ and $\sum_j c_j^2$ cancel, and what remains is $\sum_i a_i c_{n+1-i} \le \sum_i a_i c_{\pi(i)}$. Hence

$$\sum_i (a_i - c_{\pi(i)})^2 = \sum_i a_i^2 + \sum_j c_j^2 - 2\sum_i a_i c_{\pi(i)} \;\le\; \sum_i (a_i - c_{n+1-i})^2.$$

So the reversed pairing $i \mapsto n+1-i$ is the most expensive of all. By (a) some pairing costs at least $\|\mathbf{A}-\mathbf{B}\|_F^2$, so the most expensive one does too, which is the claim.

Exercise C2: Each eigenvalue keeps its own disc.

Let $\mathbf{A} \in M_n(\mathbb{C})$ be normal with **distinct** eigenvalues $\lambda_1, \dots, \lambda_n$, and let $\delta = \min_{i \ne j} |\lambda_i - \lambda_j|$. Let $\mathbf{B}$ be normal with $\|\mathbf{A}-\mathbf{B}\|_F < \delta/2$. Prove that each open disc $\{z : |z-\lambda_i| < \delta/2\}$ contains **exactly one** eigenvalue of $\mathbf{B}$, counted with multiplicity. Explain why Corollary 19.4.3 alone does not give this.

Solution. The discs are pairwise disjoint: if $|z-\lambda_i| < \delta/2$ and $|z-\lambda_j| < \delta/2$ with $i \ne j$, the triangle inequality (Theorem 0.6.4) gives $|\lambda_i - \lambda_j| < \delta$, contradicting the definition of δ. By Theorem 19.5.2 there is σ with $\sum_i |\lambda_i - \mu_{\sigma(i)}|^2 \le \|\mathbf{A}-\mathbf{B}\|_F^2 < \delta^2/4$, so $|\lambda_i - \mu_{\sigma(i)}| < \delta/2$ for every i. Thus the entry $\mu_{\sigma(i)}$ of the list lies in the i-th disc, and, the discs being disjoint, in no other. Since σ is a bijection, every entry of the list $\mu_1, \dots, \mu_n$ is $\mu_{\sigma(i)}$ for exactly one i. So the i-th disc contains exactly one entry of the list, namely $\mu_{\sigma(i)}$, which is the claim.

Corollary 19.4.3 (a), with $\|\mathbf{A}-\mathbf{B}\|_2 \le \|\mathbf{A}-\mathbf{B}\|_F < \delta/2$ (Proposition 15.3.4, or both norms being 0 if $\mathbf{A} = \mathbf{B}$, the case the proposition excludes), puts every eigenvalue of $\mathbf{B}$ in the union of the discs, but, as in the first example of this section, it allows two of them to fall in the same disc and leave another disc empty.

Exercise C3: A Jordan block of any size.

Let $n \ge 2$, $\varepsilon > 0$, $\mathbf{A} = \mathbf{J}_n(0)$ and $\mathbf{B} = \mathbf{J}_n(0) + \varepsilon \mathbf{E}_{n1}$, where $\mathbf{E}_{n1}$ is the matrix unit.

(a) Show that the characteristic polynomial of $\mathbf{B}$ is $x^n - \varepsilon$, and hence that every pairing of the eigenvalues of $\mathbf{A}$ and $\mathbf{B}$ costs $n\varepsilon^{2/n}$.

(b) Deduce that the Hoffman–Wielandt inequality fails for every pairing whenever $0 < \varepsilon < n^{n/(2n-2)}$, and that the ratio of the cost to $\|\mathbf{A}-\mathbf{B}\|_F^2$ tends to ∞ as $\varepsilon \to 0^+$.

Hint for (a): expand $\det(x\mathbf{I}-\mathbf{B})$ *along the first column.*

Solution.

(a) $x\mathbf{I}-\mathbf{B}$ has x on the diagonal, -1 on the superdiagonal, $-\varepsilon$ in position $(n,1)$ and zeros elsewhere. Expanding along the first column, the $(1,1)$ entry x multiplies the determinant of an upper triangular matrix with diagonal x, which is x^{n-1}. The $(n,1)$ entry $-\varepsilon$ carries the sign $(-1)^{n+1}$ and multiplies the determinant of the matrix left after deleting row n and column 1, which is lower triangular with

diagonal entries -1, hence has determinant $(-1)^{n-1}$. So

$$\det(x\mathbf{I} - \mathbf{B}) = x^n + (-1)^{n+1}(-\varepsilon)(-1)^{n-1} = x^n - \varepsilon.$$

Its roots are the n complex numbers z with $z^n = \varepsilon$, each of modulus $\varepsilon^{1/n}$ (these are Chapter 15's computation in Example (A Jordan block's eigenvalues move like $\varepsilon^{1/k}$)). Every eigenvalue of $\mathbf{A}$ is 0, so every pairing costs $\sum_i |0 - \mu_{\sigma(i)}|^2 = n\,\varepsilon^{2/n}$.

(b) $\mathbf{A} - \mathbf{B} = -\varepsilon \mathbf{E}_{n1}$, so $\|\mathbf{A} - \mathbf{B}\|_F^2 = \varepsilon^2$. The inequality fails for every pairing exactly when $n\varepsilon^{2/n} > \varepsilon^2$, that is, $\varepsilon^{2-2/n} < n$, that is, $\varepsilon < n^{1/(2-2/n)} = n^{n/(2n-2)}$; for $n = 2$ this is $\varepsilon < 2$, as in the text. The ratio is $n\varepsilon^{2/n}/\varepsilon^2 = n\varepsilon^{-(2n-2)/n}$, and the exponent $-(2n-2)/n$ is negative, so the ratio tends to ∞ as $\varepsilon \to 0^+$.

19.6 Hermitian Perturbations

For Hermitian matrices, Chapter 16 already gave the basic perturbation bound: each eigenvalue moves by at most $\|\mathbf{E}\|_2$, and no smaller constant is possible. This section asks what that bound does **not** tell us, and answers two such questions. The first is practical. A computation rarely hands us $\mathbf{E}$; it hands us an approximate eigenvector, and the question is how good the eigenvalue estimate it yields is. The answer is a residual bound, and when the eigenvalue is separated from the others it improves from linear to **quadratic** in the residual; that is the Kato–Temple theorem. The second concerns small eigenvalues. An absolute bound of size $\|\mathbf{E}\|_2$ says nothing about an eigenvalue much smaller than $\|\mathbf{E}\|_2$, and for perturbations of the form $\mathbf{A} \mapsto \mathbf{S}\mathbf{A}\mathbf{S}^*$ we prove a **relative** bound instead, Ostrowski's theorem, which is Sylvester's law of inertia made quantitative.

Throughout, $F = \mathbb{C}$, matrices whose eigenvalues are ordered are Hermitian, and $\lambda_1(\mathbf{A}) \geq \cdots \geq \lambda_n(\mathbf{A})$ are the eigenvalues of $\mathbf{A}$ in decreasing order, with multiplicity. Vectors are measured in $\|\cdot\|_2$, written $\|\cdot\|$ when no other norm is in sight, and $\langle \mathbf{x}, \mathbf{y} \rangle = \mathbf{y}^*\mathbf{x}$.

19.6.1 What Weyl's bound leaves open

Recall Corollary 16.3.6: if $\mathbf{A}$ and $\mathbf{E}$ are Hermitian, then $|\lambda_i(\mathbf{A} + \mathbf{E}) - \lambda_i(\mathbf{A})| \leq \|\mathbf{E}\|_2$ for every i. By Corollary 16.3.7 the constant 1 cannot be lowered, since $\mathbf{E} = t\mathbf{I}$ moves every eigenvalue by exactly $t = \|\mathbf{E}\|_2$. As a bound on **absolute** error, for an **unknown** Hermitian perturbation of known size, there is nothing more to be said.

The two assumptions in bold are where there is room. First, in practice $\mathbf{E}$ is not known at all. An iterative method stops with a unit vector $\mathbf{x}$ and a number μ that it believes to be an eigenpair, and what can be measured is the **residual** $\mathbf{r} = \mathbf{A}\mathbf{x} - \mu\mathbf{x}$. Second, an absolute error bound is only informative for eigenvalues larger than the error. For the matrix $\operatorname{diag}(1, 10^{-6})$ and a Hermitian perturbation of size 10^{-2}, Weyl's bound allows the eigenvalue 10^{-6} to end up anywhere in an interval of radius 10^{-2}, including negative numbers. Whether that is a fair description depends on the kind of perturbation, and for an important kind it is not.

19.6.2 Residual bounds

Suppose $\mathbf{x}$ is a unit vector and μ a real number, and $\mathbf{r} = \mathbf{A}\mathbf{x} - \mu\mathbf{x}$ is small. If $\mathbf{r} = \mathbf{0}$, then μ is an eigenvalue. The next theorem says that if $\mathbf{r}$ is merely small, μ is **near** an eigenvalue, with the size of $\mathbf{r}$ as the distance.

Theorem 19.6.1 — Residual Bound for Hermitian Matrices

Let $\mathbf{A} \in M_n(\mathbb{C})$ be Hermitian, let $\mathbf{x} \in \mathbb{C}^n$ with $\|\mathbf{x}\| = 1$, let $\mu \in \mathbb{R}$, and put $\mathbf{r} = \mathbf{A}\mathbf{x} - \mu\mathbf{x}$. Then some eigenvalue λ of $\mathbf{A}$ satisfies $|\lambda - \mu| \le \|\mathbf{r}\|$; that is, the interval $[\mu - \|\mathbf{r}\|, \mu + \|\mathbf{r}\|]$ contains an eigenvalue of $\mathbf{A}$.

This is the normal case of §04's Theorem 19.4.4, since a Hermitian matrix is normal. We give the direct proof from the spectral theorem instead, because the expansion it uses is the one Kato–Temple needs.

Proof. By Corollary 11.4.3 there is an orthonormal basis $(\mathbf{q}_1, \dots, \mathbf{q}_n)$ of $\mathbb{C}^n$ with $\mathbf{A}\mathbf{q}_i = \lambda_i \mathbf{q}_i$, where $\lambda_i = \lambda_i(\mathbf{A})$. Write $\mathbf{x} = \sum_i c_i \mathbf{q}_i$, with $\sum_i |c_i|^2 = \|\mathbf{x}\|^2 = 1$ by Theorem 10.2.1 (c). Then $\mathbf{r} = \sum_i c_i(\lambda_i - \mu)\mathbf{q}_i$, and by the same result

$$\|\mathbf{r}\|^2 = \sum_{i=1}^{n} |c_i|^2 (\lambda_i - \mu)^2 \;\ge\; \Big(\min_i (\lambda_i - \mu)^2\Big) \sum_{i=1}^{n} |c_i|^2 = \min_i (\lambda_i - \mu)^2.$$

Taking square roots, $\min_i |\lambda_i - \mu| \le \|\mathbf{r}\|$, as claimed. ∎

The bound holds for every real μ, and one choice of μ makes the residual smallest: the **Rayleigh quotient** $R_{\mathbf{A}}(\mathbf{x}) = \mathbf{x}^* \mathbf{A} \mathbf{x}$ of Definition 16.1.1, which for a unit vector needs no denominator. With that choice the residual is orthogonal to $\mathbf{x}$, since

$$\langle \mathbf{r}, \mathbf{x} \rangle = \mathbf{x}^* \mathbf{A} \mathbf{x} - \mu\, \mathbf{x}^* \mathbf{x} = \mu - \mu = 0,$$

and Pythagoras (Theorem 10.1.3) applied to $\mathbf{A}\mathbf{x} = \mu\mathbf{x} + \mathbf{r}$ gives

$$\|\mathbf{r}\|^2 = \|\mathbf{A}\mathbf{x}\|^2 - \mu^2 \qquad \big(\mu = R_{\mathbf{A}}(\mathbf{x}),\ \|\mathbf{x}\| = 1\big). \tag{19.6.1}$$

Exercise B3 shows that any other μ gives a larger residual. From now on, μ is the Rayleigh quotient and $\varepsilon = \|\mathbf{A}\mathbf{x} - \mu\mathbf{x}\|$ its residual.

Quick check. Let $\mathbf{A} = \operatorname{diag}(1, 3)$ and $\mathbf{x} = \frac{1}{\sqrt{2}}(1, 1)$. Compute $\mu = R_{\mathbf{A}}(\mathbf{x})$, the residual $\mathbf{r}$ and $\varepsilon = \|\mathbf{r}\|$. Which eigenvalues does the interval $[\mu - \varepsilon, \mu + \varepsilon]$ contain?

Solution. $\mathbf{A}\mathbf{x} = \frac{1}{\sqrt{2}}(1, 3)$, so $\mu = \mathbf{x}^*\mathbf{A}\mathbf{x} = \frac{1}{2}(1 + 3) = 2$ and $\mathbf{r} = \frac{1}{\sqrt{2}}(1 - 2, 3 - 2) = \frac{1}{\sqrt{2}}(-1, 1)$, with $\varepsilon = 1$. As a check, Eq. 19.6.1 gives $\|\mathbf{A}\mathbf{x}\|^2 - \mu^2 = 5 - 4 = 1$. The interval is $[1, 3]$, and it contains both eigenvalues, at its two ends. The bound is attained: a vector halfway between two eigenvectors is as bad an approximation as it can be.

19.6.3 The Kato–Temple bound

The residual bound is linear in ε, and in general no better is possible: in the Quick check, $|\lambda - \mu| = \varepsilon$ for both eigenvalues. But that example had $\mathbf{x}$ equally far from both eigenvectors. When $\mathbf{x}$ is close to one eigenvector, the Rayleigh quotient is a much better estimate than ε suggests. Exercise (C1: Why the quotient estimates eigenvalues so well) of Chapter 16 found that an eigenvector error of size δ costs only about δ^2 in the Rayleigh quotient. The trouble is that the eigenvector error cannot be measured, while the residual can. The next theorem restates the δ^2 phenomenon in terms of the residual, and the price is a hypothesis on how far the other eigenvalues are.

Here is where the gap comes in. If no eigenvalue of $\mathbf{A}$ lies strictly between two real numbers λ and β, then $(t-\lambda)(t-\beta) \geq 0$ at every eigenvalue t, so the matrix $(\mathbf{A}-\lambda\mathbf{I})(\mathbf{A}-\beta\mathbf{I})$ is positive semidefinite. Evaluating its quadratic form at $\mathbf{x}$ gives an inequality that involves only μ, ε, λ and β.

Theorem 19.6.2 — Kato–Temple Theorem

Let $\mathbf{A} \in M_n(\mathbb{C})$ be Hermitian, let $\mathbf{x} \in \mathbb{C}^n$ with $\|\mathbf{x}\| = 1$, let $\mu = \mathbf{x}^*\mathbf{A}\mathbf{x}$, and let $\varepsilon = \|\mathbf{A}\mathbf{x} - \mu\mathbf{x}\|$.

(a) Let $\beta > \mu$, and let $\lambda < \beta$ be an eigenvalue of $\mathbf{A}$ such that **no** eigenvalue of $\mathbf{A}$ lies in the open interval (λ, β). Then

$$\lambda \;\geq\; \mu - \frac{\varepsilon^2}{\beta - \mu}.$$

(b) Let $\alpha < \mu$, and let $\lambda > \alpha$ be an eigenvalue of $\mathbf{A}$ such that **no** eigenvalue of $\mathbf{A}$ lies in the open interval (α, λ). Then

$$\lambda \;\leq\; \mu + \frac{\varepsilon^2}{\mu - \alpha}.$$

In particular, if $\alpha < \mu < \beta$ and λ is the **only** eigenvalue of $\mathbf{A}$ in (α, β), then

$$\mu - \frac{\varepsilon^2}{\beta - \mu} \;\leq\; \lambda \;\leq\; \mu + \frac{\varepsilon^2}{\mu - \alpha}.$$

Idea. Compute the number $\mathbf{x}^*(\mathbf{A}-\lambda\mathbf{I})(\mathbf{A}-\beta\mathbf{I})\mathbf{x}$ two ways. ① In the eigenbasis it is $\sum_i |c_i|^2(\lambda_i - \lambda)(\lambda_i - \beta)$, and the gap hypothesis makes every term non-negative: each eigenvalue lies on or outside the interval between λ and β. ② Expanding the product, it is $\|\mathbf{A}\mathbf{x}\|^2 - (\lambda+\beta)\mu + \lambda\beta$, and Eq. 19.6.1 turns this into $\varepsilon^2 + (\mu-\lambda)(\mu-\beta)$. So $(\mu-\lambda)(\beta-\mu) \leq \varepsilon^2$; divide by the positive number $\beta - \mu$. Part (b) is the same with α in place of β.

Proof.

(a) As in the proof of Theorem 19.6.1, write $\mathbf{x} = \sum_i c_i \mathbf{q}_i$ in an orthonormal eigenbasis, $\mathbf{A}\mathbf{q}_i = \lambda_i \mathbf{q}_i$, $\sum_i |c_i|^2 = 1$. Then $(\mathbf{A}-\lambda\mathbf{I})(\mathbf{A}-\beta\mathbf{I})\mathbf{x} = \sum_i c_i(\lambda_i - \lambda)(\lambda_i - \beta)\mathbf{q}_i$, and

by Theorem 10.2.1 (b),

$$\mathbf{x}^*(\mathbf{A}-\lambda\mathbf{I})(\mathbf{A}-\beta\mathbf{I})\mathbf{x} = \sum_{i=1}^{n} |c_i|^2(\lambda_i-\lambda)(\lambda_i-\beta).$$

Each eigenvalue λ_i satisfies $\lambda_i \le \lambda$ or $\lambda_i \ge \beta$, because none lies in (λ,β). In the first case both factors are ≤ 0, in the second both are ≥ 0, since $\lambda < \beta$. So every term is ≥ 0, and the left-hand side is ≥ 0.
On the other hand, expanding the product and using $\mathbf{x}^*\mathbf{x} = 1$, $\mathbf{x}^*\mathbf{A}\mathbf{x} = \mu$ and $\mathbf{x}^*\mathbf{A}^2\mathbf{x} = (\mathbf{A}\mathbf{x})^*(\mathbf{A}\mathbf{x}) = \|\mathbf{A}\mathbf{x}\|^2$, where $\mathbf{A}^* = \mathbf{A}$,

$$\begin{aligned}\mathbf{x}^*(\mathbf{A}-\lambda\mathbf{I})(\mathbf{A}-\beta\mathbf{I})\mathbf{x} &= \|\mathbf{A}\mathbf{x}\|^2 - (\lambda+\beta)\mu + \lambda\beta \\ &= \varepsilon^2 + \mu^2 - (\lambda+\beta)\mu + \lambda\beta \\ &= \varepsilon^2 + (\mu-\lambda)(\mu-\beta),\end{aligned}$$

where the second line is Eq. 19.6.1. Hence $\varepsilon^2 + (\mu-\lambda)(\mu-\beta) \ge 0$, that is, $(\mu-\lambda)(\beta-\mu) \le \varepsilon^2$. Since $\beta-\mu > 0$, dividing gives $\mu - \lambda \le \varepsilon^2/(\beta-\mu)$, which is (a).

(b) Apply (a) to $-\mathbf{A}$, the unit vector $\mathbf{x}$, the eigenvalue $-\lambda$ and the number $-\alpha$. The Rayleigh quotient of $-\mathbf{A}$ at $\mathbf{x}$ is $-\mu$, its residual is $-(\mathbf{A}\mathbf{x}-\mu\mathbf{x})$, of the same norm ε, and $-\alpha > -\mu$. The eigenvalues of $-\mathbf{A}$ are the negatives of those of $\mathbf{A}$, so $-\lambda < -\alpha$ and none lies in $(-\lambda,-\alpha)$. Part (a) gives $-\lambda \ge -\mu - \varepsilon^2/(-\alpha+\mu)$, which is (b).

The final statement follows: if λ is the only eigenvalue in (α,β), then no eigenvalue lies in (λ,β) or in (α,λ), so (a) and (b) both apply. This proves the theorem.

■

Compare the two bounds on the error $|\lambda-\mu|$. The residual bound gives ε. Kato–Temple gives ε^2 divided by the distance from μ to the neighboring part of the spectrum. When ε is small compared with that gap, the square wins by a wide margin: a residual of 10^{-4} and a gap of 1 give an error of at most 10^{-8}. *The Rayleigh quotient's error is quadratic in the residual, provided there is a gap.* That is the reason the Rayleigh quotient is the eigenvalue estimate of choice, and Chapter 23 builds an iteration on it.

The theorem needs a number α or β that is known to lie beyond the neighboring eigenvalue, and in practice that information has to come from somewhere. The next example gets it from interlacing.

Example. (Bracketing the top eigenvalue)

Let

$$\mathbf{A} = \begin{pmatrix} 2 & 1 & 0 \\ 1 & 2 & 1 \\ 0 & 1 & 2 \end{pmatrix}, \qquad \mathbf{x} = \tfrac{1}{\sqrt{3}}(1,1,1).$$

Estimate $\lambda_1(\mathbf{A})$ from $\mathbf{x}$: compute μ and ε, the interval given by Theorem 19.6.1, and the interval given by Theorem 19.6.2, using only information that can be read off $\mathbf{A}$ without computing its eigenvalues. Compare with the true value $\lambda_1(\mathbf{A}) = 2+\sqrt{2}$.

Solution. Rayleigh quotient and residual. $\mathbf{A}(1,1,1) = (3,4,3)$, so $\mathbf{Ax} = \frac{1}{\sqrt{3}}(3,4,3)$ and

$$\mu = \mathbf{x}^*\mathbf{Ax} = \tfrac{1}{3}(3+4+3) = \tfrac{10}{3}, \qquad \|\mathbf{Ax}\|^2 = \tfrac{1}{3}(9+16+9) = \tfrac{34}{3}.$$

By Eq. 19.6.1, $\varepsilon^2 = \frac{34}{3} - \frac{100}{9} = \frac{2}{9}$, so $\varepsilon = \frac{\sqrt{2}}{3} \approx 0.471$. Directly: $\mathbf{r} = \frac{1}{\sqrt{3}}\big(3 - \frac{10}{3}, 4 - \frac{10}{3}, 3 - \frac{10}{3}\big) = \frac{1}{3\sqrt{3}}(-1,2,-1)$, of squared norm $\frac{6}{27} = \frac{2}{9}$.

Residual bound. Some eigenvalue lies in $[\frac{10}{3} - 0.471, \frac{10}{3} + 0.471] \approx [2.862, 3.805]$.

Kato–Temple. By Proposition 16.1.1, $\lambda_1(\mathbf{A}) \geq \mu = \frac{10}{3}$. For an upper bound we need $\alpha < \mu$ with no eigenvalue in (α, λ_1), which says $\lambda_2(\mathbf{A}) \leq \alpha$. Deleting the second row and column leaves $\mathbf{B} = \operatorname{diag}(2,2)$, and Cauchy's interlacing theorem (Theorem 16.4.2, with $I = \{1,3\}$) gives $\lambda_2(\mathbf{A}) \leq \lambda_1(\mathbf{B}) = 2$. So $\alpha = 2$ is allowed: $\alpha < \mu$, and no eigenvalue lies in $(2, \lambda_1)$, because $\lambda_2 \leq 2$ and $\lambda_1 \geq \frac{10}{3} > 2$. Part (b) gives

$$\lambda_1(\mathbf{A}) \;\leq\; \frac{10}{3} + \frac{2/9}{10/3 - 2} = \frac{10}{3} + \frac{2}{9}\cdot\frac{3}{4} = \frac{10}{3} + \frac{1}{6} = \frac{7}{2}.$$

So $\frac{10}{3} \leq \lambda_1(\mathbf{A}) \leq \frac{7}{2}$, an interval of width $\frac{1}{6} \approx 0.167$, against width $2\varepsilon \approx 0.943$ for the residual bound.

Check. The true value is $2+\sqrt{2} \approx 3.414$, which lies in both intervals; the other eigenvalues are 2 and $2 - \sqrt{2}$. The actual error of the Rayleigh quotient is $2 + \sqrt{2} - \frac{10}{3} \approx 0.081$, about a sixth of ε.

Kato–Temple cannot be improved in general: for $\mathbf{A} = \operatorname{diag}(\lambda_1, \lambda_2)$ with $\lambda_1 > \lambda_2$, and $\alpha = \lambda_2$ the other eigenvalue, the upper bound in (b) is an **equality** at every real unit $\mathbf{x}$ that is not an eigenvector for λ_2 (Exercise C3). At such an eigenvector the hypothesis $\alpha < \mu$ fails, since there $\mu = \lambda_2$.

Warning. **The gap hypothesis is not decoration.** Take $\mathbf{A} = \operatorname{diag}(1,0)$ and $\mathbf{x} = \frac{1}{\sqrt{2}}(1,1)$, so $\mu = \frac{1}{2}$ and $\mathbf{r} = \frac{1}{\sqrt{2}}(\frac{1}{2}, -\frac{1}{2})$, $\varepsilon^2 = \frac{1}{4}$. With $\lambda = 1$ and $\alpha = 0$, part (b) gives $1 \leq \frac{1}{2} + \frac{1/4}{1/2} = 1$, true with equality. With $\alpha = -\frac{1}{2}$ instead, the eigenvalue 0 lies in (α, λ), the hypothesis fails, and the formula would claim $1 \leq \frac{1}{2} + \frac{1/4}{1} = \frac{3}{4}$, which is false. A number α chosen too far from μ, past an unseen eigenvalue, gives a bound that is simply wrong.

19.6.4 Relative perturbations and congruence

Now the second question: small eigenvalues. Weyl's bound is absolute, and an absolute bound is useless for an eigenvalue smaller than itself. Some perturbations deserve better. In a change of variables $\mathbf{x} = \mathbf{S}^*\mathbf{y}$ with $\mathbf{S}$ invertible, the quadratic form $\mathbf{x}^*\mathbf{Ax}$ becomes $\mathbf{y}^*(\mathbf{SAS}^*)\mathbf{y}$; the matrix undergoes a **congruence**, as in Chapter 13 and in Chapter 16 §10. When $\mathbf{S}$ is close to $\mathbf{I}$, for instance when it comes from a slightly inaccurate elimination step or from rounding in a factor, $\mathbf{SAS}^*$ is a perturbation of $\mathbf{A}$, but a very structured one. Its effect on the eigenvalues is **multiplicative**.

Two facts are known already. By Theorem 16.10.1 (b), applied with $\mathbf{P} = \mathbf{S}^*$, a congruence preserves the numbers of positive, negative and zero eigenvalues; it cannot change a sign. And by Chapter 13 §05's warning, it can still move eigenvalues a long way: with $\mathbf{P} = \operatorname{diag}(2,3)$,

$\mathbf{P}^{\top}\operatorname{diag}(1,-1)\mathbf{P} = \operatorname{diag}(4,-9)$. Ostrowski's theorem measures how far.

Theorem 19.6.3 — Ostrowski's Theorem

Let $\mathbf{A} \in M_n(\mathbb{C})$ be Hermitian and let $\mathbf{S} \in M_n(\mathbb{C})$ be invertible. Then $\mathbf{SS}^*$ is positive definite, and for each $k = 1, \dots, n$ there is a real number θ_k with

$$\lambda_k(\mathbf{SAS}^*) = \theta_k\, \lambda_k(\mathbf{A}), \qquad \lambda_n(\mathbf{SS}^*) \;\le\; \theta_k \;\le\; \lambda_1(\mathbf{SS}^*).$$

In particular $\theta_k > 0$, and

$$\bigl|\lambda_k(\mathbf{SAS}^*) - \lambda_k(\mathbf{A})\bigr| \;\le\; \|\mathbf{SS}^* - \mathbf{I}\|_2\, |\lambda_k(\mathbf{A})|.$$

Idea. **Step roadmap.** Fix k and put $\mu = \lambda_k(\mathbf{A})$.

① **Shift, so the k-th eigenvalue is 0.** $\mathbf{A} - \mu\mathbf{I}$ has at most $k-1$ positive eigenvalues and at least k non-negative ones. A congruence preserves both counts (Sylvester's law), so $\mathbf{S}(\mathbf{A} - \mu\mathbf{I})\mathbf{S}^*$ has the same property, and that forces its k-th eigenvalue to be exactly 0.

② **Split.** $\mathbf{SAS}^* = \mathbf{S}(\mathbf{A} - \mu\mathbf{I})\mathbf{S}^* + \mu\mathbf{SS}^*$.

③ **Weyl.** Adding $\mu\mathbf{SS}^*$ moves the k-th eigenvalue from 0 to somewhere between the smallest and the largest eigenvalue of $\mu\mathbf{SS}^*$, which are $\mu\lambda_n(\mathbf{SS}^*)$ and $\mu\lambda_1(\mathbf{SS}^*)$ in some order, depending on the sign of μ.

Proof. For $\mathbf{x} \neq \mathbf{0}$, $\mathbf{x}^*\mathbf{SS}^*\mathbf{x} = \|\mathbf{S}^*\mathbf{x}\|^2 > 0$, because $\mathbf{S}^*$ is invertible. So $\mathbf{SS}^*$, which is Hermitian, is positive definite, and its eigenvalues are positive by Theorem 12.1.5; write $m = \lambda_n(\mathbf{SS}^*) > 0$ and $M = \lambda_1(\mathbf{SS}^*)$.

Fix k and put $\mu = \lambda_k(\mathbf{A})$. The eigenvalues of the Hermitian matrix $\mathbf{A} - \mu\mathbf{I}$ are $\lambda_i(\mathbf{A}) - \mu$, in the same decreasing order. Those with $i \ge k$ are ≤ 0, so at most $k-1$ of them are positive; those with $i \le k$ are ≥ 0, so at least k are non-negative. In the notation of Definition 16.10.1, $n_+(\mathbf{A} - \mu\mathbf{I}) \le k-1$ and $n_+(\mathbf{A} - \mu\mathbf{I}) + n_0(\mathbf{A} - \mu\mathbf{I}) \ge k$. Put $\mathbf{Y} = \mathbf{S}(\mathbf{A} - \mu\mathbf{I})\mathbf{S}^*$. This is $\mathbf{P}^*(\mathbf{A} - \mu\mathbf{I})\mathbf{P}$ with $\mathbf{P} = \mathbf{S}^*$ invertible, so by Theorem 16.10.1 (b), $\mathbf{Y}$ is Hermitian with the same inertia triple. Hence $\mathbf{Y}$ has at most $k-1$ positive eigenvalues, so $\lambda_k(\mathbf{Y}) \le 0$; and at least k non-negative ones, so $\lambda_k(\mathbf{Y}) \ge 0$. Thus $\lambda_k(\mathbf{Y}) = 0$.

Now $\mathbf{SAS}^* = \mathbf{Y} + \mu\mathbf{SS}^*$, a sum of two Hermitian matrices. By Corollary 16.3.4,

$$\lambda_n(\mu\mathbf{SS}^*) \;\le\; \lambda_k(\mathbf{SAS}^*) - \lambda_k(\mathbf{Y}) \;\le\; \lambda_1(\mu\mathbf{SS}^*),$$

and $\lambda_k(\mathbf{Y}) = 0$. If $\mu \ge 0$, multiplying by μ keeps the order of the eigenvalues, so $\lambda_n(\mu\mathbf{SS}^*) = \mu m$ and $\lambda_1(\mu\mathbf{SS}^*) = \mu M$. If $\mu < 0$, then $\mu\mathbf{SS}^* = -(|\mu|\mathbf{SS}^*)$, and by Lemma 16.3.2 its extreme eigenvalues are $\lambda_n = -|\mu|M = \mu M$ and $\lambda_1 = -|\mu|m = \mu m$. In both cases $\lambda_k(\mathbf{SAS}^*)$ lies between μm and μM. If $\mu \neq 0$, put $\theta_k = \lambda_k(\mathbf{SAS}^*)/\mu$; dividing by μ (and reversing the inequalities when $\mu < 0$) gives $m \le \theta_k \le M$. If $\mu = 0$, both ends are 0, so $\lambda_k(\mathbf{SAS}^*) = 0$, and $\theta_k = m$ will do. In either case $\theta_k \ge m > 0$.

For the last inequality, $|\lambda_k(\mathbf{SAS}^*) - \lambda_k(\mathbf{A})| = |\theta_k - 1|\,|\mu|$, and $\theta_k - 1$ lies in $[m-1, M-1]$. The numbers $m-1$ and $M-1$ are the smallest and largest eigenvalues of the Hermitian matrix $\mathbf{SS}^* - \mathbf{I}$, so by Lemma 16.3.5 both have absolute value at most $\|\mathbf{SS}^* - \mathbf{I}\|_2$, and

so does everything between them. This proves the theorem.

■

This is a quantitative Sylvester's law of inertia. Sylvester's law says that a congruence cannot change the sign of an eigenvalue; Ostrowski's theorem says that it multiplies the k-th eigenvalue by a factor θ_k that is always positive and always between the extreme eigenvalues of $\mathbf{SS}^*$. These are $\lambda_1(\mathbf{SS}^*) = \max_{\|\mathbf{y}\|=1}\|\mathbf{S}^*\mathbf{y}\|^2$ and $\lambda_n(\mathbf{SS}^*) = \min_{\|\mathbf{y}\|=1}\|\mathbf{S}^*\mathbf{y}\|^2$, by Proposition 16.1.1, since $\mathbf{y}^*\mathbf{SS}^*\mathbf{y} = \|\mathbf{S}^*\mathbf{y}\|^2$: the most and the least that the change of variables stretches a vector, squared. When $\mathbf{S}$ is close to a unitary matrix, both are close to 1, and **every** eigenvalue, however small, keeps most of its significant digits.

Quick check. Chapter 13 §05's warning used $\mathbf{A} = \operatorname{diag}(1, -1)$ and $\mathbf{P} = \operatorname{diag}(2, 3)$, with $\mathbf{P}^\top\mathbf{AP} = \operatorname{diag}(4, -9)$. Take $\mathbf{S} = \mathbf{P}^\top = \mathbf{P}$. Find θ_1, θ_2 and the interval $[\lambda_n(\mathbf{SS}^*), \lambda_1(\mathbf{SS}^*)]$. Can the interval in Theorem 19.6.3 be shortened?

Solution. $\mathbf{SS}^* = \operatorname{diag}(4, 9)$, so the interval is $[4, 9]$. The eigenvalues of $\mathbf{SAS}^* = \operatorname{diag}(4, -9)$ in decreasing order are 4 and -9, and those of $\mathbf{A}$ are 1 and -1. So $\theta_1 = 4/1 = 4$ and $\theta_2 = -9/(-1) = 9$. They sit at the two ends of the interval, so neither end can be moved inwards: the interval is sharp.

The next example shows the difference between the absolute and the relative view on a matrix whose eigenvalues differ greatly in size.

Example. (A tiny eigenvalue under a change of variables)

Let $\mathbf{A} = \operatorname{diag}(1, 10^{-6})$ and $\mathbf{S} = \left(\begin{smallmatrix} 1 & 0 \\ t & 1 \end{smallmatrix}\right)$ with $t = 10^{-2}$, the change of variables that adds t times the first coordinate to the second. Compute $\mathbf{SAS}^*$ and $\mathbf{E} = \mathbf{SAS}^* - \mathbf{A}$. What do Corollary 16.3.4 and Theorem 19.6.3 say about $\lambda_2(\mathbf{SAS}^*)$, and what is its true value?

Solution. Write $\eta = 10^{-6}$. Multiplying out,

$$\mathbf{SAS}^* = \begin{pmatrix} 1 & t \\ t & t^2 + \eta \end{pmatrix}, \qquad \mathbf{E} = \begin{pmatrix} 0 & t \\ t & t^2 \end{pmatrix},$$

with $t^2 + \eta = 1.01 \times 10^{-4}$.

Weyl. $\mathbf{E}$ has trace t^2 and determinant $-t^2$, so its eigenvalues are $\frac{1}{2}\big(t^2 \pm t\sqrt{t^2+4}\big)$, approximately 0.01005 and -0.00995. By Corollary 16.3.4,

$$10^{-6} - 0.00995 \;\le\; \lambda_2(\mathbf{SAS}^*) \;\le\; 10^{-6} + 0.01005.$$

This interval is about 10^4 times wider than the eigenvalue it is meant to locate, and it contains negative numbers.

Ostrowski. $\mathbf{SS}^* = \left(\begin{smallmatrix} 1 & t \\ t & 1+t^2 \end{smallmatrix}\right)$ has trace $2 + t^2$ and determinant 1, so its eigenvalues are $\frac{1}{2}\big(2 + t^2 \pm t\sqrt{4+t^2}\big)$, approximately 1.01005 and 0.99005. By Theorem 19.6.3,

$$0.99005 \times 10^{-6} \;\le\; \lambda_2(\mathbf{SAS}^*) \;\le\; 1.01005 \times 10^{-6}\,:$$

the eigenvalue is positive and known to within about 1%.

The truth. $\det(\mathbf{SAS}^*) = \det(\mathbf{S})^2 \det \mathbf{A} = \eta$, since $\det \mathbf{S} = 1$, and the trace is $1 + t^2 + \eta$. So the two eigenvalues multiply to η, and the larger is $1.0001\ldots$; hence $\lambda_2(\mathbf{SAS}^*) = \eta/\lambda_1(\mathbf{SAS}^*) \approx 0.99990 \times 10^{-6}$. The relative change is about 10^{-4}, well inside Ostrowski's 1%; Weyl's bound, by contrast, cannot even decide the sign.

Warning. **Weyl's bound is sharp and still useless for small eigenvalues.** It is the best possible bound on **absolute** error for **arbitrary** Hermitian $\mathbf{E}$ of a given norm, and for exactly that reason it cannot distinguish an eigenvalue of size 10^{-6} from 0 once $\|\mathbf{E}\|_2 \geq 10^{-6}$. A general Hermitian $\mathbf{E}$ really can destroy a small eigenvalue: $\mathbf{E} = -10^{-6}\mathbf{e}_2\mathbf{e}_2^\top$ sends the eigenvalue 10^{-6} of $\operatorname{diag}(1, 10^{-6})$ to 0. Relative accuracy needs a structured perturbation, such as a congruence $\mathbf{SAS}^*$ with $\mathbf{S}$ near $\mathbf{I}$.

19.6.5 Exercises

19.6.5.1 A. Check your understanding

Exercise A1.

(a) State the Kato–Temple theorem, with its hypotheses.

(b) True or false: for Hermitian $\mathbf{A}$, a unit vector $\mathbf{x}$ and real μ, the eigenvalue of $\mathbf{A}$ **closest** to μ is within $\|\mathbf{Ax} - \mu\mathbf{x}\|$ of μ. Justify your answer.

(c) True or false: for Hermitian $\mathbf{A}$ and invertible $\mathbf{S}$, $\lambda_k(\mathbf{SAS}^*)$ and $\lambda_k(\mathbf{A})$ have the same sign for every k. Justify your answer.

(d) Which of the three bounds of this section need information that is not contained in $\mathbf{A}$, $\mathbf{x}$ and μ? What information?

(e) Why can the constant 1 in Corollary 16.3.6 not be lowered, and why does that not contradict Ostrowski's theorem?

Solution.

(a) Let $\mathbf{A}$ be Hermitian, $\mathbf{x}$ a unit vector, $\mu = \mathbf{x}^*\mathbf{Ax}$, $\varepsilon = \|\mathbf{Ax} - \mu\mathbf{x}\|$. If $\beta > \mu$ and $\lambda < \beta$ is an eigenvalue with no eigenvalue in (λ, β), then $\lambda \geq \mu - \varepsilon^2/(\beta - \mu)$. If $\alpha < \mu$ and $\lambda > \alpha$ is an eigenvalue with no eigenvalue in (α, λ), then $\lambda \leq \mu + \varepsilon^2/(\mu - \alpha)$.

(b) True. Theorem 19.6.1 gives some eigenvalue within $\|\mathbf{Ax} - \mu\mathbf{x}\|$ of μ, and the closest one is at least as close.

(c) True. By Theorem 19.6.3, $\lambda_k(\mathbf{SAS}^*) = \theta_k \lambda_k(\mathbf{A})$ with $\theta_k > 0$; a positive multiple has the same sign, and 0 goes to 0.

(d) The residual bound needs nothing more. Kato–Temple needs a number α or β beyond the neighboring eigenvalue, that is, a lower bound on the gap; in Example (Bracketing the top eigenvalue) it came from interlacing. Ostrowski's theorem is not about an approximate eigenvector, but it needs $\mathbf{S}$, or at least the extreme eigenvalues of $\mathbf{SS}^*$.

(e) $\mathbf{E} = t\mathbf{I}$ moves every eigenvalue by exactly $t = \|\mathbf{E}\|_2$. Ostrowski's theorem is about the perturbations $\mathbf{SAS}^* - \mathbf{A}$, which form a special class; $\mathbf{A} + t\mathbf{I}$ is not of the form $\mathbf{SAS}^*$ in general (for $\mathbf{A} = \mathbf{0}$ it never is, when $t \neq 0$). A better bound for a smaller class contradicts nothing.

19.6.5.2 B. Practice

Exercise B1: Three bounds for one estimate.

Let $\mathbf{A} = \left(\begin{smallmatrix} 5 & 2 \\ 2 & 2 \end{smallmatrix}\right)$ and $\mathbf{x} = \frac{1}{\sqrt{10}}(3, 1)$.

(a) Compute $\mu = \mathbf{x}^*\mathbf{A}\mathbf{x}$ and $\varepsilon = \|\mathbf{A}\mathbf{x} - \mu\mathbf{x}\|$, and the interval given by Theorem 19.6.1.

(b) Using Theorem 16.4.2 to bound $\lambda_2(\mathbf{A})$, apply Theorem 19.6.2 to bracket $\lambda_1(\mathbf{A})$.

(c) Find the eigenvalues of $\mathbf{A}$ exactly. Hence compare the actual error of μ with ε and with the Kato–Temple bound.

Solution.

(a) $\mathbf{A}(3, 1) = (17, 8)$, so $\mu = \frac{1}{10}(3 \cdot 17 + 1 \cdot 8) = \frac{59}{10} = 5.9$. The residual is $\frac{1}{\sqrt{10}}\big((17, 8) - 5.9(3, 1)\big) = \frac{1}{\sqrt{10}}(-0.7, 2.1)$, so $\varepsilon^2 = \frac{1}{10}(0.49 + 4.41) = 0.49$ and $\varepsilon = 0.7$. Some eigenvalue lies in $[5.2, 6.6]$.

(b) Deleting the first row and column leaves (2), so Theorem 16.4.2 gives $\lambda_2(\mathbf{A}) \le 2$. Also $\lambda_1(\mathbf{A}) \ge \mu = 5.9$ by Proposition 16.1.1. So with $\alpha = 2 < \mu$, no eigenvalue lies in $(2, \lambda_1)$, and part (b) of Theorem 19.6.2 gives

$$\lambda_1(\mathbf{A}) \;\le\; 5.9 + \frac{0.49}{5.9 - 2} = 5.9 + \frac{0.49}{3.9} \approx 6.026.$$

Hence $5.9 \le \lambda_1(\mathbf{A}) \le 6.026$.

(c) $\mathbf{A}$ has trace 7 and determinant 6, so its eigenvalues are 6 and 1; indeed $\mathbf{A}(2, 1) = (12, 6)$. The actual error of μ is $6 - 5.9 = 0.1$. The residual bound allows 0.7, seven times too much; Kato–Temple allows 0.126, within about 26% of the truth.

Exercise B2: Ostrowski's factors.

Let $\mathbf{A} = \operatorname{diag}(2, -1)$ and $\mathbf{S} = \left(\begin{smallmatrix} 1 & 1 \\ 0 & 1 \end{smallmatrix}\right)$. Compute $\mathbf{S}\mathbf{A}\mathbf{S}^*$ and its eigenvalues, the eigenvalues of $\mathbf{S}\mathbf{S}^*$, and the factors θ_1, θ_2 of Theorem 19.6.3. Hence verify the theorem for this pair.

Solution. $\mathbf{A}\mathbf{S}^* = \operatorname{diag}(2, -1)\left(\begin{smallmatrix} 1 & 0 \\ 1 & 1 \end{smallmatrix}\right) = \left(\begin{smallmatrix} 2 & 0 \\ -1 & -1 \end{smallmatrix}\right)$, and

$$\mathbf{S}\mathbf{A}\mathbf{S}^* = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}\begin{pmatrix} 2 & 0 \\ -1 & -1 \end{pmatrix} = \begin{pmatrix} 1 & -1 \\ -1 & -1 \end{pmatrix},$$

with trace 0 and determinant -2, so eigenvalues $\pm\sqrt{2}$. Next $\mathbf{S}\mathbf{S}^* = \left(\begin{smallmatrix} 2 & 1 \\ 1 & 1 \end{smallmatrix}\right)$, with trace 3 and determinant 1, so eigenvalues $\frac{3 \pm \sqrt{5}}{2} \approx 2.618$ and 0.382.

Then $\theta_1 = \lambda_1(\mathbf{S}\mathbf{A}\mathbf{S}^*)/\lambda_1(\mathbf{A}) = \sqrt{2}/2 \approx 0.707$ and $\theta_2 = (-\sqrt{2})/(-1) = \sqrt{2} \approx 1.414$. Both lie in $[0.382, 2.618]$, as the theorem says, and both are positive, so the signs $+, -$ are preserved.

Exercise B3: The Rayleigh quotient minimizes the residual.

Let $\mathbf{A}$ be Hermitian and $\mathbf{x}$ a unit vector, with $\rho = \mathbf{x}^*\mathbf{A}\mathbf{x}$. Prove that for every real ν,

$$\|\mathbf{A}\mathbf{x} - \nu\mathbf{x}\|^2 = \|\mathbf{A}\mathbf{x} - \rho\mathbf{x}\|^2 + (\nu - \rho)^2.$$

Hence deduce that among all real ν, the residual bound of Theorem 19.6.1 is sharpest at $\nu = \rho$.

Solution. Write $\mathbf{Ax} - \nu\mathbf{x} = (\mathbf{Ax} - \rho\mathbf{x}) + (\rho - \nu)\mathbf{x}$. The first vector is orthogonal to $\mathbf{x}$, since $\langle \mathbf{Ax} - \rho\mathbf{x}, \mathbf{x}\rangle = \mathbf{x}^*\mathbf{Ax} - \rho = 0$. By Theorem 10.1.3,

$$\|\mathbf{Ax} - \nu\mathbf{x}\|^2 = \|\mathbf{Ax} - \rho\mathbf{x}\|^2 + (\rho - \nu)^2\|\mathbf{x}\|^2 = \|\mathbf{Ax} - \rho\mathbf{x}\|^2 + (\nu - \rho)^2.$$

Hence $\|\mathbf{Ax} - \nu\mathbf{x}\| \geq \|\mathbf{Ax} - \rho\mathbf{x}\|$, with equality only for $\nu = \rho$. The interval $[\nu - \|\mathbf{Ax} - \nu\mathbf{x}\|, \nu + \|\mathbf{Ax} - \nu\mathbf{x}\|]$ of Theorem 19.6.1 therefore has its smallest radius at $\nu = \rho$.

19.6.5.3 C. Going deeper

Exercise C1: A residual that guarantees an eigenvalue.

Let $\mathbf{A}$ be Hermitian, $\mathbf{x}$ a unit vector, $\mu = \mathbf{x}^*\mathbf{Ax}$ and $\varepsilon = \|\mathbf{Ax} - \mu\mathbf{x}\|$.

(a) Let $\alpha < \mu < \beta$. Prove that if $\varepsilon^2 < (\mu - \alpha)(\beta - \mu)$, then $\mathbf{A}$ has an eigenvalue in (α, β).

(b) Deduce that $\mathbf{A}$ has an eigenvalue in $[\mu - \varepsilon, \mu + \varepsilon]$, which is Theorem 19.6.1 again, for this choice of μ.

Hint for (a): if there is none, consider $\mathbf{x}^*(\mathbf{A} - \alpha\mathbf{I})(\mathbf{A} - \beta\mathbf{I})\mathbf{x}$.

Solution.

(a) Suppose no eigenvalue lies in (α, β). Then every eigenvalue t satisfies $t \leq \alpha$ or $t \geq \beta$, so $(t - \alpha)(t - \beta) \geq 0$. As in the proof of Theorem 19.6.2, with α in place of λ,

$$0 \;\leq\; \mathbf{x}^*(\mathbf{A} - \alpha\mathbf{I})(\mathbf{A} - \beta\mathbf{I})\mathbf{x} = \varepsilon^2 + (\mu - \alpha)(\mu - \beta),$$

so $\varepsilon^2 \geq (\mu - \alpha)(\beta - \mu)$, contradicting the hypothesis. Hence some eigenvalue lies in (α, β).

(b) Let d be the smallest distance from μ to an eigenvalue of $\mathbf{A}$, and suppose $d > \varepsilon$. Choose s with $\varepsilon < s < d$, and apply (a) with $\alpha = \mu - s$ and $\beta = \mu + s$: the hypothesis holds, since $(\mu - \alpha)(\beta - \mu) = s^2 > \varepsilon^2$. So some eigenvalue lies in $(\mu - s, \mu + s)$, at distance less than $s < d$ from μ, contradicting the choice of d. Hence $d \leq \varepsilon$, which is the claim.

Exercise C2: Relative bounds need structured perturbations.

(a) Let $\mathbf{A}$ be Hermitian and $\mathbf{S} = \mathbf{I} + \mathbf{F}$ with $\mathbf{F} \in M_n(\mathbb{C})$. Prove that

$$\big|\lambda_k(\mathbf{SAS}^*) - \lambda_k(\mathbf{A})\big| \;\leq\; \big(2\|\mathbf{F}\|_2 + \|\mathbf{F}\|_2^2\big)\,|\lambda_k(\mathbf{A})|$$

for every k, whenever $\mathbf{S}$ is invertible.

(b) Show that there is **no** constant c such that $|\lambda_k(\mathbf{A} + \mathbf{E}) - \lambda_k(\mathbf{A})| \leq c\|\mathbf{E}\|_2|\lambda_k(\mathbf{A})|$ for all Hermitian $\mathbf{A}$, $\mathbf{E}$ and all k.

Hint for (a): expand $\mathbf{SS}^* - \mathbf{I}$, *and show first that* $\|\mathbf{F}^*\|_2 = \|\mathbf{F}\|_2$.

Solution.

(a) First, $\|\mathbf{F}^*\|_2 \le \|\mathbf{F}\|_2$: for every $\mathbf{x}$, by Theorem 10.1.5 and Theorem 15.3.2 (a),

$$\|\mathbf{F}^*\mathbf{x}\|^2 = \langle \mathbf{F}\mathbf{F}^*\mathbf{x}, \mathbf{x}\rangle \le \|\mathbf{F}\mathbf{F}^*\mathbf{x}\|\,\|\mathbf{x}\| \le \|\mathbf{F}\|_2\|\mathbf{F}^*\mathbf{x}\|\,\|\mathbf{x}\|,$$

so $\|\mathbf{F}^*\mathbf{x}\| \le \|\mathbf{F}\|_2\|\mathbf{x}\|$ (trivially if $\mathbf{F}^*\mathbf{x} = \mathbf{0}$), and the reverse inequality follows by applying this to $\mathbf{F}^*$, since $(\mathbf{F}^*)^* = \mathbf{F}$. Now $\mathbf{S}\mathbf{S}^* - \mathbf{I} = \mathbf{F} + \mathbf{F}^* + \mathbf{F}\mathbf{F}^*$, so by the triangle inequality for $\|\cdot\|_2$, which is a norm by Theorem 15.3.2 (b), and by part (d) of the same theorem,

$$\|\mathbf{S}\mathbf{S}^* - \mathbf{I}\|_2 \le \|\mathbf{F}\|_2 + \|\mathbf{F}^*\|_2 + \|\mathbf{F}\|_2\|\mathbf{F}^*\|_2 = 2\|\mathbf{F}\|_2 + \|\mathbf{F}\|_2^2.$$

The last inequality of Theorem 19.6.3 then gives the claim.

(b) Take $\mathbf{A} = \operatorname{diag}(1, 0)$ and $\mathbf{E} = \operatorname{diag}(0, t)$ with $t > 0$. Then $\lambda_2(\mathbf{A}) = 0$ and $\lambda_2(\mathbf{A} + \mathbf{E}) = \min(1, t) > 0$, so the left side is positive while the right side is $c\,t \cdot 0 = 0$. No constant c works. By (a), such an $\mathbf{E}$ is not of the form $\mathbf{S}\mathbf{A}\mathbf{S}^* - \mathbf{A}$: congruence can never move the eigenvalue 0.

Exercise C3: Kato–Temple is sharp.

Let $\lambda_1 > \lambda_2$ be real, $\mathbf{A} = \operatorname{diag}(\lambda_1, \lambda_2)$, and $\mathbf{x} = (\cos\phi, \sin\phi)$ with $0 < \phi < \pi/2$.

(a) Compute $\mu = \mathbf{x}^*\mathbf{A}\mathbf{x}$ and show that $\varepsilon^2 = (\lambda_1 - \lambda_2)^2 \cos^2\phi\,\sin^2\phi$.

(b) Show that Theorem 19.6.2 (b), with $\lambda = \lambda_1$ and $\alpha = \lambda_2$, holds with **equality**. Hence the constant in the Kato–Temple bound cannot be improved.

Solution. Write $c = \cos\phi$, $s = \sin\phi$ and $d = \lambda_1 - \lambda_2 > 0$.

(a) $\mathbf{A}\mathbf{x} = (\lambda_1 c, \lambda_2 s)$, so $\mu = \lambda_1 c^2 + \lambda_2 s^2$. Using $c^2 + s^2 = 1$, $\lambda_1 - \mu = ds^2$ and $\lambda_2 - \mu = -dc^2$. The residual is $\mathbf{A}\mathbf{x} - \mu\mathbf{x} = \big((\lambda_1 - \mu)c, (\lambda_2 - \mu)s\big) = (ds^2 c, -dc^2 s)$, so

$$\varepsilon^2 = d^2 s^4 c^2 + d^2 c^4 s^2 = d^2 c^2 s^2 (s^2 + c^2) = d^2 c^2 s^2.$$

(b) Here $\alpha = \lambda_2 < \mu$, since $\mu - \lambda_2 = dc^2 > 0$, and no eigenvalue lies in (λ_2, λ_1). The bound reads

$$\mu + \frac{\varepsilon^2}{\mu - \lambda_2} = \mu + \frac{d^2 c^2 s^2}{dc^2} = \mu + ds^2 = \lambda_1.$$

So equality holds for every $\phi \in (0, \pi/2)$, and no smaller multiple of $\varepsilon^2/(\mu - \alpha)$ would give a valid bound.

19.7 The Sylvester Equation Revisited

Chapter 11 settled when the equation $\mathbf{A}\mathbf{X} - \mathbf{X}\mathbf{B} = \mathbf{C}$ can be solved: over $\mathbb{C}$ it has exactly one solution for every $\mathbf{C}$ if and only if $\mathbf{A}$ and $\mathbf{B}$ have no common eigenvalue (Theorem 11.10.2). It then set a question aside. "The quantitative version — *how badly* conditioned the equation is when the spectra are close but disjoint — is a separate matter, and belongs with perturbation theory in Chapter 19." Chapter 7, which first wrote the equation as a linear system, said the same thing more briefly: "its quantitative form appears in Chapter 19." This section pays both

debts. It attaches to each pair $(\mathbf{A}, \mathbf{B})$ a number that says how large a solution can be, computes it exactly for normal pairs, shows how badly it can behave otherwise, and proves a bound in the spectral norm for Hermitian pairs whose spectra sit on opposite sides of a gap.

The reason to want these bounds now is that Sections 9 and 10 need them. In Section 9 the error in a computed invariant subspace turns out to satisfy a Sylvester equation, and in Section 10 so does the error in a square root or a polar factor. Each of those three errors is measured by one of the bounds proved here, applied once.

Throughout, the field is $\mathbb{C}$, $\mathbf{A} \in M_m(\mathbb{C})$ and $\mathbf{B} \in M_n(\mathbb{C})$, and $\mathbf{X}, \mathbf{C} \in M_{m\times n}(\mathbb{C})$. We write $\mathcal{S} = \mathcal{S}_{\mathbf{A},\mathbf{B}}$ for the Sylvester operator $\mathbf{X} \mapsto \mathbf{AX} - \mathbf{XB}$ of Definition 11.10.1, and $\mathbf{K} = \mathbf{I}_n \otimes \mathbf{A} - \mathbf{B}^{\top} \otimes \mathbf{I}_m$ for its matrix, so that $\operatorname{vec}(\mathcal{S}(\mathbf{X})) = \mathbf{K} \operatorname{vec} \mathbf{X}$ by Eq. 11.10.1. The eigenvalues of $\mathbf{A}$ are $\lambda_1, \dots, \lambda_m$ and those of $\mathbf{B}$ are $\mu_1, \dots, \mu_n$, with multiplicity. Every bound names its norm: $\|\cdot\|_F$ is the Frobenius norm and $\|\cdot\|_2$ the spectral norm.

19.7.1 How large can the solution be?

Start with the smallest case, $m = n = 1$. The equation is $(a - b)x = c$, and when $a \neq b$ its solution is $x = c/(a - b)$. So the size of the answer is governed by one number, the distance $|a - b|$ between the two "spectra": the closer they are, the larger x can be for a given c.

The natural guess for larger matrices is that the distance between the two spectra, $\min_{i,j}|\lambda_i - \mu_j|$, plays the same role, so that $\|\mathbf{X}\|_F \leq \|\mathbf{C}\|_F / \min_{i,j}|\lambda_i - \mu_j|$. We will see that this guess is right for normal pairs and can be wrong by any factor otherwise. The number that really controls the solution is the smallest amount by which $\mathcal{S}$ can stretch a matrix, and it deserves a name.

The separation of $\mathbf{A}$ *and* $\mathbf{B}$ *is the least that the Sylvester operator can shrink a matrix of unit size.*

Definition 19.7.1 — Separation

Let $\mathbf{A} \in M_m(\mathbb{C})$ and $\mathbf{B} \in M_n(\mathbb{C})$. The **separation** of $\mathbf{A}$ and $\mathbf{B}$ is

$$\operatorname{sep}_F(\mathbf{A}, \mathbf{B}) \coloneqq \min\big\{ \|\mathbf{AX} - \mathbf{XB}\|_F : \mathbf{X} \in M_{m\times n}(\mathbb{C}),\ \|\mathbf{X}\|_F = 1 \big\}.$$

In words: we run over **every** matrix $\mathbf{X}$ of the right shape whose Frobenius norm is exactly 1, apply the Sylvester operator, measure the result in the Frobenius norm, and take the **smallest** value. By homogeneity, $\|\mathbf{AX} - \mathbf{XB}\|_F \geq \operatorname{sep}_F(\mathbf{A}, \mathbf{B})\|\mathbf{X}\|_F$ for **every** $\mathbf{X}$, and $\operatorname{sep}_F(\mathbf{A}, \mathbf{B})$ is the largest constant with this property. The order matters: $\operatorname{sep}_F(\mathbf{A}, \mathbf{B})$ belongs to $\mathbf{X} \mapsto \mathbf{AX} - \mathbf{XB}$, and $\operatorname{sep}_F(\mathbf{B}, \mathbf{A})$ to a different operator on a different space. The subscript F records the norm, as in $\|\cdot\|_F$.

Well-definedness. A minimum over an infinite set needs to exist, and the first part of Proposition 19.7.1 below shows that it does, without any appeal to compactness: it is the smallest singular value of $\mathbf{K}$.

Examples.

1. $m = n = 1$**.** Then $\mathbf{X} = (x)$ with $|x| = 1$, and $|ax - xb| = |a - b|$. So $\operatorname{sep}_F(a, b) = |a - b|$, the one-dimensional picture above.

2. **Equal matrices.** For square $\mathbf{A}$, $\operatorname{sep}_F(\mathbf{A}, \mathbf{A}) = 0$: the matrix $\mathbf{X} = \mathbf{I}_m/\sqrt{m}$ has $\|\mathbf{X}\|_F = 1$ and $\mathbf{AX} - \mathbf{XA} = \mathbf{0}$. This degenerate case matters because it is the extreme of a shared eigenvalue, and the first property below says that any shared eigenvalue forces the separation to 0.
3. **Diagonal matrices.** If $\mathbf{A} = \operatorname{diag}(\lambda_1, \dots, \lambda_m)$ and $\mathbf{B} = \operatorname{diag}(\mu_1, \dots, \mu_n)$, then $(\mathbf{AX} - \mathbf{XB})_{ij} = (\lambda_i - \mu_j)x_{ij}$, so $\mathcal{S}$ multiplies each entry by its own factor. The smallest stretch is the smallest factor in modulus, and $\operatorname{sep}_F(\mathbf{A}, \mathbf{B}) = \min_{i,j}|\lambda_i - \mu_j|$. The proof of Theorem 19.7.2 below writes this out.

Non-example by minimal change. Drop the normalization and take $\min\{\|\mathbf{AX} - \mathbf{XB}\|_F : \mathbf{X} \neq \mathbf{0}\}$ instead. The set of values is still non-empty and bounded below, but its infimum is 0 for every pair, and when the spectra are disjoint it is never attained: replacing $\mathbf{X}$ by $t\mathbf{X}$ multiplies the value by t, and t can be as small as we like, while the value 0 is taken at some $\mathbf{X} \neq \mathbf{0}$ exactly when the two spectra meet (Theorem 11.10.2), as they do in the second example above, where $\mathbf{A} = \mathbf{B}$ and $\mathbf{X} = \mathbf{I}_m$. It is exactly the clause $\|\mathbf{X}\|_F = 1$ that fails, and it is what turns a meaningless infimum into a measurement of the operator.

Why the Frobenius norm. Vectorization lists the entries of $\mathbf{X}$ in one column, so $\|\operatorname{vec}\mathbf{X}\|_2 = \|\mathbf{X}\|_F$: vec is an isometry from $(M_{m\times n}(\mathbb{C}), \|\cdot\|_F)$ to $(\mathbb{C}^{mn}, \|\cdot\|_2)$. That turns sep_F into a question about the ordinary matrix $\mathbf{K}$, which the singular value decomposition answers. With $\|\cdot\|_2$ on both sides the minimum is also a sensible quantity, but it has no such formula, and we will not need it: the spectral-norm results below go through a different argument.

> *Warning.* **The separation is not the distance between the spectra.** It is at most that distance, by part (c) of the proposition below, but it can be far smaller. For $\mathbf{A} = \begin{pmatrix} 1 & t \\ 0 & 1 \end{pmatrix}$ and the 1×1 matrix $\mathbf{B} = (0)$, the spectra $\{1\}$ and $\{0\}$ are at distance 1 for every t, yet $\operatorname{sep}_F(\mathbf{A}, \mathbf{B}) < 1/t$ for $t > 0$ (Example (Separation Far Below the Gap)). Whenever $\mathbf{A}$ or $\mathbf{B}$ is not normal, compute the separation; do not read it off the eigenvalues.

Everything we need about the separation is collected in one proposition.

Proposition 19.7.1 — Properties of the Separation

Let $\mathbf{A} \in M_m(\mathbb{C})$, $\mathbf{B} \in M_n(\mathbb{C})$, and $\mathbf{K} = \mathbf{I}_n \otimes \mathbf{A} - \mathbf{B}^{\top} \otimes \mathbf{I}_m$.

(a) The minimum defining $\operatorname{sep}_F(\mathbf{A}, \mathbf{B})$ exists, and $\operatorname{sep}_F(\mathbf{A}, \mathbf{B}) = \sigma_{mn}(\mathbf{K})$, the smallest singular value of $\mathbf{K}$.

(b) $\operatorname{sep}_F(\mathbf{A}, \mathbf{B}) > 0$ if and only if $\operatorname{spec}(\mathbf{A}) \cap \operatorname{spec}(\mathbf{B}) = \varnothing$.

(c) $\operatorname{sep}_F(\mathbf{A}, \mathbf{B}) \leq \min_{i,j}|\lambda_i - \mu_j|$.

(d) If $\operatorname{spec}(\mathbf{A}) \cap \operatorname{spec}(\mathbf{B}) = \varnothing$, then for every $\mathbf{C}$ the unique solution of $\mathbf{AX} - \mathbf{XB} = \mathbf{C}$ satisfies

$$\|\mathbf{X}\|_F \leq \frac{\|\mathbf{C}\|_F}{\operatorname{sep}_F(\mathbf{A}, \mathbf{B})},$$

and equality holds for some $\mathbf{C} \neq \mathbf{0}$.

(e) For unitary $\mathbf{U} \in \mathrm{U}(m)$ and $\mathbf{V} \in \mathrm{U}(n)$, $\operatorname{sep}_F(\mathbf{U}^*\mathbf{AU}, \mathbf{V}^*\mathbf{BV}) = \operatorname{sep}_F(\mathbf{A}, \mathbf{B})$.

(f) If $n = 1$ and $\mathbf{B} = (\mu)$, then $\operatorname{sep}_F(\mathbf{A}, \mathbf{B}) = \sigma_m(\mathbf{A} - \mu\mathbf{I}_m)$, the smallest singular value of $\mathbf{A} - \mu\mathbf{I}_m$.

Idea. Part (a) is the isometry vec plus the fact that the smallest stretch of a square matrix is its smallest singular value. Part (b) is Sylvester's theorem, read through (a). Part (c) needs one good test matrix: an eigenvector of $\mathbf{A}$ times a left eigenvector of $\mathbf{B}$ is multiplied by $\lambda - \mu$ under $\mathcal{S}$, exactly as in the 1×1 case. Part (d) is the definition read backwards. Part (e) holds because unitary factors change neither the set of unit matrices nor the Frobenius norm. Part (f) is the case $n = 1$ of (a), where $\mathbf{K}$ is nothing but $\mathbf{A} - \mu\mathbf{I}_m$.

Proof.

(a) Let $\mathbf{X} \in M_{m\times n}(\mathbb{C})$ and $\mathbf{x} = \operatorname{vec}\mathbf{X}$. The entries of $\mathbf{x}$ are those of $\mathbf{X}$, so $\|\mathbf{x}\|_2 = \|\mathbf{X}\|_F$, and likewise $\|\mathbf{AX} - \mathbf{XB}\|_F = \|\mathbf{Kx}\|_2$ by Eq. 11.10.1. Since vec is a bijection from $M_{m\times n}(\mathbb{C})$ onto $\mathbb{C}^{mn}$ (Definition 7.4.2), the set whose minimum defines $\operatorname{sep}_F(\mathbf{A}, \mathbf{B})$ equals $\{\|\mathbf{Kx}\|_2 : \|\mathbf{x}\|_2 = 1\}$. By Lemma 16.9.1 (b) with k equal to the size mn of $\mathbf{K}$, the head subspace is all of $\mathbb{C}^{mn}$, and the minimum of $\|\mathbf{Kx}\|/\|\mathbf{x}\|$ over $\mathbf{x} \neq \mathbf{0}$ exists and equals $\sigma_{mn}(\mathbf{K})$. Restricting to unit vectors changes nothing, since the quotient is unchanged when $\mathbf{x}$ is scaled.

(b) By Theorem 12.8.1, the number of non-zero singular values of $\mathbf{K}$ is $\operatorname{rank}\mathbf{K}$. Since $\sigma_{mn}(\mathbf{K})$ is the smallest, it is non-zero exactly when all mn of them are, that is, when $\operatorname{rank}\mathbf{K} = mn$, which says that $\mathbf{K}$ is invertible (Theorem 2.4.4). By Eq. 11.10.1, $\mathbf{K}$ is invertible exactly when $\mathcal{S}$ is, and by Theorem 11.10.2 ((a) $\Leftrightarrow$ (b)) that happens exactly when $\operatorname{spec}(\mathbf{A}) \cap \operatorname{spec}(\mathbf{B}) = \varnothing$. Combining with (a) proves (b).

(c) Fix i, j. Choose an eigenvector $\mathbf{x}$ of $\mathbf{A}$ for λ_i, and, by Proposition 8.10.5 (b), a left eigenvector $\mathbf{y}$ of $\mathbf{B}$ for μ_j, so that $\mathbf{y}^\top\mathbf{B} = \mu_j\mathbf{y}^\top$ (Definition 8.10.1). Scale both to length 1, and put $\mathbf{X} = \mathbf{x}\mathbf{y}^\top$. Its (p, q) entry is $x_p y_q$, so

$$\|\mathbf{X}\|_F^2 = \sum_{p,q} |x_p|^2 |y_q|^2 = \|\mathbf{x}\|^2 \|\mathbf{y}\|^2 = 1.$$

By associativity, $\mathbf{AX}-\mathbf{XB} = (\mathbf{Ax})\mathbf{y}^\top - \mathbf{x}(\mathbf{y}^\top\mathbf{B}) = (\lambda_i - \mu_j)\mathbf{X}$. Hence $\operatorname{sep}_F(\mathbf{A}, \mathbf{B}) \leq \|(\lambda_i - \mu_j)\mathbf{X}\|_F = |\lambda_i - \mu_j|$. This holds for every pair (i, j), so it holds for the minimum.

(d) By Theorem 11.10.2 the solution $\mathbf{X}$ exists and is unique. If $\mathbf{X} = \mathbf{0}$ there is nothing to prove. Otherwise $\mathbf{X}/\|\mathbf{X}\|_F$ has Frobenius norm 1, so by Definition 19.7.1

$$\operatorname{sep}_F(\mathbf{A}, \mathbf{B}) \leq \frac{\|\mathbf{AX} - \mathbf{XB}\|_F}{\|\mathbf{X}\|_F} = \frac{\|\mathbf{C}\|_F}{\|\mathbf{X}\|_F},$$

and $\operatorname{sep}_F(\mathbf{A}, \mathbf{B}) > 0$ by (b), so we may rearrange. For equality, take $\mathbf{X}_0$ with $\|\mathbf{X}_0\|_F = 1$ attaining the minimum, which exists by (a), and put $\mathbf{C} = \mathbf{AX}_0 - \mathbf{X}_0\mathbf{B}$. Then $\mathbf{C} \neq \mathbf{0}$, because $\|\mathbf{C}\|_F = \operatorname{sep}_F(\mathbf{A}, \mathbf{B}) > 0$, and the unique solution is $\mathbf{X}_0$, for which the two sides are both 1.

(e) Put $\mathbf{A}' = \mathbf{U}^*\mathbf{AU}$ and $\mathbf{B}' = \mathbf{V}^*\mathbf{BV}$. For every $\mathbf{X}$,

$$\mathbf{A}'(\mathbf{U}^*\mathbf{XV}) - (\mathbf{U}^*\mathbf{XV})\mathbf{B}' = \mathbf{U}^*(\mathbf{AX} - \mathbf{XB})\mathbf{V},$$

because $\mathbf{UU}^* = \mathbf{I}_m$ and $\mathbf{VV}^* = \mathbf{I}_n$. By Lemma 11.11.1, $\|\mathbf{U}^*\mathbf{XV}\|_F = \|\mathbf{X}\|_F$ and the right side has Frobenius norm $\|\mathbf{AX} - \mathbf{XB}\|_F$. The map $\mathbf{X} \mapsto \mathbf{U}^*\mathbf{XV}$ is a bijection of $M_{m\times n}(\mathbb{C})$, with inverse $\mathbf{Y} \mapsto \mathbf{UYV}^*$, so it carries the matrices of Frobenius norm 1 onto themselves. Hence the two minima are taken over the same set of values, and they are equal.

(f) With $n = 1$ and $\mathbf{B} = (\mu)$, the Kronecker matrix is $\mathbf{K} = \mathbf{I}_1 \otimes \mathbf{A} - (\mu) \otimes \mathbf{I}_m = \mathbf{A} - \mu \mathbf{I}_m$, of size $mn = m$. So (a) gives $\operatorname{sep}_F(\mathbf{A}, \mathbf{B}) = \sigma_m(\mathbf{A} - \mu \mathbf{I}_m)$.

■

Part (d) is the quantitative form that Chapter 7 and Chapter 11 promised, and it says more than an inequality. The number $1/\operatorname{sep}_F(\mathbf{A}, \mathbf{B})$ is **exactly** the largest factor by which solving the equation can magnify the data, measured in the Frobenius norm. Since $\mathcal{S}$ is linear, it is also the factor for errors: if $\mathbf{C}$ is replaced by $\mathbf{C} + \Delta\mathbf{C}$, the solution moves by $\mathcal{S}^{-1}(\Delta\mathbf{C})$, whose norm is at most $\|\Delta\mathbf{C}\|_F / \operatorname{sep}_F(\mathbf{A}, \mathbf{B})$, and some $\Delta\mathbf{C}$ achieves this. A small separation is the precise meaning of "badly conditioned". Part (c) says that close spectra always make the separation small. The rest of the section asks whether the converse holds, that is, whether well-separated spectra make it large.

Quick check. Part (f) of Proposition 19.7.1 was read off the Kronecker matrix. Prove it instead straight from Definition 19.7.1, without vectorizing: for $\mathbf{B} = (\mu)$, unwind what the matrices $\mathbf{X}$ of Frobenius norm 1 are.

Solution. Here $n = 1$, so $\mathbf{X} = \mathbf{x}$ is a column in $\mathbb{C}^m$ with $\|\mathbf{x}\|_F = \|\mathbf{x}\|$, and $\mathbf{A}\mathbf{x} - \mathbf{x}\mu = (\mathbf{A} - \mu \mathbf{I}_m)\mathbf{x}$. So $\operatorname{sep}_F(\mathbf{A}, \mathbf{B}) = \min_{\|\mathbf{x}\|=1} \|(\mathbf{A} - \mu \mathbf{I}_m)\mathbf{x}\|$, which is $\sigma_m(\mathbf{A} - \mu \mathbf{I}_m)$ by Lemma 16.9.1 (b) with $k = m$.

19.7.2 Normal pairs: the separation is the gap

For normal matrices the naive guess is right, and the proof is the diagonal example written out.

Theorem 19.7.2 — Separation of Normal Matrices

Let $\mathbf{A} \in M_m(\mathbb{C})$ and $\mathbf{B} \in M_n(\mathbb{C})$ be **normal**, with eigenvalues $\lambda_1, \dots, \lambda_m$ and $\mu_1, \dots, \mu_n$. Then

$$\operatorname{sep}_F(\mathbf{A}, \mathbf{B}) = \min_{i,j} |\lambda_i - \mu_j|.$$

Consequently, if $\delta = \min_{i,j} |\lambda_i - \mu_j| > 0$, the unique solution of $\mathbf{A}\mathbf{X} - \mathbf{X}\mathbf{B} = \mathbf{C}$ satisfies $\|\mathbf{X}\|_F \le \|\mathbf{C}\|_F / \delta$.

Idea. Unitary diagonalization costs nothing in the Frobenius norm, by Proposition 19.7.1 (e). Once both matrices are diagonal, the operator scales the (i, j) entry by $\lambda_i - \mu_j$, so the total shrinkage is a weighted average of the $|\lambda_i - \mu_j|^2$, and a weighted average is at least the smallest weight.

Proof. By Corollary 11.4.3 there are unitary $\mathbf{U} \in \mathrm{U}(m)$ and $\mathbf{V} \in \mathrm{U}(n)$ with $\mathbf{U}^* \mathbf{A} \mathbf{U} = \mathbf{\Lambda} := \operatorname{diag}(\lambda_1, \dots, \lambda_m)$ and $\mathbf{V}^* \mathbf{B} \mathbf{V} = \mathbf{M} := \operatorname{diag}(\mu_1, \dots, \mu_n)$. By Proposition 19.7.1 (e), $\operatorname{sep}_F(\mathbf{A}, \mathbf{B}) = \operatorname{sep}_F(\mathbf{\Lambda}, \mathbf{M})$.

Let $\mathbf{X} = (x_{ij})$ have $\|\mathbf{X}\|_F = 1$, and put $\delta = \min_{i,j} |\lambda_i - \mu_j|$. The (i, j) entry of $\mathbf{\Lambda}\mathbf{X} - \mathbf{X}\mathbf{M}$ is $\lambda_i x_{ij} - x_{ij} \mu_j = (\lambda_i - \mu_j) x_{ij}$, since multiplying by a diagonal matrix on the left scales

rows and on the right scales columns. Hence

$$\begin{aligned}\|\mathbf{\Lambda X} - \mathbf{XM}\|_F^2 &= \sum_{i,j} |\lambda_i - \mu_j|^2 |x_{ij}|^2 \\ &\geq \delta^2 \sum_{i,j} |x_{ij}|^2 = \delta^2.\end{aligned}$$

Therefore $\operatorname{sep}_F(\mathbf{\Lambda}, \mathbf{M}) \geq \delta$. The reverse inequality is Proposition 19.7.1 (c). This proves the equality, and the bound on $\mathbf{X}$ is then Proposition 19.7.1 (d).

■

The theorem answers the question of the opening completely in the normal case: there, how badly conditioned the equation is depends on the spectra and on nothing else. In particular it applies to Hermitian pairs, which is the case Section 9 needs.

Example. (A Normal Pair)

Let

$$\mathbf{A} = \begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix}, \qquad \mathbf{B} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}.$$

Compute $\operatorname{sep}_F(\mathbf{A}, \mathbf{B})$ in two ways: from Theorem 19.7.2, and from the singular values of $\mathbf{K}$.

Solution. The matrix $\mathbf{A}$ is real symmetric, hence normal, with $p_{\mathbf{A}}(x) = (x-2)^2 - 1 = (x-1)(x-3)$, so its eigenvalues are $1, 3$. The matrix $\mathbf{B}$ is real with $\mathbf{B}^\top \mathbf{B} = \mathbf{I}_2 = \mathbf{B}\mathbf{B}^\top$, hence normal, and $p_{\mathbf{B}}(x) = x^2 + 1$, so its eigenvalues are $\pm i$. The four distances are

$$|1 \mp i| = \sqrt{2}, \qquad |3 \mp i| = \sqrt{10},$$

so Theorem 19.7.2 gives $\operatorname{sep}_F(\mathbf{A}, \mathbf{B}) = \sqrt{2}$.

For the second computation, $\mathbf{B}^\top = \left(\begin{smallmatrix} 0 & 1 \\ -1 & 0 \end{smallmatrix}\right)$, and by Definition 7.4.1, in 2×2 blocks,

$$\mathbf{K} = \mathbf{I}_2 \otimes \mathbf{A} - \mathbf{B}^\top \otimes \mathbf{I}_2 = \begin{pmatrix} \mathbf{A} & -\mathbf{I}_2 \\ \mathbf{I}_2 & \mathbf{A} \end{pmatrix}.$$

Since $\mathbf{K}$ is real, $\mathbf{K}^* = \mathbf{K}^\top$, so the singular values of $\mathbf{K}$ are the non-negative square roots of the eigenvalues of $\mathbf{K}^\top \mathbf{K}$ (Definition 12.8.1). Since $\mathbf{A}$ is real symmetric, block multiplication (Theorem 7.1.1) gives

$$\begin{aligned}\mathbf{K}^\top \mathbf{K} &= \begin{pmatrix} \mathbf{A} & \mathbf{I}_2 \\ -\mathbf{I}_2 & \mathbf{A} \end{pmatrix} \begin{pmatrix} \mathbf{A} & -\mathbf{I}_2 \\ \mathbf{I}_2 & \mathbf{A} \end{pmatrix} \\ &= \begin{pmatrix} \mathbf{A}^2 + \mathbf{I}_2 & \mathbf{0} \\ \mathbf{0} & \mathbf{A}^2 + \mathbf{I}_2 \end{pmatrix}.\end{aligned}$$

The eigenvalues of $\mathbf{A}^2 + \mathbf{I}_2$ are $1^2 + 1 = 2$ and $3^2 + 1 = 10$ (Theorem 8.10.1), so the singular values of $\mathbf{K}$ are $\sqrt{10}, \sqrt{10}, \sqrt{2}, \sqrt{2}$. The smallest is $\sqrt{2}$, in agreement with Proposition 19.7.1 (a).

19.7.3 Non-normal pairs: the separation can collapse

For a non-normal pair the inequality of Proposition 19.7.1 (c) can be strict, and by as large a factor as we please. The smallest example uses a 1×1 matrix $\mathbf{B}$, so that Proposition 19.7.1 (f) computes the separation.

Example. (Separation Far Below the Gap)

For a real number $t \geq 0$, let

$$\mathbf{A} = \begin{pmatrix} 1 & t \\ 0 & 1 \end{pmatrix}, \qquad \mathbf{B} = (0).$$

Compute $\operatorname{sep}_F(\mathbf{A}, \mathbf{B})$ and compare it with the distance between the spectra. Then, for $t = 99/10$, solve $\mathbf{AX} - \mathbf{XB} = \mathbf{C}$ with $\mathbf{C} = \mathbf{e}_2$ and compare the size of the solution with the guess $\|\mathbf{C}\|_F / \min|\lambda_i - \mu_j|$.

Solution. The spectra are $\operatorname{spec}(\mathbf{A}) = \{1\}$ (triangular, Theorem 8.7.4) and $\operatorname{spec}(\mathbf{B}) = \{0\}$, at distance 1 for every t. By Proposition 19.7.1 (f) with $\mu = 0$, $\operatorname{sep}_F(\mathbf{A}, \mathbf{B}) = \sigma_2(\mathbf{A})$, the square root of the smaller eigenvalue of

$$\mathbf{A}^{\top}\mathbf{A} = \begin{pmatrix} 1 & t \\ t & 1 + t^2 \end{pmatrix}.$$

Its characteristic polynomial is $(z - 1)(z - 1 - t^2) - t^2 = z^2 - (2 + t^2)z + 1$. Both roots are positive and their product is 1, so the smaller is the reciprocal of the larger, $\sigma_2(\mathbf{A}) = 1/\sigma_1(\mathbf{A})$. Solving the quadratic,

$$\sigma_2(\mathbf{A})^2 = \frac{2 + t^2 - t\sqrt{t^2 + 4}}{2} = \left(\frac{\sqrt{t^2 + 4} - t}{2}\right)^2,$$

as expanding the square confirms. Hence

$$\operatorname{sep}_F(\mathbf{A}, \mathbf{B}) = \frac{\sqrt{t^2 + 4} - t}{2} = \frac{2}{\sqrt{t^2 + 4} + t},$$

where the second form multiplies top and bottom by $\sqrt{t^2 + 4} + t$. The second form is less than $2/(2t) = 1/t$ for $t > 0$, because $\sqrt{t^2 + 4} > t$. The spectra stay at distance 1, and the separation tends to 0 as $t \to \infty$.

For $t = 99/10$ we have $t^2 + 4 = 10201/100$, whose square root is $101/10$, so

$$\operatorname{sep}_F(\mathbf{A}, \mathbf{B}) = \frac{1}{2}\left(\frac{101}{10} - \frac{99}{10}\right) = \frac{1}{10}.$$

The equation is $\mathbf{Ax} = \mathbf{e}_2$ for the column $\mathbf{x} = \mathbf{X}$, so $\mathbf{x} = \mathbf{A}^{-1}\mathbf{e}_2 = (-t, 1)$, since $\mathbf{A}^{-1} = \left(\begin{smallmatrix} 1 & -t \\ 0 & 1 \end{smallmatrix}\right)$. Its length is $\sqrt{t^2 + 1} = \sqrt{9901}/10 \approx 9.95$. The guess from the eigenvalues was $\|\mathbf{C}\|_F/1 = 1$, wrong by a factor of almost 10. The true bound $\|\mathbf{C}\|_F / \operatorname{sep}_F(\mathbf{A}, \mathbf{B}) = 10$ from Proposition 19.7.1 (d) is almost attained, and it is attained when $\mathbf{C}$ is a unit left singular vector of $\mathbf{A}$ for σ_2.

The example has a second reading. The eigenvalue 1 of $\mathbf{A}$ is far from 0, yet a perturbation of $\mathbf{A}$ of size $\operatorname{sep}_F(\mathbf{A},\mathbf{B}) = 1/10$ in the spectral norm makes 0 an eigenvalue, because that is how far $\mathbf{A}$ is from the singular matrices (Corollary 16.9.7). Exercise C1 below shows that, for every pair, no perturbation of spectral norm less than $\operatorname{sep}_F(\mathbf{A},\mathbf{B})$ can create a common eigenvalue, and that when $\mathbf{B}$ is 1×1 one of exactly that size can. For a non-normal pair, the distance between the spectra measures the wrong thing, and the separation measures the right one.

19.7.4 A one-sided bound in the spectral norm

Section 9 will measure the angle between two invariant subspaces, and the largest such angle is a spectral norm, not a Frobenius norm. For Hermitian pairs, Theorem 19.7.2 already gives $\|\mathbf{X}\|_F \le \|\mathbf{C}\|_F/\delta$. The spectral-norm analogue with the same constant is **false** in general: Exercise C2 below exhibits real diagonal $\mathbf{A}$ and $\mathbf{B}$ whose spectra interlace at distance 1, yet $\|\mathbf{X}\|_2 > \|\mathbf{C}\|_2$. What rescues the spectral norm is a stronger hypothesis on where the spectra lie: all of $\operatorname{spec}(\mathbf{A})$ on one side of a gap and all of $\operatorname{spec}(\mathbf{B})$ on the other.

Theorem 19.7.3 — One-Sided Sylvester Bound

Let $\mathbf{A}\in M_m(\mathbb{C})$ and $\mathbf{B}\in M_n(\mathbb{C})$ be Hermitian, and let $\alpha>\beta$ be real numbers with

$$\mathbf{A}\succeq \alpha\mathbf{I}_m, \qquad \mathbf{B}\preceq \beta\mathbf{I}_n.$$

Then for every $\mathbf{C}\in M_{m\times n}(\mathbb{C})$ the equation $\mathbf{AX}-\mathbf{XB}=\mathbf{C}$ has exactly one solution, and it satisfies

$$\|\mathbf{X}\|_2 \le \frac{\|\mathbf{C}\|_2}{\alpha-\beta}, \qquad \|\mathbf{X}\|_F \le \frac{\|\mathbf{C}\|_F}{\alpha-\beta}.$$

Idea. The **singular-pair trick.** A single pair of vectors sees the whole spectral norm of $\mathbf{X}$: by the singular value decomposition there are unit vectors $\mathbf{u},\mathbf{v}$ with $\mathbf{Xv}=s\mathbf{u}$ and $\mathbf{X}^*\mathbf{u}=s\mathbf{v}$, where $s=\|\mathbf{X}\|_2$. Sandwich the equation between them. The left side becomes $\mathbf{u}^*\mathbf{AXv}-\mathbf{u}^*\mathbf{XBv}=s(\mathbf{u}^*\mathbf{Au}-\mathbf{v}^*\mathbf{Bv})$, a real number at least $s(\alpha-\beta)$ because of the two one-sided hypotheses. The right side becomes $\mathbf{u}^*\mathbf{Cv}$, which is at most $\|\mathbf{C}\|_2$ in modulus. The one-sided hypotheses are used exactly once, to make both quadratic forms pull in the same direction.

Proof. **Existence and uniqueness.** Let $\lambda\in\operatorname{spec}(\mathbf{A})$ with unit eigenvector $\mathbf{x}$. Then $\lambda=\langle\mathbf{Ax},\mathbf{x}\rangle\ge\alpha$, because $\langle(\mathbf{A}-\alpha\mathbf{I}_m)\mathbf{x},\mathbf{x}\rangle\ge 0$ by Definition 12.1.1 and Definition 12.5.1. Likewise every $\mu\in\operatorname{spec}(\mathbf{B})$ satisfies $\mu\le\beta<\alpha$. So $\operatorname{spec}(\mathbf{A})\cap\operatorname{spec}(\mathbf{B})=\varnothing$, and Theorem 11.10.2 gives exactly one solution $\mathbf{X}$.

The spectral norm. Put $s=\|\mathbf{X}\|_2$, which equals $\sigma_1(\mathbf{X})$ by Theorem 15.3.3 (c). If $s=0$ there is nothing to prove. Otherwise $\mathbf{X}$ has rank at least 1, and Theorem 12.8.1 with Eq. 12.8.3 (for $i=1$) gives unit vectors $\mathbf{u}\in\mathbb{C}^m$ and $\mathbf{v}\in\mathbb{C}^n$ with

$$\mathbf{Xv}=s\mathbf{u}, \qquad \mathbf{X}^*\mathbf{u}=s\mathbf{v}. \tag{19.7.1}$$

Taking adjoints in the second, $\mathbf{u}^*\mathbf{X}=s\mathbf{v}^*$. Multiply $\mathbf{AX}-\mathbf{XB}=\mathbf{C}$ by $\mathbf{u}^*$ on the left

and $\mathbf{v}$ on the right:

$$\begin{aligned}\mathbf{u}^{*}\mathbf{C}\mathbf{v} &= \mathbf{u}^{*}\mathbf{A}(\mathbf{X}\mathbf{v}) - (\mathbf{u}^{*}\mathbf{X})\mathbf{B}\mathbf{v} \\ &= s\,\mathbf{u}^{*}\mathbf{A}\mathbf{u} - s\,\mathbf{v}^{*}\mathbf{B}\mathbf{v}.\end{aligned}$$

Since $\mathbf{A} - \alpha\mathbf{I}_m \succeq 0$ and $\mathbf{u}$ is a unit vector, $\mathbf{u}^{*}\mathbf{A}\mathbf{u} - \alpha = \langle(\mathbf{A} - \alpha\mathbf{I}_m)\mathbf{u}, \mathbf{u}\rangle \geq 0$. Since $\beta\mathbf{I}_n - \mathbf{B} \succeq 0$, likewise $\mathbf{v}^{*}\mathbf{B}\mathbf{v} \leq \beta$. Hence $\mathbf{u}^{*}\mathbf{C}\mathbf{v}$ is real and

$$\mathbf{u}^{*}\mathbf{C}\mathbf{v} \geq s(\alpha - \beta).$$

On the other hand, by the Cauchy–Schwarz inequality (Theorem 10.1.5) and Theorem 15.3.2 (a),

$$|\mathbf{u}^{*}\mathbf{C}\mathbf{v}| \leq \|\mathbf{u}\|\,\|\mathbf{C}\mathbf{v}\| \leq \|\mathbf{C}\|_2.$$

Combining, $s(\alpha - \beta) \leq \|\mathbf{C}\|_2$, and dividing by $\alpha - \beta > 0$ gives the first bound.

The Frobenius norm. Hermitian matrices are normal. Every $\lambda_i \geq \alpha$ and every $\mu_j \leq \beta$, as shown above, so $\lambda_i - \mu_j \geq \alpha - \beta$ for all i, j. By Theorem 19.7.2, $\operatorname{sep}_F(\mathbf{A}, \mathbf{B}) = \min_{i,j}(\lambda_i - \mu_j) \geq \alpha - \beta$, and Proposition 19.7.1 (d) gives $\|\mathbf{X}\|_F \leq \|\mathbf{C}\|_F / \operatorname{sep}_F(\mathbf{A}, \mathbf{B}) \leq \|\mathbf{C}\|_F/(\alpha - \beta)$. This proves the theorem.

■

The trick deserves its name because it is portable. Whenever a matrix $\mathbf{X}$ satisfies a linear equation and one wants $\|\mathbf{X}\|_2$, take a top singular pair of $\mathbf{X}$ itself and test the equation against it. The spectral norm is then attained on the test, and the rest is a pair of scalar inequalities. Notice what was **not** used: the size of the gap between individual eigenvalues. Only the two half-lines $[\alpha, \infty)$ and $(-\infty, \beta]$ matter, which is why the bound survives when $\mathbf{A}$ and $\mathbf{B}$ have many eigenvalues each.

Remark. The one-sided hypothesis does real work in the spectral-norm bound, as Exercise C2 shows. When the spectra of two Hermitian matrices are merely at distance δ, in any interlaced pattern, the spectral-norm bound does hold with a larger constant: $\|\mathbf{X}\|_2 \leq (\pi/2)\|\mathbf{C}\|_2/\delta$, and $\pi/2$ cannot be improved. We do not prove this, and nothing in the book depends on it.

The form of the theorem used most often has a plus sign and two positive definite matrices. It is a direct translation.

Corollary 19.7.4 — Sylvester Bound for Positive Matrices

Let $\mathbf{S} \in M_m(\mathbb{C})$ and $\mathbf{T} \in M_n(\mathbb{C})$ be Hermitian with $\mathbf{S} \succeq \alpha\mathbf{I}_m$ and $\mathbf{T} \succeq \beta\mathbf{I}_n$, where $\alpha + \beta > 0$. Then for every $\mathbf{C} \in M_{m\times n}(\mathbb{C})$ the equation

$$\mathbf{S}\mathbf{X} + \mathbf{X}\mathbf{T} = \mathbf{C}$$

has exactly one solution, and it satisfies

$$\|\mathbf{X}\|_2 \leq \frac{\|\mathbf{C}\|_2}{\alpha + \beta}, \qquad \|\mathbf{X}\|_F \leq \frac{\|\mathbf{C}\|_F}{\alpha + \beta}.$$

Proof. The equation reads $\mathbf{S}\mathbf{X} - \mathbf{X}(-\mathbf{T}) = \mathbf{C}$. The matrix $-\mathbf{T}$ is Hermitian, and $-\beta\mathbf{I}_n - (-\mathbf{T}) = \mathbf{T} - \beta\mathbf{I}_n \succeq 0$, so $-\mathbf{T} \preceq -\beta\mathbf{I}_n$. Since $\alpha > -\beta$, Theorem 19.7.3 applies to the pair $(\mathbf{S}, -\mathbf{T})$ with the numbers α and $-\beta$, and $\alpha - (-\beta) = \alpha + \beta$.

■

The hypothesis is weaker than it looks: α or β may be negative, provided their sum is positive. The typical case is $\mathbf{S}, \mathbf{T} \succ 0$ with $\alpha = \lambda_m(\mathbf{S})$ and $\beta = \lambda_n(\mathbf{T})$, the smallest eigenvalues, which are the best constants because $\mathbf{S} \succeq \lambda_m(\mathbf{S})\mathbf{I}_m$ (Lemma 12.5.2). Section 10 applies the corollary twice in this form, once with $\mathbf{S}$ and $\mathbf{T}$ the square roots of two positive definite matrices and once with them the positive factors of two polar decompositions.

Example. (The Bound Can Be Attained)

Let $\mathbf{S} = \begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix}$, $\mathbf{T} = (1)$ and $\mathbf{C} = \begin{pmatrix} 4 \\ -4 \end{pmatrix}$. Solve $\mathbf{SX} + \mathbf{XT} = \mathbf{C}$ and compare with Corollary 19.7.4.

Solution. The eigenvalues of $\mathbf{S}$ are 1 and 3 (as for $\mathbf{A}$ in Example (A Normal Pair)), so $\mathbf{S} \succeq 1 \cdot \mathbf{I}_2$ by Lemma 12.5.2, and $\mathbf{T} \succeq 1$. The corollary applies with $\alpha = \beta = 1$ and predicts $\|\mathbf{X}\|_2 \le \|\mathbf{C}\|_2/2$.

Here $\mathbf{X} = \mathbf{x}$ is a column and the equation is $(\mathbf{S} + \mathbf{I}_2)\mathbf{x} = \mathbf{C}$, with

$$\mathbf{S} + \mathbf{I}_2 = \begin{pmatrix} 3 & 1 \\ 1 & 3 \end{pmatrix}, \qquad (\mathbf{S} + \mathbf{I}_2)^{-1} = \frac{1}{8}\begin{pmatrix} 3 & -1 \\ -1 & 3 \end{pmatrix}.$$

So $\mathbf{x} = \frac{1}{8}(12 + 4, -4 - 12) = (2, -2)$. For a column, the spectral and Frobenius norms are both the Euclidean length, so $\|\mathbf{X}\|_2 = 2\sqrt{2}$, while $\|\mathbf{C}\|_2/2 = 4\sqrt{2}/2 = 2\sqrt{2}$. The bound is an equality.

The reason is visible: $\mathbf{C}$ is an eigenvector of $\mathbf{S}$ for its smallest eigenvalue 1, so $(\mathbf{S}+\mathbf{I}_2)\mathbf{C} = 2\mathbf{C}$, and the solution is $\mathbf{x} = \mathbf{C}/2$, of norm exactly $\|\mathbf{C}\|_2/(\alpha + \beta)$. The data sits where both one-sided hypotheses are tight.

19.7.5 Exercises

19.7.5.1 A. Check your understanding

Exercise A1.

(a) Define $\mathrm{sep}_F(\mathbf{A}, \mathbf{B})$ for $\mathbf{A} \in M_m(\mathbb{C})$ and $\mathbf{B} \in M_n(\mathbb{C})$, and state how it is computed from the Kronecker matrix $\mathbf{K}$.

(b) True or false: $\mathrm{sep}_F(\mathbf{A}, \mathbf{B}) = \min_{i,j}|\lambda_i - \mu_j|$ for all square $\mathbf{A}, \mathbf{B}$. Justify your answer.

(c) True or false: $\mathrm{sep}_F(\mathbf{A} + c\mathbf{I}_m, \mathbf{B} + c\mathbf{I}_n) = \mathrm{sep}_F(\mathbf{A}, \mathbf{B})$ for every $c \in \mathbb{C}$. Justify your answer.

(d) State the bound on the solution of $\mathbf{AX} - \mathbf{XB} = \mathbf{C}$ in terms of the separation, including its hypothesis.

(e) In the proof of Theorem 19.7.3, which vectors are the equation multiplied by, and where are the hypotheses $\mathbf{A} \succeq \alpha\mathbf{I}_m$ and $\mathbf{B} \preceq \beta\mathbf{I}_n$ used?

Solution.

(a) $\operatorname{sep}_F(\mathbf{A},\mathbf{B}) = \min\{\|\mathbf{AX}-\mathbf{XB}\|_F : \|\mathbf{X}\|_F = 1\}$, the minimum over $\mathbf{X} \in M_{m\times n}(\mathbb{C})$ (Definition 19.7.1). It equals $\sigma_{mn}(\mathbf{K})$, the smallest singular value of $\mathbf{K} = \mathbf{I}_n \otimes \mathbf{A} - \mathbf{B}^\top \otimes \mathbf{I}_m$ (Proposition 19.7.1 (a)).

(b) False. It is true for normal pairs (Theorem 19.7.2), but Example (Separation Far Below the Gap) has spectra at distance 1 and separation $1/10$ when $t = 99/10$. What is always true is the inequality $\le$ of Proposition 19.7.1 (c).

(c) True. For every $\mathbf{X}$, $(\mathbf{A}+c\mathbf{I}_m)\mathbf{X}-\mathbf{X}(\mathbf{B}+c\mathbf{I}_n) = \mathbf{AX}+c\mathbf{X}-\mathbf{XB}-c\mathbf{X} = \mathbf{AX}-\mathbf{XB}$, so the two minima are taken over the same set of values.

(d) If $\operatorname{spec}(\mathbf{A})\cap\operatorname{spec}(\mathbf{B}) = \varnothing$, the unique solution satisfies $\|\mathbf{X}\|_F \le \|\mathbf{C}\|_F/\operatorname{sep}_F(\mathbf{A},\mathbf{B})$, and equality holds for some $\mathbf{C} \neq \mathbf{0}$ (Proposition 19.7.1 (d)).

(e) By $\mathbf{u}^*$ on the left and $\mathbf{v}$ on the right, where $\mathbf{u},\mathbf{v}$ are unit vectors with $\mathbf{Xv} = s\mathbf{u}$ and $\mathbf{X}^*\mathbf{u} = s\mathbf{v}$, $s = \|\mathbf{X}\|_2$. The hypotheses give $\mathbf{u}^*\mathbf{Au} \ge \alpha$ and $\mathbf{v}^*\mathbf{Bv} \le \beta$, which make $\mathbf{u}^*\mathbf{Cv} = s(\mathbf{u}^*\mathbf{Au} - \mathbf{v}^*\mathbf{Bv})$ at least $s(\alpha-\beta)$.

19.7.5.2 B. Practice

Exercise B1: A positive Sylvester equation.

Let

$$\mathbf{S} = \begin{pmatrix} 3 & 1 \\ 1 & 3 \end{pmatrix}, \quad \mathbf{T} = \begin{pmatrix} 1 & 0 \\ 0 & 2 \end{pmatrix}, \quad \mathbf{C} = \begin{pmatrix} 3 & 4 \\ -3 & -4 \end{pmatrix}.$$

(a) Find the largest α and β with $\mathbf{S} \succeq \alpha\mathbf{I}_2$ and $\mathbf{T} \succeq \beta\mathbf{I}_2$, and state the bound that Corollary 19.7.4 gives for $\|\mathbf{X}\|_2$.

(b) Solve $\mathbf{SX} + \mathbf{XT} = \mathbf{C}$, column by column.

(c) Compute $\|\mathbf{X}\|_2$ and $\|\mathbf{C}\|_2$, and check the bound. Hence decide whether the bound is attained here.

Solution.

(a) $p_{\mathbf{S}}(x) = (x-3)^2 - 1 = (x-2)(x-4)$, so $\lambda_2(\mathbf{S}) = 2$, and $\lambda_2(\mathbf{T}) = 1$. By Lemma 12.5.2, $\langle \mathbf{Sx},\mathbf{x}\rangle \ge 2$ for unit $\mathbf{x}$, with equality at an eigenvector, so $\alpha = 2$ is the largest constant with $\mathbf{S} \succeq \alpha\mathbf{I}_2$; likewise $\beta = 1$. The corollary gives $\|\mathbf{X}\|_2 \le \|\mathbf{C}\|_2/3$.

(b) Since $\mathbf{T}$ is diagonal, column j of $\mathbf{XT}$ is t_{jj} times column j of $\mathbf{X}$. So column j of the equation is $(\mathbf{S} + t_{jj}\mathbf{I}_2)\mathbf{x}_j = \mathbf{c}_j$. For $j = 1$: $\left(\begin{smallmatrix} 4 & 1 \\ 1 & 4 \end{smallmatrix}\right)\mathbf{x}_1 = (3,-3)$, and $\mathbf{x}_1 = (1,-1)$ works, since $4-1 = 3$ and $1-4 = -3$. For $j = 2$: $\left(\begin{smallmatrix} 5 & 1 \\ 1 & 5 \end{smallmatrix}\right)\mathbf{x}_2 = (4,-4)$, and $\mathbf{x}_2 = (1,-1)$ works. The solution is unique by Corollary 19.7.4, so

$$\mathbf{X} = \begin{pmatrix} 1 & 1 \\ -1 & -1 \end{pmatrix}.$$

(c) Both matrices have rank one: $\mathbf{X} = \mathbf{ab}^\top$ with $\mathbf{a} = (1,-1)$, $\mathbf{b} = (1,1)$, and $\mathbf{C} = \mathbf{ac}^\top$ with $\mathbf{c} = (3,4)$. For a rank-one matrix $\mathbf{ab}^\top$, the spectral norm equals the Frobenius norm (Proposition 15.3.4), which is $\|\mathbf{a}\|\,\|\mathbf{b}\|$ by the computation in Proposition 19.7.1 (c). So $\|\mathbf{X}\|_2 = \sqrt{2}\cdot\sqrt{2} = 2$ and $\|\mathbf{C}\|_2 = \sqrt{2}\cdot 5 = 5\sqrt{2}$. The bound reads $2 \le 5\sqrt{2}/3 \approx 2.357$, which holds. It is not attained. Each column of $\mathbf{C}$ lies along the eigenvector $(1,-1)$ of $\mathbf{S}$ for $\alpha = 2$, but the second column is paired with

$t_{22} = 2$ rather than $\beta = 1$, so the second column of $\mathbf{X}$ is $\mathbf{c}_2/4$, not $\mathbf{c}_2/3$.

Exercise B2: Separations of four pairs.

For each pair, compute $\operatorname{sep}_F(\mathbf{A}, \mathbf{B})$ and decide whether it equals $\min_{i,j}|\lambda_i - \mu_j|$. Justify your answer.

(a) $\mathbf{A} = \operatorname{diag}(1, 3)$, $\mathbf{B} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$.

(b) $\mathbf{A} = \begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix}$, $\mathbf{B} = (-1)$.

(c) $\mathbf{A} = \begin{pmatrix} 0 & -2 \\ 2 & 0 \end{pmatrix}$, $\mathbf{B} = \operatorname{diag}(1, -1)$.

(d) $\mathbf{A} = \begin{pmatrix} 1 & 4 \\ 0 & 1 \end{pmatrix}$, $\mathbf{B} = (0)$.

Solution.

(a) $\mathbf{B}$ is real symmetric with eigenvalues ± 1, and $1 \in \operatorname{spec}(\mathbf{A}) \cap \operatorname{spec}(\mathbf{B})$. So $\operatorname{sep}_F(\mathbf{A}, \mathbf{B}) = 0$ by Proposition 19.7.1 (b), which equals the minimum distance $|1 - 1| = 0$.

(b) Both matrices are real symmetric, hence normal. The eigenvalues of $\mathbf{A}$ are $1, 3$ and that of $\mathbf{B}$ is -1, so Theorem 19.7.2 gives $\operatorname{sep}_F(\mathbf{A}, \mathbf{B}) = \min(2, 4) = 2$. It equals the minimum distance.

(c) $\mathbf{A}^\top \mathbf{A} = 4\mathbf{I}_2 = \mathbf{A}\mathbf{A}^\top$, so $\mathbf{A}$ is normal, with $p_{\mathbf{A}}(x) = x^2 + 4$ and eigenvalues $\pm 2i$. $\mathbf{B}$ is diagonal. The distances $|\pm 2i \mp 1|$ all equal $\sqrt{5}$, so $\operatorname{sep}_F(\mathbf{A}, \mathbf{B}) = \sqrt{5}$ by Theorem 19.7.2, equal to the minimum distance.

(d) This is Example (Separation Far Below the Gap) with $t = 4$: $\operatorname{sep}_F(\mathbf{A}, \mathbf{B}) = (\sqrt{20} - 4)/2 = \sqrt{5} - 2 \approx 0.236$, while the spectra $\{1\}$ and $\{0\}$ are at distance 1. They are not equal. The theorem does not apply because $\mathbf{A}$ is not normal: $\mathbf{A}^\top \mathbf{A} = \left(\begin{smallmatrix} 1 & 4 \\ 4 & 17 \end{smallmatrix}\right) \neq \left(\begin{smallmatrix} 17 & 4 \\ 4 & 1 \end{smallmatrix}\right) = \mathbf{A}\mathbf{A}^\top$.

Exercise B3: A symmetric Sylvester equation.

Let $\mathbf{A} \in M_n(\mathbb{C})$ be Hermitian with $\mathbf{A} \succeq 2\mathbf{I}_n$, and let $\mathbf{C} \in M_n(\mathbb{C})$.

(a) Prove that $\mathbf{A}\mathbf{X} + \mathbf{X}\mathbf{A} = \mathbf{C}$ has exactly one solution, and that it satisfies $\|\mathbf{X}\|_2 \leq \|\mathbf{C}\|_2/4$.

(b) Prove that if $\mathbf{C}$ is Hermitian, then so is $\mathbf{X}$.

Solution.

(a) Apply Corollary 19.7.4 with $\mathbf{S} = \mathbf{T} = \mathbf{A}$ and $\alpha = \beta = 2$. Since $\alpha + \beta = 4 > 0$, the equation has exactly one solution, and $\|\mathbf{X}\|_2 \leq \|\mathbf{C}\|_2/4$.

(b) Take the adjoint of $\mathbf{A}\mathbf{X} + \mathbf{X}\mathbf{A} = \mathbf{C}$. Since $\mathbf{A}^* = \mathbf{A}$ and $\mathbf{C}^* = \mathbf{C}$, we get $\mathbf{X}^*\mathbf{A} + \mathbf{A}\mathbf{X}^* = \mathbf{C}$, so $\mathbf{X}^*$ is also a solution. By the uniqueness in (a), $\mathbf{X}^* = \mathbf{X}$.

19.7.5.3 C. Going deeper

Exercise C1: The separation is stable, and it measures a distance.

Let $\mathbf{A} \in M_m(\mathbb{C})$, $\mathbf{B} \in M_n(\mathbb{C})$, $\mathbf{E} \in M_m(\mathbb{C})$ and $\mathbf{F} \in M_n(\mathbb{C})$.

(a) Prove that $\|\mathbf{EX}\|_F \le \|\mathbf{E}\|_2\|\mathbf{X}\|_F$ and $\|\mathbf{XF}\|_F \le \|\mathbf{F}\|_2\|\mathbf{X}\|_F$ for every $\mathbf{X} \in M_{m\times n}(\mathbb{C})$.

(b) Prove that $|\operatorname{sep}_F(\mathbf{A}+\mathbf{E}, \mathbf{B}+\mathbf{F}) - \operatorname{sep}_F(\mathbf{A}, \mathbf{B})| \le \|\mathbf{E}\|_2 + \|\mathbf{F}\|_2$.

(c) Now let $n = 1$ and $\mathbf{B} = (\mu)$. Prove that there is $\mathbf{E}$ with $\|\mathbf{E}\|_2 = \operatorname{sep}_F(\mathbf{A}, \mathbf{B})$ such that μ is an eigenvalue of $\mathbf{A} + \mathbf{E}$.

(d) Hence, for $t = 99/10$ in Example (Separation Far Below the Gap), exhibit the size of a perturbation of $\mathbf{A}$ that makes 0 an eigenvalue, and explain why the eigenvalue gap 1 is a poor guide to how close the pair is to having a common eigenvalue.

Hint for (c): use a singular value decomposition of $\mathbf{A} - \mu\mathbf{I}_m$.

Solution.

(a) Let $\mathbf{x}_1, \dots, \mathbf{x}_n$ be the columns of $\mathbf{X}$. The columns of $\mathbf{EX}$ are $\mathbf{E}\mathbf{x}_q$, so by Theorem 15.3.2 (a)

$$\|\mathbf{EX}\|_F^2 = \sum_q \|\mathbf{E}\mathbf{x}_q\|^2 \le \|\mathbf{E}\|_2^2 \sum_q \|\mathbf{x}_q\|^2 = \|\mathbf{E}\|_2^2\|\mathbf{X}\|_F^2.$$

For the second, $\|\mathbf{XF}\|_F = \|(\mathbf{XF})^*\|_F = \|\mathbf{F}^*\mathbf{X}^*\|_F$, since conjugate transposition does not change the moduli of the entries. By the first part this is at most $\|\mathbf{F}^*\|_2\|\mathbf{X}^*\|_F = \|\mathbf{F}^*\|_2\|\mathbf{X}\|_F$. Finally $\|\mathbf{F}^*\|_2 = \|\mathbf{F}\|_2$: if $\mathbf{F} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^*$ is a singular value decomposition, then $\mathbf{F}^* = \mathbf{V}\mathbf{\Sigma}^\top\mathbf{U}^*$ is one for $\mathbf{F}^*$, with the same diagonal, so $\sigma_1(\mathbf{F}^*) = \sigma_1(\mathbf{F})$ by Theorem 12.8.2 and Theorem 15.3.3 (c).

(b) Let $\|\mathbf{X}\|_F = 1$. By the triangle inequality and (a),

$$\begin{aligned}\|(\mathbf{A}+\mathbf{E})\mathbf{X} - \mathbf{X}(\mathbf{B}+\mathbf{F})\|_F &\ge \|\mathbf{AX} - \mathbf{XB}\|_F - \|\mathbf{EX}\|_F - \|\mathbf{XF}\|_F \\ &\ge \operatorname{sep}_F(\mathbf{A}, \mathbf{B}) - \|\mathbf{E}\|_2 - \|\mathbf{F}\|_2.\end{aligned}$$

Taking the minimum over $\mathbf{X}$ gives $\operatorname{sep}_F(\mathbf{A}+\mathbf{E}, \mathbf{B}+\mathbf{F}) \ge \operatorname{sep}_F(\mathbf{A}, \mathbf{B}) - \|\mathbf{E}\|_2 - \|\mathbf{F}\|_2$. Applying this to the pair $(\mathbf{A}+\mathbf{E}, \mathbf{B}+\mathbf{F})$ with the perturbations $-\mathbf{E}, -\mathbf{F}$ gives the reverse inequality, and together they are the claim.

(c) By Proposition 19.7.1 (f), $s := \operatorname{sep}_F(\mathbf{A}, \mathbf{B}) = \sigma_m(\mathbf{A} - \mu\mathbf{I}_m)$. Let $\mathbf{A} - \mu\mathbf{I}_m = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^*$ be a singular value decomposition (Theorem 12.8.1), with last columns $\mathbf{u}_m$ of $\mathbf{U}$ and $\mathbf{v}_m$ of $\mathbf{V}$. Then $(\mathbf{A} - \mu\mathbf{I}_m)\mathbf{v}_m = s\mathbf{u}_m$, comparing column m of $(\mathbf{A} - \mu\mathbf{I}_m)\mathbf{V} = \mathbf{U}\mathbf{\Sigma}$. Put $\mathbf{E} = -s\,\mathbf{u}_m\mathbf{v}_m^*$. Then $(\mathbf{A}+\mathbf{E}-\mu\mathbf{I}_m)\mathbf{v}_m = s\mathbf{u}_m - s\mathbf{u}_m(\mathbf{v}_m^*\mathbf{v}_m) = \mathbf{0}$ with $\mathbf{v}_m \neq \mathbf{0}$, so μ is an eigenvalue of $\mathbf{A} + \mathbf{E}$. Also $\|\mathbf{E}\mathbf{x}\| = s|\mathbf{v}_m^*\mathbf{x}| \le s\|\mathbf{x}\|$ by Cauchy–Schwarz, with equality at $\mathbf{x} = \mathbf{v}_m$, so $\|\mathbf{E}\|_2 = s$.

(d) With $\mu = 0$ and $\operatorname{sep}_F(\mathbf{A}, (0)) = 1/10$, part (c) gives a perturbation of spectral norm $1/10$ after which 0 is an eigenvalue of $\mathbf{A} + \mathbf{E}$, so $\mathbf{A} + \mathbf{E}$ and $\mathbf{B}$ share an eigenvalue. The eigenvalues 1 and 0 are at distance 1, but a perturbation ten times smaller than that distance destroys the solvability of the equation. By (b) with $\mathbf{F} = \mathbf{0}$, no perturbation of spectral norm less than $1/10$ can do it, since it leaves the separation positive. So the separation, not the eigenvalue gap, is the distance to a shared eigenvalue here.

Exercise C2: Interlaced spectra break the spectral-norm bound.

Let $\mathbf{A} = \operatorname{diag}(0, 2)$, $\mathbf{B} = \operatorname{diag}(1, 3)$ and $\mathbf{C} = \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}$.

(a) Show that every eigenvalue of $\mathbf{A}$ is at distance at least 1 from every eigenvalue of $\mathbf{B}$, and explain why Theorem 19.7.3 does not apply with $\alpha - \beta = 1$.

(b) Solve $\mathbf{AX} - \mathbf{XB} = \mathbf{C}$.

(c) Show that $\|\mathbf{X}\|_2 > \|\mathbf{C}\|_2$.

(d) Verify directly that $\|\mathbf{X}\|_F \le \|\mathbf{C}\|_F$, as Theorem 19.7.2 requires.

Hint for (c): compute $\mathbf{C}^\top\mathbf{C}$, and test $\mathbf{X}$ on the vector $(1, 1)$.

Solution.

(a) The eigenvalues are $0, 2$ and $1, 3$, and the four differences $\lambda_i - \mu_j$ are $-1, -3, 1, -1$, all of modulus at least 1. The theorem needs $\mathbf{A} \succeq \alpha\mathbf{I}$ and $\mathbf{B} \preceq \beta\mathbf{I}$ with $\alpha > \beta$, that is, every eigenvalue of $\mathbf{A}$ above every eigenvalue of $\mathbf{B}$, or, applying it to $(-\mathbf{A}, -\mathbf{B})$, every one below. Neither holds, since $0 < 1 < 2 < 3$ interlace. Applied honestly, the best one-sided constants are $\alpha = 0$ and $\beta = 3$, and $\alpha > \beta$ fails.

(b) As in the diagonal example after Definition 19.7.1, $(\mathbf{AX} - \mathbf{XB})_{ij} = (a_{ii} - b_{jj})x_{ij}$, so $x_{ij} = c_{ij}/(a_{ii} - b_{jj})$:

$$\mathbf{X} = \begin{pmatrix} 1/(0-1) & 1/(0-3) \\ 1/(2-1) & -1/(2-3) \end{pmatrix} = \begin{pmatrix} -1 & -1/3 \\ 1 & 1 \end{pmatrix}.$$

(c) $\mathbf{C}^\top\mathbf{C} = 2\mathbf{I}_2$, so both singular values of $\mathbf{C}$ are $\sqrt{2}$ and $\|\mathbf{C}\|_2 = \sqrt{2}$ (Theorem 15.3.3 (c)). For $\mathbf{x} = (1, 1)/\sqrt{2}$, a unit vector, $\mathbf{Xx} = (-4/3, 2)/\sqrt{2}$, so

$$\|\mathbf{Xx}\|^2 = \frac{1}{2}\Big(\frac{16}{9} + 4\Big) = \frac{26}{9} > 2.$$

Hence $\|\mathbf{X}\|_2 \ge \sqrt{26}/3 > \sqrt{2} = \|\mathbf{C}\|_2$.

(d) $\|\mathbf{X}\|_F^2 = 1 + \frac{1}{9} + 1 + 1 = \frac{28}{9}$ and $\|\mathbf{C}\|_F^2 = 4$, so $\|\mathbf{X}\|_F \le \|\mathbf{C}\|_F$, in agreement with Theorem 19.7.2, which gives $\operatorname{sep}_F(\mathbf{A}, \mathbf{B}) = 1$. So the Frobenius bound with constant $1/\delta$ survives interlacing, while the spectral-norm bound with the same constant does not.

19.8 Principal Angles

The sections so far measured how far eigenvalues move. The next section asks how far **eigenvectors** move, and more generally invariant subspaces, and before it can answer it needs a way to say how far apart two subspaces are. For two lines there is an obvious answer, the angle between them. This section shows that for subspaces of dimension $k \ge 2$ one angle is not enough, and that the right replacement is a list of k angles read off from a singular value decomposition. It then proves the two facts Section 9 will use: the sines of these angles are the singular values of a matrix built from the orthogonal complement, and the largest sine is the distance between the two orthogonal projections.

Throughout, F is $\mathbb{R}$ or $\mathbb{C}$, and F^n carries its standard inner product $\langle \mathbf{x}, \mathbf{y} \rangle = \mathbf{y}^*\mathbf{x}$, with $\mathbf{x}^* = \mathbf{x}^\top$ when $F = \mathbb{R}$. For a subspace U of F^n, P_U is the orthogonal projection onto U (Definition 10.3.2), identified with its matrix in the standard basis. Singular values of a matrix with k columns follow the convention of Chapter 16 §09: $\sigma_i := 0$ for $\min(\text{rows}, k) < i \le k$, so that σ_i^2 is the i-th largest eigenvalue of $\mathbf{A}^*\mathbf{A}$ for every $i \le k$ (Eq. 16.9.1).

19.8.1 One angle is not enough

For two lines $\text{span}(\mathbf{u})$ and $\text{span}(\mathbf{w})$ there is one number to compute, the angle between them. For planes the first idea is to copy it: call the angle between U and W the **smallest** angle between a line in U and a line in W.

That idea fails at once in $\mathbb{R}^3$. Two distinct planes $U, W \subseteq \mathbb{R}^3$ always meet in a line, since

$$\dim(U \cap W) = 2 + 2 - \dim(U + W) \ge 4 - 3 = 1$$

by Theorem 1.7.3. So the smallest angle is 0 for **every** pair of planes: it cannot tell a plane tilted by one degree from a plane at right angles.

Taking the **largest** such angle instead does no better in $\mathbb{R}^4$. Let $U = \text{span}(\mathbf{e}_1, \mathbf{e}_2)$ and compare

$$W_1 = \text{span}(\mathbf{e}_1, \mathbf{e}_3), \qquad W_2 = \text{span}(\mathbf{e}_3, \mathbf{e}_4).$$

Each contains a vector perpendicular to all of U (namely $\mathbf{e}_3$), so each has a line at angle $\pi/2$ from U. But W_1 shares the whole line $\text{span}(\mathbf{e}_1)$ with U, while W_2 is perpendicular to U in every direction. One number cannot record both facts. A list can: $(0, \pi/2)$ for W_1 and $(\pi/2, \pi/2)$ for W_2. The rest of this section explains where such a list comes from in general, when the subspaces are not lined up with the coordinate axes.

Two subspaces can be given orthonormal bases that face each other in pairs; the principal angles are the angles between the partners.

19.8.2 Principal angles

Everything will be computed from orthonormal bases written as the columns of a matrix, so we first record how such matrices behave.

Let $U \subseteq F^n$ be a subspace with $\dim U = k \ge 1$. An **orthonormal basis matrix** of U is a matrix $\mathbf{Q} \in M_{n\times k}(F)$ whose columns form an orthonormal basis of U. One exists: apply Gram–Schmidt (Theorem 10.2.2) to any basis of U.

Lemma 19.8.1 — Orthonormal Basis Matrices

Let $U \subseteq F^n$ have dimension $k \ge 1$ and let $\mathbf{Q} \in M_{n\times k}(F)$ be an orthonormal basis matrix of U.

(a) $\mathbf{Q}^*\mathbf{Q} = \mathbf{I}_k$ and $P_U = \mathbf{Q}\mathbf{Q}^*$.

(b) $\|\mathbf{Q}\mathbf{y}\| = \|\mathbf{y}\|$ for every $\mathbf{y} \in F^k$. For every matrix $\mathbf{Y}$ with k rows and every matrix $\mathbf{Z}$ with k columns,

$$\|\mathbf{Q}\mathbf{Y}\|_2 = \|\mathbf{Y}\|_2, \quad \|\mathbf{Q}\mathbf{Y}\|_F = \|\mathbf{Y}\|_F,$$
$$\|\mathbf{Z}\mathbf{Q}^*\|_2 = \|\mathbf{Z}\|_2, \quad \|\mathbf{Z}\mathbf{Q}^*\|_F = \|\mathbf{Z}\|_F.$$

(c) Every orthonormal basis matrix of U is $\mathbf{QR}$ for some $\mathbf{R} \in \mathrm{U}(k)$ (orthogonal when $F = \mathbb{R}$).

(d) $\mathbf{I}_n - P_U = P_{U^\perp}$. If moreover $k < n$ and $\mathbf{Q}_\perp \in M_{n\times(n-k)}(F)$ is an orthonormal basis matrix of $U^\perp$, then the square matrix $(\mathbf{Q} \mid \mathbf{Q}_\perp)$ is unitary, and

$$\mathbf{Q}\mathbf{Q}^* + \mathbf{Q}_\perp\mathbf{Q}_\perp^* = \mathbf{I}_n.$$

Proof.

(a) The (i, j) entry of $\mathbf{Q}^*\mathbf{Q}$ is $\mathbf{q}_i^*\mathbf{q}_j = \langle \mathbf{q}_j, \mathbf{q}_i\rangle = \delta_{ij}$, because the columns $\mathbf{q}_1, \dots, \mathbf{q}_k$ are orthonormal. By Theorem 10.3.3 (a), for every $\mathbf{v} \in F^n$,

$$P_U\mathbf{v} = \sum_{i=1}^{k} \langle \mathbf{v}, \mathbf{q}_i\rangle \mathbf{q}_i = \sum_{i=1}^{k} \mathbf{q}_i(\mathbf{q}_i^*\mathbf{v}) = \mathbf{Q}\mathbf{Q}^*\mathbf{v},$$

the last step being column-times-row expansion of $\mathbf{Q}\mathbf{Q}^*$.

(b) By (a), $\|\mathbf{Q}\mathbf{y}\|^2 = \mathbf{y}^*\mathbf{Q}^*\mathbf{Q}\mathbf{y} = \mathbf{y}^*\mathbf{y} = \|\mathbf{y}\|^2$. Hence $\|\mathbf{Q}\mathbf{Y}\mathbf{x}\| = \|\mathbf{Y}\mathbf{x}\|$ for every $\mathbf{x}$, and taking the maximum over unit $\mathbf{x}$ (Definition 15.3.2) gives $\|\mathbf{Q}\mathbf{Y}\|_2 = \|\mathbf{Y}\|_2$. For the Frobenius norm, $\|\mathbf{Q}\mathbf{Y}\|_F^2 = \operatorname{tr}(\mathbf{Y}^*\mathbf{Q}^*\mathbf{Q}\mathbf{Y}) = \operatorname{tr}(\mathbf{Y}^*\mathbf{Y}) = \|\mathbf{Y}\|_F^2$. Next, $\|\mathbf{Z}\mathbf{Q}^*\|_F^2 = \operatorname{tr}(\mathbf{Q}\mathbf{Z}^*\mathbf{Z}\mathbf{Q}^*) = \operatorname{tr}(\mathbf{Z}^*\mathbf{Z}\mathbf{Q}^*\mathbf{Q}) = \|\mathbf{Z}\|_F^2$, by Theorem 0.9.6 (c). For the spectral norm, let $\mathbf{x} \in F^n$. By the first sentence and (a), $\|\mathbf{Q}^*\mathbf{x}\| = \|\mathbf{Q}\mathbf{Q}^*\mathbf{x}\| = \|P_U\mathbf{x}\| \le \|\mathbf{x}\|$ (Theorem 10.3.3 (c)). So $\|\mathbf{Z}\mathbf{Q}^*\mathbf{x}\| \le \|\mathbf{Z}\|_2\|\mathbf{Q}^*\mathbf{x}\| \le \|\mathbf{Z}\|_2\|\mathbf{x}\|$ by Theorem 15.3.2 (a), and $\|\mathbf{Z}\mathbf{Q}^*\|_2 \le \|\mathbf{Z}\|_2$. Conversely, choose a unit $\mathbf{y} \in F^k$ with $\|\mathbf{Z}\mathbf{y}\| = \|\mathbf{Z}\|_2$ (Lemma 15.3.1). Then $\mathbf{x} = \mathbf{Q}\mathbf{y}$ is a unit vector with $\mathbf{Z}\mathbf{Q}^*\mathbf{x} = \mathbf{Z}\mathbf{y}$, so $\|\mathbf{Z}\mathbf{Q}^*\|_2 \ge \|\mathbf{Z}\|_2$.

(c) Let $\mathbf{Q}'$ be another orthonormal basis matrix of U, and put $\mathbf{R} = \mathbf{Q}^*\mathbf{Q}' \in M_k(F)$. Each column of $\mathbf{Q}'$ lies in U, where P_U is the identity, so $\mathbf{Q}' = P_U\mathbf{Q}' = \mathbf{Q}\mathbf{Q}^*\mathbf{Q}' = \mathbf{Q}\mathbf{R}$ by (a). Then $\mathbf{R}^*\mathbf{R} = \mathbf{Q}'^*\mathbf{Q}\mathbf{Q}^*\mathbf{Q}' = \mathbf{Q}'^*P_U\mathbf{Q}' = \mathbf{Q}'^*\mathbf{Q}' = \mathbf{I}_k$, so the square matrix $\mathbf{R}$ is unitary (Definition 10.7.2).

(d) For the first identity, let $\mathbf{v} \in F^n$ and write $\mathbf{v} = \mathbf{u} + \mathbf{w}$ with $\mathbf{u} \in U$ and $\mathbf{w} \in U^\perp$, which is possible in exactly one way by Theorem 10.3.2 (a). Then $P_U\mathbf{v} = \mathbf{u}$ by Definition 10.3.2. Since $(U^\perp)^\perp = U$ by Theorem 10.3.2 (b), the splitting $\mathbf{v} = \mathbf{w}+\mathbf{u}$ is also the one that defines $P_{U^\perp}$, so $P_{U^\perp}\mathbf{v} = \mathbf{w} = \mathbf{v} - P_U\mathbf{v}$. As $\mathbf{v}$ was arbitrary, $\mathbf{I}_n - P_U = P_{U^\perp}$. Nothing here restricts k: when $k = n$, $U^\perp = \{\mathbf{0}\}$ and both sides are $\mathbf{0}$.

Now let $k < n$. The columns of $\mathbf{Q}$ and of $\mathbf{Q}_\perp$ are orthonormal, and each column of $\mathbf{Q}$ is orthogonal to each column of $\mathbf{Q}_\perp$ because $U \perp U^\perp$. Their number is $k+(n-k) = n$, by Theorem 10.3.2 (c). So the square matrix $\mathbf{O} = (\mathbf{Q} \mid \mathbf{Q}_\perp) \in M_n(F)$ satisfies $\mathbf{O}^*\mathbf{O} = \mathbf{I}_n$, hence is unitary, and then $\mathbf{O}\mathbf{O}^* = \mathbf{I}_n$ as well, since $\mathbf{O}^* = \mathbf{O}^{-1}$. By block multiplication (Theorem 7.1.1), $\mathbf{O}\mathbf{O}^* = \mathbf{Q}\mathbf{Q}^* + \mathbf{Q}_\perp\mathbf{Q}_\perp^*$. This also re-proves the first identity here, since $\mathbf{Q}_\perp\mathbf{Q}_\perp^* = P_{U^\perp}$ by (a) applied to $U^\perp$.

■

Now the definition. The question is how much of U survives when it is projected into W. By parts (a) and (b) of the lemma, for a unit vector $\mathbf{u} = \mathbf{Q}_U\mathbf{y}$ of U the surviving length is $\|P_W\mathbf{u}\| = \|\mathbf{Q}_W\mathbf{Q}_W^*\mathbf{u}\| = \|\mathbf{Q}_W^*\mathbf{u}\| = \|(\mathbf{Q}_W^*\mathbf{Q}_U)\mathbf{y}\|$. So the matrix $\mathbf{Q}_W^*\mathbf{Q}_U$ records the answer for every direction of U at once, and its singular values are the stretch factors along the best directions.

Definition 19.8.1 — Principal Angles

Let $U, W \subseteq F^n$ be subspaces with

$$1 \le k = \dim U \le l = \dim W,$$

and let $\mathbf{Q}_U \in M_{n\times k}(F)$ and $\mathbf{Q}_W \in M_{n\times l}(F)$ be orthonormal basis matrices of U and W. The **principal angles** between U and W are the k numbers

$$0 \le \theta_1 \le \theta_2 \le \cdots \le \theta_k \le \frac{\pi}{2}$$

determined by

$$\cos\theta_i = \sigma_i(\mathbf{Q}_W^* \mathbf{Q}_U) \qquad (i = 1, \dots, k).$$

We write $\Theta(U, W) = \operatorname{diag}(\theta_1, \dots, \theta_k)$ and $\sin\Theta(U, W) = \operatorname{diag}(\sin\theta_1, \dots, \sin\theta_k)$.

In words: fix orthonormal bases of the two subspaces, form the $l \times k$ matrix whose (i, j) entry is the inner product of the j-th basis vector of U with the i-th basis vector of W, and take its k singular values. These lie in $[0, 1]$, as we check next, so each is the cosine of exactly one angle in $[0, \pi/2]$. The largest cosine gives the **smallest** angle, so the decreasing singular values produce increasing angles. The number of angles is the **smaller** dimension, k, and the definition asks for $k \le l$; for a pair with $\dim U > \dim W$, swap the names. The two notations at the end are for use in norms: $\|\sin\Theta(U, W)\|_2 = \sin\theta_k$, the largest entry of a non-negative diagonal matrix (Lemma 16.3.5), and $\|\sin\Theta(U, W)\|_F = \left(\sum_i \sin^2\theta_i\right)^{1/2}$.

Well-definedness. Three things need checking. The answer must not depend on the orthonormal bases chosen. The singular values must be at most 1, or there is no angle. And when $k = l$ the definition treats U and W asymmetrically, so we should check that swapping them changes nothing.

Proposition 19.8.2 — Principal Angles Are Well Defined

In the setting of Definition 19.8.1, put $\mathbf{M} = \mathbf{Q}_W^* \mathbf{Q}_U \in M_{l\times k}(F)$.

(a) The singular values of $\mathbf{M}$ do not depend on the choice of the orthonormal basis matrices $\mathbf{Q}_U$ and $\mathbf{Q}_W$.

(b) $1 \ge \sigma_1(\mathbf{M}) \ge \cdots \ge \sigma_k(\mathbf{M}) \ge 0$, so $\theta_1, \dots, \theta_k$ exist, are unique, and are non-decreasing.

(c) $\sigma_i(\mathbf{Q}_U^* \mathbf{Q}_W) = \sigma_i(\mathbf{M})$ for $i = 1, \dots, k$. In particular, if $k = l$, the principal angles between W and U are those between U and W.

(d) If $k = 1$ and $U = \operatorname{span}(\mathbf{u})$ with $\|\mathbf{u}\| = 1$, then $\cos\theta_1 = \|P_W \mathbf{u}\|$. If also $l = 1$ and $W = \operatorname{span}(\mathbf{w})$ with $\|\mathbf{w}\| = 1$, then $\cos\theta_1 = |\langle \mathbf{u}, \mathbf{w}\rangle|$.

Proof.

(a) By Lemma 19.8.1 (c), any other choices are $\mathbf{Q}_U\mathbf{R}$ and $\mathbf{Q}_W\mathbf{R}'$ with $\mathbf{R} \in \mathrm{U}(k)$ and $\mathbf{R}' \in \mathrm{U}(l)$. The new matrix is $\mathbf{M}' = \mathbf{R}'^* \mathbf{M} \mathbf{R}$, and

$$\mathbf{M}'^* \mathbf{M}' = \mathbf{R}^* \mathbf{M}^* \mathbf{R}' \mathbf{R}'^* \mathbf{M} \mathbf{R} = \mathbf{R}^* (\mathbf{M}^* \mathbf{M}) \mathbf{R},$$

using $\mathbf{R}'\mathbf{R}'^{*} = \mathbf{I}_l$. Since $\mathbf{R}^{*} = \mathbf{R}^{-1}$, this is similar to $\mathbf{M}^{*}\mathbf{M}$, so the two have the same characteristic polynomial (Theorem 6.10.3) and the same eigenvalues with multiplicity. By Definition 12.8.1, $\mathbf{M}'$ and $\mathbf{M}$ have the same singular values.

(b) By Theorem 15.3.2 (d) and Lemma 19.8.1 (b), $\|\mathbf{M}\|_2 \le \|\mathbf{Q}_W^{*}\|_2 \|\mathbf{Q}_U\|_2$, and $\|\mathbf{Q}_U\|_2 = \|\mathbf{Q}_U\mathbf{I}_k\|_2 = \|\mathbf{I}_k\|_2 = 1$ by Theorem 15.3.2 (c). Also $\|\mathbf{Q}_W^{*}\mathbf{x}\| = \|P_W\mathbf{x}\| \le \|\mathbf{x}\|$, as in the proof of that lemma, so $\|\mathbf{Q}_W^{*}\|_2 \le 1$. Hence $\sigma_1(\mathbf{M}) = \|\mathbf{M}\|_2 \le 1$ by Theorem 15.3.3 (c), and all singular values lie in $[0,1]$. The cosine is a strictly decreasing bijection from $[0,\pi/2]$ onto $[0,1]$, so each $\sigma_i(\mathbf{M})$ is $\cos\theta_i$ for exactly one $\theta_i \in [0,\pi/2]$, and $\sigma_1 \ge \cdots \ge \sigma_k$ gives $\theta_1 \le \cdots \le \theta_k$.

(c) Let $\mathbf{M} = \mathbf{Y}\mathbf{\Sigma}\mathbf{Z}^{*}$ be a singular value decomposition (Theorem 12.8.1). Then $\mathbf{M}^{*} = \mathbf{Z}\mathbf{\Sigma}^{\top}\mathbf{Y}^{*}$, where $\mathbf{Z}, \mathbf{Y}$ are unitary and $\mathbf{\Sigma}^{\top} \in M_{k\times l}(\mathbb{R})$ carries the same diagonal entries $\sigma_1(\mathbf{M}) \ge \cdots \ge \sigma_k(\mathbf{M})$ and zeros elsewhere. So this is a factorization of $\mathbf{M}^{*}$ of the shape in Theorem 12.8.1, and Theorem 12.8.2 gives $\sigma_i(\mathbf{M}^{*}) = \sigma_i(\mathbf{M})$. Since $\mathbf{M}^{*} = \mathbf{Q}_U^{*}\mathbf{Q}_W$, this is the first claim. When $k = l$, the principal angles between W and U are defined by $\sigma_i(\mathbf{Q}_U^{*}\mathbf{Q}_W)$, so they coincide with those between U and W.

(d) With $\mathbf{Q}_U = \mathbf{u}$, the matrix $\mathbf{M} = \mathbf{Q}_W^{*}\mathbf{u}$ is a single column, and its one singular value is $(\mathbf{M}^{*}\mathbf{M})^{1/2} = \|\mathbf{Q}_W^{*}\mathbf{u}\|$. By Lemma 19.8.1 (b) and (a), $\|\mathbf{Q}_W^{*}\mathbf{u}\| = \|\mathbf{Q}_W\mathbf{Q}_W^{*}\mathbf{u}\| = \|P_W\mathbf{u}\|$. If $l = 1$ and $\mathbf{Q}_W = \mathbf{w}$, then $\mathbf{M} = \mathbf{w}^{*}\mathbf{u} = \langle \mathbf{u}, \mathbf{w}\rangle$, whose singular value is $|\langle \mathbf{u}, \mathbf{w}\rangle|$.

■

Examples.

1. **Two lines in $\mathbb{R}^2$.** For $\mathbf{u} = \mathbf{e}_1$ and $\mathbf{w} = (1,1)/\sqrt{2}$, part (d) gives $\cos\theta_1 = 1/\sqrt{2}$, so $\theta_1 = \pi/4$. Replacing $\mathbf{w}$ by $-\mathbf{w}$ changes neither the line nor the answer.
2. **Nested subspaces.** If $U \subseteq W$, then every column of $\mathbf{Q}_U$ is fixed by P_W, so $\mathbf{M}^{*}\mathbf{M} = \mathbf{Q}_U^{*}\mathbf{Q}_W\mathbf{Q}_W^{*}\mathbf{Q}_U = \mathbf{Q}_U^{*}P_W\mathbf{Q}_U = \mathbf{Q}_U^{*}\mathbf{Q}_U = \mathbf{I}_k$. All singular values are 1 and all principal angles are 0. The degenerate case $U = W$ is included, and it is the reason the angles start at 0.
3. **Perpendicular subspaces.** If $U \subseteq W^{\perp}$, every entry of $\mathbf{M}$ is the inner product of a vector of U with a vector of W, hence 0, so all principal angles are $\pi/2$.
4. **The planes of the opening.** For $U = \operatorname{span}(\mathbf{e}_1, \mathbf{e}_2)$ and $W_1 = \operatorname{span}(\mathbf{e}_1, \mathbf{e}_3)$, take the standard vectors as orthonormal bases. Then $\mathbf{M} = \mathbf{Q}_{W_1}^{\top}\mathbf{Q}_U = \left(\begin{smallmatrix} 1 & 0 \\ 0 & 0 \end{smallmatrix}\right)$, with singular values $1, 0$, so the principal angles are $(0, \pi/2)$. For $W_2 = \operatorname{span}(\mathbf{e}_3, \mathbf{e}_4)$ we are in Example 3, with angles $(\pi/2, \pi/2)$. These are the two lists that the single-number attempts could not tell apart.

Non-example by minimal change. In Example 4, replace the orthonormal basis $(\mathbf{e}_1, \mathbf{e}_3)$ of W_1 by the basis $(\mathbf{e}_1, (\mathbf{e}_1 + \mathbf{e}_3)/\sqrt{2})$, whose vectors still have length 1 but are no longer orthogonal. The matrix of inner products becomes $\left(\begin{smallmatrix} 1 & 0 \\ 1/\sqrt{2} & 0 \end{smallmatrix}\right)$, with largest singular value $\sqrt{3/2} > 1$, and no angle has that cosine. What fails is the orthogonality of the columns of $\mathbf{Q}_W$: without it, $\mathbf{Q}_W\mathbf{Q}_W^{*}$ is not the projection P_W, and the matrix no longer measures how much of U survives in W.

Why this definition: the principal vectors. The singular value decomposition of $\mathbf{M}$ does more than produce numbers. It produces bases of U and W in which the whole configuration is visible, and this is the precise meaning of the slogan.

Proposition 19.8.3 — Principal Vectors

In the setting of Definition 19.8.1, let $\mathbf{Q}_W^* \mathbf{Q}_U = \mathbf{Y}\mathbf{\Sigma}\mathbf{Z}^*$ be a singular value decomposition, with $\mathbf{Y} \in M_l(F)$ and $\mathbf{Z} \in M_k(F)$ unitary, columns $\mathbf{y}_1, \dots, \mathbf{y}_l$ and $\mathbf{z}_1, \dots, \mathbf{z}_k$. Put

$$\mathbf{u}_i = \mathbf{Q}_U \mathbf{z}_i \ (1 \le i \le k), \qquad \mathbf{w}_j = \mathbf{Q}_W \mathbf{y}_j \ (1 \le j \le l).$$

Then $(\mathbf{u}_1, \dots, \mathbf{u}_k)$ is an orthonormal basis of U, $(\mathbf{w}_1, \dots, \mathbf{w}_l)$ is an orthonormal basis of W, and

$$\langle \mathbf{u}_i, \mathbf{w}_j \rangle = \begin{cases} \cos\theta_i & \text{if } i = j, \\ 0 & \text{if } i \ne j. \end{cases}$$

Proof. The matrix $\mathbf{Q}_U \mathbf{Z}$ has columns $\mathbf{u}_1, \dots, \mathbf{u}_k$, all in U, and $(\mathbf{Q}_U \mathbf{Z})^* (\mathbf{Q}_U \mathbf{Z}) = \mathbf{Z}^* \mathbf{Z} = \mathbf{I}_k$ by Lemma 19.8.1 (a). So the $\mathbf{u}_i$ are k orthonormal vectors of U. They are linearly independent (Theorem 10.1.4), and $\dim U = k$, so they form a basis. The same argument applies to the $\mathbf{w}_j$ in W. Finally,

$$\langle \mathbf{u}_i, \mathbf{w}_j \rangle = \mathbf{w}_j^* \mathbf{u}_i = \mathbf{y}_j^* (\mathbf{Q}_W^* \mathbf{Q}_U) \mathbf{z}_i = \mathbf{y}_j^* \mathbf{Y}\mathbf{\Sigma}\mathbf{Z}^* \mathbf{z}_i = \mathbf{e}_j^* \mathbf{\Sigma} \mathbf{e}_i,$$

which is the (j, i) entry of $\mathbf{\Sigma}$: it equals $\sigma_i = \cos\theta_i$ when $j = i$, and 0 otherwise.

■

So U and W have orthonormal bases that face each other in pairs. Each $\mathbf{u}_i$ makes the angle θ_i with its partner $\mathbf{w}_i$, in the sense of part (d) of the proposition, and is perpendicular to every other $\mathbf{w}_j$. The last $l - k$ vectors of W have no partner, and they are perpendicular to all of U. The vectors $\mathbf{u}_i, \mathbf{w}_i$ are called **principal vectors**. Two subspaces, however they sit in F^n, look like a list of k independent pairs of lines, and the principal angles are the angles within the pairs.

The principal vectors are usually **not** the basis vectors one started with. For $U = W = \mathbb{R}^2$ with bases $(\mathbf{e}_1, \mathbf{e}_2)$ and $((\mathbf{e}_1 + \mathbf{e}_2)/\sqrt{2}, (\mathbf{e}_1 - \mathbf{e}_2)/\sqrt{2})$, each given basis vector of U is at angle $\pi/4$ from each given basis vector of W. The principal angles are nevertheless $0, 0$, by Example 2, since the subspaces are equal. Pairing the given columns one by one measures the bases, not the subspaces.

Warning. **Lines have no orientation, so principal angles use $|\langle \mathbf{u}, \mathbf{w} \rangle|$ and lie in $[0, \pi/2]$.** The angle of Definition 10.1.5 is between **vectors** in a **real** space, and it can reach π. For $\mathbf{u} = \mathbf{e}_1$ and $\mathbf{w} = -\mathbf{e}_1$ in $\mathbb{R}^2$ that angle is π, yet $\operatorname{span}(\mathbf{u}) = \operatorname{span}(\mathbf{w})$ and the principal angle is 0. Over $\mathbb{C}$ the vector angle is not even defined: $\mathbf{u} = \mathbf{e}_1$ and $\mathbf{w} = i\mathbf{e}_1$ span the same complex line, $\langle \mathbf{u}, \mathbf{w} \rangle = \bar{i} = -i$ is not real, and the principal angle is again 0 because $|-i| = 1$.

Quick check. Find the principal angle between the line $U = \operatorname{span}\big((1, 2, 2)\big)$ and the plane $W = \{\mathbf{x} \in \mathbb{R}^3 : x_3 = 0\}$.

Solution. Here $k = 1 \le 2 = l$. The unit vector $\mathbf{u} = \frac{1}{3}(1, 2, 2)$ spans U, and $P_W \mathbf{u} = \frac{1}{3}(1, 2, 0)$, since $(\mathbf{e}_1, \mathbf{e}_2)$ is an orthonormal basis of W (Theorem 10.3.3 (a)). By Proposition 19.8.2 (d), $\cos\theta_1 = \|P_W \mathbf{u}\| = \sqrt{5}/3$. So $\theta_1 = \arccos(\sqrt{5}/3) \approx 41.8°$, and $\sin\theta_1 = 2/3$, which is the distance from $\mathbf{u}$ to the plane.

19.8.3 Sines and the orthogonal complement

The cosines measure how much of U survives projection into W. What Section 9 can actually bound is the part that does **not** survive: the component of U in $W^{\perp}$. Pythagoras says the two parts are complementary, and the theorem makes this exact.

Theorem 19.8.4 — Sines of Principal Angles

Let $U, W \subseteq F^n$ with $1 \le k = \dim U \le l = \dim W$, principal angles $\theta_1 \le \cdots \le \theta_k$, and orthonormal basis matrices $\mathbf{Q}_U, \mathbf{Q}_W$.

(a) Suppose $l < n$, and let $\mathbf{Q}_{W^{\perp}} \in M_{n\times(n-l)}(F)$ be an orthonormal basis matrix of $W^{\perp}$. Put $\mathbf{M} = \mathbf{Q}_W^{*}\mathbf{Q}_U$ and $\mathbf{N} = \mathbf{Q}_{W^{\perp}}^{*}\mathbf{Q}_U \in M_{(n-l)\times k}(F)$. Then

$$\mathbf{M}^{*}\mathbf{M} + \mathbf{N}^{*}\mathbf{N} = \mathbf{I}_k,$$

and the eigenvalues of $\mathbf{N}^{*}\mathbf{N}$, with multiplicity, are $\sin^2\theta_1, \dots, \sin^2\theta_k$. Equivalently, $\sigma_i(\mathbf{N}) = \sin\theta_{k+1-i}$ for $i = 1, \dots, k$, with the convention for σ_i stated at the start of the section.

(b) For every $l \le n$,

$$\|(\mathbf{I} - P_W)P_U\|_2 = \|(\mathbf{I} - P_W)\mathbf{Q}_U\|_2 = \sin\theta_k = \|\sin\Theta(U, W)\|_2,$$

and

$$\|(\mathbf{I} - P_W)P_U\|_F = \|(\mathbf{I} - P_W)\mathbf{Q}_U\|_F = \|\sin\Theta(U, W)\|_F.$$

Idea. Split the identity of F^n along $W \oplus W^{\perp}$ and sandwich it between $\mathbf{Q}_U^{*}$ and $\mathbf{Q}_U$. That gives two Hermitian $k \times k$ matrices adding up to $\mathbf{I}_k$, and such matrices share their eigenvectors, with eigenvalues c and $1-c$. The first has eigenvalues $\cos^2\theta_i$ by definition, so the second has eigenvalues $\sin^2\theta_i$. Part (b) then removes the orthonormal factors, which change no norm.

Proof.

(a) By Lemma 19.8.1 (d) applied to W, $\mathbf{I}_n = \mathbf{Q}_W\mathbf{Q}_W^{*} + \mathbf{Q}_{W^{\perp}}\mathbf{Q}_{W^{\perp}}^{*}$. Multiplying on the left by $\mathbf{Q}_U^{*}$ and on the right by $\mathbf{Q}_U$, and using $\mathbf{Q}_U^{*}\mathbf{Q}_U = \mathbf{I}_k$ (part (a) of the lemma), gives $\mathbf{I}_k = \mathbf{M}^{*}\mathbf{M} + \mathbf{N}^{*}\mathbf{N}$.
The matrix $\mathbf{M}^{*}\mathbf{M} \in M_k(F)$ is Hermitian (real symmetric when $F = \mathbb{R}$). By Corollary 11.4.3 (or Corollary 11.5.2 when $F = \mathbb{R}$) there is an orthonormal basis $\mathbf{z}_1, \dots, \mathbf{z}_k$ of F^k consisting of eigenvectors of $\mathbf{M}^{*}\mathbf{M}$. Since $\mathbf{M}$ has $l \ge k$ rows, all k eigenvalues of $\mathbf{M}^{*}\mathbf{M}$ are squared singular values (Definition 12.8.1), so we may number the $\mathbf{z}_i$ so that $\mathbf{M}^{*}\mathbf{M}\mathbf{z}_i = \sigma_i(\mathbf{M})^2\mathbf{z}_i = \cos^2\theta_i\,\mathbf{z}_i$. Then

$$\mathbf{N}^{*}\mathbf{N}\mathbf{z}_i = (\mathbf{I}_k - \mathbf{M}^{*}\mathbf{M})\mathbf{z}_i = (1 - \cos^2\theta_i)\mathbf{z}_i = \sin^2\theta_i\,\mathbf{z}_i.$$

So the unitary matrix with columns $\mathbf{z}_1, \dots, \mathbf{z}_k$ diagonalizes $\mathbf{N}^{*}\mathbf{N}$ with diagonal $\sin^2\theta_1, \dots, \sin^2\theta_k$, and these are its eigenvalues with multiplicity (Theorem 6.10.3). The sine is increasing on $[0, \pi/2]$, so in decreasing order they read $\sin^2\theta_k \ge \cdots \ge \sin^2\theta_1 \ge 0$. By Eq. 16.9.1, the i-th largest eigenvalue of $\mathbf{N}^{*}\mathbf{N}$ is $\sigma_i(\mathbf{N})^2$ for every $i \le k$, with the stated convention. Taking non-negative square roots gives $\sigma_i(\mathbf{N}) = \sin\theta_{k+1-i}$.

(b) If $l = n$, then $W = F^n$, so $U \subseteq W$ and every $\theta_i = 0$ (Example 2 above), while $\mathbf{I} - P_W = \mathbf{0}$; all four norms are 0. Suppose $l < n$. By Lemma 19.8.1 (d) and (a),

$$(\mathbf{I} - P_W)\mathbf{Q}_U = \mathbf{Q}_{W^\perp}\mathbf{Q}_{W^\perp}^*\mathbf{Q}_U = \mathbf{Q}_{W^\perp}\mathbf{N},$$

and $(\mathbf{I}-P_W)P_U = \mathbf{Q}_{W^\perp}\mathbf{N}\mathbf{Q}_U^*$. By part (b) of the lemma, applied to $\mathbf{Q}_{W^\perp}$ and then to $\mathbf{Q}_U$, both matrices have the spectral and Frobenius norms of $\mathbf{N}$. Now $\|\mathbf{N}\|_2 = \sigma_1(\mathbf{N}) = \sin\theta_k$ by Theorem 15.3.3 (c) and part (a). Also $\|\mathbf{N}\|_F^2 = \operatorname{tr}(\mathbf{N}^*\mathbf{N})$, which is the sum of the eigenvalues of $\mathbf{N}^*\mathbf{N}$ (Theorem 8.3.3), that is $\sum_i \sin^2\theta_i = \|\sin\Theta(U,W)\|_F^2$. This proves the theorem.

■

Part (b) has a plain geometric reading. For a unit vector $\mathbf{u} \in U$, the vector $(\mathbf{I} - P_W)\mathbf{u}$ is the error in approximating $\mathbf{u}$ from W, and its length is the distance from $\mathbf{u}$ to W (Theorem 10.3.5). So $\sin\theta_k$ is the **largest distance from a unit vector of U to W**, and θ_k is the worst angle any direction of U makes with W. That is the number to bound when one asks whether a computed subspace is close to the true one, and part (a) turns it into the norm of the concrete matrix $\mathbf{Q}_{W^\perp}^*\mathbf{Q}_U$. In Section 9, U will be an invariant subspace of $\mathbf{A}$ and W the corresponding one for $\mathbf{A} + \mathbf{E}$. The columns of $\mathbf{Q}_{W^\perp}$ will be the remaining eigenvectors of $\mathbf{A} + \mathbf{E}$, and $\mathbf{N}$ will turn out to satisfy a Sylvester equation, so the bounds of Section 7 will apply to it.

19.8.4 The distance between two subspaces

A subspace is determined by its orthogonal projection, since $U = \operatorname{im} P_U$ by Theorem 3.10.1 (b), applied to $F^n = U \oplus U^\perp$. So a second natural way to compare U and W is the size of $P_U - P_W$. When the dimensions agree, this measures exactly the largest principal angle.

Theorem 19.8.5 — The Distance Between Projections

Let $U, W \subseteq F^n$ with $\dim U = \dim W = k \geq 1$, and principal angles $\theta_1 \leq \cdots \leq \theta_k$. Then

(a) $\|P_U - P_W\|_2 = \sin\theta_k$;
(b) $\|P_U - P_W\|_F = \sqrt{2}\,\|\sin\Theta(U,W)\|_F$;
(c) $\|P_U - P_W\|_2 \leq 1$, with equality if and only if $U \cap W^\perp \neq \{\mathbf{0}\}$.

Idea. For (b), the **squared** Frobenius norm of the Hermitian matrix $\mathbf{D} = P_U - P_W$ is $\operatorname{tr}(\mathbf{D}^2)$, which expands into traces of projections: $k + k - 2\operatorname{tr}(P_U P_W)$, and $\operatorname{tr}(P_U P_W) = \sum \cos^2\theta_i$. For (a), split $\mathbf{x} = \mathbf{x}_1 + \mathbf{x}_2$ along $U \oplus U^\perp$. Then $\mathbf{D}$ sends $\mathbf{x}_1$ to $(\mathbf{I} - P_W)\mathbf{x}_1 \in W^\perp$ and $\mathbf{x}_2$ to $-P_W\mathbf{x}_2 \in W$, so Pythagoras separates the two contributions. The first is controlled by the sines for (U, W), the second by the sines for (W, U), and equal dimensions make these the same list.

Proof. Put $\mathbf{D} = P_U - P_W$, and let $\mathbf{Q}_U, \mathbf{Q}_W$ be orthonormal basis matrices and $\mathbf{M} = \mathbf{Q}_W^*\mathbf{Q}_U \in M_k(F)$.

(b) By Lemma 19.8.1 (a), $P_U = \mathbf{Q}_U\mathbf{Q}_U^*$ and $P_W = \mathbf{Q}_W\mathbf{Q}_W^*$ are Hermitian and satisfy

$P_U^2 = P_U$, $P_W^2 = P_W$. Hence $\mathbf{D}$ is Hermitian and

$$\begin{aligned}\|\mathbf{D}\|_F^2 &= \operatorname{tr}(\mathbf{D}^*\mathbf{D}) = \operatorname{tr}(\mathbf{D}^2)\\ &= \operatorname{tr}(P_U) + \operatorname{tr}(P_W) - \operatorname{tr}(P_U P_W) - \operatorname{tr}(P_W P_U).\end{aligned}$$

By Theorem 0.9.6 (c), $\operatorname{tr}(P_U) = \operatorname{tr}(\mathbf{Q}_U^*\mathbf{Q}_U) = \operatorname{tr}(\mathbf{I}_k) = k$, likewise $\operatorname{tr}(P_W) = k$, and $\operatorname{tr}(P_W P_U) = \operatorname{tr}(P_U P_W)$. Also

$$\begin{aligned}\operatorname{tr}(P_U P_W) &= \operatorname{tr}(\mathbf{Q}_U\mathbf{Q}_U^*\mathbf{Q}_W\mathbf{Q}_W^*)\\ &= \operatorname{tr}(\mathbf{Q}_W^*\mathbf{Q}_U\mathbf{Q}_U^*\mathbf{Q}_W) = \operatorname{tr}(\mathbf{M}\mathbf{M}^*),\end{aligned}$$

and $\operatorname{tr}(\mathbf{M}\mathbf{M}^*) = \|\mathbf{M}^*\|_F^2 = \|\mathbf{M}\|_F^2 = \operatorname{tr}(\mathbf{M}^*\mathbf{M}) = \sum_i \cos^2\theta_i$, since the eigenvalues of $\mathbf{M}^*\mathbf{M}$ are $\cos^2\theta_1, \dots, \cos^2\theta_k$ (Definition 12.8.1, Theorem 8.3.3). Therefore

$$\|\mathbf{D}\|_F^2 = 2k - 2\sum_{i=1}^{k}\cos^2\theta_i = 2\sum_{i=1}^{k}\sin^2\theta_i,$$

which is (b).

(c) Put $s = \sin\theta_k$. By Theorem 19.8.4 (b), $\|(\mathbf{I} - P_W)P_U\|_2 = s$. The same theorem with the roles of U and W exchanged, which is allowed because $\dim W = \dim U$, gives $\|(\mathbf{I} - P_U)P_W\|_2 = s$ too, because by Proposition 19.8.2 (c) the principal angles between W and U are those between U and W.

Let $\mathbf{x} \in F^n$, and write $\mathbf{x}_1 = P_U\mathbf{x} \in U$ and $\mathbf{x}_2 = \mathbf{x} - \mathbf{x}_1 \in U^\perp$ (Definition 10.3.2). Then $P_U\mathbf{x} = \mathbf{x}_1$ and $P_W\mathbf{x} = P_W\mathbf{x}_1 + P_W\mathbf{x}_2$, so

$$\mathbf{D}\mathbf{x} = (\mathbf{I} - P_W)\mathbf{x}_1 - P_W\mathbf{x}_2.$$

The first term lies in $W^\perp$ and the second in W, by Theorem 10.3.2, so they are orthogonal, and by Theorem 10.1.3

$$\|\mathbf{D}\mathbf{x}\|^2 = \|(\mathbf{I} - P_W)\mathbf{x}_1\|^2 + \|P_W\mathbf{x}_2\|^2. \tag{19.8.1}$$

We bound the two terms. Since $\mathbf{x}_1 = P_U\mathbf{x}_1$, $\|(\mathbf{I} - P_W)\mathbf{x}_1\| = \|(\mathbf{I} - P_W)P_U\mathbf{x}_1\| \le s\|\mathbf{x}_1\|$ by Theorem 15.3.2 (a). For the second term, P_W is Hermitian and idempotent and $\mathbf{x}_2 = (\mathbf{I} - P_U)\mathbf{x}_2$, so

$$\begin{aligned}\|P_W\mathbf{x}_2\|^2 &= \langle P_W\mathbf{x}_2, \mathbf{x}_2\rangle = \langle P_W\mathbf{x}_2, (\mathbf{I} - P_U)\mathbf{x}_2\rangle\\ &= \langle (\mathbf{I} - P_U)P_W(P_W\mathbf{x}_2), \mathbf{x}_2\rangle \le s\,\|P_W\mathbf{x}_2\|\,\|\mathbf{x}_2\|,\end{aligned}$$

using Theorem 10.3.3 (b) for $\mathbf{I} - P_U = P_{U^\perp}$ (Lemma 19.8.1 (d)), then $P_W = P_W^2$, then Cauchy–Schwarz (Theorem 10.1.5) with $\|(\mathbf{I} - P_U)P_W\|_2 = s$. Hence $\|P_W\mathbf{x}_2\| \le s\|\mathbf{x}_2\|$, the case $P_W\mathbf{x}_2 = \mathbf{0}$ being trivial. Adding, and using $\|\mathbf{x}_1\|^2 + \|\mathbf{x}_2\|^2 = \|\mathbf{x}\|^2$ (Theorem 10.1.3),

$$\|\mathbf{D}\mathbf{x}\|^2 \le s^2\big(\|\mathbf{x}_1\|^2 + \|\mathbf{x}_2\|^2\big) = s^2\|\mathbf{x}\|^2.$$

So $\|\mathbf{D}\|_2 \le s$. For the reverse, Theorem 19.8.4 (b) gives $\|(\mathbf{I} - P_W)\mathbf{Q}_U\|_2 = s$, and by Lemma 15.3.1 there is a unit $\mathbf{y} \in F^k$ with $\|(\mathbf{I} - P_W)\mathbf{Q}_U\mathbf{y}\| = s$. The vector $\mathbf{x} = \mathbf{Q}_U\mathbf{y} \in U$ is a unit vector (Lemma 19.8.1 (b)) with $P_U\mathbf{x} = \mathbf{x}$, so $\mathbf{D}\mathbf{x} = (\mathbf{I} - P_W)\mathbf{x}$ and $\|\mathbf{D}\mathbf{x}\| = s$. Hence $\|\mathbf{D}\|_2 = s$.

(c) By (a) and Proposition 19.8.2 (b), $\|\mathbf{D}\|_2 = \sin\theta_k \le 1$, with equality if and only if $\cos\theta_k = \sigma_k(\mathbf{M}) = 0$. The square matrix $\mathbf{M}$ has $\sigma_k(\mathbf{M}) = 0$ if and only if $\operatorname{rank}\mathbf{M} < k$ (Theorem 12.8.1), that is, if and only if $\mathbf{My} = \mathbf{0}$ for some $\mathbf{y} \neq \mathbf{0}$. Put $\mathbf{u} = \mathbf{Q}_U\mathbf{y}$, which is a non-zero vector of U exactly when $\mathbf{y} \neq \mathbf{0}$, by Lemma 19.8.1 (b). Then $\mathbf{My} = \mathbf{Q}_W^*\mathbf{u}$, and $\mathbf{Q}_W^*\mathbf{u} = \mathbf{0}$ if and only if $P_W\mathbf{u} = \mathbf{Q}_W\mathbf{Q}_W^*\mathbf{u} = \mathbf{0}$, again by parts (b) and (a) of the lemma. Finally $P_W\mathbf{u} = \mathbf{0}$ means that $\mathbf{u} \in \ker P_W = W^\perp$, by Theorem 3.10.1 (b) applied to $F^n = W \oplus W^\perp$. So equality holds if and only if U contains a non-zero vector of $W^\perp$.

■

The factor $\sqrt{2}$ in (b) has a clean explanation. When $k = l$, the principal vectors of Proposition 19.8.3 give $P_U = \sum_i \mathbf{u}_i\mathbf{u}_i^*$ and $P_W = \sum_i \mathbf{w}_i\mathbf{w}_i^*$ (Lemma 19.8.1 (a)), so $P_U - P_W$ is a sum of the k terms $\mathbf{u}_i\mathbf{u}_i^* - \mathbf{w}_i\mathbf{w}_i^*$. These act in the mutually orthogonal planes $\operatorname{span}(\mathbf{u}_i, \mathbf{w}_i)$. Each term is Hermitian with trace 0 and rank at most 2, so its non-zero eigenvalues are a pair $\pm t_i$, and being Hermitian it is normal, so $\|\mathbf{u}_i\mathbf{u}_i^* - \mathbf{w}_i\mathbf{w}_i^*\|_F^2 = t_i^2 + t_i^2$ by Theorem 11.11.2. On the other hand, expanding the trace with $\mathbf{u}_i^*\mathbf{u}_i = \mathbf{w}_i^*\mathbf{w}_i = 1$ and $|\langle \mathbf{u}_i, \mathbf{w}_i\rangle| = \cos\theta_i$ (Proposition 19.8.3),

$$\|\mathbf{u}_i\mathbf{u}_i^* - \mathbf{w}_i\mathbf{w}_i^*\|_F^2 = 2 - 2|\langle \mathbf{u}_i, \mathbf{w}_i\rangle|^2 = 2\sin^2\theta_i,$$

so $t_i = \sin\theta_i$. Each angle is therefore counted twice in the Frobenius norm and once in the spectral norm. The worked example below shows the $\pm$ pairs explicitly.

Example. (Two Planes in Four Dimensions)

Let $U = \operatorname{span}(\mathbf{e}_1, \mathbf{e}_2) \subseteq \mathbb{R}^4$ and $W = \operatorname{span}(\mathbf{a}, \mathbf{b})$, where

$$\mathbf{a} = (3, 4, 4, 3), \qquad \mathbf{b} = (3, -4, 4, -3).$$

Find the principal angles, a pair of principal vectors for each, the sines from Theorem 19.8.4, and $\|P_U - P_W\|$ in both norms. Then check the last two numbers directly.

Solution. **Orthonormal bases.** $\langle \mathbf{a}, \mathbf{b}\rangle = 9 - 16 + 16 - 9 = 0$ and $\|\mathbf{a}\|^2 = \|\mathbf{b}\|^2 = 50$, so $\mathbf{Q}_W = \frac{1}{5\sqrt{2}}(\mathbf{a} \mid \mathbf{b})$ is an orthonormal basis matrix of W, and $\mathbf{Q}_U = (\mathbf{e}_1 \mid \mathbf{e}_2)$. The matrix $\mathbf{Q}_W^\top\mathbf{Q}_U$ holds the first two entries of $\mathbf{a}$ and $\mathbf{b}$:

$$\mathbf{M} = \mathbf{Q}_W^\top\mathbf{Q}_U = \frac{1}{5\sqrt{2}}\begin{pmatrix} 3 & 4 \\ 3 & -4 \end{pmatrix}, \qquad \mathbf{M}^\top\mathbf{M} = \begin{pmatrix} 9/25 & 0 \\ 0 & 16/25 \end{pmatrix}.$$

So the singular values are $4/5$ and $3/5$, and

$$\theta_1 = \arccos\tfrac{4}{5} \approx 36.87^\circ, \qquad \theta_2 = \arccos\tfrac{3}{5} \approx 53.13^\circ.$$

Note $\sin\theta_1 = 3/5 = \cos\theta_2$, so $\theta_1 + \theta_2 = \pi/2$ here.

Principal vectors. The eigenvector of $\mathbf{M}^\top\mathbf{M}$ for $16/25$ is $\mathbf{z}_1 = \mathbf{e}_2$, and $\mathbf{y}_1 = \mathbf{Mz}_1/\sigma_1 = \frac{1}{5\sqrt{2}}(4, -4) \cdot \frac{5}{4} = \frac{1}{\sqrt{2}}(1, -1)$. By Proposition 19.8.3,

$$\mathbf{u}_1 = \mathbf{e}_2, \qquad \mathbf{w}_1 = \mathbf{Q}_W\mathbf{y}_1 = \tfrac{1}{10}(\mathbf{a} - \mathbf{b}) = \left(0, \tfrac{4}{5}, 0, \tfrac{3}{5}\right),$$

and $\langle \mathbf{u}_1, \mathbf{w}_1\rangle = 4/5$. Likewise $\mathbf{z}_2 = \mathbf{e}_1$, $\mathbf{y}_2 = \frac{1}{\sqrt{2}}(1, 1)$, $\mathbf{u}_2 = \mathbf{e}_1$ and $\mathbf{w}_2 = \frac{1}{10}(\mathbf{a} + \mathbf{b}) = (\frac{3}{5}, 0, \frac{4}{5}, 0)$, with $\langle \mathbf{u}_2, \mathbf{w}_2\rangle = 3/5$, while $\langle \mathbf{u}_1, \mathbf{w}_2\rangle = \langle \mathbf{u}_2, \mathbf{w}_1\rangle = 0$. So W is obtained from

U by tilting $\mathbf{e}_2$ towards $\mathbf{e}_4$ through θ_1 and $\mathbf{e}_1$ towards $\mathbf{e}_3$ through θ_2, in two perpendicular planes.

Sines. The vectors $\mathbf{c} = (4, -3, -3, 4)$ and $\mathbf{d} = (4, 3, -3, -4)$ are orthogonal to $\mathbf{a}$, to $\mathbf{b}$ and to each other:

$$\langle \mathbf{c}, \mathbf{a} \rangle = 12 - 12 - 12 + 12 = 0, \quad \langle \mathbf{c}, \mathbf{b} \rangle = 12 + 12 - 12 - 12 = 0,$$
$$\langle \mathbf{d}, \mathbf{a} \rangle = 12 + 12 - 12 - 12 = 0, \quad \langle \mathbf{d}, \mathbf{b} \rangle = 12 - 12 - 12 + 12 = 0,$$

and $\langle \mathbf{c}, \mathbf{d} \rangle = 16 - 9 + 9 - 16 = 0$. Also $\|\mathbf{c}\|^2 = \|\mathbf{d}\|^2 = 50$. Since $\dim W^\perp = 2$ (Theorem 10.3.2 (c)), $\mathbf{Q}_{W^\perp} = \frac{1}{5\sqrt{2}}(\mathbf{c} \mid \mathbf{d})$ is an orthonormal basis matrix of $W^\perp$, and

$$\mathbf{N} = \mathbf{Q}_{W^\perp}^\top \mathbf{Q}_U = \frac{1}{5\sqrt{2}} \begin{pmatrix} 4 & -3 \\ 4 & 3 \end{pmatrix}, \qquad \mathbf{N}^\top \mathbf{N} = \begin{pmatrix} 16/25 & 0 \\ 0 & 9/25 \end{pmatrix}.$$

Its eigenvalues are $16/25 = \sin^2\theta_2$ and $9/25 = \sin^2\theta_1$, and $\mathbf{M}^\top\mathbf{M} + \mathbf{N}^\top\mathbf{N} = \mathbf{I}_2$, as Theorem 19.8.4 (a) says.

Distances. By Theorem 19.8.5, $\|P_U - P_W\|_2 = \sin\theta_2 = 4/5$ and $\|P_U - P_W\|_F = \sqrt{2}\left(\frac{9}{25} + \frac{16}{25}\right)^{1/2} = \sqrt{2}$.

Direct check. By Lemma 19.8.1 (a), $P_W = \mathbf{Q}_W\mathbf{Q}_W^\top = \frac{1}{50}(\mathbf{a}\mathbf{a}^\top + \mathbf{b}\mathbf{b}^\top)$, and

$$P_W = \frac{1}{50} \begin{pmatrix} 18 & 0 & 24 & 0 \\ 0 & 32 & 0 & 24 \\ 24 & 0 & 32 & 0 \\ 0 & 24 & 0 & 18 \end{pmatrix}, \qquad P_U = \operatorname{diag}(1, 1, 0, 0).$$

In $\mathbf{D} = P_U - P_W$, coordinates $1, 3$ do not interact with coordinates $2, 4$, and the two 2×2 blocks are

$$\frac{1}{50} \begin{pmatrix} 32 & -24 \\ -24 & -32 \end{pmatrix}, \qquad \frac{1}{50} \begin{pmatrix} 18 & -24 \\ -24 & -18 \end{pmatrix}.$$

Each is symmetric with trace 0, so its eigenvalues are $\pm\sqrt{-\det}$: $\pm\frac{1}{50}\sqrt{32^2 + 24^2} = \pm\frac{4}{5}$ and $\pm\frac{1}{50}\sqrt{18^2 + 24^2} = \pm\frac{3}{5}$. So $\mathbf{D}$ has eigenvalues $\pm\frac{4}{5}, \pm\frac{3}{5}$. By Lemma 16.3.5, $\|\mathbf{D}\|_2 = 4/5$, and $\|\mathbf{D}\|_F^2 = \operatorname{tr}(\mathbf{D}^2) = 2\left(\frac{16}{25} + \frac{9}{25}\right) = 2$. Both agree with the theorem, and the eigenvalues come in the $\pm\sin\theta_i$ pairs described before the example.

Remark. **A metric, and why the dimensions must match.** On the set of k-dimensional subspaces of F^n, the number $d(U, W) = \|P_U - P_W\|_2 = \sin\theta_k$ is a metric. It is symmetric. It is zero only when $P_U = P_W$, that is, when $U = \operatorname{im} P_U = \operatorname{im} P_W = W$. And it satisfies the triangle inequality because $\|\cdot\|_2$ is a norm (Theorem 15.3.2 (b)). Between subspaces of **different** dimensions it is useless. If $k < l$, then $\dim(W \cap U^\perp) \geq l + (n - k) - n > 0$ by Theorem 1.7.3, so some unit $\mathbf{w} \in W$ is perpendicular to U. For it $(P_U - P_W)\mathbf{w} = -\mathbf{w}$, so $\|P_U - P_W\|_2 \geq 1$. On the other hand, Eq. 19.8.1, which did not use the dimensions, together with $\|P\mathbf{v}\| \leq \|\mathbf{v}\|$ for orthogonal projections (Theorem 10.3.3 (c)), gives $\|P_U - P_W\|_2 \leq 1$. So the distance is exactly 1, whatever the principal angles are. This is why Section 9 always compares invariant subspaces of the same dimension.

19.8.5 Exercises

19.8.5.1 A. Check your understanding

Exercise A1.

(a) Define the principal angles between subspaces $U, W \subseteq F^n$ with $1 \le \dim U \le \dim W$.

(b) True or false: if $U \subseteq W$, then every principal angle between U and W is 0. Justify your answer.

(c) True or false: the principal angle between $\operatorname{span}(\mathbf{u})$ and $\operatorname{span}(-\mathbf{u})$, for $\mathbf{u} \neq \mathbf{0}$, is π. Justify your answer.

(d) True or false: if $U \cap W \neq \{\mathbf{0}\}$, then $\theta_1 = 0$. Justify your answer.

(e) State the formula for $\|P_U - P_W\|_2$ in terms of principal angles, with its hypothesis.

(f) True or false: for two distinct lines U, W in $\mathbb{R}^2$, $\|P_U - P_W\|_2 < 1$. Justify your answer.

Solution.

(a) Choose orthonormal basis matrices $\mathbf{Q}_U \in M_{n\times k}(F)$ and $\mathbf{Q}_W \in M_{n\times l}(F)$. The principal angles $0 \le \theta_1 \le \cdots \le \theta_k \le \pi/2$ are defined by $\cos\theta_i = \sigma_i(\mathbf{Q}_W^*\mathbf{Q}_U)$, $i = 1, \dots, k$ (Definition 19.8.1). They do not depend on the bases (Proposition 19.8.2).

(b) True. As in Example 2 after Proposition 19.8.2, $\mathbf{M}^*\mathbf{M} = \mathbf{Q}_U^* P_W \mathbf{Q}_U = \mathbf{Q}_U^*\mathbf{Q}_U = \mathbf{I}_k$, so every $\cos\theta_i = 1$.

(c) False. The two lines are equal, so the angle is 0: with $\mathbf{u}_0 = \mathbf{u}/\|\mathbf{u}\|$, $|\langle \mathbf{u}_0, -\mathbf{u}_0\rangle| = 1$ (Proposition 19.8.2 (d)). The value π is the angle between the vectors $\mathbf{u}$ and $-\mathbf{u}$ of Definition 10.1.5, which is a different notion.

(d) True. Take a unit $\mathbf{u} \in U \cap W$ and write $\mathbf{u} = \mathbf{Q}_U\mathbf{y}$ with $\|\mathbf{y}\| = 1$ (Lemma 19.8.1 (b)). Then $\|\mathbf{M}\mathbf{y}\| = \|\mathbf{Q}_W^*\mathbf{u}\| = \|P_W\mathbf{u}\| = \|\mathbf{u}\| = 1$, so $\sigma_1(\mathbf{M}) = \|\mathbf{M}\|_2 \ge 1$. With Proposition 19.8.2 (b), $\cos\theta_1 = 1$.

(e) If $\dim U = \dim W = k \ge 1$, then $\|P_U - P_W\|_2 = \sin\theta_k$, the sine of the largest principal angle (Theorem 19.8.5 (a)).

(f) False. The two axes $U = \operatorname{span}(\mathbf{e}_1)$ and $W = \operatorname{span}(\mathbf{e}_2)$ have $U \cap W^\perp = U \neq \{\mathbf{0}\}$, so $\|P_U - P_W\|_2 = 1$ by Theorem 19.8.5 (c). Directly, $P_U - P_W = \operatorname{diag}(1, -1)$.

19.8.5.2 B. Practice

Exercise B1: Two planes in three dimensions.

Let $U = \operatorname{span}(\mathbf{e}_1, \mathbf{e}_2)$ and $W = \operatorname{span}\big((1,0,0), (1,3,4)\big)$ in $\mathbb{R}^3$.

(a) Find an orthonormal basis matrix of W.

(b) Compute the principal angles between U and W.

(c) Hence compute $\|P_U - P_W\|_2$ and $\|P_U - P_W\|_F$.

(d) Explain why $\theta_1 = 0$ could have been predicted without computation.

Solution.

(a) Gram–Schmidt: $\mathbf{q}_1 = \mathbf{e}_1$, and $(1,3,4) - \langle (1,3,4), \mathbf{e}_1 \rangle \mathbf{e}_1 = (0,3,4)$, of length 5, so $\mathbf{q}_2 = (0, \frac{3}{5}, \frac{4}{5})$ and $\mathbf{Q}_W = (\mathbf{q}_1 \mid \mathbf{q}_2)$.

(b) With $\mathbf{Q}_U = (\mathbf{e}_1 \mid \mathbf{e}_2)$, the matrix $\mathbf{M} = \mathbf{Q}_W^{\top} \mathbf{Q}_U$ holds the first two entries of $\mathbf{q}_1$ and $\mathbf{q}_2$:

$$\mathbf{M} = \begin{pmatrix} 1 & 0 \\ 0 & 3/5 \end{pmatrix}.$$

It is diagonal with non-negative entries, so $\mathbf{M}^{\top}\mathbf{M} = \operatorname{diag}(1, \frac{9}{25})$ and the singular values are 1 and $\frac{3}{5}$. So $\theta_1 = 0$ and $\theta_2 = \arccos \frac{3}{5} \approx 53.13°$, with $\sin \theta_2 = \frac{4}{5}$.

(c) By Theorem 19.8.5, $\|P_U - P_W\|_2 = \sin \theta_2 = \frac{4}{5}$ and $\|P_U - P_W\|_F = \sqrt{2}\,(0 + \frac{16}{25})^{1/2} = \frac{4\sqrt{2}}{5}$.

(d) Two planes in $\mathbb{R}^3$ meet in a line (Theorem 1.7.3, as in the opening of the section), and a common unit vector forces $\cos \theta_1 = 1$ (Exercise A1 (d)). Here the common line is $\operatorname{span}(\mathbf{e}_1)$.

Exercise B2: Which projections are at distance one?.

Determine, for each pair, whether $\|P_U - P_W\|_2 = 1$. Justify your answer.

(a) $U = \operatorname{span}(\mathbf{e}_1, \mathbf{e}_2)$ and $W = \operatorname{span}(\mathbf{e}_2, \mathbf{e}_3)$ in $\mathbb{R}^3$.

(b) $U = \operatorname{span}\big((1,1,0)\big)$ and $W = \operatorname{span}\big((1,-1,1)\big)$ in $\mathbb{R}^3$.

(c) $U = \operatorname{span}(\mathbf{e}_1, \mathbf{e}_2)$ and $W = \operatorname{span}\big((1,0,1),(0,1,1)\big)$ in $\mathbb{R}^3$.

(d) $U = \operatorname{span}\big((1,2,3)\big)$ and $W = \operatorname{span}\big((1,0,0),(0,1,0)\big)$ in $\mathbb{R}^3$.

Solution.

(a) Yes. $W^{\perp} = \operatorname{span}(\mathbf{e}_1) \subseteq U$, so $U \cap W^{\perp} \neq \{\mathbf{0}\}$, and Theorem 19.8.5 (c) applies since both dimensions are 2.

(b) Yes. $\langle (1,1,0), (1,-1,1) \rangle = 0$, so $U \subseteq W^{\perp}$, and (c) of the theorem applies with $k = 1$.

(c) No. Both are planes, and $W^{\perp} = \operatorname{span}\big((1,1,-1)\big)$, since $(1,1,-1)$ is orthogonal to both spanning vectors of W and $\dim W^{\perp} = 1$. This vector has non-zero third entry, so it is not in U, and $U \cap W^{\perp} = \{\mathbf{0}\}$. By the theorem, $\|P_U - P_W\|_2 < 1$. (In fact the principal angles are 0 and $\arccos(1/\sqrt{3})$, so the distance is $\sqrt{2/3}$.)

(d) Yes, for a different reason: the dimensions are 1 and 2, and the remark after Example (Two Planes in Four Dimensions) shows that $\|P_U - P_W\|_2 = 1$ whenever the dimensions differ. The theorem itself does not apply. Its principal angle $\theta_1 = \arccos(\sqrt{5}/\sqrt{14})$ is far from $\pi/2$, which illustrates why the projection distance is only used for equal dimensions.

Exercise B3: Two lines.

Let $\mathbf{u}, \mathbf{w} \in F^n$ be unit vectors and $c = |\langle \mathbf{u}, \mathbf{w} \rangle|$. Prove that

$$\|\mathbf{u}\mathbf{u}^* - \mathbf{w}\mathbf{w}^*\|_2 = \sqrt{1 - c^2}, \qquad \|\mathbf{u}\mathbf{u}^* - \mathbf{w}\mathbf{w}^*\|_F = \sqrt{2}\,\sqrt{1 - c^2}.$$

Solution. Let $U = \operatorname{span}(\mathbf{u})$ and $W = \operatorname{span}(\mathbf{w})$, both of dimension 1. By Lemma 19.8.1 (a) with $\mathbf{Q}_U = \mathbf{u}$ and $\mathbf{Q}_W = \mathbf{w}$, $P_U = \mathbf{u}\mathbf{u}^*$ and $P_W = \mathbf{w}\mathbf{w}^*$. By Proposition 19.8.2 (d), the single principal angle satisfies $\cos\theta_1 = c$, so $\sin\theta_1 = \sqrt{1-c^2}$, since $\sin\theta_1 \geq 0$ on $[0, \pi/2]$. Now Theorem 19.8.5 (a) and (b) with $k = 1$ give $\|P_U - P_W\|_2 = \sin\theta_1$ and $\|P_U - P_W\|_F = \sqrt{2}\sin\theta_1$, which are the two claims.

19.8.5.3 C. Going deeper

Exercise C1: Counting zero and right angles.

Let $U, W \subseteq F^n$ with $1 \leq k = \dim U \leq l = \dim W$, orthonormal basis matrices $\mathbf{Q}_U, \mathbf{Q}_W$, and $\mathbf{M} = \mathbf{Q}_W^* \mathbf{Q}_U$.

(a) Prove that $\mathbf{y}^*(\mathbf{I}_k - \mathbf{M}^*\mathbf{M})\mathbf{y} = \|(\mathbf{I} - P_W)\mathbf{Q}_U\mathbf{y}\|^2$ for every $\mathbf{y} \in F^k$.

(b) Deduce that the number of principal angles equal to 0 is $\dim(U \cap W)$.

(c) Prove that the number of principal angles equal to $\pi/2$ is $\dim(U \cap W^\perp)$.

Hint for (b): a positive semidefinite matrix $\mathbf{B}$ *with* $\mathbf{y}^*\mathbf{B}\mathbf{y} = 0$ *has* $\mathbf{B}\mathbf{y} = \mathbf{0}$.

Solution.

(a) Let $\mathbf{u} = \mathbf{Q}_U\mathbf{y}$. By Lemma 19.8.1 (a) and (b), $\mathbf{y}^*\mathbf{y} = \|\mathbf{u}\|^2$ and $\mathbf{y}^*\mathbf{M}^*\mathbf{M}\mathbf{y} = \|\mathbf{Q}_W^*\mathbf{u}\|^2 = \|P_W\mathbf{u}\|^2$. Since $\mathbf{u} = P_W\mathbf{u} + (\mathbf{I} - P_W)\mathbf{u}$ with the two parts orthogonal (Theorem 10.3.2), Theorem 10.1.3 gives $\|\mathbf{u}\|^2 - \|P_W\mathbf{u}\|^2 = \|(\mathbf{I} - P_W)\mathbf{u}\|^2$.

(b) Put $\mathbf{B} = \mathbf{I}_k - \mathbf{M}^*\mathbf{M}$. It is Hermitian, and by (a) it is positive semidefinite (Definition 12.1.1). Its eigenvalues are $1 - \cos^2\theta_i = \sin^2\theta_i$, with an orthonormal eigenbasis $\mathbf{z}_1, \ldots, \mathbf{z}_k$ (as in the proof of Theorem 19.8.4). So the number of i with $\theta_i = 0$ is the number of zero eigenvalues, which is $\dim\ker\mathbf{B}$.
We claim $\ker\mathbf{B} = \{\mathbf{y} : \mathbf{Q}_U\mathbf{y} \in W\}$. If $\mathbf{B}\mathbf{y} = \mathbf{0}$, then $\mathbf{y}^*\mathbf{B}\mathbf{y} = 0$, so $(\mathbf{I} - P_W)\mathbf{Q}_U\mathbf{y} = \mathbf{0}$ by (a), and $\mathbf{Q}_U\mathbf{y} = P_W\mathbf{Q}_U\mathbf{y} \in W$. Conversely, if $\mathbf{Q}_U\mathbf{y} \in W$, then $\mathbf{y}^*\mathbf{B}\mathbf{y} = 0$ by (a). Writing $\mathbf{y} = \sum_i c_i\mathbf{z}_i$, this says $\sum_i \sin^2\theta_i |c_i|^2 = 0$. So $c_i = 0$ whenever $\sin\theta_i \neq 0$, and then $\mathbf{B}\mathbf{y} = \sum_i c_i \sin^2\theta_i \mathbf{z}_i = \mathbf{0}$. This proves the claim; the second half of it is the fact in the hint, proved here for this $\mathbf{B}$.
The map $\mathbf{y} \mapsto \mathbf{Q}_U\mathbf{y}$ is linear and injective (Lemma 19.8.1 (b)). It carries $\ker\mathbf{B}$ onto $\{\mathbf{u} \in U : \mathbf{u} \in W\} = U \cap W$, because every vector of U is $\mathbf{Q}_U\mathbf{y}$ for some $\mathbf{y}$. So $\dim\ker\mathbf{B} = \dim(U \cap W)$.

(c) $\theta_i = \pi/2$ exactly when $\sigma_i(\mathbf{M}) = 0$. The number of non-zero singular values of $\mathbf{M}$ is $\operatorname{rank}\mathbf{M}$ (Theorem 12.8.1), so the number of zero ones among the k is $k - \operatorname{rank}\mathbf{M} = \dim\ker\mathbf{M}$, by the Rank–Nullity Theorem (Theorem 3.3.1) for $\mathbf{y} \mapsto \mathbf{M}\mathbf{y}$ on F^k. Next, $\mathbf{M}\mathbf{y} = \mathbf{Q}_W^*\mathbf{Q}_U\mathbf{y} = \mathbf{0}$ if and only if $P_W\mathbf{Q}_U\mathbf{y} = \mathbf{Q}_W(\mathbf{Q}_W^*\mathbf{Q}_U\mathbf{y}) = \mathbf{0}$, because $\mathbf{Q}_W$ is injective. That holds if and only if $\mathbf{Q}_U\mathbf{y} \in W^\perp$. As in (b), $\mathbf{y} \mapsto \mathbf{Q}_U\mathbf{y}$ carries $\ker\mathbf{M}$ injectively onto $U \cap W^\perp$, so the count is $\dim(U \cap W^\perp)$.

Exercise C2: The smallest angle as a maximum.

Let $U, W \subseteq F^n$ with $1 \leq k = \dim U \leq l = \dim W$ and principal angles $\theta_1 \leq \cdots \leq \theta_k$.

(a) Prove that

$$\cos\theta_1 = \max\bigl\{|\langle \mathbf{u}, \mathbf{w}\rangle| : \mathbf{u} \in U,\ \mathbf{w} \in W,\ \|\mathbf{u}\| = \|\mathbf{w}\| = 1\bigr\},$$

and that the maximum is attained at the principal vectors $\mathbf{u}_1, \mathbf{w}_1$.

(b) Deduce that θ_1 is the smallest principal angle between a line of U and a line of W, which is the notion tried and rejected at the start of the section.

(c) Hence explain, in one sentence, why θ_1 alone cannot distinguish the pairs (U, W_1) and (U, U) of the opening, but the full list θ_1, θ_2 can.

Solution.

(a) Let $\mathbf{u} \in U$ and $\mathbf{w} \in W$ be unit vectors. By Lemma 19.8.1 (a) and (b), $\mathbf{u} = \mathbf{Q}_U\mathbf{y}$ and $\mathbf{w} = \mathbf{Q}_W\mathbf{z}$ with $\mathbf{y} = \mathbf{Q}_U^*\mathbf{u}$ and $\mathbf{z} = \mathbf{Q}_W^*\mathbf{w}$ unit vectors. Then $\langle \mathbf{u}, \mathbf{w}\rangle = \mathbf{z}^*\mathbf{Q}_W^*\mathbf{Q}_U\mathbf{y} = \mathbf{z}^*\mathbf{M}\mathbf{y}$, and by Cauchy–Schwarz and Theorem 15.3.2 (a),

$$|\langle \mathbf{u}, \mathbf{w}\rangle| \le \|\mathbf{z}\|\,\|\mathbf{M}\mathbf{y}\| \le \|\mathbf{M}\|_2 = \sigma_1(\mathbf{M}) = \cos\theta_1,$$

using Theorem 15.3.3 (c). By Proposition 19.8.3, the unit vectors $\mathbf{u}_1 \in U$ and $\mathbf{w}_1 \in W$ satisfy $\langle \mathbf{u}_1, \mathbf{w}_1\rangle = \cos\theta_1$, so the maximum exists and equals $\cos\theta_1$.

(b) By Proposition 19.8.2 (d), the principal angle between the lines $\operatorname{span}(\mathbf{u})$ and $\operatorname{span}(\mathbf{w})$ is $\arccos|\langle \mathbf{u}, \mathbf{w}\rangle|$. Since $\arccos$ is decreasing, the smallest such angle corresponds to the largest $|\langle \mathbf{u}, \mathbf{w}\rangle|$, which by (a) is $\cos\theta_1$.

(c) Both pairs share a line, so both have $\theta_1 = 0$, and the first number cannot separate them. The second angle is $\pi/2$ for (U, W_1) and 0 for (U, U), by Examples 4 and 2 after Proposition 19.8.2.

19.9 The Davis–Kahan Theorem

Weyl's inequality settled the eigenvalues of a Hermitian matrix: under a Hermitian perturbation $\mathbf{E}$, each of them moves by at most $\|\mathbf{E}\|_2$, whatever the matrix and however its eigenvalues are spaced. Eigenvectors are a different matter, and this section is about them. Section 8 supplied the yardstick, the principal angles between two subspaces, and Section 7 supplied the tool, bounds for the equation $\mathbf{A}\mathbf{X} - \mathbf{X}\mathbf{B} = \mathbf{Y}$. The theorem of this section is what happens when the two meet: the perturbation of an invariant subspace satisfies a Sylvester equation, and the bounds of Section 7 then measure it.

Throughout, $\mathbf{A}$ and $\widetilde{\mathbf{A}} = \mathbf{A} + \mathbf{E}$ are Hermitian matrices in $M_n(\mathbb{C})$, so $\mathbf{E} = \widetilde{\mathbf{A}} - \mathbf{A}$ is Hermitian too, and $1 \le k \le n-1$. As everywhere in this chapter, $\|\cdot\|_2$ is the spectral norm and $\|\cdot\|_F$ the Frobenius norm, and every bound names the norm it holds in. For a subspace we write $\operatorname{col}(\mathbf{Q})$ for the column space of a matrix $\mathbf{Q}$ whose columns span it.

19.9.1 Eigenvectors can move a long way

Before any theorem, here is what goes wrong. The example is as small as it can be, and every number in it is exact.

Example. (A tiny perturbation that turns the eigenvectors through 45°)

Let $0 < \eta < 1$ and

$$\mathbf{A} = \begin{pmatrix} 1+\eta & 0 \\ 0 & 1-\eta \end{pmatrix}, \qquad \mathbf{E} = \eta \begin{pmatrix} -1 & 1 \\ 1 & 1 \end{pmatrix}.$$

Compare the eigenvalues and the eigenvectors of $\mathbf{A}$ and of $\widetilde{\mathbf{A}} = \mathbf{A} + \mathbf{E}$, and compute $\|\mathbf{E}\|_2$.

Solution. Adding, $\widetilde{\mathbf{A}} = \left(\begin{smallmatrix} 1 & \eta \\ \eta & 1 \end{smallmatrix}\right)$. Since

$$\widetilde{\mathbf{A}} \begin{pmatrix} 1 \\ 1 \end{pmatrix} = (1+\eta) \begin{pmatrix} 1 \\ 1 \end{pmatrix}, \qquad \widetilde{\mathbf{A}} \begin{pmatrix} 1 \\ -1 \end{pmatrix} = (1-\eta) \begin{pmatrix} 1 \\ -1 \end{pmatrix},$$

the eigenvalues of $\widetilde{\mathbf{A}}$ are $1+\eta$ and $1-\eta$: **exactly** those of $\mathbf{A}$. The eigenvectors are another story. For the eigenvalue $1+\eta$, the matrix $\mathbf{A}$ has the unit eigenvector $\mathbf{e}_1$ and $\widetilde{\mathbf{A}}$ has $\frac{1}{\sqrt{2}}(1,1)$; the two lines they span meet at the angle $\pi/4$, because $|\langle \mathbf{e}_1, \frac{1}{\sqrt{2}}(1,1)\rangle| = \frac{1}{\sqrt{2}} = \cos\frac{\pi}{4}$. The same happens for $1-\eta$, with $\mathbf{e}_2$ and $\frac{1}{\sqrt{2}}(1,-1)$.

The matrix $\mathbf{E}/\eta$ is Hermitian and squares to $2\mathbf{I}_2$, so its eigenvalues are $\pm\sqrt{2}$ (it has trace 0), and by Lemma 16.3.5

$$\|\mathbf{E}\|_2 = \sqrt{2}\,\eta.$$

So as $\eta \to 0^+$ the perturbation vanishes, the eigenvalues do not move at all, and yet the eigenvectors of $\widetilde{\mathbf{A}}$ stay a full 45° away from those of $\mathbf{A}$.

The rotation does not shrink with η. What does shrink with η is the distance 2η between the two eigenvalues of $\mathbf{A}$, and that is the whole story: the two eigenvalues are so close that a perturbation of their own size can mix their eigenvectors freely. An eigenvector bound must therefore divide by a gap, and the natural guess is "angle $\lesssim$ perturbation / gap". Here that ratio is $\sqrt{2}\eta/2\eta = 1/\sqrt{2} = \sin(\pi/4)$, which is exactly the sine of the angle. The theorem below turns the guess into an inequality, and this example will turn out to attain it.

Warning. **Well-conditioned eigenvalues do not make well-conditioned eigenvectors.** Corollary 16.3.6 guarantees that every eigenvalue of a Hermitian matrix moves by at most $\|\mathbf{E}\|_2$, with no mention of gaps, and it is tempting to expect the same of eigenvectors. Example (A tiny perturbation that turns the eigenvectors through 45°) refutes this: a perturbation of size $\sqrt{2}\,\eta$ leaves every eigenvalue fixed and turns every eigenvector through $\pi/4$, however small η is. No inequality of the form $\sin\theta \le C\|\mathbf{E}\|_2$, with C depending only on n, can hold.

19.9.2 Two norms, three facts

The proofs of this section and the next shuffle unitary factors and matrices with orthonormal columns in and out of norms, sometimes the spectral one and sometimes the Frobenius one. The facts needed are elementary, but they are needed so often that they are worth collecting once. Part (c) is mostly quoted: its norm identities for a matrix with orthonormal columns are Lemma 19.8.1 (b) of Section 8, read with $U = \mathrm{col}(\mathbf{X})$, and for the Frobenius norm the unitary

invariance is Lemma 11.11.1. The rest — (a), (b) and the inequality $\|\mathbf{X}^*\mathbf{N}\| \le \|\mathbf{N}\|$ — is proved below, and what the lemma is really for is to have all of it, in both norms, in one place.

Lemma 19.9.1 — Moving Factors in and out of the Two Norms

Let $\|\cdot\|$ stand for either $\|\cdot\|_2$ or $\|\cdot\|_F$, the same one throughout each statement.

(a) $\|\mathbf{M}^*\| = \|\mathbf{M}\|$ for every $\mathbf{M} \in M_{m\times n}(\mathbb{C})$.

(b) $\|\mathbf{XMY}\| \le \|\mathbf{X}\|_2\,\|\mathbf{M}\|\,\|\mathbf{Y}\|_2$ whenever the product is defined.

(c) If $\mathbf{X} \in M_{m\times k}(\mathbb{C})$ has orthonormal columns, that is $\mathbf{X}^*\mathbf{X} = \mathbf{I}_k$, then $\|\mathbf{X}\|_2 = 1$, $\|\mathbf{XM}\| = \|\mathbf{M}\|$ and $\|\mathbf{X}^*\mathbf{N}\| \le \|\mathbf{N}\|$ for all $\mathbf{M} \in M_{k\times n}(\mathbb{C})$ and $\mathbf{N} \in M_{m\times n}(\mathbb{C})$. In particular $\|\mathbf{UMV}\| = \|\mathbf{M}\|$ for unitary $\mathbf{U}$ and $\mathbf{V}$.

Proof.

(a) For $\|\cdot\|_F$ this holds because $\mathbf{M}^*$ has the same entries as $\mathbf{M}$ up to position and conjugation. For $\|\cdot\|_2$, let $\mathbf{x} \in \mathbb{C}^n$. By Theorem 10.1.5 and Theorem 15.3.2 (a), applied twice,

$$\|\mathbf{Mx}\|^2 = \langle \mathbf{M}^*\mathbf{Mx}, \mathbf{x}\rangle \le \|\mathbf{M}^*\mathbf{Mx}\|\,\|\mathbf{x}\| \le \|\mathbf{M}^*\|_2\|\mathbf{M}\|_2\|\mathbf{x}\|^2.$$

Taking the maximum over unit $\mathbf{x}$ gives $\|\mathbf{M}\|_2^2 \le \|\mathbf{M}^*\|_2\|\mathbf{M}\|_2$, hence $\|\mathbf{M}\|_2 \le \|\mathbf{M}^*\|_2$ when $\mathbf{M} \neq \mathbf{0}$ (and trivially when $\mathbf{M} = \mathbf{0}$). Applying this to $\mathbf{M}^*$, whose conjugate transpose is $\mathbf{M}$, gives the reverse inequality.

(b) For $\|\cdot\|_2$ this is Theorem 15.3.2 (d) used twice. For $\|\cdot\|_F$, let $\mathbf{m}_1, \dots, \mathbf{m}_n$ be the columns of $\mathbf{M}$. The columns of $\mathbf{XM}$ are the $\mathbf{Xm}_j$, and the squared Frobenius norm is the sum of the squared lengths of the columns, so

$$\|\mathbf{XM}\|_F^2 = \sum_j \|\mathbf{Xm}_j\|^2 \le \|\mathbf{X}\|_2^2 \sum_j \|\mathbf{m}_j\|^2 = \|\mathbf{X}\|_2^2\|\mathbf{M}\|_F^2.$$

For a factor on the right, (a) and the left-hand case give $\|\mathbf{MY}\|_F = \|\mathbf{Y}^*\mathbf{M}^*\|_F \le \|\mathbf{Y}^*\|_2\|\mathbf{M}^*\|_F = \|\mathbf{Y}\|_2\|\mathbf{M}\|_F$. Combining the two cases gives (b).

(c) For every $\mathbf{v} \in \mathbb{C}^k$, $\|\mathbf{Xv}\|^2 = \mathbf{v}^*\mathbf{X}^*\mathbf{Xv} = \|\mathbf{v}\|^2$. Hence $\|\mathbf{X}\|_2 = 1$, and multiplying by $\mathbf{X}$ changes the length of no column, so $\|\mathbf{XM}\|_F = \|\mathbf{M}\|_F$ and $\|\mathbf{XMv}\| = \|\mathbf{Mv}\|$ for every $\mathbf{v}$, which gives $\|\mathbf{XM}\|_2 = \|\mathbf{M}\|_2$. Next, $\|\mathbf{X}^*\|_2 = \|\mathbf{X}\|_2 = 1$ by (a), so $\|\mathbf{X}^*\mathbf{N}\| \le \|\mathbf{N}\|$ by (b). Finally, for unitary $\mathbf{U}$ and $\mathbf{V}$ both $\mathbf{U}$ and $\mathbf{V}^*$ have orthonormal columns, so $\|\mathbf{UMV}\| = \|\mathbf{MV}\| = \|\mathbf{V}^*\mathbf{M}^*\| = \|\mathbf{M}^*\| = \|\mathbf{M}\|$, using (a) twice.

■

Part (c) is the one used most. Its inequality $\|\mathbf{X}^*\mathbf{N}\| \le \|\mathbf{N}\|$ says that reading $\mathbf{N}$ in only some of the coordinates of an orthonormal basis can only lose mass, never gain it.

19.9.3 The perturbation of a subspace is a Sylvester equation

Fix the data. A Hermitian matrix is normal, so by Corollary 11.4.3 there is a unitary $\mathbf{Q} \in M_n(\mathbb{C})$ with $\mathbf{Q}^*\mathbf{A}\mathbf{Q}$ diagonal, the eigenvalues appearing in any order we like, and they are real by Theorem 11.2.1. Choose k of them, list them first, and split the columns accordingly:

$$\mathbf{Q} = \begin{pmatrix} \mathbf{Q}_1 & \mathbf{Q}_2 \end{pmatrix}, \qquad \mathbf{Q}^*\mathbf{A}\mathbf{Q} = \begin{pmatrix} \mathbf{\Lambda}_1 & \mathbf{0} \\ \mathbf{0} & \mathbf{\Lambda}_2 \end{pmatrix},$$

with $\mathbf{Q}_1 \in M_{n\times k}(\mathbb{C})$ and $\mathbf{\Lambda}_1 \in M_k(\mathbb{R})$, $\mathbf{\Lambda}_2 \in M_{n-k}(\mathbb{R})$ diagonal. Do the same for $\widetilde{\mathbf{A}}$, producing $\widetilde{\mathbf{Q}} = \begin{pmatrix} \widetilde{\mathbf{Q}}_1 & \widetilde{\mathbf{Q}}_2 \end{pmatrix}$, $\widetilde{\mathbf{\Lambda}}_1$ and $\widetilde{\mathbf{\Lambda}}_2$. Reading $\mathbf{A}\mathbf{Q} = \mathbf{Q}(\mathbf{\Lambda}_1 \oplus \mathbf{\Lambda}_2)$ column by column,

$$\mathbf{A}\mathbf{Q}_1 = \mathbf{Q}_1\mathbf{\Lambda}_1, \qquad \widetilde{\mathbf{A}}\widetilde{\mathbf{Q}}_2 = \widetilde{\mathbf{Q}}_2\widetilde{\mathbf{\Lambda}}_2,$$

so the columns of $\mathbf{Q}_1$ are orthonormal eigenvectors of $\mathbf{A}$, and $U = \operatorname{col}(\mathbf{Q}_1)$ is a k-dimensional subspace invariant under $\mathbf{A}$. Likewise $W = \operatorname{col}(\widetilde{\mathbf{Q}}_1)$ is a k-dimensional subspace invariant under $\widetilde{\mathbf{A}}$. The question is how far apart U and W are, and Section 8 answers "measure the principal angles $\theta_1 \le \cdots \le \theta_k$ of Definition 19.8.1".

Put

$$\mathbf{X} := \widetilde{\mathbf{Q}}_2^*\mathbf{Q}_1 \in M_{(n-k)\times k}(\mathbb{C}).$$

It measures the angles, and it satisfies an equation.

The unperturbed subspace, read in the perturbed complement, solves a Sylvester equation whose coefficients are the two spectra and whose right-hand side is the perturbation.

Lemma 19.9.2 — The Subspace Perturbation Equation

In the notation above,

$$\widetilde{\mathbf{\Lambda}}_2\mathbf{X} - \mathbf{X}\mathbf{\Lambda}_1 = \widetilde{\mathbf{Q}}_2^*\mathbf{E}\mathbf{Q}_1, \tag{19.9.1}$$

and the non-zero singular values of $\mathbf{X}$ are the non-zero sines $\sin\theta_i$ of the principal angles between $U = \operatorname{col}(\mathbf{Q}_1)$ and $W = \operatorname{col}(\widetilde{\mathbf{Q}}_1)$, with multiplicity. In particular

$$\|\mathbf{X}\|_F = \|\sin\Theta(U,W)\|_F, \qquad \|\mathbf{X}\|_2 = \sin\theta_k = \|\sin\Theta(U,W)\|_2,$$

where $\sin\Theta(U,W) = \operatorname{diag}(\sin\theta_1, \dots, \sin\theta_k)$.

Idea. Compute $\widetilde{\mathbf{Q}}_2^*\widetilde{\mathbf{A}}\mathbf{Q}_1$ twice. Letting $\widetilde{\mathbf{A}}$ act to the left, on the perturbed eigenvectors, produces $\widetilde{\mathbf{\Lambda}}_2$. Writing $\widetilde{\mathbf{A}} = \mathbf{A}+\mathbf{E}$ and letting $\mathbf{A}$ act to the right, on the unperturbed ones, produces $\mathbf{\Lambda}_1$, plus an error term that carries $\mathbf{E}$. The difference of the two computations is the identity.

Proof. Taking conjugate transposes in $\widetilde{\mathbf{A}}\widetilde{\mathbf{Q}}_2 = \widetilde{\mathbf{Q}}_2\widetilde{\mathbf{\Lambda}}_2$, and using $\widetilde{\mathbf{A}}^* = \widetilde{\mathbf{A}}$ and $\widetilde{\mathbf{\Lambda}}_2^* = \widetilde{\mathbf{\Lambda}}_2$ (a real diagonal matrix), gives $\widetilde{\mathbf{Q}}_2^*\widetilde{\mathbf{A}} = \widetilde{\mathbf{\Lambda}}_2\widetilde{\mathbf{Q}}_2^*$. Hence

$$\widetilde{\mathbf{Q}}_2^*\widetilde{\mathbf{A}}\mathbf{Q}_1 = \widetilde{\mathbf{\Lambda}}_2\widetilde{\mathbf{Q}}_2^*\mathbf{Q}_1 = \widetilde{\mathbf{\Lambda}}_2\mathbf{X}.$$

On the other hand $\widetilde{\mathbf{A}} = \mathbf{A} + \mathbf{E}$ and $\mathbf{A}\mathbf{Q}_1 = \mathbf{Q}_1\mathbf{\Lambda}_1$, so

$$\begin{aligned}\widetilde{\mathbf{Q}}_2^*\widetilde{\mathbf{A}}\mathbf{Q}_1 &= \widetilde{\mathbf{Q}}_2^*\mathbf{Q}_1\mathbf{\Lambda}_1 + \widetilde{\mathbf{Q}}_2^*\mathbf{E}\mathbf{Q}_1 \\ &= \mathbf{X}\mathbf{\Lambda}_1 + \widetilde{\mathbf{Q}}_2^*\mathbf{E}\mathbf{Q}_1.\end{aligned}$$

Subtracting the two expressions gives Eq. 19.9.1.

For the angles: the columns of the unitary $\widetilde{\mathbf{Q}}$ form an orthonormal basis of $\mathbb{C}^n$ (Theorem 10.7.3), so the $n-k$ columns of $\widetilde{\mathbf{Q}}_2$ are orthonormal and orthogonal to every column of $\widetilde{\mathbf{Q}}_1$. They therefore span a subspace of $W^\perp$ of dimension $n-k$, which is all of $W^\perp$ because $\dim W^\perp = n-k$ by Theorem 10.3.2 (c). So $\widetilde{\mathbf{Q}}_2$ is a matrix whose columns are an orthonormal basis of $W^\perp$, and Theorem 19.8.4 (a) says that the singular values of $\widetilde{\mathbf{Q}}_2^*\mathbf{Q}_1 = \mathbf{X}$ are the $\sin\theta_i$, as a multiset completed by zeros; zeros change neither a sum of squares nor a maximum of non-negative numbers. For the two norms, $\mathbf{I} - P_W = P_{W^\perp} = \widetilde{\mathbf{Q}}_2\widetilde{\mathbf{Q}}_2^*$ by Lemma 19.8.1 (d) and (a), so $(\mathbf{I} - P_W)\mathbf{Q}_1 = \widetilde{\mathbf{Q}}_2\mathbf{X}$, and Lemma 19.9.1 (c) removes the factor $\widetilde{\mathbf{Q}}_2$:

$$\|\mathbf{X}\|_F = \|(\mathbf{I} - P_W)\mathbf{Q}_1\|_F, \qquad \|\mathbf{X}\|_2 = \|(\mathbf{I} - P_W)\mathbf{Q}_1\|_2.$$

By Theorem 19.8.4 (b), applied with U and W, these are $\|\sin\Theta(U,W)\|_F$ and $\sin\theta_k = \|\sin\Theta(U,W)\|_2$. This proves the lemma.

■

Quick check. Take $\mathbf{A} = \widetilde{\mathbf{A}} = \mathbf{I}_2$, so $\mathbf{E} = \mathbf{0}$, with $k = 1$, $\mathbf{Q}_1 = \mathbf{e}_1$ and $\widetilde{\mathbf{Q}}_1 = \frac{1}{\sqrt{2}}(1,1)$; both are legitimate choices of unit eigenvector. The subspaces U and W are 45° apart, although the matrices are equal. What does Eq. 19.9.1 say here, and why is there no contradiction?

Solution. Here $\mathbf{\Lambda}_1 = (1)$ and $\widetilde{\mathbf{\Lambda}}_2 = (1)$, so the equation reads $1\cdot\mathbf{X} - \mathbf{X}\cdot 1 = \mathbf{0}$, which **every** 1×1 matrix satisfies. The equation holds, as it must, but it does not determine $\mathbf{X}$, and $\mathbf{X} = \widetilde{\mathbf{Q}}_2^*\mathbf{Q}_1 = \frac{1}{\sqrt{2}}(1,-1)\cdot\mathbf{e}_1 = \frac{1}{\sqrt{2}} = \sin\frac{\pi}{4}$ is one of its many solutions. The trouble is that the spectra of $\widetilde{\mathbf{\Lambda}}_2$ and $\mathbf{\Lambda}_1$ overlap. The theorems below assume that they are separated, and then the equation has exactly one solution (Theorem 11.10.2), which is small when the right-hand side is.

19.9.4 The $\sin\Theta$ theorem in the Frobenius norm

With the identity in hand, the theorem is a matter of dividing by the gap. The gap that matters compares **perturbed** eigenvalues outside the subspace with **unperturbed** eigenvalues inside it, because those are the two coefficient matrices of the equation.

Theorem 19.9.3 — The Davis–Kahan $\sin\Theta$ Theorem

Let $\mathbf{A}, \widetilde{\mathbf{A}} = \mathbf{A} + \mathbf{E} \in M_n(\mathbb{C})$ be Hermitian, let $1 \le k \le n-1$, and let $\mathbf{Q} = \begin{pmatrix}\mathbf{Q}_1 & \mathbf{Q}_2\end{pmatrix}$ and $\widetilde{\mathbf{Q}} = \begin{pmatrix}\widetilde{\mathbf{Q}}_1 & \widetilde{\mathbf{Q}}_2\end{pmatrix}$ be unitary, with $\mathbf{Q}_1, \widetilde{\mathbf{Q}}_1 \in M_{n\times k}(\mathbb{C})$, such that

$$\mathbf{Q}^*\mathbf{A}\mathbf{Q} = \mathbf{\Lambda}_1 \oplus \mathbf{\Lambda}_2, \qquad \widetilde{\mathbf{Q}}^*\widetilde{\mathbf{A}}\widetilde{\mathbf{Q}} = \widetilde{\mathbf{\Lambda}}_1 \oplus \widetilde{\mathbf{\Lambda}}_2$$

are real diagonal. Suppose there is a $\delta > 0$ such that $|\mu - \lambda| \geq \delta$ for **every** diagonal entry μ of $\widetilde{\mathbf{\Lambda}}_2$ and **every** diagonal entry λ of $\mathbf{\Lambda}_1$. Then the principal angles $\Theta = \Theta(\mathrm{col}(\mathbf{Q}_1), \mathrm{col}(\widetilde{\mathbf{Q}}_1))$ satisfy

$$\|\sin\Theta\|_F \;\leq\; \frac{\|\mathbf{E}\mathbf{Q}_1\|_F}{\delta} \;\leq\; \frac{\sqrt{k}\,\|\mathbf{E}\|_2}{\delta}.$$

Idea. Eq. 19.9.1 is a Sylvester equation whose two coefficient matrices are diagonal, hence normal, and for a normal pair the separation of Section 7 is exactly the distance between the two spectra. The hypothesis says that this distance is at least δ, so Section 7's bound divides the right-hand side by δ. What is left is Lemma 19.9.2, which reads the size of $\mathbf{X}$ as the size of $\sin\Theta$.

Proof. Write $\mu_1, \dots, \mu_{n-k}$ for the diagonal entries of $\widetilde{\mathbf{\Lambda}}_2$, $\lambda_1, \dots, \lambda_k$ for those of $\mathbf{\Lambda}_1$, and $\mathbf{Y} = \widetilde{\mathbf{Q}}_2^{*}\mathbf{E}\mathbf{Q}_1$, so that $\widetilde{\mathbf{\Lambda}}_2\mathbf{X} - \mathbf{X}\mathbf{\Lambda}_1 = \mathbf{Y}$ by Lemma 19.9.2. A diagonal matrix is normal, and its eigenvalues are its diagonal entries, so Theorem 19.7.2 gives

$$\mathrm{sep}_F(\widetilde{\mathbf{\Lambda}}_2, \mathbf{\Lambda}_1) = \min_{i,j}|\mu_i - \lambda_j| \;\geq\; \delta > 0.$$

In particular the two spectra are disjoint, so $\mathbf{X}$ is the **unique** solution of that equation (Theorem 11.10.2), and Proposition 19.7.1 (d) applies to it:

$$\|\mathbf{X}\|_F \;\leq\; \frac{\|\mathbf{Y}\|_F}{\mathrm{sep}_F(\widetilde{\mathbf{\Lambda}}_2, \mathbf{\Lambda}_1)} \;\leq\; \frac{\|\mathbf{Y}\|_F}{\delta}.$$

The columns of $\widetilde{\mathbf{Q}}_2$ are orthonormal, so Lemma 19.9.1 (c) gives $\|\mathbf{Y}\|_F = \|\widetilde{\mathbf{Q}}_2^{*}(\mathbf{E}\mathbf{Q}_1)\|_F \leq \|\mathbf{E}\mathbf{Q}_1\|_F$. By Lemma 19.9.1 (b), $\|\mathbf{E}\mathbf{Q}_1\|_F \leq \|\mathbf{E}\|_2\|\mathbf{Q}_1\|_F$, and $\|\mathbf{Q}_1\|_F = \sqrt{k}$ because $\mathbf{Q}_1$ has k unit columns. Finally $\|\mathbf{X}\|_F = \|\sin\Theta\|_F$ by Lemma 19.9.2. Chaining the three inequalities proves the theorem. ∎

The right-hand side is a Lipschitz bound with constant $1/\delta$, and it is sharp. In Example (A tiny perturbation that turns the eigenvectors through 45°), take $k = 1$, $\mathbf{Q}_1 = \mathbf{e}_1$ with $\mathbf{\Lambda}_1 = (1 + \eta)$, and $\widetilde{\mathbf{Q}}_2 = \frac{1}{\sqrt{2}}(1, -1)$ with $\widetilde{\mathbf{\Lambda}}_2 = (1 - \eta)$. Then $\delta = 2\eta$ and $\mathbf{E}\mathbf{e}_1 = \eta(-1, 1)$ has length $\sqrt{2}\,\eta$, so the theorem gives

$$\sin\theta_1 \leq \frac{\sqrt{2}\,\eta}{2\eta} = \frac{1}{\sqrt{2}},$$

and the true angle is $\pi/4$, whose sine is exactly $1/\sqrt{2}$. The large rotation there was not a failure of the theorem. It is what the theorem predicts when the gap is no bigger than the perturbation.

Remark. The roles of $\mathbf{A}$ and $\widetilde{\mathbf{A}}$ may be exchanged, since $\mathbf{A} = \widetilde{\mathbf{A}} + (-\mathbf{E})$ and the principal angles between U and W are those between W and U (a matrix and its conjugate transpose have the same singular values). This gives the companion bound $\|\sin\Theta\|_F \leq \|\mathbf{E}\widetilde{\mathbf{Q}}_1\|_F/\delta'$, where δ' separates the diagonal of $\mathbf{\Lambda}_2$ from that of $\widetilde{\mathbf{\Lambda}}_1$. Use whichever one's data are at hand.

19.9.5 A one-sided version in the spectral norm

The Frobenius theorem controls all k angles at once. Often only the largest angle matters, $\|\sin\Theta\|_2 = \sin\theta_k$, and the Frobenius theorem bounds it too, since $\|\sin\Theta\|_2 \le \|\sin\Theta\|_F$. But its right-hand side $\|\mathbf{E}\mathbf{Q}_1\|_F$ can be $\sqrt{k}$ times $\|\mathbf{E}\mathbf{Q}_1\|_2$, and for large k that factor is a real loss. When the two spectra are separated by a single point, one entirely above it and the other entirely below, the one-sided bound of Section 7 removes it.

Theorem 19.9.4 — The $\sin\Theta$ Theorem, One-Sided Case

In the setting of Theorem 19.9.3, suppose instead that there are $a \in \mathbb{R}$ and $\delta > 0$ such that either

(i) every eigenvalue in $\mathbf{\Lambda}_1$ is $\ge a$ and every eigenvalue in $\widetilde{\mathbf{\Lambda}}_2$ is $\le a - \delta$, or
(ii) every eigenvalue in $\mathbf{\Lambda}_1$ is $\le a$ and every eigenvalue in $\widetilde{\mathbf{\Lambda}}_2$ is $\ge a + \delta$.

Then

$$\|\sin\Theta\|_2 = \sin\theta_k \;\le\; \frac{\|\mathbf{E}\mathbf{Q}_1\|_2}{\delta} \;\le\; \frac{\|\mathbf{E}\|_2}{\delta}.$$

Proof. Let $\mathbf{X} = \widetilde{\mathbf{Q}}_2^*\mathbf{Q}_1$ and $\mathbf{Y} = \widetilde{\mathbf{Q}}_2^*\mathbf{E}\mathbf{Q}_1$, so that $\widetilde{\mathbf{\Lambda}}_2\mathbf{X} - \mathbf{X}\mathbf{\Lambda}_1 = \mathbf{Y}$ by Lemma 19.9.2. For a real diagonal matrix, $\mathbf{\Lambda} \succeq \alpha\mathbf{I}$ means that every diagonal entry is at least α (Theorem 12.1.4 (b), applied to $\mathbf{\Lambda} - \alpha\mathbf{I}$).

Case (ii). Here $\widetilde{\mathbf{\Lambda}}_2 \succeq (a+\delta)\mathbf{I}$ and $\mathbf{\Lambda}_1 \preceq a\mathbf{I}$, with $a + \delta > a$. By Theorem 19.7.3, applied with $\widetilde{\mathbf{\Lambda}}_2$ and $\mathbf{\Lambda}_1$ in the roles of its two Hermitian coefficients, the solution of $\widetilde{\mathbf{\Lambda}}_2\mathbf{X} - \mathbf{X}\mathbf{\Lambda}_1 = \mathbf{Y}$, which is unique because the two spectra are disjoint, satisfies $\|\mathbf{X}\|_2 \le \|\mathbf{Y}\|_2/\delta$.

Case (i). Multiply the equation by -1: $(-\widetilde{\mathbf{\Lambda}}_2)\mathbf{X} - \mathbf{X}(-\mathbf{\Lambda}_1) = -\mathbf{Y}$, where now $-\widetilde{\mathbf{\Lambda}}_2 \succeq (\delta - a)\mathbf{I}$ and $-\mathbf{\Lambda}_1 \preceq -a\mathbf{I}$, and $(\delta - a) - (-a) = \delta > 0$. So case (ii)'s argument applies and gives $\|\mathbf{X}\|_2 \le \|-\mathbf{Y}\|_2/\delta = \|\mathbf{Y}\|_2/\delta$.

In both cases, Lemma 19.9.1 (c) and (b) give $\|\mathbf{Y}\|_2 \le \|\mathbf{E}\mathbf{Q}_1\|_2 \le \|\mathbf{E}\|_2\|\mathbf{Q}_1\|_2 = \|\mathbf{E}\|_2$, and $\|\mathbf{X}\|_2 = \sin\theta_k$ by Lemma 19.9.2. This proves the theorem. ∎

The typical use is the top of the spectrum: $\mathbf{\Lambda}_1$ holds the k largest eigenvalues of $\mathbf{A}$, and $\widetilde{\mathbf{\Lambda}}_2$ the $n - k$ smallest of $\widetilde{\mathbf{A}}$. Then (i) holds with $a = \lambda_k(\mathbf{A})$ and $\delta = \lambda_k(\mathbf{A}) - \lambda_{k+1}(\widetilde{\mathbf{A}})$, provided that number is positive.

Remark. Davis and Kahan proved more. If the eigenvalues in $\mathbf{\Lambda}_1$ lie in an interval $[a, b]$ and every eigenvalue in $\widetilde{\mathbf{\Lambda}}_2$ lies outside $(a-\delta, b+\delta)$, on either side, then the spectral bound $\sin\theta_k \le \|\mathbf{E}\mathbf{Q}_1\|_2/\delta$ still holds. The proof needs more than the one-sided Sylvester bound, and we do not give it. Nothing in this book depends on it. When the two spectra merely avoid each other by δ, interleaved in any pattern, what we have proved is the Frobenius theorem, and through $\|\sin\Theta\|_2 \le \|\sin\Theta\|_F$ the spectral consequence $\sin\theta_k \le \|\mathbf{E}\mathbf{Q}_1\|_F/\delta$.

19.9.6 Single eigenvectors

The most common question is about one eigenvector. A simple eigenvalue has a one-dimensional eigenspace, so its unit eigenvector is determined up to a unimodular factor, and the right measure of how far it moves is the angle between the two **lines**. For unit vectors $\mathbf{x}$ and $\widetilde{\mathbf{x}}$ we write $\theta(\mathbf{x},\widetilde{\mathbf{x}}) \in [0,\pi/2]$ for that angle, so that $\cos\theta(\mathbf{x},\widetilde{\mathbf{x}}) = |\langle \widetilde{\mathbf{x}}, \mathbf{x}\rangle|$. This is the single principal angle between $\operatorname{span}(\mathbf{x})$ and $\operatorname{span}(\widetilde{\mathbf{x}})$, since the 1×1 matrix $\mathbf{x}^*\widetilde{\mathbf{x}}$ has the singular value $|\mathbf{x}^*\widetilde{\mathbf{x}}|$.

The theorem needs a separation between the perturbed eigenvalues of $\widetilde{\mathbf{A}}$ and the unperturbed one of $\mathbf{A}$. In practice only $\mathbf{A}$ is known, and Weyl's inequality converts a gap in the spectrum of $\mathbf{A}$ into the separation the theorem wants.

Corollary 19.9.5 — Perturbation of a Single Eigenvector

Let $\mathbf{A}, \widetilde{\mathbf{A}} = \mathbf{A} + \mathbf{E} \in M_n(\mathbb{C})$ be Hermitian, let $\lambda_i(\mathbf{A})$ be a **simple** eigenvalue of $\mathbf{A}$ with unit eigenvector $\mathbf{x}$, and put

$$\gamma := \min_{j \neq i} |\lambda_i(\mathbf{A}) - \lambda_j(\mathbf{A})| > 0.$$

If $\|\mathbf{E}\|_2 < \gamma/2$, then $\lambda_i(\widetilde{\mathbf{A}})$ is a simple eigenvalue of $\widetilde{\mathbf{A}}$, and every unit eigenvector $\widetilde{\mathbf{x}}$ of $\widetilde{\mathbf{A}}$ for it satisfies

$$\sin\theta(\mathbf{x},\widetilde{\mathbf{x}}) \;\le\; \frac{\|\mathbf{E}\|_2}{\gamma - \|\mathbf{E}\|_2} \;\le\; \frac{2\|\mathbf{E}\|_2}{\gamma}.$$

Idea. Apply the theorem with $k = 1$. The only thing to supply is δ: every eigenvalue $\lambda_j(\widetilde{\mathbf{A}})$ with $j \neq i$ sits within $\|\mathbf{E}\|_2$ of $\lambda_j(\mathbf{A})$ by Weyl, which is at least γ away from $\lambda_i(\mathbf{A})$. So the separation is at least $\gamma - \|\mathbf{E}\|_2$, by the triangle inequality. The hypothesis $\|\mathbf{E}\|_2 < \gamma/2$ keeps $\lambda_i(\widetilde{\mathbf{A}})$ away from its neighbors too, so that "the" eigenvector makes sense.

Proof. Put $\varepsilon = \|\mathbf{E}\|_2$. By Corollary 16.3.6, $|\lambda_j(\widetilde{\mathbf{A}}) - \lambda_j(\mathbf{A})| \le \varepsilon$ for every j. Hence for $j \neq i$, by the triangle inequality in $\mathbb{R}$,

$$\begin{aligned} |\lambda_j(\widetilde{\mathbf{A}}) - \lambda_i(\mathbf{A})| &\ge |\lambda_j(\mathbf{A}) - \lambda_i(\mathbf{A})| - |\lambda_j(\widetilde{\mathbf{A}}) - \lambda_j(\mathbf{A})| \\ &\ge \gamma - \varepsilon, \end{aligned}$$

and similarly $|\lambda_j(\widetilde{\mathbf{A}}) - \lambda_i(\widetilde{\mathbf{A}})| \ge \gamma - 2\varepsilon > 0$. So $\lambda_i(\widetilde{\mathbf{A}})$ differs from every other $\lambda_j(\widetilde{\mathbf{A}})$, and it is a simple eigenvalue of $\widetilde{\mathbf{A}}$.

By Corollary 11.4.3 there is a unitary matrix whose columns are eigenvectors of $\widetilde{\mathbf{A}}$, with the eigenvalue $\lambda_i(\widetilde{\mathbf{A}})$ first. That eigenspace is one-dimensional, so the first column is $c\widetilde{\mathbf{x}}$ with $|c| = 1$, and replacing it by $\widetilde{\mathbf{x}}$ keeps the columns orthonormal eigenvectors. Call the result $\widetilde{\mathbf{Q}} = \begin{pmatrix} \widetilde{\mathbf{x}} & \widetilde{\mathbf{Q}}_2 \end{pmatrix}$. Then $\widetilde{\mathbf{\Lambda}}_2$ is diagonal with entries $\lambda_j(\widetilde{\mathbf{A}})$, $j \neq i$. In the same way build $\mathbf{Q} = \begin{pmatrix} \mathbf{x} & \mathbf{Q}_2 \end{pmatrix}$ for $\mathbf{A}$, with $\mathbf{\Lambda}_1 = (\lambda_i(\mathbf{A}))$. By the display, the hypothesis of Theorem 19.9.3 holds with $k = 1$ and $\delta = \gamma - \varepsilon > 0$, so

$$\sin\theta(\mathbf{x},\widetilde{\mathbf{x}}) = \|\sin\Theta\|_F \le \frac{\|\mathbf{E}\mathbf{x}\|}{\gamma - \varepsilon} \le \frac{\varepsilon}{\gamma - \varepsilon},$$

using $\|\mathbf{E}\mathbf{x}\| \le \|\mathbf{E}\|_2\|\mathbf{x}\| = \varepsilon$. Finally $\varepsilon < \gamma/2$ gives $\gamma - \varepsilon > \gamma/2$, so $\varepsilon/(\gamma-\varepsilon) \le 2\varepsilon/\gamma$. This proves the corollary.

■

To first order in $\|\mathbf{E}\|_2$ the bound reads $\sin\theta \lesssim \|\mathbf{E}\|_2/\gamma$: *an eigenvector is as well conditioned as its eigenvalue is isolated.* The constant cannot be improved, and Exercise (C2: The constant in the eigenvector bound is sharp) shows it. The factor 2 in the cruder form is the price of the hypothesis $\|\mathbf{E}\|_2 < \gamma/2$, nothing more. In Example (A tiny perturbation that turns the eigenvectors through 45°), $\gamma = 2\eta$ and $\|\mathbf{E}\|_2 = \sqrt{2}\,\eta > \gamma/2$, so the corollary does not apply there.

Example. (The theorem and the corollary, side by side)

Let $\mathbf{A} = \operatorname{diag}(2, 0)$ and $\mathbf{E} = \frac{3}{4}\left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$. Find the exact angle between the eigenvectors of $\mathbf{A}$ and of $\widetilde{\mathbf{A}} = \mathbf{A} + \mathbf{E}$ for the larger eigenvalue, and compare it with the bounds of Theorem 19.9.3 and Corollary 19.9.5.

Solution. Exact. $\widetilde{\mathbf{A}} = \left(\begin{smallmatrix} 2 & 3/4 \\ 3/4 & 0 \end{smallmatrix}\right)$ has trace 2 and determinant $-\frac{9}{16}$, so its eigenvalues are $1 \pm \sqrt{1 + 9/16} = 1 \pm \frac{5}{4}$, that is $\frac{9}{4}$ and $-\frac{1}{4}$. For $\frac{9}{4}$, the first row of $\widetilde{\mathbf{A}} - \frac{9}{4}\mathbf{I}$ is $(-\frac{1}{4}, \frac{3}{4})$, which is orthogonal to $(3, 1)$, and the second row $(\frac{3}{4}, -\frac{9}{4})$ is a multiple of the first; so $\widetilde{\mathbf{x}} = \frac{1}{\sqrt{10}}(3, 1)$. With $\mathbf{x} = \mathbf{e}_1$,

$$\cos\theta = \frac{3}{\sqrt{10}}, \qquad \sin\theta = \frac{1}{\sqrt{10}} \approx 0.316.$$

The theorem. Take $\mathbf{\Lambda}_1 = (2)$ and $\widetilde{\mathbf{\Lambda}}_2 = (-\frac{1}{4})$, so $\delta = \frac{9}{4}$. Since $\mathbf{E}\mathbf{e}_1 = (0, \frac{3}{4})$, the bound is $\frac{3}{4}/\frac{9}{4} = \frac{1}{3} \approx 0.333$, within six percent of the truth.

The corollary. The gap is $\gamma = 2$, and $\mathbf{E}$ is $\frac{3}{4}$ times a Hermitian matrix with eigenvalues ± 1, so $\|\mathbf{E}\|_2 = \frac{3}{4} < 1 = \gamma/2$. The bound is $\frac{3/4}{2 - 3/4} = \frac{3}{5} = 0.6$, and its cruder form is $2 \cdot \frac{3}{4}/2 = \frac{3}{4}$.

The theorem is nearly exact because it uses the perturbed eigenvalue $-\frac{1}{4}$ itself. The corollary knows only that this eigenvalue lies within $\frac{3}{4}$ of 0, and it must allow for the worst case $\frac{3}{4}$, which would leave a separation of only $\frac{5}{4}$.

19.9.7 Clusters: the subspace is stable when the vectors are not

Example (A tiny perturbation that turns the eigenvectors through 45°) looks like bad news for eigenvectors, and it is, for **individual** eigenvectors of close eigenvalues. But the theorem was stated for subspaces, and that is its real strength. The subspace spanned by the eigenvectors of a cluster of eigenvalues is governed by the gap between the cluster and the rest of the spectrum. The gaps inside the cluster do not enter.

Example. (A stable plane with unstable lines inside it)

Let $0 < \eta < 1$ and

$$\mathbf{A} = \begin{pmatrix} 1+\eta & 0 & 0 \\ 0 & 1-\eta & 0 \\ 0 & 0 & -2 \end{pmatrix}, \qquad \mathbf{E} = \eta \begin{pmatrix} -1 & 1 & 0 \\ 1 & 1 & 0 \\ 0 & 0 & 0 \end{pmatrix}.$$

Compare what happens to the eigenvectors for $1 \pm \eta$ with what happens to the plane they span. Then bound the motion of that plane under **any** Hermitian perturbation $\mathbf{E}'$ with $\|\mathbf{E}'\|_2 = \varepsilon < 3 - \eta$.

Solution. The upper-left 2×2 block is Example (A tiny perturbation that turns the eigenvectors through 45°). So the eigenvalues of $\widetilde{\mathbf{A}} = \mathbf{A} + \mathbf{E}$ are again $1+\eta, 1-\eta, -2$, and the eigenvectors for $1 \pm \eta$ turn through $\pi/4$, to $\frac{1}{\sqrt{2}}(1, \pm 1, 0)$. But they turn **inside** the plane $U = \operatorname{span}(\mathbf{e}_1, \mathbf{e}_2)$, which is invariant under both matrices. So the plane has not moved at all: both principal angles between U and the new plane $W = U$ are 0.

Theorem 19.9.3 with $k = 2$ sees this. Take $\mathbf{Q}_1 = \begin{pmatrix} \mathbf{e}_1 & \mathbf{e}_2 \end{pmatrix}$, $\mathbf{\Lambda}_1 = \operatorname{diag}(1+\eta, 1-\eta)$ and $\widetilde{\mathbf{\Lambda}}_2 = (-2)$. The separation is $\delta = (1-\eta) - (-2) = 3 - \eta$, and $\|\mathbf{E}\mathbf{Q}_1\|_F = \|\mathbf{E}\|_F = 2\eta$, so

$$\|\sin\Theta\|_F \le \frac{2\eta}{3-\eta}.$$

This is small with η, and it has no 2η in its denominator. (The true value is 0; the theorem does not know that $\mathbf{E}$ happens to preserve U.)

For a general Hermitian $\mathbf{E}'$ with $\|\mathbf{E}'\|_2 = \varepsilon$, Corollary 16.3.6 puts the smallest eigenvalue of $\mathbf{A} + \mathbf{E}'$ at most $-2 + \varepsilon$, while the eigenvalues of $\mathbf{\Lambda}_1$ are at least $1 - \eta$. So case (i) of Theorem 19.9.4 holds with $a = 1 - \eta$ and $\delta = 3 - \eta - \varepsilon > 0$, and the plane moves by

$$\sin\theta_2 \le \frac{\varepsilon}{3-\eta-\varepsilon}.$$

The individual eigenvectors are covered by Corollary 19.9.5 only when $\varepsilon < \eta$, and then only with a bound of order $\varepsilon/(2\eta)$.

This is the practical lesson of the section. When a matrix has a cluster of close eigenvalues, do not ask for the individual eigenvectors of the cluster. They are ill-conditioned and may be meaningless at the precision of the data. Ask for an orthonormal basis of the invariant subspace of the whole cluster, which is as stable as the cluster is isolated. Numerical eigensolvers act on this advice.

19.9.8 Exercises

19.9.8.1 A. Check your understanding

Exercise A1.

(a) State the subspace perturbation equation Eq. 19.9.1, and say which matrix in it measures the principal angles.

(b) In Theorem 19.9.3, which two lists of eigenvalues must be separated by δ? Why not the eigenvalues of $\mathbf{A}$ inside and outside the subspace?

(c) True or false: "if $\|\mathbf{E}\|_2$ is tiny compared with $\|\mathbf{A}\|_2$, then every unit eigenvector of $\mathbf{A}+\mathbf{E}$ is close to a unit eigenvector of $\mathbf{A}$". Justify.

(d) Why is $\|\sin\Theta\|_2 \le \|\sin\Theta\|_F$, and when does Theorem 19.9.4 improve on what the Frobenius theorem gives for $\|\sin\Theta\|_2$?

(e) Which earlier result turns the bound on the matrix $\mathbf{X} = \widetilde{\mathbf{Q}}_2^{*}\mathbf{Q}_1$ into a bound on angles?

Solution.

(a) $\widetilde{\mathbf{\Lambda}}_2\mathbf{X} - \mathbf{X}\mathbf{\Lambda}_1 = \widetilde{\mathbf{Q}}_2^{*}\mathbf{E}\mathbf{Q}_1$, with $\mathbf{X} = \widetilde{\mathbf{Q}}_2^{*}\mathbf{Q}_1$; by Lemma 19.9.2 the singular values of $\mathbf{X}$ are the sines of the principal angles between $\operatorname{col}(\mathbf{Q}_1)$ and $\operatorname{col}(\widetilde{\mathbf{Q}}_1)$, together with zeros.

(b) The diagonal of $\widetilde{\mathbf{\Lambda}}_2$, the eigenvalues of the **perturbed** matrix belonging to the complement, against the diagonal of $\mathbf{\Lambda}_1$, the eigenvalues of the **unperturbed** matrix belonging to the subspace. These are the two coefficient matrices of the Sylvester equation, and the proof divides by their separation, which Theorem 19.7.2 computes as the smallest of those differences. A gap inside the spectrum of $\mathbf{A}$ alone is useful only after Corollary 16.3.6 converts it, as in Corollary 19.9.5.

(c) False. In Example (A tiny perturbation that turns the eigenvectors through 45°), $\|\mathbf{E}\|_2 = \sqrt{2}\,\eta$ can be as small as we like compared with $\|\mathbf{A}\|_2 = 1+\eta$, yet each unit eigenvector of $\mathbf{A}+\mathbf{E}$ makes the angle $\pi/4$ with every unit eigenvector of $\mathbf{A}$, which are the multiples of $\mathbf{e}_1$ and $\mathbf{e}_2$. What controls eigenvectors is the perturbation relative to the gap, not relative to the matrix.

(d) $\|\sin\Theta\|_2 = \sin\theta_k$ is one of the numbers whose squares sum to $\|\sin\Theta\|_F^2$. The Frobenius theorem gives $\sin\theta_k \le \|\mathbf{E}\mathbf{Q}_1\|_F/\delta$, and $\|\mathbf{E}\mathbf{Q}_1\|_F$ can be as large as $\sqrt{k}\,\|\mathbf{E}\mathbf{Q}_1\|_2$. When the two spectra lie on opposite sides of a gap of width δ, Theorem 19.9.4 replaces it by $\|\mathbf{E}\mathbf{Q}_1\|_2$, which is never worse and can be $\sqrt{k}$ times smaller.

(e) Theorem 19.8.4, applied with $W = \operatorname{col}(\widetilde{\mathbf{Q}}_1)$ and the orthonormal basis $\widetilde{\mathbf{Q}}_2$ of $W^{\perp}$.

19.9.8.2 B. Practice

Exercise B1: How far does the top eigenvector move?.

Let

$$\mathbf{A} = \begin{pmatrix} 5 & 0 & 0 \\ 0 & 2 & 0 \\ 0 & 0 & -1 \end{pmatrix}, \qquad \mathbf{E} = \frac{1}{2}\begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix},$$

and let $\widetilde{\mathbf{x}}$ be a unit eigenvector of $\widetilde{\mathbf{A}} = \mathbf{A}+\mathbf{E}$ for its largest eigenvalue.

(a) Compute $\|\mathbf{E}\|_2$ and the gap γ of $\lambda_1(\mathbf{A}) = 5$.

(b) Use Corollary 19.9.5 to bound $\sin\theta(\mathbf{e}_1, \widetilde{\mathbf{x}})$.

(c) Use Theorem 19.9.3, with the separation estimated by Corollary 16.3.6, to obtain a better bound. Hence show that the angle is less than 13°.

(d) Check that 2 is an eigenvalue of $\widetilde{\mathbf{A}}$ and find the other two. Recompute the bound of (c) with the exact separation.

Solution.

(a) The matrix $\mathbf{M} = 2\mathbf{E}$ is symmetric with characteristic polynomial $t^3 - 2t = t(t^2-2)$, so its eigenvalues are $0, \pm\sqrt{2}$ and $\|\mathbf{E}\|_2 = \frac{1}{2}\sqrt{2} = \frac{\sqrt{2}}{2} \approx 0.707$ by Lemma 16.3.5. The eigenvalues of $\mathbf{A}$ are $5, 2, -1$, so $\gamma = 5 - 2 = 3$.

(b) $\|\mathbf{E}\|_2 \approx 0.707 < 1.5 = \gamma/2$, so the corollary applies:

$$\sin\theta \le \frac{\sqrt{2}/2}{3 - \sqrt{2}/2} \approx 0.308.$$

(c) By Corollary 16.3.6, $\lambda_2(\widetilde{\mathbf{A}}) \le 2 + \frac{\sqrt{2}}{2}$ and $\lambda_3(\widetilde{\mathbf{A}}) \le -1 + \frac{\sqrt{2}}{2}$, so both lie at distance at least $\delta = 3 - \frac{\sqrt{2}}{2} \approx 2.293$ from 5. Apply Theorem 19.9.3 with $k = 1$, $\mathbf{Q}_1 = \mathbf{e}_1$, $\mathbf{\Lambda}_1 = (5)$ and $\widetilde{\mathbf{\Lambda}}_2 = \operatorname{diag}(\lambda_2(\widetilde{\mathbf{A}}), \lambda_3(\widetilde{\mathbf{A}}))$. Since $\mathbf{E}\mathbf{e}_1 = (0, \frac{1}{2}, 0)$,

$$\sin\theta \le \frac{\|\mathbf{E}\mathbf{e}_1\|}{\delta} = \frac{1/2}{3 - \sqrt{2}/2} \approx 0.218.$$

The gain over (b) comes from $\|\mathbf{E}\mathbf{e}_1\| = \frac{1}{2}$ replacing $\|\mathbf{E}\|_2 \approx 0.707$. Since $\sin 13^\circ \approx 0.225 > 0.218$ and sin increases on $[0, \pi/2]$, the angle is less than 13°.

(d) $\widetilde{\mathbf{A}} - 2\mathbf{I} = \begin{pmatrix} 3 & 1/2 & 0 \\ 1/2 & 0 & 1/2 \\ 0 & 1/2 & -3 \end{pmatrix}$ sends $(1, -6, -1)$ to $(3-3,\ \frac{1}{2} - \frac{1}{2},\ -3+3) = \mathbf{0}$, so 2 is an eigenvalue. The other two have sum $\operatorname{tr}\widetilde{\mathbf{A}} - 2 = 4$ and product $\det\widetilde{\mathbf{A}}/2$, where expanding along the first row gives $\det\widetilde{\mathbf{A}} = 5(-2 - \frac{1}{4}) - \frac{1}{2}(-\frac{1}{2}) = -11$. So they are the roots of $t^2 - 4t - \frac{11}{2}$, namely $2 \pm \sqrt{19/2} \approx 5.082, -1.082$. The exact separation of $\{2, 2 - \sqrt{19/2}\}$ from 5 is 3, and the bound becomes $\frac{1/2}{3} = \frac{1}{6} \approx 0.167$. (A direct computation of $\widetilde{\mathbf{x}}$ gives $\sin\theta \approx 0.163$.)

Exercise B2: Which theorem applies?.

In each case $\mathbf{A}$ and $\widetilde{\mathbf{A}}$ are Hermitian 4×4 matrices, $k = 2$, $\mathbf{\Lambda}_1$ lists the eigenvalues of $\mathbf{A}$ belonging to $\mathbf{Q}_1$, $\widetilde{\mathbf{\Lambda}}_2$ lists the eigenvalues of $\widetilde{\mathbf{A}}$ belonging to $\widetilde{\mathbf{Q}}_2$, and $\|\mathbf{E}\mathbf{Q}_1\|_2 = 0.2$, $\|\mathbf{E}\mathbf{Q}_1\|_F = 0.25$. Determine which of Theorem 19.9.3 and Theorem 19.9.4 apply, and give the best bound on $\sin\theta_k$ that they yield. Justify your answer.

(a) $\mathbf{\Lambda}_1 = \operatorname{diag}(3, 2)$, $\widetilde{\mathbf{\Lambda}}_2 = \operatorname{diag}(0.4, -1)$.

(b) $\mathbf{\Lambda}_1 = \operatorname{diag}(3, 0)$, $\widetilde{\mathbf{\Lambda}}_2 = \operatorname{diag}(1.9, 5)$.

(c) $\mathbf{\Lambda}_1 = \operatorname{diag}(2, 1)$, $\widetilde{\mathbf{\Lambda}}_2 = \operatorname{diag}(2, -1)$.

(d) $\mathbf{\Lambda}_1 = \operatorname{diag}(-1, -2)$, $\widetilde{\mathbf{\Lambda}}_2 = \operatorname{diag}(0.5, 4)$.

Solution.

(a) Every eigenvalue in $\mathbf{\Lambda}_1$ is ≥ 2 and both in $\widetilde{\mathbf{\Lambda}}_2$ are $\le 0.4 = 2 - 1.6$. So case (i) of the one-sided theorem holds with $a = 2$, $\delta = 1.6$, and $\sin\theta_2 \le 0.2/1.6 = 0.125$. The Frobenius theorem also applies, with the smallest of the four differences, $\delta = 2 - 0.4 = 1.6$, but gives only $\sin\theta_2 \le \|\sin\Theta\|_F \le 0.25/1.6 \approx 0.156$.

(b) The value 1.9 lies **between** 0 and 3, so no point has one list entirely above it and the other entirely below, and the one-sided theorem does not apply. The Frobenius theorem applies with $\delta = \min(1.1, 1.9, 2, 5) = 1.1$, the four differences being $|1.9-3|$, $|1.9-0|$, $|5-3|$ and $|5-0|$. It gives $\sin\theta_2 \le \|\sin\Theta\|_F \le 0.25/1.1 \approx$

0.227.

(c) $|2-2|=0$, so no $\delta>0$ exists and **neither** theorem applies. The check after Lemma 19.9.2 shows why nothing can be said in general: an eigenvalue of $\widetilde{\mathbf{A}}$ outside the subspace coincides with one of $\mathbf{A}$ inside it, and then the equation need not determine $\mathbf{X}$.

(d) Every eigenvalue in $\mathbf{\Lambda}_1$ is ≤ -1 and both in $\widetilde{\mathbf{\Lambda}}_2$ are $\ge 0.5 = -1+1.5$, so case (ii) holds with $a=-1$ and $\delta=1.5$: $\sin\theta_2 \le 0.2/1.5 \approx 0.133$. The Frobenius theorem, with $\delta = 0.5-(-1) = 1.5$ again, gives $0.25/1.5 \approx 0.167$.

Exercise B3: The same bounds for the projections.

In the setting of Theorem 19.9.3, let $U=\operatorname{col}(\mathbf{Q}_1)$ and $W=\operatorname{col}(\widetilde{\mathbf{Q}}_1)$, with orthogonal projections P_U and P_W. Prove that

$$\|P_U - P_W\|_F \le \frac{\sqrt{2}\,\|\mathbf{E}\mathbf{Q}_1\|_F}{\delta},$$

and that under the hypotheses of Theorem 19.9.4, $\|P_U-P_W\|_2 \le \|\mathbf{E}\mathbf{Q}_1\|_2/\delta$.

Solution. Both subspaces have dimension k, so Theorem 19.8.5 applies: $\|P_U-P_W\|_F = \sqrt{2}\,\|\sin\Theta\|_F$ and $\|P_U-P_W\|_2 = \sin\theta_k$. By Theorem 19.9.3, $\sqrt{2}\,\|\sin\Theta\|_F \le \sqrt{2}\,\|\mathbf{E}\mathbf{Q}_1\|_F/\delta$, which is the first claim. By Theorem 19.9.4, $\sin\theta_k \le \|\mathbf{E}\mathbf{Q}_1\|_2/\delta$, which is the second.

19.9.8.3 C. Going deeper

Exercise C1: A bound that needs only the perturbed matrix.

Let $\widetilde{\mathbf{A}} \in M_n(\mathbb{C})$ be Hermitian with $\widetilde{\mathbf{Q}} = \begin{pmatrix}\widetilde{\mathbf{Q}}_1 & \widetilde{\mathbf{Q}}_2\end{pmatrix}$ and $\widetilde{\mathbf{\Lambda}}_2$ as in the text. Let $\mathbf{Z} \in M_{n\times k}(\mathbb{C})$ be **any** matrix with orthonormal columns, not necessarily eigenvectors of anything, and put

$$\mathbf{M} = \mathbf{Z}^*\widetilde{\mathbf{A}}\mathbf{Z} \in M_k(\mathbb{C}), \qquad \mathbf{R} = \widetilde{\mathbf{A}}\mathbf{Z} - \mathbf{Z}\mathbf{M}.$$

(a) Prove that if every eigenvalue of the Hermitian matrix $\mathbf{M}$ differs from every diagonal entry of $\widetilde{\mathbf{\Lambda}}_2$ by at least $\delta>0$, then the principal angles between $\operatorname{col}(\mathbf{Z})$ and $\operatorname{col}(\widetilde{\mathbf{Q}}_1)$ satisfy $\|\sin\Theta\|_F \le \|\mathbf{R}\|_F/\delta$.

(b) Deduce: let $\lambda_i(\widetilde{\mathbf{A}})$ be a **simple** eigenvalue of $\widetilde{\mathbf{A}}$, let $\mathbf{z}$ be a unit vector, $\mu = \mathbf{z}^*\widetilde{\mathbf{A}}\mathbf{z}$ and $\mathbf{r} = \widetilde{\mathbf{A}}\mathbf{z} - \mu\mathbf{z}$. If every eigenvalue of $\widetilde{\mathbf{A}}$ other than $\lambda_i(\widetilde{\mathbf{A}})$ lies at distance at least δ from μ, then a unit eigenvector $\widetilde{\mathbf{x}}$ for $\lambda_i(\widetilde{\mathbf{A}})$ satisfies $\sin\theta(\mathbf{z},\widetilde{\mathbf{x}}) \le \|\mathbf{r}\|/\delta$.

Hint: diagonalize $\mathbf{M}$ *and compute* $\widetilde{\mathbf{Q}}_2^*\mathbf{R}$ *in two ways.*

Solution.

(a) $\mathbf{M}^* = \mathbf{Z}^*\widetilde{\mathbf{A}}^*\mathbf{Z} = \mathbf{M}$, so by Corollary 11.4.3 and Theorem 11.2.1, $\mathbf{M} = \mathbf{V}\mathbf{D}\mathbf{V}^*$ with $\mathbf{V}\in M_k(\mathbb{C})$ unitary and $\mathbf{D}$ real diagonal, holding the eigenvalues of $\mathbf{M}$. Put $\mathbf{Z}' = \mathbf{Z}\mathbf{V}$, which has orthonormal columns, since $\mathbf{Z}'^*\mathbf{Z}' = \mathbf{V}^*\mathbf{V} = \mathbf{I}_k$, and the same column space as $\mathbf{Z}$, since $\mathbf{V}$ is invertible. Then $\mathbf{R}\mathbf{V} = \widetilde{\mathbf{A}}\mathbf{Z}' - \mathbf{Z}\mathbf{V}\mathbf{D} = \widetilde{\mathbf{A}}\mathbf{Z}' - \mathbf{Z}'\mathbf{D}$.

As in the proof of Lemma 19.9.2, $\widetilde{\mathbf{Q}}_2^*\widetilde{\mathbf{A}} = \widetilde{\mathbf{\Lambda}}_2\widetilde{\mathbf{Q}}_2^*$, so with $\mathbf{X}' = \widetilde{\mathbf{Q}}_2^*\mathbf{Z}'$,

$$\widetilde{\mathbf{Q}}_2^*\mathbf{R}\mathbf{V} = \widetilde{\mathbf{\Lambda}}_2\mathbf{X}' - \mathbf{X}'\mathbf{D}.$$

Both coefficient matrices are real diagonal, hence normal, and their diagonal entries differ by at least δ, so, as in the proof of Theorem 19.9.3, Theorem 19.7.2 and Proposition 19.7.1 (d) give $\|\mathbf{X}'\|_F \le \|\widetilde{\mathbf{Q}}_2^*\mathbf{R}\mathbf{V}\|_F/\delta$. By Lemma 19.9.1 (c), $\|\widetilde{\mathbf{Q}}_2^*\mathbf{R}\mathbf{V}\|_F \le \|\mathbf{R}\mathbf{V}\|_F = \|\mathbf{R}\|_F$. Finally, by Theorem 19.8.4 applied as in Lemma 19.9.2, with $\operatorname{col}(\mathbf{Z}') = \operatorname{col}(\mathbf{Z})$ in place of $\operatorname{col}(\mathbf{Q}_1)$, $\|\mathbf{X}'\|_F = \|\sin\Theta\|_F$. This proves (a).

(b) Take $k = 1$ and $\mathbf{Z} = \mathbf{z}$. Then $\mathbf{M} = (\mu)$, $\mathbf{R} = \mathbf{r}$, and the only eigenvalue of $\mathbf{M}$ is μ. Since $\lambda_i(\widetilde{\mathbf{A}})$ is simple, its eigenspace is the line $\operatorname{span}(\widetilde{\mathbf{x}})$, so we may choose $\widetilde{\mathbf{Q}}$ with first column $\widetilde{\mathbf{x}}$ and $\widetilde{\mathbf{\Lambda}}_2$ holding the other eigenvalues of $\widetilde{\mathbf{A}}$, as in the proof of Corollary 19.9.5. Part (a) gives $\sin\theta(\mathbf{z},\widetilde{\mathbf{x}}) \le \|\mathbf{r}\|/\delta$. This is the eigenvector companion of a residual bound: everything on the right is computable from $\mathbf{z}$ and $\widetilde{\mathbf{A}}$ and a gap estimate, with no unperturbed matrix in sight.

Exercise C2: The constant in the eigenvector bound is sharp.

Let $g > 0$ and $e > 0$, and let $\mathbf{A} = \operatorname{diag}(g, 0)$, $\mathbf{E} = e\left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$.

(a) Show that a unit eigenvector $\widetilde{\mathbf{x}}$ of $\mathbf{A} + \mathbf{E}$ for its larger eigenvalue makes an angle $\theta \in [0, \pi/4)$ with $\mathbf{e}_1$ satisfying $\tan 2\theta = 2e/g$.

(b) Deduce that $\sin\theta \cdot g/e \to 1$ as $e \to 0^+$.

(c) Hence show that for no constant $c < 1$ is it true that $\sin\theta(\mathbf{x},\widetilde{\mathbf{x}}) \le c\,\|\mathbf{E}\|_2/\gamma$ for all sufficiently small Hermitian $\mathbf{E}$, in the setting of Corollary 19.9.5.

Solution.

(a) The larger eigenvalue of $\widetilde{\mathbf{A}} = \left(\begin{smallmatrix} g & e \\ e & 0 \end{smallmatrix}\right)$ is $\lambda_+ = h + s$, where $h = g/2$ and $s = \sqrt{h^2 + e^2}$. The first row of $\widetilde{\mathbf{A}} - \lambda_+\mathbf{I}$ is $(g - \lambda_+, e) = (h - s, e)$, so $(e, s - h)$ spans the eigenline, and $s - h > 0$. The angle with $\mathbf{e}_1$ therefore satisfies $\tan\theta = t := (s - h)/e > 0$. Using $s^2 = h^2 + e^2$,

$$1 - t^2 = \frac{e^2 - (s-h)^2}{e^2} = \frac{2h(s-h)}{e^2} > 0,$$

so $t < 1$, that is $\theta < \pi/4$, and

$$\begin{aligned}\tan 2\theta = \frac{2t}{1-t^2} &= \frac{2(s-h)}{e} \cdot \frac{e^2}{2h(s-h)} \\ &= \frac{e}{h} = \frac{2e}{g}.\end{aligned}$$

(b) From (a), $\cos 2\theta = 1/\sqrt{1 + \tan^2 2\theta} = g/\sqrt{g^2 + 4e^2}$, since $2\theta \in [0, \pi/2)$. Hence

$$\begin{aligned}\sin^2\theta = \frac{1 - \cos 2\theta}{2} &= \frac{\sqrt{g^2 + 4e^2} - g}{2\sqrt{g^2 + 4e^2}} \\ &= \frac{2e^2}{\sqrt{g^2 + 4e^2}\left(\sqrt{g^2 + 4e^2} + g\right)},\end{aligned}$$

multiplying above and below by $\sqrt{g^2+4e^2}+g$. So

$$\Big(\frac{g\sin\theta}{e}\Big)^2 = \frac{2g^2}{\sqrt{g^2+4e^2}\,\big(\sqrt{g^2+4e^2}+g\big)},$$

which tends to $2g^2/(g\cdot 2g)=1$ as $e\to 0^+$, by continuity of the square root.

(c) Here $\mathbf{x}=\mathbf{e}_1$, $\gamma=g$, and $\|\mathbf{E}\|_2=e$, since $\mathbf{E}/e$ is Hermitian with eigenvalues ±1. If $\sin\theta\le c\,e/g$ held for all small $e>0$ with some $c<1$, then $\sin\theta\cdot g/e\le c$ for those e, contradicting (b). So to first order in $\|\mathbf{E}\|_2$, the bound $\|\mathbf{E}\|_2/(\gamma-\|\mathbf{E}\|_2)$ of Corollary 19.9.5 cannot be improved by any constant factor.

19.10 Singular Values and Polar Factors

Chapter 16 §09 proved that singular values are perfectly conditioned: $|\sigma_i(\mathbf{A}+\mathbf{E})-\sigma_i(\mathbf{A})|\le\|\mathbf{E}\|_2$, for any matrices at all. This section finishes that story and then starts a new one. First the Frobenius-norm version, Mirsky's theorem, which follows from Section 5's Hoffman–Wielandt inequality once the Hermitian dilation of Chapter 16 turns singular values into eigenvalues. Then the polar decomposition $\mathbf{A}=\mathbf{UP}$: how far do the unitary factor and the positive factor move when $\mathbf{A}$ does? Both answers come from one tool used twice, the bound of Section 7 for a Sylvester equation with positive coefficients.

Throughout, the field is $\mathbb{C}$, $\|\cdot\|_2$ is the spectral norm and $\|\cdot\|_F$ the Frobenius norm, and Lemma 19.9.1 of Section 9 is used freely to move unitary factors and conjugate transposes in and out of either norm. For $\mathbf{A}\in M_{m\times n}(\mathbb{C})$ we put $p=\min(m,n)$, and $\sigma_1(\mathbf{A})\ge\cdots\ge\sigma_p(\mathbf{A})\ge 0$ are its singular values (Definition 12.8.1).

19.10.1 Singular values in the Frobenius norm

Here is where Chapter 16 left the question. Its Corollary 16.9.5 says that for **any** $\mathbf{A},\mathbf{E}\in M_{m\times n}(\mathbb{C})$,

$$|\sigma_i(\mathbf{A}+\mathbf{E})-\sigma_i(\mathbf{A})|\le\|\mathbf{E}\|_2\qquad(1\le i\le p),$$

with no symmetry, squareness or smallness assumed. In the language of Section 5 this is a bound on the largest entry of the vector of differences, and the matching is simply by index. What it does not give is a good bound on **all** the differences together. Squaring and adding p copies of it gives

$$\sum_{i=1}^{p}\big(\sigma_i(\mathbf{A}+\mathbf{E})-\sigma_i(\mathbf{A})\big)^2\le p\,\|\mathbf{E}\|_2^2,$$

and the factor p grows with the size of the matrices. For Hermitian eigenvalues, Section 5 removed that factor: Corollary 19.5.4 bounds the sum of squares by $\|\mathbf{E}\|_F^2$, with no dependence on n. Chapter 16 recorded, in Proposition 16.9.3, a device for carrying any theorem about Hermitian eigenvalues over to singular values, and promised that this chapter would lean on it. Here it is.

Theorem 19.10.1 — Mirsky's Theorem

Let $\mathbf{A}, \mathbf{B} \in M_{m\times n}(\mathbb{C})$ and $p = \min(m, n)$. Then

$$\sum_{i=1}^{p} \big(\sigma_i(\mathbf{A}) - \sigma_i(\mathbf{B})\big)^2 \;\le\; \|\mathbf{A} - \mathbf{B}\|_F^2.$$

Idea. Replace each matrix by its Hermitian dilation $\mathcal{H}(\cdot)$, whose eigenvalues are $\pm\sigma_i$ and zeros. Listed decreasingly, the eigenvalues of $\mathcal{H}(\mathbf{A})$ are $\sigma_1(\mathbf{A}), \dots, \sigma_p(\mathbf{A})$, then the zeros, then $-\sigma_p(\mathbf{A}), \dots, -\sigma_1(\mathbf{A})$, and the positions depend only on m and n, so $\mathcal{H}(\mathbf{B})$ has the same pattern. Apply the Hermitian Hoffman–Wielandt inequality to the two dilations. On the left each difference $\sigma_i(\mathbf{A}) - \sigma_i(\mathbf{B})$ appears twice, once from the top and once from the bottom, while the zeros cancel against zeros. On the right each entry of $\mathbf{A} - \mathbf{B}$ appears twice, once in each off-diagonal block. The two factors of 2 cancel.

Proof. For $\mathbf{M} \in M_{m\times n}(\mathbb{C})$, $\mathcal{H}(\mathbf{M}) = \left(\begin{smallmatrix} \mathbf{0} & \mathbf{M} \\ \mathbf{M}^* & \mathbf{0} \end{smallmatrix}\right)$ is Hermitian (Proposition 16.9.3). Since conjugate transposition is additive,

$$\mathcal{H}(\mathbf{A}) - \mathcal{H}(\mathbf{B}) = \begin{pmatrix} \mathbf{0} & \mathbf{A}-\mathbf{B} \\ (\mathbf{A}-\mathbf{B})^* & \mathbf{0} \end{pmatrix} = \mathcal{H}(\mathbf{A} - \mathbf{B}),$$

and since the entries of $\mathcal{H}(\mathbf{M})$ are those of $\mathbf{M}$, those of $\mathbf{M}^*$ and zeros,

$$\|\mathcal{H}(\mathbf{M})\|_F^2 = \|\mathbf{M}\|_F^2 + \|\mathbf{M}^*\|_F^2 = 2\|\mathbf{M}\|_F^2. \tag{19.10.1}$$

By Proposition 16.9.3, the eigenvalues of $\mathcal{H}(\mathbf{A}) \in M_{m+n}(\mathbb{C})$, with multiplicity, are $\pm\sigma_1(\mathbf{A}), \dots, \pm\sigma_p(\mathbf{A})$ together with $m + n - 2p$ zeros. Since every $\sigma_i(\mathbf{A}) \ge 0$, the list

$$\begin{aligned} \sigma_1(\mathbf{A}) \ge \cdots \ge \sigma_p(\mathbf{A}) \;&\ge\; \underbrace{0 \ge \cdots \ge 0}_{m+n-2p} \\ &\ge\; -\sigma_p(\mathbf{A}) \ge \cdots \ge -\sigma_1(\mathbf{A}) \end{aligned}$$

is decreasing, and a multiset of real numbers has only one decreasing listing. So, with $N = m + n$,

$$\lambda_i(\mathcal{H}(\mathbf{A})) = \begin{cases} \sigma_i(\mathbf{A}) & 1 \le i \le p, \\ 0 & p < i \le N - p, \\ -\sigma_{N+1-i}(\mathbf{A}) & N - p < i \le N. \end{cases}$$

The same formula holds for $\mathbf{B}$, with the **same** three ranges of i, because m, n and p are the same. Hence, summing over the three ranges, and writing $j = N+1-i$ in the third,

$$\begin{aligned} \sum_{i=1}^{N} \big(\lambda_i(\mathcal{H}(\mathbf{A})) - \lambda_i(\mathcal{H}(\mathbf{B}))\big)^2 &= \sum_{i=1}^{p} \big(\sigma_i(\mathbf{A}) - \sigma_i(\mathbf{B})\big)^2 + 0 \\ &\quad + \sum_{j=1}^{p} \big(-\sigma_j(\mathbf{A}) + \sigma_j(\mathbf{B})\big)^2 \\ &= 2\sum_{i=1}^{p} \big(\sigma_i(\mathbf{A}) - \sigma_i(\mathbf{B})\big)^2. \end{aligned}$$

By Corollary 19.5.4, applied to the Hermitian matrices $\mathcal{H}(\mathbf{A})$ and $\mathcal{H}(\mathbf{B})$, the left-hand side is at most $\|\mathcal{H}(\mathbf{A}) - \mathcal{H}(\mathbf{B})\|_F^2 = \|\mathcal{H}(\mathbf{A}-\mathbf{B})\|_F^2 = 2\|\mathbf{A}-\mathbf{B}\|_F^2$, by Eq. 19.10.1. Dividing by 2 proves the theorem.

■

This is the payment Chapter 16 §09 promised when it said that Chapter 19 leans on the dilation for perturbation bounds. Together with Corollary 16.9.5, it bounds the vector of singular-value differences in the two norms one reaches for first: its largest entry by $\|\mathbf{A}-\mathbf{B}\|_2$, its Euclidean length by $\|\mathbf{A}-\mathbf{B}\|_F$. Chapter 20 puts both inside one statement covering every unitarily invariant norm.

Note what was **not** assumed. Theorem 19.5.2 needs normal matrices, and Section 5 showed by a Jordan-block pair that it fails without normality. Mirsky's theorem holds for every pair of matrices, square or not, because the dilation manufactures the Hermitian hypothesis instead of assuming it.

Example. (Two matrices that differ in one entry)

Let $\mathbf{A} = \left(\begin{smallmatrix} 2 & 1 \\ 1 & 2 \end{smallmatrix}\right)$ and $\mathbf{B} = \left(\begin{smallmatrix} 2 & 1 \\ 0 & 2 \end{smallmatrix}\right)$. Compute the singular values of both, and compare the two sides of Theorem 19.10.1 with what Corollary 16.9.5 alone would give.

Solution. $\mathbf{A}$ is symmetric with $\mathbf{A}(1,1) = 3(1,1)$ and $\mathbf{A}(1,-1) = (1,-1)$, so $\mathbf{A}^{\top}\mathbf{A} = \mathbf{A}^2$ has eigenvalues 9 and 1, and $\sigma(\mathbf{A}) = (3,1)$. For $\mathbf{B}$,

$$\mathbf{B}^{\top}\mathbf{B} = \begin{pmatrix} 4 & 2 \\ 2 & 5 \end{pmatrix},$$

with trace 9 and determinant 16, so its eigenvalues are $\frac{9 \pm \sqrt{17}}{2}$. These are perfect squares: $\left(\frac{\sqrt{17}\pm 1}{2}\right)^2 = \frac{18 \pm 2\sqrt{17}}{4} = \frac{9 \pm \sqrt{17}}{2}$. Hence

$$\sigma_1(\mathbf{B}) = \frac{\sqrt{17}+1}{2} \approx 2.562, \qquad \sigma_2(\mathbf{B}) = \frac{\sqrt{17}-1}{2} \approx 1.562.$$

The difference $\mathbf{A}-\mathbf{B} = \left(\begin{smallmatrix} 0 & 0 \\ 1 & 0 \end{smallmatrix}\right)$ has $\|\mathbf{A}-\mathbf{B}\|_F = \|\mathbf{A}-\mathbf{B}\|_2 = 1$. The left side of Mirsky's inequality is

$$\left(\frac{5-\sqrt{17}}{2}\right)^2 + \left(\frac{3-\sqrt{17}}{2}\right)^2 = \frac{(42-10\sqrt{17})+(26-6\sqrt{17})}{4} = 17 - 4\sqrt{17} \approx 0.508,$$

comfortably below 1. The index-by-index bound gives $|\sigma_i(\mathbf{A}) - \sigma_i(\mathbf{B})| \le 1$ for each i; the actual values are about 0.438 and 0.562. On its own it bounds the sum of squares only by 2, and Mirsky halves that.

Quick check. Let $\mathbf{A} = \operatorname{diag}(3,1)$ and $\mathbf{B} = \operatorname{diag}(1,3)$. Compute both sides of Theorem 19.10.1. Why is the left side not $(3-1)^2 + (1-3)^2$?

Solution. Both matrices have singular values $(3,1)$ in decreasing order, so the left side is 0, while $\|\mathbf{A}-\mathbf{B}\|_F^2 = \|\operatorname{diag}(2,-2)\|_F^2 = 8$. The theorem compares the **sorted** lists, the i-th largest with the i-th largest. Pairing the diagonal entries by position would give 8, which is also allowed, but it is not what the theorem measures.

Warning. **Stable singular values do not mean stable singular vectors.** Take $0 < \eta < 1$, $\mathbf{A} = \operatorname{diag}(1+\eta, 1-\eta)$ and $\mathbf{B} = \left(\begin{smallmatrix} 1 & \eta \\ \eta & 1 \end{smallmatrix}\right)$, the pair of Example (A tiny perturbation that turns the eigenvectors through 45°). Both are positive definite with eigenvalues $1 \pm \eta$, so both have singular values $1 \pm \eta$, and the left side of Mirsky's

inequality is 0. But the right singular vector for σ_1 is $\mathbf{e}_1$ for $\mathbf{A}$ and $\frac{1}{\sqrt{2}}(1,1)$ for $\mathbf{B}$, a 45° turn, while $\|\mathbf{A}-\mathbf{B}\|_F = 2\eta$ is as small as we like. As with eigenvectors, singular vectors are controlled by gaps. Applying Section 9 to the dilations $\mathcal{H}(\mathbf{A})$ and $\mathcal{H}(\mathbf{B})$, whose eigenvectors are built from the singular vectors, is one way to bound them.

19.10.2 The square root is Lipschitz away from zero

The second half of the section is about the polar decomposition, and its positive factor is a square root, $|\mathbf{A}| = (\mathbf{A}^*\mathbf{A})^{1/2}$. So we start with square roots.

For positive numbers there is an exact formula for how far a square root moves:

$$\sqrt{p}-\sqrt{q} = \frac{p-q}{\sqrt{p}+\sqrt{q}},$$

the usual trick of multiplying by the conjugate. It shows that the square root is Lipschitz on $[c,\infty)$ with constant $1/(2\sqrt{c})$, and that no constant works near 0. For matrices the trick fails as written: with $\mathbf{S}=\mathbf{P}^{1/2}$ and $\mathbf{T}=\mathbf{Q}^{1/2}$, the product $(\mathbf{S}-\mathbf{T})(\mathbf{S}+\mathbf{T}) = \mathbf{S}^2+\mathbf{S}\mathbf{T}-\mathbf{T}\mathbf{S}-\mathbf{T}^2$ is $\mathbf{P}-\mathbf{Q}$ only when $\mathbf{S}$ and $\mathbf{T}$ commute. But a different grouping of the same terms works with no commuting at all:

$$\mathbf{S}(\mathbf{S}-\mathbf{T})+(\mathbf{S}-\mathbf{T})\mathbf{T} = \mathbf{S}^2-\mathbf{S}\mathbf{T}+\mathbf{S}\mathbf{T}-\mathbf{T}^2 = \mathbf{P}-\mathbf{Q}. \tag{19.10.2}$$

This says that $\mathbf{X}=\mathbf{S}-\mathbf{T}$ solves the Sylvester equation $\mathbf{S}\mathbf{X}+\mathbf{X}\mathbf{T}=\mathbf{P}-\mathbf{Q}$, whose coefficients are positive definite. That is exactly the situation of Corollary 19.7.4.

Theorem 19.10.2 — Perturbation of the Square Root

Let $\mathbf{P},\mathbf{Q}\in M_n(\mathbb{C})$ be positive definite. Then

$$\|\mathbf{P}^{1/2}-\mathbf{Q}^{1/2}\| \;\le\; \frac{\|\mathbf{P}-\mathbf{Q}\|}{\lambda_n(\mathbf{P})^{1/2}+\lambda_n(\mathbf{Q})^{1/2}},$$

where $\|\cdot\|$ is either $\|\cdot\|_2$ or $\|\cdot\|_F$.

Proof. Put $\mathbf{S}=\mathbf{P}^{1/2}$ and $\mathbf{T}=\mathbf{Q}^{1/2}$, the positive square roots of Theorem 12.2.1. By that theorem the eigenvalues of $\mathbf{S}$ are the non-negative square roots of those of $\mathbf{P}$, and $t\mapsto\sqrt{t}$ is increasing, so the smallest eigenvalue of $\mathbf{S}$ is $\alpha := \lambda_n(\mathbf{P})^{1/2}$, which is positive because $\mathbf{P}\succ 0$. Every eigenvalue of the Hermitian matrix $\mathbf{S}-\alpha\mathbf{I}$ is therefore non-negative, so $\mathbf{S}\succeq\alpha\mathbf{I}$ by Theorem 12.1.4 (b). In the same way $\mathbf{T}\succeq\beta\mathbf{I}$ with $\beta := \lambda_n(\mathbf{Q})^{1/2}>0$.

By Eq. 19.10.2, $\mathbf{X}=\mathbf{S}-\mathbf{T}$ satisfies $\mathbf{S}\mathbf{X}+\mathbf{X}\mathbf{T}=\mathbf{P}-\mathbf{Q}$. Since $\alpha+\beta>0$, Corollary 19.7.4 applies to this equation, whose solution is therefore unique and equal to $\mathbf{X}$, and gives

$$\|\mathbf{S}-\mathbf{T}\| \le \frac{\|\mathbf{P}-\mathbf{Q}\|}{\alpha+\beta}$$

in both the spectral and the Frobenius norm. This proves the theorem. ∎

For $n = 1$ this is the scalar identity, as an inequality that happens to be an equality. It is sharp for every n: with $\mathbf{P} = \operatorname{diag}(4, 100)$ and $\mathbf{Q} = \operatorname{diag}(1, 100)$, $\mathbf{P}^{1/2} - \mathbf{Q}^{1/2} = \operatorname{diag}(1, 0)$ has both norms equal to 1, and the bound is $3/(2+1) = 1$; padding both matrices with a further block $100\,\mathbf{I}_{n-2}$ changes neither side of the inequality, so the equality holds for every $n \geq 2$. The difference sits exactly in the direction where both matrices are smallest, which is the worst place for it.

Remark. The proof used only $\alpha + \beta > 0$, so the conclusion holds as soon as one of $\mathbf{P}$ and $\mathbf{Q}$ is positive definite and the other positive semidefinite.

Warning. **The square root is not Lipschitz on all positive semidefinite matrices.** Take $\mathbf{P} = \varepsilon \mathbf{I}_n$ with $0 < \varepsilon < 1$ and $\mathbf{Q} = \mathbf{0}$. Then $\|\mathbf{P} - \mathbf{Q}\|_2 = \varepsilon$, while $\mathbf{P}^{1/2} - \mathbf{Q}^{1/2} = \sqrt{\varepsilon}\,\mathbf{I}_n$ has spectral norm $\sqrt{\varepsilon}$, which is larger by the factor $1/\sqrt{\varepsilon}$. That factor is unbounded as $\varepsilon \to 0^+$, so no inequality $\|\mathbf{P}^{1/2} - \mathbf{Q}^{1/2}\|_2 \leq C\|\mathbf{P} - \mathbf{Q}\|_2$ can hold for all $\mathbf{P}, \mathbf{Q} \succeq 0$. The denominator of the theorem is what records this. By the remark the theorem still applies, with denominator $\sqrt{\varepsilon} + 0$, and the bound $\varepsilon/\sqrt{\varepsilon} = \sqrt{\varepsilon}$ is attained. Exercise (C1: The square root is continuous everywhere) shows that the square root is nevertheless continuous everywhere, with a square-root modulus.

19.10.3 The positive polar factor

Recall Theorem 12.9.1: every $\mathbf{A} \in M_n(\mathbb{C})$ is a unitary matrix times the positive semidefinite $|\mathbf{A}| = (\mathbf{A}^*\mathbf{A})^{1/2}$, and when $\mathbf{A}$ is invertible both factors are unique. In this section we write the decomposition as

$$\mathbf{A} = \mathbf{U}\mathbf{P}, \qquad \mathbf{U} \text{ unitary}, \qquad \mathbf{P} = |\mathbf{A}|,$$

keeping the letter $\mathbf{W}$ for another use below. For invertible $\mathbf{A}$ the matrix $\mathbf{A}^*\mathbf{A}$ is positive definite, since $\mathbf{x}^*\mathbf{A}^*\mathbf{A}\mathbf{x} = \|\mathbf{A}\mathbf{x}\|^2 > 0$ for $\mathbf{x} \neq \mathbf{0}$. Its eigenvalues are the $\sigma_i(\mathbf{A})^2$ (Definition 12.8.1), so

$$\lambda_n(\mathbf{A}^*\mathbf{A}) = \sigma_n(\mathbf{A})^2 > 0, \qquad \mathbf{P} = |\mathbf{A}| \succeq \sigma_n(\mathbf{A})\,\mathbf{I},$$

the second because the eigenvalues of $|\mathbf{A}|$ are the square roots $\sigma_i(\mathbf{A})$ (Theorem 12.2.1) and Theorem 12.1.4 (b) applies to $|\mathbf{A}| - \sigma_n(\mathbf{A})\mathbf{I}$ as before.

Theorem 19.10.3 — Perturbation of the Positive Polar Factor

Let $\mathbf{A}, \mathbf{B} \in M_n(\mathbb{C})$ be invertible. Then

$$\| \,|\mathbf{A}| - |\mathbf{B}|\, \| \;\leq\; \frac{\left(\|\mathbf{A}\|_2 + \|\mathbf{B}\|_2\right)\|\mathbf{A} - \mathbf{B}\|}{\sigma_n(\mathbf{A}) + \sigma_n(\mathbf{B})},$$

where $\|\cdot\|$ is either $\|\cdot\|_2$ or $\|\cdot\|_F$.

Proof. Both $\mathbf{A}^*\mathbf{A}$ and $\mathbf{B}^*\mathbf{B}$ are positive definite, with $\lambda_n(\mathbf{A}^*\mathbf{A})^{1/2} = \sigma_n(\mathbf{A})$ and $\lambda_n(\mathbf{B}^*\mathbf{B})^{1/2} = \sigma_n(\mathbf{B})$, as just shown. So Theorem 19.10.2 gives

$$\| \,|\mathbf{A}| - |\mathbf{B}|\, \| \leq \frac{\|\mathbf{A}^*\mathbf{A} - \mathbf{B}^*\mathbf{B}\|}{\sigma_n(\mathbf{A}) + \sigma_n(\mathbf{B})}.$$

Now $\mathbf{A}^*\mathbf{A} - \mathbf{B}^*\mathbf{B} = \mathbf{A}^*(\mathbf{A} - \mathbf{B}) + (\mathbf{A} - \mathbf{B})^*\mathbf{B}$, as expanding the right side shows. By

Lemma 19.9.1 (b) and (a),

$$\|\mathbf{A}^*(\mathbf{A}-\mathbf{B})\| \le \|\mathbf{A}^*\|_2\|\mathbf{A}-\mathbf{B}\| = \|\mathbf{A}\|_2\|\mathbf{A}-\mathbf{B}\|,$$

and likewise $\|(\mathbf{A}-\mathbf{B})^*\mathbf{B}\| \le \|(\mathbf{A}-\mathbf{B})^*\|\,\|\mathbf{B}\|_2 = \|\mathbf{A}-\mathbf{B}\|\,\|\mathbf{B}\|_2$. The triangle inequality for the norm (Theorem 15.3.2 (b) for $\|\cdot\|_2$, Corollary 10.1.6 for the Frobenius norm, which is induced by an inner product) gives $\|\mathbf{A}^*\mathbf{A}-\mathbf{B}^*\mathbf{B}\| \le (\|\mathbf{A}\|_2+\|\mathbf{B}\|_2)\|\mathbf{A}-\mathbf{B}\|$, and substituting proves the theorem.

■

When $\mathbf{B}$ is close to $\mathbf{A}$, the constant is about $2\|\mathbf{A}\|_2/(2\sigma_n(\mathbf{A})) = \kappa_2(\mathbf{A})$, the condition number of Chapter 15. So by this estimate $|\mathbf{A}|$ is as sensitive as $\mathbf{A}$ is ill-conditioned. It is a crude estimate, as the example below shows. Sharper ones are known, but this is the one the Sylvester bound gives with no extra work.

19.10.4 The unitary polar factor

For a non-zero complex number, the unitary polar factor is the phase $z/|z|$. If two numbers z and w have the same modulus r, their phases differ by exactly $|z-w|/r$. So the phase moves at the rate of the perturbation divided by the modulus, and it is undefined at $z=0$. The theorem below is the matrix form of this, with σ_n as the modulus.

Theorem 19.10.4 — Perturbation of the Unitary Polar Factor

Let $\mathbf{A},\mathbf{B} \in M_n(\mathbb{C})$ be invertible, with polar decompositions (Theorem 12.9.1) $\mathbf{A}=\mathbf{U}\mathbf{P}$ and $\mathbf{B}=\mathbf{V}\mathbf{Q}$, where $\mathbf{U},\mathbf{V}$ are unitary, $\mathbf{P}=|\mathbf{A}|$ and $\mathbf{Q}=|\mathbf{B}|$. Then

$$\|\mathbf{U}-\mathbf{V}\| \;\le\; \frac{2\,\|\mathbf{A}-\mathbf{B}\|}{\sigma_n(\mathbf{A})+\sigma_n(\mathbf{B})},$$

where $\|\cdot\|$ is either $\|\cdot\|_2$ or $\|\cdot\|_F$.

Idea. Measure $\mathbf{U}$ against $\mathbf{V}$ by the single unitary matrix $\mathbf{W}=\mathbf{V}^*\mathbf{U}$, which equals $\mathbf{I}$ exactly when $\mathbf{U}=\mathbf{V}$; then $\|\mathbf{U}-\mathbf{V}\| = \|\mathbf{W}-\mathbf{I}\|$. Now write $\mathbf{A}-\mathbf{B}$ in the two polar frames. Seen through $\mathbf{V}^*$ on the left it is $\mathbf{W}\mathbf{P}-\mathbf{Q}$. Its conjugate transpose, seen through $\mathbf{U}$ on the right, is $\mathbf{P}-\mathbf{Q}\mathbf{W}$. The difference of these two expressions is $(\mathbf{W}-\mathbf{I})\mathbf{P}+\mathbf{Q}(\mathbf{W}-\mathbf{I})$, a Sylvester equation for $\mathbf{W}-\mathbf{I}$ with positive definite coefficients $\mathbf{Q}$ and $\mathbf{P}$, and its right-hand side has norm at most $2\|\mathbf{A}-\mathbf{B}\|$.

Proof. Put $\mathbf{W}=\mathbf{V}^*\mathbf{U}$, which is unitary. Since $\mathbf{U}^*\mathbf{U}=\mathbf{V}^*\mathbf{V}=\mathbf{I}$, $\mathbf{P}^*=\mathbf{P}$ and $\mathbf{Q}^*=\mathbf{Q}$,

$$\begin{aligned}\mathbf{V}^*(\mathbf{A}-\mathbf{B}) &= \mathbf{V}^*\mathbf{U}\mathbf{P}-\mathbf{V}^*\mathbf{V}\mathbf{Q} = \mathbf{W}\mathbf{P}-\mathbf{Q},\\ (\mathbf{A}-\mathbf{B})^*\mathbf{U} &= \mathbf{P}\mathbf{U}^*\mathbf{U}-\mathbf{Q}\mathbf{V}^*\mathbf{U} = \mathbf{P}-\mathbf{Q}\mathbf{W}.\end{aligned}$$

Subtracting the second identity from the first,

$$\begin{aligned}\mathbf{V}^*(\mathbf{A}-\mathbf{B})-(\mathbf{A}-\mathbf{B})^*\mathbf{U} &= \mathbf{W}\mathbf{P}-\mathbf{P}+\mathbf{Q}\mathbf{W}-\mathbf{Q}\\ &= \mathbf{Q}(\mathbf{W}-\mathbf{I})+(\mathbf{W}-\mathbf{I})\mathbf{P}.\end{aligned} \tag{19.10.3}$$

So $\mathbf{X} = \mathbf{W} - \mathbf{I}$ solves $\mathbf{QX} + \mathbf{XP} = \mathbf{Y}$, with $\mathbf{Y}$ the left side of Eq. 19.10.3. As shown before Theorem 19.10.3, $\mathbf{Q} \succeq \sigma_n(\mathbf{B})\mathbf{I}$ and $\mathbf{P} \succeq \sigma_n(\mathbf{A})\mathbf{I}$, and $\sigma_n(\mathbf{A}) + \sigma_n(\mathbf{B}) > 0$. So Corollary 19.7.4, applied with $\mathbf{Q}$ and $\mathbf{P}$ as its two coefficients, gives

$$\|\mathbf{W} - \mathbf{I}\| \le \frac{\|\mathbf{Y}\|}{\sigma_n(\mathbf{A}) + \sigma_n(\mathbf{B})}$$

in both norms. By Lemma 19.9.1 (c) and (a), $\|\mathbf{V}^*(\mathbf{A} - \mathbf{B})\| = \|\mathbf{A} - \mathbf{B}\|$ and $\|(\mathbf{A} - \mathbf{B})^*\mathbf{U}\| = \|(\mathbf{A}-\mathbf{B})^*\| = \|\mathbf{A}-\mathbf{B}\|$, so $\|\mathbf{Y}\| \le 2\|\mathbf{A}-\mathbf{B}\|$ by the triangle inequality. Finally $\mathbf{U} - \mathbf{V} = \mathbf{V}(\mathbf{V}^*\mathbf{U} - \mathbf{I}) = \mathbf{V}(\mathbf{W} - \mathbf{I})$, so $\|\mathbf{U} - \mathbf{V}\| = \|\mathbf{W} - \mathbf{I}\|$ by Lemma 19.9.1 (c). Combining the three displays proves the theorem.

■

Notice the difference from Theorem 19.10.3. There the constant was a condition number, but here only σ_n appears. The unitary factor feels how close $\mathbf{A}$ is to the singular matrices, which is $\sigma_n(\mathbf{A})$ by Corollary 16.9.7, and nothing else.

Quick check. For $n = 1$, what does the theorem say about two non-zero complex numbers z and w? Test it on $z = 1$, $w = -1$.

Solution. A non-zero $z \in \mathbb{C} = M_1(\mathbb{C})$ has polar decomposition $z = \frac{z}{|z|} \cdot |z|$, with $\sigma_1(z) = |z|$, and both norms are the modulus. So the theorem says

$$\left|\frac{z}{|z|} - \frac{w}{|w|}\right| \le \frac{2|z - w|}{|z| + |w|}.$$

For $z = 1$, $w = -1$ both sides equal 2. So the constant 2 in the theorem cannot be lowered, even for $n = 1$.

Example. (The polar factors of two nearby matrices)

Let $\mathbf{A} = \left(\begin{smallmatrix} 3 & 0 \\ 4 & 5 \end{smallmatrix}\right)$, whose polar decomposition Example (A polar decomposition) found to be $\mathbf{U} = \frac{1}{\sqrt{5}}\left(\begin{smallmatrix} 2 & -1 \\ 1 & 2 \end{smallmatrix}\right)$, $|\mathbf{A}| = \sqrt{5}\left(\begin{smallmatrix} 2 & 1 \\ 1 & 2 \end{smallmatrix}\right)$, with $\sigma(\mathbf{A}) = (3\sqrt{5}, \sqrt{5})$. Let $\mathbf{B} = \left(\begin{smallmatrix} 3 & 0 \\ 6 & 5 \end{smallmatrix}\right)$. Find the polar decomposition of $\mathbf{B}$, compute $\|\mathbf{U} - \mathbf{V}\|$, and compare it with Theorem 19.10.4.

Solution. *Finding* $\mathbf{V}$. For a real 2×2 matrix of positive determinant, look for $\mathbf{V}$ among the rotations $\mathbf{R}_\varphi = \left(\begin{smallmatrix} c & -s \\ s & c \end{smallmatrix}\right)$, with $c = \cos\varphi$, $s = \sin\varphi$. For $\mathbf{B} = (b_{ij})$, the off-diagonal entries of $\mathbf{R}_\varphi^\top \mathbf{B}$ are $cb_{12} + sb_{22}$ and $-sb_{11} + cb_{21}$, and they agree exactly when $(b_{11} + b_{22})s = (b_{21} - b_{12})c$. For our $\mathbf{B}$ this reads $8s = 6c$, so $(c, s) = (\frac{4}{5}, \frac{3}{5})$, and

$$\mathbf{V} = \frac{1}{5}\begin{pmatrix} 4 & -3 \\ 3 & 4 \end{pmatrix},$$

$$\mathbf{V}^\top\mathbf{B} = \frac{1}{5}\begin{pmatrix} 4 & 3 \\ -3 & 4 \end{pmatrix}\begin{pmatrix} 3 & 0 \\ 6 & 5 \end{pmatrix} = \begin{pmatrix} 6 & 3 \\ 3 & 4 \end{pmatrix}.$$

This symmetric matrix has trace 10 and determinant 15, so both its eigenvalues, $5 \pm \sqrt{10}$, are positive, and it is positive definite. Thus $\mathbf{B} = \mathbf{V}(\mathbf{V}^\top\mathbf{B})$ is a unitary matrix times a positive definite one. Squaring gives $(\mathbf{V}^\top\mathbf{B})^2 = \mathbf{B}^\top\mathbf{V}\mathbf{V}^\top\mathbf{B} = \mathbf{B}^\top\mathbf{B}$, so $\mathbf{V}^\top\mathbf{B} = |\mathbf{B}|$ by uniqueness of the positive square root (Theorem 12.2.1). Since $\mathbf{B}$ is invertible, Theorem 12.9.1 now gives $\mathbf{V}$ as its unitary polar factor. Its singular values are the

eigenvalues of $|\mathbf{B}|$, $\sigma(\mathbf{B}) = (5+\sqrt{10}, 5-\sqrt{10}) \approx (8.162, 1.838)$. The same recipe applied to $\mathbf{A}$ gives $8s = 4c$, which recovers $\mathbf{U}$.

The distance. $\mathbf{U}$ and $\mathbf{V}$ are the rotations through angles $\varphi_{\mathbf{A}}$ and $\varphi_{\mathbf{B}}$ with

$$\cos(\varphi_{\mathbf{B}} - \varphi_{\mathbf{A}}) = \tfrac{2}{\sqrt{5}} \cdot \tfrac{4}{5} + \tfrac{1}{\sqrt{5}} \cdot \tfrac{3}{5} = \tfrac{11}{5\sqrt{5}}.$$

For two rotations, $(\mathbf{U}-\mathbf{V})^{\top}(\mathbf{U}-\mathbf{V}) = 2\mathbf{I} - (\mathbf{U}^{\top}\mathbf{V} + \mathbf{V}^{\top}\mathbf{U}) = \big(2 - 2\cos(\varphi_{\mathbf{B}} - \varphi_{\mathbf{A}})\big)\mathbf{I}$, so both singular values of $\mathbf{U}-\mathbf{V}$ equal $\sqrt{2 - 22/(5\sqrt{5})}$ and

$$\|\mathbf{U}-\mathbf{V}\|_2 \approx 0.180, \qquad \|\mathbf{U}-\mathbf{V}\|_F \approx 0.254.$$

The bound. $\mathbf{A}-\mathbf{B} = \left(\begin{smallmatrix} 0 & 0 \\ -2 & 0 \end{smallmatrix}\right)$, so $\|\mathbf{A}-\mathbf{B}\|_2 = \|\mathbf{A}-\mathbf{B}\|_F = 2$, and

$$\frac{2 \cdot 2}{\sigma_2(\mathbf{A}) + \sigma_2(\mathbf{B})} = \frac{4}{\sqrt{5} + 5 - \sqrt{10}} \approx 0.982$$

in both norms. The theorem holds, with a factor of about 5 to spare in the spectral norm and 4 in the Frobenius norm. For the positive factors, Theorem 19.10.3 gives

$$\| \, |\mathbf{A}| - |\mathbf{B}| \, \| \le \frac{(3\sqrt{5} + 5 + \sqrt{10}) \cdot 2}{\sqrt{5} + 5 - \sqrt{10}} \approx 7.30,$$

while $|\mathbf{A}| - |\mathbf{B}| = \left(\begin{smallmatrix} 2\sqrt{5}-6 & \sqrt{5}-3 \\ \sqrt{5}-3 & 2\sqrt{5}-4 \end{smallmatrix}\right)$ has spectral norm about 1.79 and Frobenius norm about 1.93. That bound is correct but crude, as promised.

Warning. **At a singular matrix the unitary factor jumps, and no bound of this kind survives.** For $0 < \varepsilon \le 1$ let

$$\mathbf{A}_\varepsilon = \operatorname{diag}(1, \varepsilon) = \mathbf{I}\,\operatorname{diag}(1, \varepsilon),$$
$$\mathbf{B}_\varepsilon = \operatorname{diag}(1, -\varepsilon) = \operatorname{diag}(1, -1)\,\operatorname{diag}(1, \varepsilon).$$

These are polar decompositions: the unitary factors are $\mathbf{U} = \mathbf{I}$ and $\mathbf{V} = \operatorname{diag}(1, -1)$, and both positive factors are $\operatorname{diag}(1, \varepsilon)$. As $\varepsilon \to 0^{+}$, both matrices tend to the singular $\operatorname{diag}(1, 0)$, and $\|\mathbf{A}_\varepsilon - \mathbf{B}_\varepsilon\| = 2\varepsilon \to 0$ in both norms. Yet $\mathbf{U} - \mathbf{V} = \operatorname{diag}(0, 2)$ has spectral and Frobenius norm 2 for every ε. So the unitary factor has no limit at $\operatorname{diag}(1, 0)$, and it cannot be chosen continuously there. This matches the non-uniqueness in Theorem 12.9.1: both $\mathbf{I}$ and $\operatorname{diag}(1, -1)$ are unitary polar factors of $\operatorname{diag}(1, 0)$. The theorem, with $\sigma_2(\mathbf{A}_\varepsilon) = \sigma_2(\mathbf{B}_\varepsilon) = \varepsilon$, gives the bound $(2 \cdot 2\varepsilon)/(2\varepsilon) = 2$, which is attained. Padding both matrices with an identity block, $\mathbf{A}_\varepsilon \oplus \mathbf{I}_{n-2}$ and $\mathbf{B}_\varepsilon \oplus \mathbf{I}_{n-2}$, gives the same equality for every $n \ge 2$: the constant 2 cannot be improved, and the denominator cannot be dropped.

Corollary 12.9.2 identified the unitary polar factor as the unitary matrix nearest to $\mathbf{A}$ in the Frobenius norm. Theorem 19.10.4 adds that for invertible $\mathbf{A}$ this nearest unitary matrix moves continuously with $\mathbf{A}$, at a rate no worse than $2/(\sigma_n(\mathbf{A}) + \sigma_n(\mathbf{B}))$. A matrix that has drifted from unitarity can therefore be put back reliably, as long as it stays well away from the singular matrices.

19.10.5 Exercises

19.10.5.1 A. Check your understanding

Exercise A1.

(a) State Mirsky's theorem. In its proof by the Hermitian dilation of Proposition 16.9.3, where does each of the two factors of 2 come from?

(b) True or false: $|\sigma_i(\mathbf{A}) - \sigma_i(\mathbf{B})| \le \|\mathbf{A} - \mathbf{B}\|_F$ for every i. Justify.

(c) True or false: the unitary polar factor is a continuous function of $\mathbf{A}$ on the invertible matrices, and it extends continuously to all of $M_n(\mathbb{C})$. Justify.

(d) Which identity turns the perturbation of a square root into a Sylvester equation, and which result then bounds it?

(e) Why does Theorem 19.10.4 hold in both the spectral and the Frobenius norm?

Solution.

(a) Theorem 19.10.1: $\sum_{i=1}^{p}(\sigma_i(\mathbf{A}) - \sigma_i(\mathbf{B}))^2 \le \|\mathbf{A} - \mathbf{B}\|_F^2$. On the eigenvalue side, each difference $\sigma_i(\mathbf{A}) - \sigma_i(\mathbf{B})$ occurs twice in the sorted spectra of the dilations, once as σ_i near the top and once as $-\sigma_i$ near the bottom. On the norm side, each entry of $\mathbf{A} - \mathbf{B}$ occurs twice in $\mathcal{H}(\mathbf{A} - \mathbf{B})$, once in $\mathbf{A} - \mathbf{B}$ and once, conjugated, in $(\mathbf{A} - \mathbf{B})^*$ (Eq. 19.10.1).

(b) True. Every term of the sum in Mirsky's theorem is non-negative, so each one is at most the sum, which is at most $\|\mathbf{A} - \mathbf{B}\|_F^2$. (It also follows from Corollary 16.9.5 and $\|\cdot\|_2 \le \|\cdot\|_F$, Proposition 15.3.4.)

(c) False as a whole. The first half is true: by Theorem 19.10.4, $\|\mathbf{U} - \mathbf{V}\|_2 \le 2\|\mathbf{A} - \mathbf{B}\|_2/(\sigma_n(\mathbf{A}) + \sigma_n(\mathbf{B}))$, which tends to 0 as $\mathbf{B} \to \mathbf{A}$ for fixed invertible $\mathbf{A}$, because $\sigma_n(\mathbf{B}) \ge 0$. The second half is false: in the last warning of the section, $\mathbf{A}_\varepsilon$ and $\mathbf{B}_\varepsilon$ both tend to $\mathrm{diag}(1, 0)$ while their unitary factors stay at distance 2, so no value at $\mathrm{diag}(1, 0)$ makes the factor continuous there.

(d) $\mathbf{S}(\mathbf{S}-\mathbf{T})+(\mathbf{S}-\mathbf{T})\mathbf{T} = \mathbf{S}^2 - \mathbf{T}^2$ (Eq. 19.10.2), which exhibits $\mathbf{S} - \mathbf{T}$ as the solution of $\mathbf{SX} + \mathbf{XT} = \mathbf{P} - \mathbf{Q}$. Section 7's Corollary 19.7.4 bounds that solution.

(e) Each step holds in both norms: Corollary 19.7.4 is stated for both, and so are the facts of Lemma 19.9.1 used to remove the unitary factors and conjugate transposes.

19.10.5.2 B. Practice

Exercise B1: Mirsky by hand.

Let $\mathbf{A} = \left(\begin{smallmatrix} 3 & 0 \\ 4 & 5 \end{smallmatrix}\right)$, with $\sigma(\mathbf{A}) = (3\sqrt{5}, \sqrt{5})$ from Example (A polar decomposition), and $\mathbf{B} = \left(\begin{smallmatrix} 3 & 0 \\ 4 & 3 \end{smallmatrix}\right)$.

(a) Show that $\sigma(\mathbf{B}) = (\sqrt{13} + 2, \sqrt{13} - 2)$.

(b) Verify Theorem 19.10.1 for this pair.

(c) What bound on $\sum_i(\sigma_i(\mathbf{A}) - \sigma_i(\mathbf{B}))^2$ does Corollary 16.9.5 give? Hence say what Mirsky's theorem gains here.

Solution.

(a) $\mathbf{B}^\top\mathbf{B} = \left(\begin{smallmatrix} 25 & 12 \\ 12 & 9 \end{smallmatrix}\right)$ has trace 34 and determinant $225 - 144 = 81$, so its eigenvalues are $17 \pm \sqrt{289 - 81} = 17 \pm 4\sqrt{13}$. Since $(\sqrt{13} \pm 2)^2 = 17 \pm 4\sqrt{13}$ and $\sqrt{13} - 2 > 0$, the singular values are $\sqrt{13} \pm 2 \approx 5.606, 1.606$.

(b) $\mathbf{A} - \mathbf{B} = \operatorname{diag}(0, 2)$, so $\|\mathbf{A} - \mathbf{B}\|_F^2 = 4$. The left side is

$$\begin{aligned}(3\sqrt{5} - \sqrt{13} - 2)^2 + (\sqrt{5} - \sqrt{13} + 2)^2 \\ = 84 - 8\sqrt{65} - 8\sqrt{5} \approx 1.613,\end{aligned}$$

expanding each square (the $\sqrt{13}$ terms cancel). Indeed $1.613 \leq 4$.

(c) $\|\mathbf{A} - \mathbf{B}\|_2 = 2$, so each $|\sigma_i(\mathbf{A}) - \sigma_i(\mathbf{B})| \leq 2$, and the sum of the two squares is at most 8. Mirsky's theorem gives 4, half as much. The true value is about 1.613: the differences are about 1.103 and 0.631.

Exercise B2: A square root that does not commute.

Let $\mathbf{S} = \left(\begin{smallmatrix} 3 & 2 \\ 2 & 3 \end{smallmatrix}\right)$, $\mathbf{T} = \left(\begin{smallmatrix} 3 & 2 \\ 2 & 4 \end{smallmatrix}\right)$, $\mathbf{P} = \mathbf{S}^2$ and $\mathbf{Q} = \mathbf{T}^2$.

(a) Compute $\mathbf{P}$ and $\mathbf{Q}$, and explain why $\mathbf{S} = \mathbf{P}^{1/2}$ and $\mathbf{T} = \mathbf{Q}^{1/2}$.

(b) Find $\lambda_2(\mathbf{P})$ and $\lambda_2(\mathbf{Q})^{1/2}$.

(c) Compute $\|\mathbf{P} - \mathbf{Q}\|_2$ and $\|\mathbf{P} - \mathbf{Q}\|_F$, and hence the two bounds of Theorem 19.10.2. Compare them with $\|\mathbf{S} - \mathbf{T}\|$.

Solution.

(a) Squaring, $\mathbf{P} = \left(\begin{smallmatrix} 13 & 12 \\ 12 & 13 \end{smallmatrix}\right)$ and $\mathbf{Q} = \left(\begin{smallmatrix} 13 & 14 \\ 14 & 20 \end{smallmatrix}\right)$. $\mathbf{S}$ is symmetric with eigenvalues 5 and 1 (eigenvectors $(1, \pm 1)$), and $\mathbf{T}$ is symmetric with trace 7 and determinant 8, so both eigenvalues of each are positive, and $\mathbf{S}, \mathbf{T} \succ 0$. By the uniqueness in Theorem 12.2.1, $\mathbf{S} = \mathbf{P}^{1/2}$ and $\mathbf{T} = \mathbf{Q}^{1/2}$.

(b) The eigenvalues of $\mathbf{P}$ are 25 and 1, so $\lambda_2(\mathbf{P}) = 1$. The eigenvalues of $\mathbf{T}$ are $\frac{7 \pm \sqrt{17}}{2}$, and by Theorem 12.2.1 those of $\mathbf{Q}$ are their squares, so $\lambda_2(\mathbf{Q})^{1/2} = \lambda_2(\mathbf{T}) = \frac{7 - \sqrt{17}}{2} \approx 1.438$.

(c) $\mathbf{P} - \mathbf{Q} = \left(\begin{smallmatrix} 0 & -2 \\ -2 & -7 \end{smallmatrix}\right)$ is symmetric with characteristic polynomial $t^2 + 7t - 4$, so its eigenvalues are $\frac{-7 \pm \sqrt{65}}{2}$, and by Lemma 16.3.5 $\|\mathbf{P} - \mathbf{Q}\|_2 = \frac{7 + \sqrt{65}}{2} \approx 7.531$. Also $\|\mathbf{P} - \mathbf{Q}\|_F = \sqrt{4 + 4 + 49} = \sqrt{57} \approx 7.550$. The denominator is $1 + 1.438 = 2.438$, so the bounds are about 3.089 (spectral) and 3.096 (Frobenius). Since $\mathbf{S} - \mathbf{T} = \operatorname{diag}(0, -1)$, both of its norms equal 1. Hence the theorem holds here with a factor of about 3 to spare. It is not an equality because $\mathbf{S} - \mathbf{T}$ does not sit along the eigenvector of $\mathbf{P}$ and $\mathbf{Q}$ where both are smallest.

Exercise B3: A nearly sharp instance.

Let $\mathbf{A} = 2\mathbf{I}_2$ and $\mathbf{B} = \left(\begin{smallmatrix} 2 & -1 \\ 1 & 2 \end{smallmatrix}\right)$.

(a) Find the polar decompositions of $\mathbf{A}$ and $\mathbf{B}$.

(b) Compute $\|\mathbf{U} - \mathbf{V}\|_2$ and $\|\mathbf{U} - \mathbf{V}\|_F$, and compare them with the bounds of Theorem 19.10.4.

(c) Compute $\| \, |\mathbf{A}| - |\mathbf{B}| \, \|_2$ and the bound of Theorem 19.10.3.

Solution.

(a) $\mathbf{A} = \mathbf{I} \cdot 2\mathbf{I}$, with $\mathbf{U} = \mathbf{I}$ and $|\mathbf{A}| = 2\mathbf{I} \succ 0$. The columns of $\mathbf{B}$ are orthogonal, each of length $\sqrt{5}$, so $\mathbf{V} = \frac{1}{\sqrt{5}}\mathbf{B}$ is orthogonal and $\mathbf{B} = \mathbf{V} \cdot \sqrt{5}\,\mathbf{I}$, with $\sqrt{5}\,\mathbf{I} \succ 0$. Both matrices are invertible, so these are their polar decompositions (Theorem 12.9.1), and $\sigma_2(\mathbf{A}) = 2$, $\sigma_2(\mathbf{B}) = \sqrt{5}$.

(b) $\mathbf{V}$ is the rotation with $\cos\varphi = \frac{2}{\sqrt{5}}$, so, as in Example (The polar factors of two nearby matrices), $(\mathbf{U}-\mathbf{V})^{\top}(\mathbf{U}-\mathbf{V}) = (2 - 2\cos\varphi)\mathbf{I} = (2 - \frac{4}{\sqrt{5}})\mathbf{I}$. Hence $\|\mathbf{U} - \mathbf{V}\|_2 = \sqrt{2 - 4/\sqrt{5}} \approx 0.4595$ and $\|\mathbf{U} - \mathbf{V}\|_F = \sqrt{2}\,\|\mathbf{U} - \mathbf{V}\|_2 \approx 0.6498$. Next, $\mathbf{A} - \mathbf{B} = \left(\begin{smallmatrix} 0 & 1 \\ -1 & 0 \end{smallmatrix}\right)$ is orthogonal, so $\|\mathbf{A} - \mathbf{B}\|_2 = 1$ and $\|\mathbf{A} - \mathbf{B}\|_F = \sqrt{2}$. The bounds are

$$\frac{2 \cdot 1}{2 + \sqrt{5}} \approx 0.4721, \qquad \frac{2\sqrt{2}}{2 + \sqrt{5}} \approx 0.6677.$$

Both hold, and each is within 3% of the true value.

(c) $|\mathbf{A}| - |\mathbf{B}| = (2 - \sqrt{5})\mathbf{I}$, of spectral norm $\sqrt{5} - 2 \approx 0.236$. The bound is $(\|\mathbf{A}\|_2 + \|\mathbf{B}\|_2)\|\mathbf{A} - \mathbf{B}\|_2/(2 + \sqrt{5}) = (2 + \sqrt{5}) \cdot 1/(2 + \sqrt{5}) = 1$, a factor of about 4 larger.

19.10.5.3 C. Going deeper

Exercise C1: The square root is continuous everywhere.

Let $\mathbf{S}, \mathbf{T} \in M_n(\mathbb{C})$ be positive semidefinite.

(a) Let λ be an eigenvalue of the Hermitian matrix $\mathbf{S} - \mathbf{T}$, with unit eigenvector $\mathbf{x}$. Prove that $\mathbf{S}^2 - \mathbf{T}^2 = (\mathbf{S} - \mathbf{T})^2 + (\mathbf{S} - \mathbf{T})\mathbf{T} + \mathbf{T}(\mathbf{S} - \mathbf{T})$, and that $\mathbf{x}^*(\mathbf{S}^2 - \mathbf{T}^2)\mathbf{x} = \lambda^2 + 2\lambda\,\mathbf{x}^*\mathbf{T}\mathbf{x}$.

(b) Deduce that if $\lambda \geq 0$ then $\lambda^2 \leq \|\mathbf{S}^2 - \mathbf{T}^2\|_2$.

(c) Prove that $\|\mathbf{P}^{1/2} - \mathbf{Q}^{1/2}\|_2 \leq \|\mathbf{P} - \mathbf{Q}\|_2^{1/2}$ for all positive semidefinite $\mathbf{P}, \mathbf{Q} \in M_n(\mathbb{C})$, and show that the exponent $\frac{1}{2}$ cannot be replaced by anything larger.

Hint: for (c), apply (b) to the pair $(\mathbf{S}, \mathbf{T})$ or to the pair $(\mathbf{T}, \mathbf{S})$, according to the sign of the eigenvalue of $\mathbf{S} - \mathbf{T}$ of largest modulus.

Solution.

(a) Expanding, $(\mathbf{S} - \mathbf{T})^2 + (\mathbf{S} - \mathbf{T})\mathbf{T} + \mathbf{T}(\mathbf{S} - \mathbf{T}) = \mathbf{S}^2 - \mathbf{S}\mathbf{T} - \mathbf{T}\mathbf{S} + \mathbf{T}^2 + \mathbf{S}\mathbf{T} - \mathbf{T}^2 + \mathbf{T}\mathbf{S} - \mathbf{T}^2 = \mathbf{S}^2 - \mathbf{T}^2$. Since $(\mathbf{S} - \mathbf{T})\mathbf{x} = \lambda\mathbf{x}$ with λ real (Theorem 11.2.1) and $\mathbf{S} - \mathbf{T}$ Hermitian, also $\mathbf{x}^*(\mathbf{S} - \mathbf{T}) = \lambda\mathbf{x}^*$. Hence $\mathbf{x}^*(\mathbf{S} - \mathbf{T})^2\mathbf{x} = \lambda^2\mathbf{x}^*\mathbf{x} = \lambda^2$, $\mathbf{x}^*(\mathbf{S} - \mathbf{T})\mathbf{T}\mathbf{x} = \lambda\,\mathbf{x}^*\mathbf{T}\mathbf{x}$ and $\mathbf{x}^*\mathbf{T}(\mathbf{S} - \mathbf{T})\mathbf{x} = \lambda\,\mathbf{x}^*\mathbf{T}\mathbf{x}$. Adding gives the claim.

(b) $\mathbf{x}^*\mathbf{T}\mathbf{x} \geq 0$ because $\mathbf{T} \succeq 0$, so if $\lambda \geq 0$, (a) gives $\lambda^2 \leq \mathbf{x}^*(\mathbf{S}^2 - \mathbf{T}^2)\mathbf{x}$. By Theorem 10.1.5 and Theorem 15.3.2 (a), $\mathbf{x}^*\mathbf{M}\mathbf{x} \leq \|\mathbf{M}\mathbf{x}\|\|\mathbf{x}\| \leq \|\mathbf{M}\|_2$ for any $\mathbf{M}$ and unit $\mathbf{x}$. So $\lambda^2 \leq \|\mathbf{S}^2 - \mathbf{T}^2\|_2$.

(c) Put $\mathbf{S} = \mathbf{P}^{1/2}$ and $\mathbf{T} = \mathbf{Q}^{1/2}$, so $\mathbf{S}^2 - \mathbf{T}^2 = \mathbf{P} - \mathbf{Q}$. By Lemma 16.3.5, $\|\mathbf{S} - \mathbf{T}\|_2 = |\lambda|$ for some eigenvalue λ of $\mathbf{S} - \mathbf{T}$. If $\lambda \geq 0$, (b) gives $\lambda^2 \leq \|\mathbf{P} - \mathbf{Q}\|_2$. If $\lambda < 0$, then $-\lambda > 0$ is an eigenvalue of $\mathbf{T} - \mathbf{S}$, and (b) applied to the pair $(\mathbf{T}, \mathbf{S})$ gives $\lambda^2 \leq \|\mathbf{T}^2 - \mathbf{S}^2\|_2 = \|\mathbf{P} - \mathbf{Q}\|_2$. In both cases $\|\mathbf{P}^{1/2} - \mathbf{Q}^{1/2}\|_2 = |\lambda| \leq \|\mathbf{P} - \mathbf{Q}\|_2^{1/2}$.

For the exponent, take $\mathbf{P} = \varepsilon\mathbf{I}$ and $\mathbf{Q} = \mathbf{0}$ with $0 < \varepsilon < 1$, as in the warning after Theorem 19.10.2. Then $\|\mathbf{P}^{1/2} - \mathbf{Q}^{1/2}\|_2 = \varepsilon^{1/2}$ and $\|\mathbf{P} - \mathbf{Q}\|_2 = \varepsilon$. If $\varepsilon^{1/2} \le C\varepsilon^r$ held for all small ε with some $r > \frac{1}{2}$, then $C \ge \varepsilon^{1/2-r} \to \infty$ as $\varepsilon \to 0^+$, which is impossible. So the square root, which is not Lipschitz near singular matrices, is still continuous on all positive semidefinite matrices, with modulus $t \mapsto t^{1/2}$.

Exercise C2: Both Eckart–Young lower bounds from perturbation theory.

Let $\mathbf{A} \in M_{m\times n}(\mathbb{C})$, let $0 \le k < p = \min(m, n)$, and let $\mathbf{B} \in M_{m\times n}(\mathbb{C})$ have rank at most k.

(a) Explain why $\sigma_i(\mathbf{B}) = 0$ for $i > k$.

(b) Prove, using Theorem 19.10.1, that $\|\mathbf{A} - \mathbf{B}\|_F^2 \ge \sum_{i=k+1}^{p} \sigma_i(\mathbf{A})^2$.

(c) Prove, using Corollary 16.9.5, that $\|\mathbf{A} - \mathbf{B}\|_2 \ge \sigma_{k+1}(\mathbf{A})$.

(d) Compare with Theorem 12.10.3 and Theorem 16.9.6.

Solution.

(a) By Theorem 12.8.3 the number of non-zero singular values of $\mathbf{B}$ is $\operatorname{rank}\mathbf{B} \le k$, and they come first in the decreasing list, so $\sigma_i(\mathbf{B}) = 0$ for $i > k$.

(b) By Theorem 19.10.1, and dropping the non-negative terms with $i \le k$,

$$\begin{aligned}\|\mathbf{A} - \mathbf{B}\|_F^2 &\ge \sum_{i=1}^{p} \big(\sigma_i(\mathbf{A}) - \sigma_i(\mathbf{B})\big)^2 \\ &\ge \sum_{i=k+1}^{p} \big(\sigma_i(\mathbf{A}) - 0\big)^2,\end{aligned}$$

using (a) in the last step.

(c) By Corollary 16.9.5 with $i = k + 1 \le p$ and $\mathbf{E} = \mathbf{B} - \mathbf{A}$,

$$\sigma_{k+1}(\mathbf{A}) = \big|\sigma_{k+1}(\mathbf{A}) - \sigma_{k+1}(\mathbf{B})\big| \le \|\mathbf{B} - \mathbf{A}\|_2 = \|\mathbf{A} - \mathbf{B}\|_2,$$

using (a) and $\sigma_{k+1}(\mathbf{A}) \ge 0$.

(d) These are exactly the lower-bound halves of the Frobenius and the spectral Eckart–Young theorems. Both theorems also show that the bounds are attained, by the truncation $\mathbf{A}_k$, which has singular values $\sigma_1(\mathbf{A}), \dots, \sigma_k(\mathbf{A}), 0, \dots, 0$, so that it makes every term with $i \le k$ vanish. So "the best rank-k approximation" is a perturbation theorem read backwards: no matrix of rank k can be closer to $\mathbf{A}$ than the singular values of $\mathbf{A}$ allow, because singular values cannot move further than the perturbation.

Exercise C3: The nearest unitary to an almost-unitary matrix.

Let $\mathbf{E} \in M_n(\mathbb{C})$ with $\|\mathbf{E}\|_2 < 1$, let $\mathbf{A} = \mathbf{I} + \mathbf{E}$, and let $\mathbf{U}$ be the unitary polar factor of $\mathbf{A}$.

(a) Prove that $\sigma_n(\mathbf{A}) \ge 1 - \|\mathbf{E}\|_2 > 0$, so that $\mathbf{A}$ is invertible.

(b) Prove that $\|\mathbf{U} - \mathbf{I}\| \le 2\|\mathbf{E}\|/(2 - \|\mathbf{E}\|_2)$ in both the spectral and the Frobenius

norm.

(c) Deduce that if $\|\mathbf{E}\|_2 \le \frac{1}{2}$ then $\|\mathbf{U}-\mathbf{I}\|_F \le \frac{4}{3}\|\mathbf{E}\|_F$. Compare with the bound $\|\mathbf{U}-\mathbf{I}\|_F \le 2\|\mathbf{E}\|_F$ that Corollary 12.9.2 and the triangle inequality give with no computation.

Solution.

(a) The identity has all singular values equal to 1. By Corollary 16.9.5 with $i = n$, $|\sigma_n(\mathbf{I}+\mathbf{E})-1| \le \|\mathbf{E}\|_2$, so $\sigma_n(\mathbf{A}) \ge 1-\|\mathbf{E}\|_2 > 0$. An $n\times n$ matrix with n non-zero singular values has rank n (Theorem 12.8.3), so $\mathbf{A}$ is invertible.

(b) Apply Theorem 19.10.4 to $\mathbf{A}$ and $\mathbf{B} = \mathbf{I}$, whose polar decomposition is $\mathbf{I} = \mathbf{I}\cdot\mathbf{I}$, with $\mathbf{V} = \mathbf{I}$ and $\sigma_n(\mathbf{I}) = 1$. Since $\mathbf{A}-\mathbf{I} = \mathbf{E}$,

$$\|\mathbf{U}-\mathbf{I}\| \le \frac{2\|\mathbf{E}\|}{\sigma_n(\mathbf{A})+1} \le \frac{2\|\mathbf{E}\|}{2-\|\mathbf{E}\|_2},$$

using (a) to bound the denominator from below. This holds in both norms because the theorem does.

(c) If $\|\mathbf{E}\|_2 \le \frac{1}{2}$ then $2-\|\mathbf{E}\|_2 \ge \frac{3}{2}$, and (b) in the Frobenius norm gives $\|\mathbf{U}-\mathbf{I}\|_F \le \frac{4}{3}\|\mathbf{E}\|_F$.

For comparison, Corollary 12.9.2 says that $\mathbf{U}$ is at least as close to $\mathbf{A}$ as any unitary matrix is, and $\mathbf{I}$ is one, so $\|\mathbf{A}-\mathbf{U}\|_F \le \|\mathbf{A}-\mathbf{I}\|_F = \|\mathbf{E}\|_F$. The triangle inequality then gives

$$\|\mathbf{U}-\mathbf{I}\|_F \le \|\mathbf{U}-\mathbf{A}\|_F + \|\mathbf{A}-\mathbf{I}\|_F \le 2\|\mathbf{E}\|_F.$$

So the soft argument already locates $\mathbf{U}$ within $2\|\mathbf{E}\|_F$ of $\mathbf{I}$. Part (b) improves the constant to $\frac{4}{3}$ when $\|\mathbf{E}\|_2 \le \frac{1}{2}$, and to $2/(2-\|\mathbf{E}\|_2)$, which tends to 1, as $\mathbf{E}\to\mathbf{0}$. It also gives the spectral-norm statement, about which Corollary 12.9.2 says nothing.

19.11 Condition Numbers of Eigenvalues

The Bauer–Fike theorem of §04 bounds the movement of every eigenvalue of a diagonalizable matrix at once, by $\kappa_2(\mathbf{X})\|\mathbf{E}\|_2$ (Theorem 19.4.2). That is one number for the whole spectrum, and it depends on a choice of eigenvector matrix $\mathbf{X}$. §04 warned that a well-behaved eigenvalue can sit inside a badly conditioned $\mathbf{X}$, so the bound can be far too pessimistic for some eigenvalues. This section asks about **one** eigenvalue at a time. If λ is a simple eigenvalue of $\mathbf{A}$, how fast does it move when $\mathbf{A}$ is pushed in a direction $\mathbf{E}$? The answer is an exact derivative, $\mathbf{y}^*\mathbf{E}\mathbf{x}/(\mathbf{y}^*\mathbf{x})$, built from a right and a left eigenvector. Its worst size over all $\mathbf{E}$ with $\|\mathbf{E}\|_2 = 1$ is the condition number of that eigenvalue.

The field is $\mathbb{C}$. Throughout, $\mathbf{A}, \mathbf{E} \in M_n(\mathbb{C})$, and $\|\cdot\|$ on vectors is the Euclidean norm.

19.11.1 Left and right eigenvectors

Chapter 8 defined a left eigenvector as a non-zero $\mathbf{y}$ with $\mathbf{y}^\top\mathbf{A} = \lambda\mathbf{y}^\top$ (Definition 8.10.1). Over $\mathbb{C}$ it is more convenient to put a conjugate on it. In this section, a **left eigenvector** of $\mathbf{A}$ for λ

is a non-zero $\mathbf{y} \in \mathbb{C}^n$ with

$$\mathbf{y}^*\mathbf{A} = \lambda\,\mathbf{y}^*,$$

which is the same as $\mathbf{A}^*\mathbf{y} = \overline{\lambda}\,\mathbf{y}$. Since $\mathbf{y}^* = \overline{\mathbf{y}}^{\top}$, the equation $\mathbf{y}^*\mathbf{A} = \lambda\mathbf{y}^*$ says exactly that $\overline{\mathbf{y}}$ is a left eigenvector in the sense of Definition 8.10.1. So the two conventions differ only by conjugating the vector. The conjugate is worth it for one reason: the number $\mathbf{y}^*\mathbf{x}$ is then the standard inner product $\langle \mathbf{x}, \mathbf{y} \rangle$ of Chapter 10, and Cauchy–Schwarz applies to it.

For a **simple** eigenvalue, that is, one of algebraic multiplicity 1 (Definition 8.3.1), the right and left eigenvectors are as rigid as they can be, and they are never orthogonal. That last fact is what the whole section divides by.

Lemma 19.11.1 — Left and Right Eigenvectors of a Simple Eigenvalue

Let $\mathbf{A} \in M_n(\mathbb{C})$ and let λ be a simple eigenvalue of $\mathbf{A}$, with a right eigenvector $\mathbf{x}$ and a left eigenvector $\mathbf{y}$.

(a) The right eigenvectors of $\mathbf{A}$ for λ are exactly the non-zero multiples of $\mathbf{x}$, and the left eigenvectors are exactly the non-zero multiples of $\mathbf{y}$.

(b) $\mathbf{y}^*\mathbf{x} \neq 0$.

Idea. Split λ off from the rest of the spectrum. In a basis that begins with $\mathbf{x}$, the matrix becomes block triangular with the 1×1 block (λ) in the corner and a block $\mathbf{B}$ with $\lambda \notin \operatorname{spec}(\mathbf{B})$. Chapter 11 §10 clears the off-diagonal corner whenever the two diagonal blocks have disjoint spectra, so $\mathbf{A}$ is similar to $(\lambda) \oplus \mathbf{B}$. In that picture everything is visible: $\mathbf{e}_1$ is the right eigenvector, $\mathbf{e}_1^*$ the left one, and $\mathbf{e}_1^*\mathbf{e}_1 = 1$.

Proof. If $n = 1$, both claims hold because every non-zero vector of $\mathbb{C}^1$ is a multiple of every other, and $\mathbf{y}^*\mathbf{x} = \overline{y_1}x_1$ is a product of two non-zero numbers. Let $n \geq 2$.

By Theorem 1.6.5, extend the independent list $(\mathbf{x})$ to a basis of $\mathbb{C}^n$, and let $\mathbf{P}_0$ be the invertible matrix with these columns, so that $\mathbf{P}_0\mathbf{e}_1 = \mathbf{x}$. Then $\mathbf{P}_0^{-1}\mathbf{A}\mathbf{P}_0\mathbf{e}_1 = \mathbf{P}_0^{-1}\lambda\mathbf{x} = \lambda\mathbf{e}_1$, so

$$\mathbf{P}_0^{-1}\mathbf{A}\mathbf{P}_0 = \begin{pmatrix} \lambda & \mathbf{c} \\ \mathbf{0} & \mathbf{B} \end{pmatrix}$$

for some $\mathbf{c} \in M_{1\times(n-1)}(\mathbb{C})$ and $\mathbf{B} \in M_{n-1}(\mathbb{C})$. By Theorem 6.10.3 and Theorem 6.8.4, $p_{\mathbf{A}}(x) = (x-\lambda)\,p_{\mathbf{B}}(x)$. If $p_{\mathbf{B}}(\lambda) = 0$, then $x-\lambda$ would divide $p_{\mathbf{B}}$ by the Factor Theorem (Lemma 2.7.1), so $(x-\lambda)^2$ would divide $p_{\mathbf{A}}$, against $a_{\mathbf{A}}(\lambda) = 1$. Hence $\lambda \notin \operatorname{spec}(\mathbf{B})$ (Theorem 8.2.1). The spectra $\{\lambda\}$ and $\operatorname{spec}(\mathbf{B})$ are disjoint, so by Corollary 11.10.3 (c) and (a) there is $\mathbf{Q} = \left(\begin{smallmatrix} 1 & \mathbf{z} \\ \mathbf{0} & \mathbf{I}_{n-1} \end{smallmatrix}\right)$ with $\mathbf{Q}^{-1}\mathbf{P}_0^{-1}\mathbf{A}\mathbf{P}_0\mathbf{Q} = (\lambda) \oplus \mathbf{B}$. Put $\mathbf{P} = \mathbf{P}_0\mathbf{Q}$. Then

$$\mathbf{P}^{-1}\mathbf{A}\mathbf{P} = (\lambda) \oplus \mathbf{B}, \qquad \mathbf{P}\mathbf{e}_1 = \mathbf{P}_0\mathbf{Q}\mathbf{e}_1 = \mathbf{P}_0\mathbf{e}_1 = \mathbf{x}.$$

(a) Let $\mathbf{A}\mathbf{v} = \lambda\mathbf{v}$ and write $\mathbf{P}^{-1}\mathbf{v} = (u_1, \mathbf{u}')$ with $\mathbf{u}' \in \mathbb{C}^{n-1}$. Then $((\lambda) \oplus \mathbf{B})\mathbf{P}^{-1}\mathbf{v} = \lambda\mathbf{P}^{-1}\mathbf{v}$, whose last $n-1$ rows say $(\mathbf{B} - \lambda\mathbf{I})\mathbf{u}' = \mathbf{0}$. Since $\lambda \notin \operatorname{spec}(\mathbf{B})$, the matrix $\mathbf{B} - \lambda\mathbf{I}$ is invertible (Theorem 8.2.1), so $\mathbf{u}' = \mathbf{0}$ and $\mathbf{v} = u_1\mathbf{P}\mathbf{e}_1 = u_1\mathbf{x}$. For the left side, let $\mathbf{w}^*\mathbf{A} = \lambda\mathbf{w}^*$ and write $\mathbf{w}^*\mathbf{P} = (w_1, \mathbf{w}'^*)$. Then $(\mathbf{w}^*\mathbf{P})((\lambda) \oplus \mathbf{B}) = \lambda\,\mathbf{w}^*\mathbf{P}$, whose last $n-1$ entries say $\mathbf{w}'^*(\mathbf{B} - \lambda\mathbf{I}) = \mathbf{0}$. Multiplying on the right by $(\mathbf{B} - \lambda\mathbf{I})^{-1}$ gives $\mathbf{w}' = \mathbf{0}$, so $\mathbf{w}^* = w_1\mathbf{e}_1^*\mathbf{P}^{-1}$. Every left eigenvector is therefore a multiple of the non-zero row $\mathbf{e}_1^*\mathbf{P}^{-1}$, and in particular every left eigenvector is a multiple of

any other. This proves (a).

(b) By the computation just made, $\mathbf{y}^* = w_1 \mathbf{e}_1^* \mathbf{P}^{-1}$ with $w_1 \neq 0$, because $\mathbf{y} \neq \mathbf{0}$. Hence

$$\mathbf{y}^*\mathbf{x} = w_1\, \mathbf{e}_1^*\mathbf{P}^{-1}\mathbf{P}\mathbf{e}_1 = w_1\, \mathbf{e}_1^*\mathbf{e}_1 = w_1 \neq 0.$$

This proves the lemma.

■

The proof produced a little more than was asked: the left eigenvector $\mathbf{e}_1^*\mathbf{P}^{-1}$ is normalized against $\mathbf{x}$, in the sense that $(\mathbf{e}_1^*\mathbf{P}^{-1})\mathbf{x} = 1$. This is the one-eigenvalue version of the biorthogonal normalization $\mathbf{y}_i^\top \mathbf{v}_i = 1$ of Proposition 8.10.7, and it exists for a simple eigenvalue of any matrix, diagonalizable or not.

Warning. **Simple is essential: at a Jordan block, the two eigenvectors are orthogonal.** For $\mathbf{J}_2(0) = \left(\begin{smallmatrix} 0 & 1 \\ 0 & 0 \end{smallmatrix}\right)$ the only eigenvalue is 0, twice. The right eigenvectors are the multiples of $\mathbf{x} = \mathbf{e}_1$, since $\mathbf{J}_2(0)\mathbf{e}_1 = \mathbf{0}$. The left eigenvectors are the multiples of $\mathbf{y} = \mathbf{e}_2$, since $\mathbf{e}_2^*\mathbf{J}_2(0)$ is the second row, which is zero. So $\mathbf{y}^*\mathbf{x} = 0$. Every formula in this section that divides by $\mathbf{y}^*\mathbf{x}$ is meaningless here, and §03's example shows why it must be: the eigenvalues of $\mathbf{J}_2(0) + t\mathbf{E}_{21}$ are $\pm\sqrt{t}$, which have no derivative at $t = 0$.

Quick check. Let $\mathbf{A} = \left(\begin{smallmatrix} 1 & 1 \\ 0 & 2 \end{smallmatrix}\right)$. Find a right and a left eigenvector for the eigenvalue 1, and check that $\mathbf{y}^*\mathbf{x} \neq 0$.

Solution. $\mathbf{A}\mathbf{e}_1 = \mathbf{e}_1$, so $\mathbf{x} = \mathbf{e}_1$. A left eigenvector solves $\mathbf{y}^*(\mathbf{A}-\mathbf{I}) = \mathbf{0}$, and $\mathbf{A}-\mathbf{I} = \left(\begin{smallmatrix} 0 & 1 \\ 0 & 1 \end{smallmatrix}\right)$; for $\mathbf{y}^* = (a, b)$ this reads $(0, a+b) = (0, 0)$, so $\mathbf{y} = (1, -1)$ will do. Then $\mathbf{y}^*\mathbf{x} = 1 \neq 0$, as Lemma 19.11.1 (b) requires. Here $\mathbf{y}$ is not a multiple of $\mathbf{x}$: the matrix is not normal.

19.11.2 The derivative of a simple eigenvalue

Now move $\mathbf{A}$ along a straight line $\mathbf{A} + t\mathbf{E}$, with t real. Chapter 15 proved that the eigenvalues move continuously (Corollary 15.7.4), but only as an unnumbered list, and Proposition 15.7.2 showed that no single eigenvalue can be followed continuously in general. A simple eigenvalue is the exception: it stays isolated from the rest for small t, so "the eigenvalue near λ" makes sense. The theorem says that this eigenvalue is differentiable at $t = 0$, and it names the derivative.

Theorem 19.11.2 — Derivative of a Simple Eigenvalue

Let $\mathbf{A} \in M_n(\mathbb{C})$, let λ be a simple eigenvalue of $\mathbf{A}$ with a right eigenvector $\mathbf{x}$ and a left eigenvector $\mathbf{y}$, and let $\mathbf{E} \in M_n(\mathbb{C})$. Then there are $r > 0$ and $t_0 > 0$ with the following properties.

(a) For every **real** t with $|t| < t_0$, the matrix $\mathbf{A} + t\mathbf{E}$ has **exactly one** eigenvalue, counted with algebraic multiplicity, in the open disc $\{z \in \mathbb{C} : |z - \lambda| < r\}$. Call it $\lambda(t)$. Thus $\lambda(0) = \lambda$, and $\lambda(t)$ is a simple eigenvalue of $\mathbf{A} + t\mathbf{E}$.

(b) $\lambda(t) \to \lambda$ as $t \to 0$.

(c) The function $t \mapsto \lambda(t)$ is differentiable at $t = 0$, and

$$\lambda'(0) = \lim_{t\to 0} \frac{\lambda(t) - \lambda}{t} = \frac{\mathbf{y}^*\mathbf{E}\mathbf{x}}{\mathbf{y}^*\mathbf{x}}.$$

In other words, $\lambda(t) = \lambda + t\,\mathbf{y}^*\mathbf{E}\mathbf{x}/(\mathbf{y}^*\mathbf{x}) + \rho(t)$ with $\rho(t)/t \to 0$. The denominator is non-zero by Lemma 19.11.1 (b), and the quotient does not change when $\mathbf{x}$ or $\mathbf{y}$ is rescaled, which by part (a) of the lemma is the only freedom there is.

Idea. The target identity falls out of one line if we have eigenvectors $\mathbf{x}_t$ of $\mathbf{A} + t\mathbf{E}$ that converge to an eigenvector of $\mathbf{A}$: multiply $(\mathbf{A}+t\mathbf{E})\mathbf{x}_t = \lambda(t)\mathbf{x}_t$ on the left by $\mathbf{y}^*$ and use $\mathbf{y}^*\mathbf{A} = \lambda\mathbf{y}^*$, to get

$$(\lambda(t) - \lambda)\,\mathbf{y}^*\mathbf{x}_t = t\,\mathbf{y}^*\mathbf{E}\mathbf{x}_t.$$

Divide by $t\,\mathbf{y}^*\mathbf{x}_t$ and let $t \to 0$. So the plan has three steps.

① Isolate $\lambda(t)$ from the rest of the spectrum with Corollary 15.7.4.

② Produce the eigenvectors $\mathbf{x}_t$ **by a formula**. A column of the adjugate $\operatorname{adj}(\lambda(t)\mathbf{I} - \mathbf{A} - t\mathbf{E})$ is an eigenvector, and its entries are polynomials in $\lambda(t)$ and t, so it converges because $\lambda(t)$ does.

③ Check that the limit is a non-zero multiple of $\mathbf{x}$, and pass to the limit in the quotient.

Proof. Let $\lambda_1 = \lambda, \lambda_2, \dots, \lambda_n$ be the eigenvalues of $\mathbf{A}$, listed with algebraic multiplicity. Since λ is simple, $\lambda_j \neq \lambda$ for $j \geq 2$.

Step 1: the isolated eigenvalue. Put $r = \frac{1}{2}\min_{j\geq 2}|\lambda_j - \lambda|$ if $n \geq 2$, and $r = 1$ if $n = 1$; in both cases $r > 0$. By Corollary 15.7.4 with the norm $\|\cdot\|_2$ and with $\varepsilon = r$, there is $\delta > 0$ such that every $\mathbf{B}$ with $\|\mathbf{B} - \mathbf{A}\|_2 < \delta$ has eigenvalues $\mu_1, \dots, \mu_n$ that can be numbered so that $|\mu_i - \lambda_i| < r$ for every i. Put $t_0 = \delta/(\|\mathbf{E}\|_2 + 1)$. If $|t| < t_0$, then $\|(\mathbf{A}+t\mathbf{E}) - \mathbf{A}\|_2 = |t|\|\mathbf{E}\|_2 < \delta$, so the eigenvalues of $\mathbf{A}+t\mathbf{E}$ can be so numbered. Then $|\mu_1 - \lambda| < r$, while for $j \geq 2$

$$|\mu_j - \lambda| \geq |\lambda_j - \lambda| - |\mu_j - \lambda_j| > 2r - r = r$$

by Theorem 0.6.4. So exactly one entry of the list lies in the open disc of radius r about λ. This proves (a).

Step 2: continuity. Let $0 < \varepsilon < r$. By Corollary 15.7.4 again, now with this ε, there is $\delta' > 0$ such that for $|t|\|\mathbf{E}\|_2 < \delta'$ the eigenvalues of $\mathbf{A} + t\mathbf{E}$ can be numbered as $\mu'_1, \dots, \mu'_n$ with $|\mu'_i - \lambda_i| < \varepsilon$. If moreover $|t| < t_0$, then μ'_1 is an eigenvalue of $\mathbf{A} + t\mathbf{E}$ in the disc of radius $\varepsilon < r$ about λ, so $\mu'_1 = \lambda(t)$ by (a). Hence $|\lambda(t) - \lambda| < \varepsilon$ whenever $|t| < \min\bigl(t_0, \delta'/(\|\mathbf{E}\|_2 + 1)\bigr)$. This proves (b).

Step 3: an eigenvector given by a formula. Put $\mathbf{N}(t) = \lambda(t)\mathbf{I} - \mathbf{A} - t\mathbf{E}$ for $|t| < t_0$, so $\mathbf{N}(0) = \lambda\mathbf{I} - \mathbf{A}$. We first find a column of $\operatorname{adj}\mathbf{N}(0)$ that is not zero. If $n = 1$, then $\operatorname{adj}\mathbf{N}(0) = (1)$ by Definition 6.6.2. If $n \geq 2$, then $1 \leq g_{\mathbf{A}}(\lambda) \leq a_{\mathbf{A}}(\lambda) = 1$ by Theorem 8.3.1, so $\operatorname{rank}\mathbf{N}(0) = n - 1 \geq 1$ by Theorem 2.5.7. By Theorem 6.7.1 (a), $\mathbf{N}(0)$ has a non-zero $(n-1)\times(n-1)$ minor M_{ij}. Then the cofactor $C_{ij} = (-1)^{i+j}M_{ij}$ is non-zero, and it is the (j,i) entry of $\operatorname{adj}\mathbf{N}(0)$ (Definition 6.6.2). In either case some column k of $\operatorname{adj}\mathbf{N}(0)$ is non-zero. Define

$$\mathbf{x}_t = \operatorname{adj}\bigl(\mathbf{N}(t)\bigr)\,\mathbf{e}_k \qquad (|t| < t_0).$$

Since $\lambda(t)$ is an eigenvalue of $\mathbf{A}+t\mathbf{E}$, we have $\det \mathbf{N}(t) = p_{\mathbf{A}+t\mathbf{E}}(\lambda(t)) = 0$ (Theorem 8.2.1). So Theorem 6.6.2 gives $\mathbf{N}(t)\operatorname{adj}\mathbf{N}(t) = \mathbf{0}$, and in particular

$$(\mathbf{A}+t\mathbf{E})\,\mathbf{x}_t = \lambda(t)\,\mathbf{x}_t \qquad (|t| < t_0).$$

At $t=0$ this says $\mathbf{A}\mathbf{x}_0 = \lambda\mathbf{x}_0$, and $\mathbf{x}_0 \neq \mathbf{0}$ by the choice of k. By Lemma 19.11.1 (a), $\mathbf{x}_0 = c\,\mathbf{x}$ for some $c \neq 0$.

Next, $\mathbf{x}_t \to \mathbf{x}_0$ as $t \to 0$. Each entry of $\operatorname{adj}\mathbf{B}$ is $\pm$ the determinant of a submatrix of $\mathbf{B}$, or the constant 1 when $n=1$, hence a polynomial in the entries of $\mathbf{B}$ by Theorem 6.4.3. So $\mathbf{B} \mapsto \operatorname{adj}\mathbf{B}$ is continuous by Lemma 15.7.1. And $\|\mathbf{N}(t)-\mathbf{N}(0)\|_2 \le |\lambda(t)-\lambda| + |t|\|\mathbf{E}\|_2$, which tends to 0 by (b). Hence $\operatorname{adj}\mathbf{N}(t) \to \operatorname{adj}\mathbf{N}(0)$, and $\|\mathbf{x}_t - \mathbf{x}_0\| \le \|\operatorname{adj}\mathbf{N}(t) - \operatorname{adj}\mathbf{N}(0)\|_2$ by Theorem 15.3.2 (a), since $\|\mathbf{e}_k\| = 1$. So $\mathbf{x}_t \to \mathbf{x}_0$.

Step 4: the derivative. Multiply the eigen-equation of Step 3 on the left by $\mathbf{y}^*$, and use $\mathbf{y}^*\mathbf{A} = \lambda\mathbf{y}^*$:

$$\lambda\,\mathbf{y}^*\mathbf{x}_t + t\,\mathbf{y}^*\mathbf{E}\mathbf{x}_t = \lambda(t)\,\mathbf{y}^*\mathbf{x}_t, \qquad \text{so} \qquad (\lambda(t)-\lambda)\,\mathbf{y}^*\mathbf{x}_t = t\,\mathbf{y}^*\mathbf{E}\mathbf{x}_t.$$

By Cauchy–Schwarz (Theorem 10.1.5), $|\mathbf{y}^*\mathbf{x}_t - \mathbf{y}^*\mathbf{x}_0| \le \|\mathbf{y}\|\|\mathbf{x}_t - \mathbf{x}_0\| \to 0$, and likewise $\mathbf{y}^*\mathbf{E}\mathbf{x}_t \to \mathbf{y}^*\mathbf{E}\mathbf{x}_0$, because $\|\mathbf{E}\mathbf{x}_t - \mathbf{E}\mathbf{x}_0\| \le \|\mathbf{E}\|_2\|\mathbf{x}_t - \mathbf{x}_0\|$. The limit $\mathbf{y}^*\mathbf{x}_0 = c\,\mathbf{y}^*\mathbf{x}$ is non-zero by Lemma 19.11.1 (b). So there is $t_1 \in (0, t_0]$ with $|\mathbf{y}^*\mathbf{x}_t - \mathbf{y}^*\mathbf{x}_0| < |\mathbf{y}^*\mathbf{x}_0|$, and hence $\mathbf{y}^*\mathbf{x}_t \neq 0$, for $|t| < t_1$. For $0 < |t| < t_1$ we may divide:

$$\frac{\lambda(t)-\lambda}{t} = \frac{\mathbf{y}^*\mathbf{E}\mathbf{x}_t}{\mathbf{y}^*\mathbf{x}_t} \longrightarrow \frac{\mathbf{y}^*\mathbf{E}\mathbf{x}_0}{\mathbf{y}^*\mathbf{x}_0} \qquad (t \to 0),$$
$$\frac{\mathbf{y}^*\mathbf{E}\mathbf{x}_0}{\mathbf{y}^*\mathbf{x}_0} = \frac{c\,\mathbf{y}^*\mathbf{E}\mathbf{x}}{c\,\mathbf{y}^*\mathbf{x}} = \frac{\mathbf{y}^*\mathbf{E}\mathbf{x}}{\mathbf{y}^*\mathbf{x}},$$

by the algebra of limits, the denominator's limit being non-zero. This proves (c).

■

No implicit function theorem was needed. The usual textbook route to this formula differentiates $\det(z\mathbf{I}-\mathbf{A}-t\mathbf{E}) = 0$ implicitly, which presupposes that a differentiable solution $z = \lambda(t)$ exists; that is the implicit function theorem, a piece of analysis this book has not imported. The proof above needed only the continuity of Corollary 15.7.4 and the fact that the adjugate writes down an eigenvector whose entries are polynomials. The analysis consists of limits of polynomials, which is the algebra of limits.

Remark. Since $\lambda(s)$ is a simple eigenvalue of $\mathbf{A}+s\mathbf{E}$ for every $|s| < t_0$, the theorem applies again at $\mathbf{A}+s\mathbf{E}$ in place of $\mathbf{A}$. The eigenvalue it isolates there is $\lambda(s+h)$ for small h, by the uniqueness in (a). So λ is differentiable on the whole interval $(-t_0, t_0)$, with $\lambda'(s) = \mathbf{y}_s^*\mathbf{E}\mathbf{x}_s/(\mathbf{y}_s^*\mathbf{x}_s)$ for right and left eigenvectors $\mathbf{x}_s, \mathbf{y}_s$ of $\mathbf{A}+s\mathbf{E}$ for $\lambda(s)$. We need only $s=0$.

The formula has a transparent special case. If $\mathbf{A}$ is Hermitian, then $\mathbf{A}^*\mathbf{x} = \mathbf{A}\mathbf{x} = \lambda\mathbf{x}$ with λ real, so $\mathbf{x}$ is also a left eigenvector and we may take $\mathbf{y} = \mathbf{x}$:

$$\lambda'(0) = \frac{\mathbf{x}^*\mathbf{E}\mathbf{x}}{\mathbf{x}^*\mathbf{x}}.$$

When $\mathbf{E}$ is Hermitian too, this is the Rayleigh quotient $R_{\mathbf{E}}(\mathbf{x})$ of Chapter 16 (Definition 16.1.1), which lies in $[\lambda_n(\mathbf{E}), \lambda_1(\mathbf{E})]$ by Proposition 16.1.1. So $|\lambda'(0)| \le \|\mathbf{E}\|_2$ by Lemma 16.3.5, which is the first-order shadow of Weyl's bound $|\lambda_i(\mathbf{A}+\mathbf{E}) - \lambda_i(\mathbf{A})| \le \|\mathbf{E}\|_2$ (Corollary 16.3.6).

Quick check. Let $\mathbf{A} = \operatorname{diag}(d_1, \dots, d_n)$ with distinct d_i, and let $\mathbf{E} = (e_{ij})$ be arbitrary. What is the derivative at $t = 0$ of the eigenvalue of $\mathbf{A} + t\mathbf{E}$ near d_i?

Solution. The eigenvalue d_i is simple, with $\mathbf{x} = \mathbf{e}_i$ and $\mathbf{y} = \mathbf{e}_i$, since $\mathbf{e}_i^*\mathbf{A} = d_i\mathbf{e}_i^*$. So $\lambda'(0) = \mathbf{e}_i^*\mathbf{E}\mathbf{e}_i/(\mathbf{e}_i^*\mathbf{e}_i) = e_{ii}$. To first order, the eigenvalues of a perturbed diagonal matrix with distinct diagonal entries move by the diagonal of the perturbation, and the off-diagonal entries of $\mathbf{E}$ enter only at second order.

19.11.3 The condition number of a simple eigenvalue

The derivative $\mathbf{y}^*\mathbf{E}\mathbf{x}/(\mathbf{y}^*\mathbf{x})$ depends on the direction $\mathbf{E}$. To measure how sensitive λ itself is, bound it over all directions of a given size. By Cauchy–Schwarz and the definition of $\|\mathbf{E}\|_2$,

$$|\lambda'(0)| = \frac{|\mathbf{y}^*\mathbf{E}\mathbf{x}|}{|\mathbf{y}^*\mathbf{x}|} \le \frac{\|\mathbf{y}\|\,\|\mathbf{E}\mathbf{x}\|}{|\mathbf{y}^*\mathbf{x}|} \le \frac{\|\mathbf{x}\|\,\|\mathbf{y}\|}{|\mathbf{y}^*\mathbf{x}|}\,\|\mathbf{E}\|_2.$$

The factor in front of $\|\mathbf{E}\|_2$ depends on $\mathbf{A}$ and λ only. It recurs in every estimate below, so we give it a name.

The condition number of an eigenvalue is the largest factor by which a perturbation of the matrix can move that eigenvalue, to first order.

Definition 19.11.1 — Condition Number of a Simple Eigenvalue

Let $\mathbf{A} \in M_n(\mathbb{C})$ and let λ be a **simple** eigenvalue of $\mathbf{A}$, with a right eigenvector $\mathbf{x}$ and a left eigenvector $\mathbf{y}$, so $\mathbf{y}^*\mathbf{A} = \lambda\mathbf{y}^*$. The **condition number** of λ is

$$\kappa_{\mathbf{A}}(\lambda) := \frac{\|\mathbf{x}\|\,\|\mathbf{y}\|}{|\mathbf{y}^*\mathbf{x}|}.$$

In words: take any right eigenvector and any left eigenvector for λ, multiply their lengths, and divide by the modulus of their inner product. The definition is made only for a **simple** eigenvalue, which is what makes the denominator non-zero (Lemma 19.11.1 (b)). It is also what makes the number well defined: by part (a) of the lemma, any other choice is $\alpha\mathbf{x}$ and $\beta\mathbf{y}$ with $\alpha, \beta \neq 0$, and then

$$\frac{\|\alpha\mathbf{x}\|\,\|\beta\mathbf{y}\|}{|(\beta\mathbf{y})^*(\alpha\mathbf{x})|} = \frac{|\alpha|\,|\beta|\,\|\mathbf{x}\|\,\|\mathbf{y}\|}{|\overline{\beta}\alpha|\,|\mathbf{y}^*\mathbf{x}|} = \kappa_{\mathbf{A}}(\lambda).$$

The subscript $\mathbf{A}$ and the argument λ are part of the notation. They keep $\kappa_{\mathbf{A}}(\lambda)$ apart from the condition number $\kappa(\mathbf{A}) = \|\mathbf{A}\|\|\mathbf{A}^{-1}\|$ of a matrix (Definition 15.8.1).

Examples.

- **$\mathbf{A}$ 1×1 matrix.** For $\mathbf{A} = (a)$ the eigenvalue a is simple, with $x = y = 1$, so $\kappa_{\mathbf{A}}(a) = 1$. This is the degenerate case, and it is the right answer: the eigenvalue of $(a + te)$ is $a + te$, which moves exactly as fast as the matrix.
- **A diagonal matrix with distinct entries.** For d_i, the Quick check above found $\mathbf{x} = \mathbf{y} = \mathbf{e}_i$, so $\kappa_{\mathbf{A}}(d_i) = 1$. Every eigenvalue is perfectly conditioned.

- **A triangular 2×2.** For $\mathbf{A} = \left(\begin{smallmatrix} 1 & 1 \\ 0 & 2 \end{smallmatrix}\right)$ and the eigenvalue 1, the Quick check after the lemma found $\mathbf{x} = \mathbf{e}_1$ and $\mathbf{y} = (1, -1)$, with $\mathbf{y}^*\mathbf{x} = 1$. So $\kappa_{\mathbf{A}}(1) = 1 \cdot \sqrt{2}/1 = \sqrt{2}$. The single off-diagonal entry has made the eigenvalue somewhat more sensitive.

Non-example by minimal change. Change the entry 2 of the last example to $1 + s$, and let $s \to 0$. For real $s \neq 0$ the matrix $\mathbf{B}_s = \left(\begin{smallmatrix} 1 & 1 \\ 0 & 1+s \end{smallmatrix}\right)$ has the simple eigenvalue 1, with $\mathbf{x} = \mathbf{e}_1$ and $\mathbf{y} = (s, -1)$, so $\kappa_{\mathbf{B}_s}(1) = \sqrt{1 + s^2}/|s|$. At $s = 0$ the matrix is $\mathbf{J}_2(1)$, and the eigenvalue 1 is no longer simple. The right and left eigenvectors still exist, $\mathbf{e}_1$ and $\mathbf{e}_2$, but $\mathbf{y}^*\mathbf{x} = 0$, so the clause "simple" fails and the quotient is undefined. The formula for $s \neq 0$ shows that it blows up on the way.

Why this definition. Three choices in it can be checked.

- **Both lengths go in the numerator.** This makes $\kappa_{\mathbf{A}}(\lambda)$ independent of the scaling of $\mathbf{x}$ and $\mathbf{y}$, as just computed. A normalization such as $\mathbf{y}^*\mathbf{x} = 1$ alone would leave one length free.
- **The norm is the Euclidean one,** because then the bound $|\lambda'(0)| \leq \kappa_{\mathbf{A}}(\lambda)\|\mathbf{E}\|_2$ above is attained by some $\mathbf{E}$, as part (b) of the proposition below shows. So $\kappa_{\mathbf{A}}(\lambda)$ is the exact worst case, not merely an upper bound. The same number is also the worst case over $\|\mathbf{E}\|_F = 1$: the bound survives because $\|\mathbf{E}\|_2 \leq \|\mathbf{E}\|_F$ (Proposition 15.3.4), and the extremal $\mathbf{E}$ has rank one, so its two norms agree by the same proposition.
- **The name** matches Definition 15.8.1. There, $\kappa(\mathbf{A})$ is the worst factor by which $\mathbf{A}$ magnifies a relative error in $\mathbf{b}$ into a relative error in the solution of $\mathbf{A}\mathbf{x} = \mathbf{b}$. Here $\kappa_{\mathbf{A}}(\lambda)$ is the worst factor by which a change in the matrix is magnified into a change in one eigenvalue, to first order.

Warning. **A condition number is a first-order statement, not a bound.** It governs $\lambda(t)$ only for small t, through $\lambda(t) - \lambda = t\lambda'(0) + \rho(t)$, and the remainder $\rho(t)$ can be as large as the first-order term while $t\|\mathbf{E}\|_2$ still looks small. Take $\mathbf{A} = \left(\begin{smallmatrix} 1 & M \\ 0 & 2 \end{smallmatrix}\right)$ with $M > 0$, for which $\kappa_{\mathbf{A}}(1) = \sqrt{1 + M^2}$, as the worked example below computes, and $\mathbf{E} = \mathbf{E}_{21}$. At $t = -1/(4M)$ the matrix $\mathbf{A} + t\mathbf{E}$ has trace 3 and determinant $2 + \frac{1}{4}$, so both its eigenvalues equal $\frac{3}{2}$. The eigenvalue 1 has moved by $\frac{1}{2}$, while the first-order prediction is $\kappa_{\mathbf{A}}(1)\,|t|\,\|\mathbf{E}\|_2 = \sqrt{1 + M^2}/(4M)$, which is close to $\frac{1}{4}$ for large M. At that point the eigenvalue is no longer simple, and the square root in the exact formula $(3 - \sqrt{1 + 4Mt})/2$ has no derivative there.

The first payoff is a list of properties, which together say what kind of number $\kappa_{\mathbf{A}}(\lambda)$ is.

Proposition 19.11.3 — Properties of the Eigenvalue Condition Number

Let $\mathbf{A} \in M_n(\mathbb{C})$ and let λ be a simple eigenvalue of $\mathbf{A}$ with right eigenvector $\mathbf{x}$ and left eigenvector $\mathbf{y}$.

(a) $\kappa_{\mathbf{A}}(\lambda)$ does not depend on the choice of $\mathbf{x}$ and $\mathbf{y}$, and $\kappa_{\mathbf{A}}(\lambda) \geq 1$, with equality if and only if $\mathbf{y}$ is a multiple of $\mathbf{x}$.

(b) For every $\mathbf{E} \in M_n(\mathbb{C})$, the eigenvalue $\lambda(t)$ of Theorem 19.11.2 satisfies $|\lambda'(0)| \leq \kappa_{\mathbf{A}}(\lambda)\|\mathbf{E}\|_2$. Equality holds for $\mathbf{E} = \mathbf{y}\mathbf{x}^*/(\|\mathbf{x}\|\|\mathbf{y}\|)$, which has $\|\mathbf{E}\|_2 = 1$. Hence $\kappa_{\mathbf{A}}(\lambda) = \max\{|\lambda'(0)| : \|\mathbf{E}\|_2 = 1\}$.

(c) If $\mathbf{A}$ is normal, then $\kappa_{\mathbf{A}}(\mu) = 1$ for every simple eigenvalue μ of $\mathbf{A}$.

(d) If $\mathbf{A} = \mathbf{X}\mathbf{\Lambda}\mathbf{X}^{-1}$ with $\mathbf{X}$ invertible and $\mathbf{\Lambda} = \operatorname{diag}(\lambda_1, \ldots, \lambda_n)$, and λ_i is simple,

then $\kappa_{\mathbf{A}}(\lambda_i) \le \kappa_2(\mathbf{X})$.

(e) $\kappa_{\mathbf{A}}(\lambda) = 1/\cos\theta$, where $\theta \in [0, \pi/2)$ is the principal angle between the lines $\operatorname{span}(\mathbf{x})$ and $\operatorname{span}(\mathbf{y})$ (Definition 19.8.1).

Proof.

(a) Independence of the choice was checked after Definition 19.11.1. By Theorem 10.1.5, $|\mathbf{y}^*\mathbf{x}| = |\langle \mathbf{x}, \mathbf{y}\rangle| \le \|\mathbf{x}\|\|\mathbf{y}\|$, so $\kappa_{\mathbf{A}}(\lambda) \ge 1$, with equality if and only if $(\mathbf{x}, \mathbf{y})$ is linearly dependent, that is, since both are non-zero, if and only if $\mathbf{y}$ is a multiple of $\mathbf{x}$.

(b) The inequality is the display before Definition 19.11.1, with $\lambda'(0)$ given by Theorem 19.11.2 (c). For the equality, put $\mathbf{E} = \mathbf{y}\mathbf{x}^*/(\|\mathbf{x}\|\|\mathbf{y}\|)$. For every $\mathbf{v}$, $\mathbf{y}\mathbf{x}^*\mathbf{v} = (\mathbf{x}^*\mathbf{v})\,\mathbf{y}$, so $\|\mathbf{y}\mathbf{x}^*\mathbf{v}\| = |\langle \mathbf{v}, \mathbf{x}\rangle|\,\|\mathbf{y}\| \le \|\mathbf{x}\|\|\mathbf{y}\|\|\mathbf{v}\|$ by Cauchy–Schwarz, with equality at $\mathbf{v} = \mathbf{x}$. Hence $\|\mathbf{y}\mathbf{x}^*\|_2 = \|\mathbf{x}\|\|\mathbf{y}\|$ by Definition 15.3.2, and $\|\mathbf{E}\|_2 = 1$. Moreover

$$\mathbf{y}^*\mathbf{E}\mathbf{x} = \frac{(\mathbf{y}^*\mathbf{y})(\mathbf{x}^*\mathbf{x})}{\|\mathbf{x}\|\|\mathbf{y}\|} = \|\mathbf{x}\|\,\|\mathbf{y}\|, \qquad \text{so} \qquad |\lambda'(0)| = \frac{\|\mathbf{x}\|\,\|\mathbf{y}\|}{|\mathbf{y}^*\mathbf{x}|} = \kappa_{\mathbf{A}}(\lambda).$$

The maximum formula restates the inequality and its equality case.

(c) Let $\mathbf{A}\mathbf{x} = \mu\mathbf{x}$ with $\mathbf{x} \ne \mathbf{0}$. By Theorem 11.3.3, $\mathbf{A}^*\mathbf{x} = \overline{\mu}\,\mathbf{x}$, and taking conjugate transposes gives $\mathbf{x}^*\mathbf{A} = \mu\,\mathbf{x}^*$. So $\mathbf{x}$ is also a left eigenvector for μ, and (a) gives $\kappa_{\mathbf{A}}(\mu) = 1$.

(d) Write $\mathbf{x}_i = \mathbf{X}\mathbf{e}_i$ and $\mathbf{y}_i^* = \mathbf{e}_i^*\mathbf{X}^{-1}$. From $\mathbf{A}\mathbf{X} = \mathbf{X}\mathbf{\Lambda}$ and $\mathbf{X}^{-1}\mathbf{A} = \mathbf{\Lambda}\mathbf{X}^{-1}$, column i and row i give $\mathbf{A}\mathbf{x}_i = \lambda_i\mathbf{x}_i$ and $\mathbf{y}_i^*\mathbf{A} = \lambda_i\mathbf{y}_i^*$, and both vectors are non-zero because $\mathbf{X}$ is invertible. Also $\mathbf{y}_i^*\mathbf{x}_i = \mathbf{e}_i^*\mathbf{X}^{-1}\mathbf{X}\mathbf{e}_i = 1$. Now $\|\mathbf{x}_i\| \le \|\mathbf{X}\|_2\|\mathbf{e}_i\| = \|\mathbf{X}\|_2$ by Theorem 15.3.2 (a). For $\mathbf{y}_i$, Cauchy–Schwarz gives

$$\|\mathbf{y}_i\|^2 = \mathbf{y}_i^*\mathbf{y}_i = \mathbf{e}_i^*\mathbf{X}^{-1}\mathbf{y}_i \le \|\mathbf{X}^{-1}\mathbf{y}_i\| \le \|\mathbf{X}^{-1}\|_2\,\|\mathbf{y}_i\|,$$

so $\|\mathbf{y}_i\| \le \|\mathbf{X}^{-1}\|_2$, after dividing by $\|\mathbf{y}_i\| > 0$. Therefore $\kappa_{\mathbf{A}}(\lambda_i) = \|\mathbf{x}_i\|\|\mathbf{y}_i\|/1 \le \|\mathbf{X}\|_2\|\mathbf{X}^{-1}\|_2 = \kappa_2(\mathbf{X})$, by (a) and Definition 15.8.1.

(e) The vectors $\mathbf{x}/\|\mathbf{x}\|$ and $\mathbf{y}/\|\mathbf{y}\|$ are orthonormal bases of the two lines, so by Definition 19.8.1 the single principal angle satisfies $\cos\theta = \sigma_1(c)$, where $c = \mathbf{y}^*\mathbf{x}/(\|\mathbf{x}\|\|\mathbf{y}\|)$ is a 1×1 matrix. Its only singular value is $|c|$, the square root of the eigenvalue $\overline{c}c$ of c^*c (Definition 12.8.1). Hence $\cos\theta = |\mathbf{y}^*\mathbf{x}|/(\|\mathbf{x}\|\|\mathbf{y}\|) = 1/\kappa_{\mathbf{A}}(\lambda)$, which is positive by Lemma 19.11.1 (b), so $\theta < \pi/2$. This proves the proposition.

■

Part (e) is the picture to keep. An eigenvalue is well conditioned when its right and left eigenvectors point in nearly the same direction, and ill conditioned when they are nearly perpendicular. For a normal matrix they coincide, by (c). At a Jordan block they are exactly perpendicular, by the warning after the lemma.

Part (d) places the new number beside §04. Bauer–Fike bounds the movement of every eigenvalue by $\kappa_2(\mathbf{X})\|\mathbf{E}\|_2$, for every size of $\mathbf{E}$. Part (d) says that, to first order, each simple eigenvalue individually does at least as well, with its own constant $\kappa_{\mathbf{A}}(\lambda_i)$, and that constant involves no choice of $\mathbf{X}$. This is the refinement §04's warning promised. The first-order statement is sharper. The Bauer–Fike bound is global and needs no smallness.

19.11.4 A worked example

Upper triangular 2×2 matrices show everything, because their eigenvectors can be written down at once.

Example. (The condition numbers of a triangular 2×2 matrix)

Let $a, b, d \in \mathbb{C}$ with $a \neq d$, and $\mathbf{A} = \left(\begin{smallmatrix} a & b \\ 0 & d \end{smallmatrix}\right)$.

(a) Compute $\kappa_{\mathbf{A}}(a)$ and $\kappa_{\mathbf{A}}(d)$.

(b) For $a = 1$, $b = M > 0$, $d = 2$, compare with the smallest value of $\kappa_2(\mathbf{X})$ over all diagonalizing $\mathbf{X}$.

(c) For the same matrix and $\mathbf{E} = \mathbf{E}_{21}$, compute $\lambda'(0)$ for the eigenvalue 1 from Theorem 19.11.2, and compare with the exact eigenvalues of $\mathbf{A} + t\mathbf{E}$ for $M = 100$ and $t = 10^{-4}$.

Solution.

(a) Both eigenvalues are simple, since $a \neq d$. For a: $\mathbf{A}\mathbf{e}_1 = a\mathbf{e}_1$, so $\mathbf{x} = \mathbf{e}_1$. A left eigenvector solves $\mathbf{y}^*(\mathbf{A} - a\mathbf{I}) = \mathbf{0}$, where $\mathbf{A} - a\mathbf{I} = \left(\begin{smallmatrix} 0 & b \\ 0 & d-a \end{smallmatrix}\right)$. For a row $\mathbf{y}^* = (u, v)$ the product is $(0,\ ub + v(d-a))$, so $\mathbf{y}^* = (d-a, -b)$ works. Then $\mathbf{y}^*\mathbf{x} = d - a$, and

$$\kappa_{\mathbf{A}}(a) = \frac{1 \cdot \sqrt{|d-a|^2 + |b|^2}}{|d-a|} = \sqrt{1 + \frac{|b|^2}{|a-d|^2}}.$$

For d: $\mathbf{y} = \mathbf{e}_2$ is a left eigenvector, because $\mathbf{e}_2^*\mathbf{A} = (0, d) = d\,\mathbf{e}_2^*$. A right eigenvector is $\mathbf{x} = (b, d-a)$, since $(\mathbf{A} - d\mathbf{I})\mathbf{x} = \big((a-d)b + b(d-a),\ 0\big) = \mathbf{0}$. Then $\mathbf{y}^*\mathbf{x} = d - a$, and $\kappa_{\mathbf{A}}(d)$ is given by the same formula. The two condition numbers are equal. They are large exactly when the off-diagonal entry is large compared with the gap between the eigenvalues.

(b) Here $\kappa_{\mathbf{A}}(1) = \kappa_{\mathbf{A}}(2) = \sqrt{1 + M^2}$. §04 computed κ_2 for two diagonalizing matrices of this $\mathbf{A}$ (Example (A large corner, separated eigenvalues)), and the better one, with unit columns, gave $M + \sqrt{1 + M^2}$. We show that no choice does better. The eigenvectors are the multiples of $\mathbf{e}_1$ and of $(M, 1)$, and the columns of a diagonalizing $\mathbf{X}$ are eigenvectors (Theorem 8.4.1). So, up to the order of its columns, which does not change $\kappa_2(\mathbf{X})$, every diagonalizing $\mathbf{X}$ has the form $\mathbf{X} = \left(\begin{smallmatrix} \alpha & \beta M \\ 0 & \beta \end{smallmatrix}\right)$ with $\alpha, \beta \neq 0$, by Lemma 19.11.1 (a). Multiplying $\mathbf{X}$ by a scalar does not change $\kappa_2(\mathbf{X})$, so we may take $\alpha = 1$. Let $\sigma_1 \geq \sigma_2 > 0$ be the singular values of $\mathbf{X}$. They are the square roots of the eigenvalues of $\mathbf{X}^*\mathbf{X}$ (Definition 12.8.1), so $\sigma_1^2\sigma_2^2 = \det(\mathbf{X}^*\mathbf{X}) = |\det \mathbf{X}|^2$, giving $\sigma_1\sigma_2 = |\beta|$, and $\sigma_1^2 + \sigma_2^2 = \operatorname{tr}(\mathbf{X}^*\mathbf{X}) = 1 + |\beta|^2(1 + M^2)$. With $k = \kappa_2(\mathbf{X}) = \sigma_1/\sigma_2$,

$$k + \frac{1}{k} = \frac{\sigma_1^2 + \sigma_2^2}{\sigma_1\sigma_2} = \frac{1}{|\beta|} + |\beta|(1 + M^2) \geq 2\sqrt{1 + M^2},$$

by the inequality $u + v \geq 2\sqrt{uv}$ for $u, v > 0$, with equality exactly when $|\beta| = 1/\sqrt{1 + M^2}$, that is, when both columns of $\mathbf{X}$ are unit vectors. The function $k \mapsto k + 1/k$ is increasing for $k \geq 1$, so the smallest possible $\kappa_2(\mathbf{X})$ is the root

$k \geq 1$ of $k + 1/k = 2\sqrt{1+M^2}$, namely

$$\min_{\mathbf{X}} \kappa_2(\mathbf{X}) = M + \sqrt{1+M^2}.$$

Indeed $(M+\sqrt{1+M^2})^{-1} = \sqrt{1+M^2} - M$, and the two add up to $2\sqrt{1+M^2}$. So the per-eigenvalue constant $\sqrt{1+M^2}$ is smaller than the best Bauer–Fike constant, by a factor that tends to 2 as M grows, in agreement with Proposition 19.11.3 (d).

(c) With $\mathbf{x} = \mathbf{e}_1$ and $\mathbf{y}^* = (1, -M)$ from (a), $\mathbf{y}^*\mathbf{E}_{21}\mathbf{x} = \mathbf{y}^*\mathbf{e}_2 = -M$ and $\mathbf{y}^*\mathbf{x} = 1$, so

$$\lambda'(0) = -M, \qquad |\lambda'(0)| = M \leq \sqrt{1+M^2}\,\|\mathbf{E}_{21}\|_2 = \kappa_{\mathbf{A}}(1)\,\|\mathbf{E}\|_2.$$

Exactly: $\mathbf{A} + t\mathbf{E} = \left(\begin{smallmatrix} 1 & M \\ t & 2 \end{smallmatrix}\right)$ has trace 3 and determinant $2 - Mt$, so its eigenvalues are

$$\lambda_{\pm}(t) = \frac{3 \pm \sqrt{1+4Mt}}{2},$$

and the one near 1 is $\lambda_-(t)$. For $M = 100$ and $t = 10^{-4}$ we get $4Mt = 0.04$, and $\lambda_-(t) = (3 - \sqrt{1.04})/2 \approx 0.990098$. The eigenvalue has moved by about 0.0099, and the first-order prediction $|t\lambda'(0)| = Mt$ is 0.01. Differentiating $\lambda_-(t)$ directly gives $\lambda_-'(0) = -\frac{1}{4} \cdot 4M = -M$, as the theorem says.

§04 set this matrix beside Chapter 11's Example (A perturbation that moves the eigenvalues a thousand times as far), which perturbed the same corner of $\left(\begin{smallmatrix} 1 & M \\ 0 & 1 \end{smallmatrix}\right)$. There the diagonal entries are equal, and the eigenvalue 1 moved by $\sqrt{Mt}$; with $M = 100$ and $t = 10^{-4}$ that is 0.1, ten times the movement found in (c). The derivative explains the difference. With a gap of 1 between the eigenvalues, the movement is linear in t to first order, with slope M, at most $\kappa_{\mathbf{A}}(1) = \sqrt{1+M^2}$. With no gap there is no derivative at all. Chapter 11's closing remark, that a matrix with well-separated eigenvalues and a large defect behaves less dramatically, is now a formula.

19.11.5 When eigenvalues coalesce

The two computations just compared are the ends of a single family. Put

$$\mathbf{A}_s = \begin{pmatrix} 1 & M \\ 0 & 1+s \end{pmatrix} \qquad (M > 0,\ s > 0).$$

By Example (The condition numbers of a triangular 2×2 matrix) (a), with $b = M$ and $a - d = -s$,

$$\kappa_{\mathbf{A}_s}(1) = \kappa_{\mathbf{A}_s}(1+s) = \sqrt{1 + \frac{M^2}{s^2}} \;\longrightarrow\; \infty \qquad (s \to 0^+).$$

As the two eigenvalues move together, the left eigenvector $(s, -M)$ of the eigenvalue 1 turns towards $\mathbf{e}_2$, perpendicular to the right eigenvector $\mathbf{e}_1$. At $s = 0$ the matrix is a Jordan block in disguise, as Chapter 11 observed, the product $\mathbf{y}^*\mathbf{x}$ is 0, and the derivative no longer exists. Instead the eigenvalue moves by $\sqrt{Mt}$ (Example (A perturbation that moves the eigenvalues a thousand times as far)), the case $n = 2$ of the n-th root behavior of §03 (Example (The Jordan block meets Elsner's bound)).
